Ca²⁺ has been shown to inhibit the uptake and binding of aminoglycosides to the renal brush-border luminal membrane *in vitro*, and supplementary dietary Ca²⁺ attenuates experimental nephrotoxicity (Bennett *et al.*, 1982). Aminoglycosides eventually are internalized by pinocytosis. Morphologically, there is clear evidence of accumulation of drug in liposomes, a means by which aminoglycosides are trapped, concentrated (up to 50 times the plasma concentration) (Aronoff *et al.*, 1983), and prepared for extrusion into the urine as multilamellar phospholipid structures called *myeloid bodies* (Swan, 1997).

Neuromuscular Blockade. An unusual toxic reaction of acute neuromuscular blockade and apnea has been attributed to the aminoglycosides. The order of decreasing potency for blockade is neomycin, kanamycin, amikacin, gentamicin, and tobramycin. In humans, neuromuscular blockade generally has occurred after intrapleural or intraperitoneal instillation of large doses of an aminoglycoside; however, the reaction can follow intravenous, intramuscular, and even oral administration of these agents. Most episodes have occurred in association with anesthesia or the administration of other neuromuscular blocking agents. Patients with myasthenia gravis are particularly susceptible to neuromuscular blockade by aminoglycosides (*see* Chapter 8).

Aminoglycosides may inhibit prejunctional release of acetylcholine while also reducing postsynaptic sensitivity to the transmitter

(Sokoll and Gergis, 1981), but Ca²⁺ can overcome this effect, and the intravenous administration of a calcium salt is the preferred treatment for this toxicity (Singh *et al.*, 1978). Inhibitors of acetylcholinesterase (*e.g.*, *edrophonium* and *neostigmine*) also have been used with varying degrees of success.

Other Effects on the Nervous System. The administration of streptomycin may produce dysfunction of the optic nerve, including scotomas, presenting as enlargement of the blind spot. Among the less common toxic reactions to streptomycin is peripheral neuritis. This may be due either to accidental injection of a nerve during the course of parenteral therapy or to toxicity involving nerves remote from the site of antibiotic administration. Paresthesia, most commonly perioral but also present in other areas of the face or in the hands, occasionally follows the use of the antibiotic and usually appears within 30 to 60 minutes after injection of the drug. It can persist for several hours.

Other Untoward Effects. In general, the aminoglycosides have little allergenic potential; anaphylaxis and rash are unusual. Rare hypersensitivity reactions—including skin rashes, eosinophilia, fever, blood dyscrasias, angioedema, exfoliative dermatitis, stomatitis, and anaphylactic shock—have been reported. Parenterally administered aminoglycosides are not associated with pseudomembranous colitis, probably because they do not disrupt the normal anaerobic flora. Other reactions that have been attributed to individual drugs are discussed below.

STREPTOMYCIN

Streptomycin is used for the treatment of certain unusual infections generally in combination with other antimicrobial agents. Because it generally is less active than other members of the class against aerobic gram-negative rods, it has fallen into disuse. Streptomycin may be administered by deep intramuscular injection or intravenously. Intramuscular injection may be painful, with a hot, tender mass developing at the site of injection. The dose of streptomycin is 15 mg/kg per day for patients with creatinine clearances above 80 ml/min. It typically is administered as a 1000-mg single daily dose or 500 mg twice daily, resulting in peak serum concentrations of approximately 50 to 60 and 15 to 30 µg/ml and trough concentrations of less than 1 and 5 to 10 µg/ml, respectively. The total daily dose should be reduced in direct proportion to the reduction in creatinine clearance for creatinine clearances above 30 ml/min (Table 45–2).

Therapeutic Uses. Bacterial Endocarditis. Streptomycin and penicillin in combination are synergistically bactericidal *in vitro* and in animal models of infection against strains of enterococci, group D streptococci, and the various oral streptococci of the *viridans* group. A combination of penicillin G and streptomycin may be indicated for treatment of streptococcal endocarditis (Wilson *et al.*, 1995). The combination of penicillin G, which by itself is only

bacteriostatic against enterococci, and streptomycin is effective for enterococcal endocarditis. Streptomycin rarely is used for this indication, however, having been replaced almost entirely by gentamicin, because its toxicity is primarily renal and reversible, whereas that of streptomycin is vestibular and irreversible. Gentamicin also should be used when the strain of enterococcus is resistant to streptomycin (MIC >2 mg/ml). Similarly, streptomycin should be used instead of gentamicin when the strain is resistant to the latter and susceptibility has been demonstrated to streptomycin, which may occur because the enzymes that inactivate these two aminoglycosides are different.

Tularemia. Streptomycin (or gentamicin) is the drug of choice for the treatment of tularemia (Ellis *et al.*, 2002). Most cases respond to the administration of 1 g (15 to 25 mg/kg) streptomycin per day (in divided doses) for 7 to 10 days. Fluoroquinolones and tetracyclines also are effective, although the failure rate may be higher with tetracyclines.

Plague. Streptomycin is effective agent for the treatment of all forms of plague. The recommended dose is 2 g/day in two divided doses for 7 to 10 days. Gentamicin is probably as efficacious (Boulanger *et al.*, 2004).

Tuberculosis. In the treatment of tuberculosis, streptomycin always should be used in combination with at least one or two other drugs to which the causative strain is susceptible. The dose for patients with normal renal function is 15 mg/kg per day as a single intramuscular injection for 2 to 3 months and then 2 or 3 times a week thereafter.

GENTAMICIN

Gentamicin is an important agent for the treatment of many serious gram-negative bacillary infections. It is the aminoglycoside of first choice because of its low cost and reliable activity against all but the most resistant gram-negative aerobes. Gentamicin preparations are available for parenteral, ophthalmic, and topical administration.

Therapeutic Uses of Gentamicin and Other Aminoglycosides. Gentamicin, tobramycin, amikacin, and netilmicin can be used interchangeably for the treatment of most of the following infections and therefore are discussed together. For most indications, gentamicin is the preferred agent because of long experience with its use and its relatively low cost. Many different types of infections can be treated successfully with these aminoglycosides; however, owing to their toxicities, prolonged use should be restricted to the therapy of life-threatening infections and those for which a less toxic agent is contraindicated or less effective.

The typical recommended intramuscular or intravenous dose of *gentamicin sulfate* (GARAMYCIN) for adults is a loading dose of 2 mg/kg and then 3 to 5 mg/kg per day, one-third being given every 8 hours when administered as a multiple-daily-dosing regimen. The once-daily dose is 5 to 7 mg/kg given over 30 to 60 minutes for patients with normal renal function (and below this range if renal function is impaired). The upper limit of this dose range may be required to achieve therapeutic levels for trauma or burn patients, those with septic shock, and others in whom drug clearance is more rapid or volume of distribution is larger than normal. Several dosage schedules have been suggested for newborns and infants: 3 mg/kg once daily for preterm newborns younger than 35 weeks' gestation (Rastogi *et al.*, 2002; Hansen *et al.*, 2003); 4 mg/kg once daily for newborns older than 35 weeks' gestation; 5 mg/kg daily in two divided doses for neonates with severe infections; and 2 to 2.5 mg/kg every 8 hours for children up to 2 years of age. Peak plasma concentrations range from 4 to 10 µg/ml (dosing: 1.7 mg/kg every 8 hours) and 16 to 24 µg/ml (dosing: 5.1 mg/kg once daily). It should be emphasized that the recommended doses of gentamicin do not always yield desired concentrations. Periodic determinations of the plasma concentration of aminoglycosides are recommended strongly, especially in seriously ill patients, to confirm that drug concentrations are in the desired range (*see* sections on dosing above for more details). Although it has not been established exactly what plasma concentration is toxic, trough concentrations continually above 2 µg/ml have been associated with toxicity (Raveh *et al.*, 2002).

Aminoglycosides frequently are used in combination with a penicillin or a cephalosporin for the therapy of proven or suspected serious gram-negative microbial infections, especially those due to *P. aeruginosa*, *Enterobacter*, *Klebsiella*, *Serratia*, and other species resistant to less toxic antibiotics, including urinary tract infections, bacteremia, infected burns, osteomyelitis, pneumonia, peritonitis, and otitis. With few exceptions (*e.g.*, enterococcal endocarditis) (Le and Bayer, 2003), the superiority of aminoglycoside combination therapy over an effective single-drug regimen has not been demonstrated. Because of their toxicity with prolonged administration, aminoglycosides should not be used for more than a few days unless deemed essential for a successful or improved outcome. Aminoglycosides never must be mixed in the same solution with penicillins because the penicillin inactivates the aminoglycoside to a significant degree (Konishi *et al.*, 1983). Similar incompatibilities exist *in vitro* to different degrees between gentamicin and *heparin*, *amphotericin B*, and the various cephalosporins.

Urinary Tract Infections. Aminoglycosides usually are not indicated for the treatment of uncomplicated urinary tract infections, although a single intramuscular dose of gentamicin (5 mg/kg) has been effective in curing more than 90% of uncomplicated infections of the lower urinary tract (Varese *et al.*, 1980). However, as strains of *E. coli* have acquired resistance to β-lactams, *trimethoprim-sulfamethoxazole*, and *fluoroquinolones*, use of aminoglycosides may increase. In the seriously ill patient with pyelonephritis, an aminoglycoside alone or in combination with a β-lactam antibiotic offers broad and effective initial coverage. Once the microorganism is isolated and its sensitivities to antibiotics are determined, the aminoglycoside should be discontinued if the infecting microorganism is sensitive to less toxic antibiotics.

Pneumonia. The organisms that cause community-acquired pneumonia will be susceptible to broad-spectrum β-lactam antibiotics, macrolides, or a fluoroquinolone, and usually it is not necessary to add an aminoglycoside. Therapy with an aminoglycoside alone is likely to be ineffective; therapeutic concentrations are difficult to achieve owing to relatively poor penetration of drug into inflamed tissues and the associated conditions of low oxygen tension and low

pH—both of which interfere with aminoglycoside antibacterial activity. Aminoglycosides are ineffective for the treatment of pneumonia due to anaerobes or *S. pneumoniae*, which are common causes of community-acquired pneumonia. They should not be considered as effective single-drug therapy for any aerobic gram-positive cocci (including *S. aureus* or streptococci), the microorganisms commonly responsible for suppurative pneumonia or lung abscess. Thus gentamicin (or other aminoglycosides) never should be used as the sole agent to treat pneumonia acquired in the community or as the initial treatment for pneumonia acquired in the hospital (Kunin, 1977).

An aminoglycoside in combination with a β -lactam antibiotic may be used for empirical therapy of hospital-acquired pneumonia in which multiple-drug-resistant gram-negative aerobes are a likely causative agent. However, provided the companion drug is active against the causative agent, there is generally no benefit from adding an aminoglycoside. One exception may be the treatment of pneumonia caused by *P. aeruginosa*, for which combination therapy generally is recommended, with the goal of preventing the emergence of resistance.

Meningitis. Availability of third-generation cephalosporins, especially *cefotaxime* and *ceftriaxone*, has reduced the need for treatment with aminoglycosides in most cases of meningitis, except for infections caused by gram-negative organisms that are resistant to β -lactam antibiotics (e.g., species of *Pseudomonas* and *Acinetobacter*). If therapy with an aminoglycoside is necessary, in adults, 5 mg of a preservative-free formulation of gentamicin (or equivalent dose of another aminoglycoside) is administered directly intrathecally once daily (Barnes *et al.*, 2003).

Peritoneal Dialysis–Associated Peritonitis. Patients who develop peritonitis as a result of peritoneal dialysis may be treated with aminoglycoside diluted into the dialysis fluid to a concentration of 4 to 8 mg/L for gentamicin, netilmicin, or tobramycin or 6 to 12 mg/L for amikacin. Intravenous or intramuscular administration of drug is unnecessary because serum and peritoneal fluid will equilibrate rapidly.

Bacterial Endocarditis. “Synergistic” or low-dose gentamicin (3 mg/kg per day in three divided doses) in combination with a penicillin or vancomycin has been recommended in certain circumstances for treatment of bacterial endocarditis. There is good evidence that penicillin and gentamicin in combination are effective as a short-course (i.e., 2-week) regimen for uncomplicated native-valve streptococcal endocarditis. In cases of enterococcal endocarditis, concomitant administration of penicillin and gentamicin for 4 to 6 weeks has been recommended because of an unacceptably high relapse rate with penicillin alone. A large case series from Sweden, however, found that cure rates were not substantially affected by shortening the duration of aminoglycoside therapy to a median duration of 15 days (Olaison and Schadewitz, 2002). A 2-week regimen of gentamicin or tobramycin in combination with *nafcillin* is effective for the treatment of selected cases of staphylococcal tricuspid valve endocarditis in injection drug users (Chambers *et al.*, 1988), although the need to including the aminoglycoside is not established (Le and Bayer, 2003).

Aminoglycosides have no clinically proven benefit in treatment of staphylococcal mitral or aortic valve endocarditis. Because of toxicity and limited, if any, clinical benefit, aminoglycoside combination therapy has fallen from favor as a first-line regimen for treatment of endocarditis.

Sepsis. Inclusion of an aminoglycoside in an empirical regimen used to be recommended commonly for the febrile patient with granulocytopenia and for infections suspected to be caused by *P. aeruginosa*. Numerous studies using potent broad-spectrum β -lactams (e.g., carbapenems and antipseudomonal cephalosporins) have demonstrated no benefit from adding an aminoglycoside to the regimen. Most

authorities continue to recommend combination therapy of documented non-urinary tract *P. aeruginosa* infections, particularly pneumonia with bacteremia. If there is concern that an infection may be caused by a multiple-drug-resistant organism that may be susceptible only to an aminoglycoside, then adding this antibiotic to the regimen is reasonable. Evidence that aminoglycosides are beneficial for other gram-negative infections is weak if the isolate is susceptible to other antibiotics. To avoid toxicity, aminoglycosides should be used briefly and sparingly as long as other alternatives are available.

Topical Applications. Gentamicin is absorbed slowly when it is applied topically in an ointment and somewhat more rapidly when it is applied as a cream. When the antibiotic is applied to large areas of denuded body surface, as may be the case in burned patients, plasma concentrations can reach 4 μ g/ml, and 2% to 5% of the drug used may appear in the urine.

Untoward Effects. Like other aminoglycosides, the most important and serious side effects of the use of gentamicin are nephrotoxicity and irreversible ototoxicity. Intrathecal or intraventricular administration is used rarely because it may cause local inflammation and can result in radiculitis and other complications.

TOBRAMYCIN

The antimicrobial activity, pharmacokinetic properties, and toxicity profile of tobramycin (NEBCIN) are very similar to those of gentamicin. Tobramycin may be given either intramuscularly or intravenously. Dosages and serum concentrations are identical with those for gentamicin. Tobramycin (TOBREX) also is available in ophthalmic ointments and solutions.

Therapeutic Uses. Indications for the use of tobramycin are the same as those for gentamicin. The superior activity of tobramycin against *P. aeruginosa* makes it the preferred aminoglycoside for treatment of serious infections caused by this organism. It usually should be used concurrently with an antipseudomonal β -lactam antibiotic. In contrast to gentamicin, tobramycin shows poor activity in combination with penicillin against many strains of enterococci. Most strains of *E. faecium* are highly resistant. Tobramycin is ineffective against mycobacteria.

Untoward Effects. Tobramycin, like other aminoglycosides, causes nephrotoxicity and ototoxicity. Studies in experimental animals suggest that tobramycin may be less toxic to hair cells in the cochlear and vestibular end organs and cause less renal tubular damage than does gentamicin. However, clinical data are less convincing.

AMIKACIN

The spectrum of antimicrobial activity of amikacin (AMIKIN) is the broadest of the group. Because of its resistance to many of the aminoglycoside-inactivating enzymes, it has a

special role in hospitals where gentamicin- and tobramycin-resistant microorganisms are prevalent. Amikacin is similar to kanamycin in dosage and pharmacokinetic properties.

The recommended dose of amikacin is 15 mg/kg per day as a single daily dose or divided into two or three equal portions, which must be reduced for patients with renal failure. The drug is absorbed rapidly after intramuscular injection, and peak concentrations in plasma approximate 20 $\mu\text{g/ml}$ after injection of 7.5 mg/kg. An intravenous infusion of the same dose over a 30-minute period produces a peak concentration in plasma of nearly 40 $\mu\text{g/ml}$ at the end of the infusion, which falls to about 20 $\mu\text{g/ml}$ 30 minutes later. The concentration 12 hours after a 7.5 mg/kg dose typically is between 5 and 10 $\mu\text{g/ml}$. A 15 mg/kg once-daily dose produces peak concentrations that are between 50 and 60 $\mu\text{g/ml}$ and a trough of less than 1 $\mu\text{g/ml}$.

Therapeutic Uses. Amikacin has become the preferred agent for the initial treatment of serious nosocomial gram-negative bacillary infections in hospitals where resistance to gentamicin and tobramycin has become a significant problem. Amikacin is active against the vast majority of aerobic gram-negative bacilli in the community and the hospital. This includes most strains of *Serratia*, *Proteus*, and *P. aeruginosa*. It is active against nearly all strains of *Klebsiella*, *Enterobacter*, and *E. coli* that are resistant to gentamicin and tobramycin. Most resistance to amikacin is found among strains of *Acinetobacter*, *Providencia*, and *Flavobacter* and strains of *Pseudomonas* other than *P. aeruginosa*; these all are unusual pathogens. Like tobramycin, amikacin is less active than gentamicin against enterococci and should not be used. Amikacin is not active against the majority of gram-positive anaerobic bacteria. It is active against *M. tuberculosis* (99% of strains inhibited by 4 $\mu\text{g/ml}$), including streptomycin-resistant strains and atypical mycobacteria. It has been used in the treatment of disseminated atypical mycobacterial infection in acquired immunodeficiency syndrome (AIDS) patients.

Untoward Effects. As with the other aminoglycosides, amikacin causes ototoxicity and nephrotoxicity. Auditory deficits are produced most commonly.

NETILMICIN

Netilmicin (NETROMYCIN) is the latest of the aminoglycosides to be marketed. It is similar to gentamicin and tobramycin in its pharmacokinetic properties and dosage. Its antibacterial activity is broad against aerobic gram-negative bacilli. Like amikacin, it is not metabolized by the majority of the aminoglycoside-inactivating enzymes, and it therefore may be active against certain bacteria that are resistant to gentamicin.

The recommended dose of netilmicin for complicated urinary tract infections in adults is 1.5 to 2 mg/kg every 12 hours. For other serious systemic infections, a total daily dose of 4 to 7 mg/kg is administered as a single dose or two to three divided doses. Children should receive 3 to 7 mg/kg per day in two to three divided doses; neonates receive 3.5 to 5 mg/kg per day as a single daily dose

(Gosden *et al.*, 2001). The distribution and elimination of netilmicin, gentamicin, and tobramycin are very similar. An intravenous infusion of 2 mg/kg netilmicin given over a 60-minute period results in a peak plasma concentration of approximately 11 $\mu\text{g/ml}$ (Luft *et al.*, 1978). The half-time for elimination is usually 2 to 2.5 hours in adults and increases with renal insufficiency.

Therapeutic Uses. Netilmicin is useful for the treatment of serious infections owing to susceptible Enterobacteriaceae and other aerobic gram-negative bacilli. It is effective against certain gentamicin-resistant pathogens, with the exception of enterococci (Panwalker *et al.*, 1978).

Untoward Effects. As with other aminoglycosides, netilmicin also may produce ototoxicity and nephrotoxicity. Animal models have suggested that netilmicin may be less toxic than other aminoglycosides (Luft *et al.*, 1976), but this remains to be proven in humans (Tange *et al.*, 1995).

KANAMYCIN

The use of kanamycin has declined markedly because its spectrum of activity is limited compared with other aminoglycosides, and it is among the most toxic.

Kanamycin sulfate (KANTREX) is available for injection and oral use. The parenteral dose for adults is 15 mg/kg per day (two to four equally divided and spaced doses), with a maximum of 1.5 g/day. Children may be given up to 15 mg/kg per day.

Therapeutic Uses. Kanamycin is all but obsolete, and there are few indications for its use. Kanamycin has been employed to treat tuberculosis in combination with other effective drugs. It has no therapeutic advantage over streptomycin or amikacin and probably is more toxic; either should be used instead, depending on susceptibility of the isolate.

Prophylactic Uses. Kanamycin can be administered orally as adjunctive therapy in cases of hepatic encephalopathy. The dose is 4 to 6 g/day for 36 to 72 hours; quantities as large as 12 g/day (in divided doses) have been given.

Untoward Effects. Kanamycin is ototoxic and nephrotoxic. Like neomycin (*see below*), its oral administration can cause malabsorption and superinfection. The untoward effects of the oral administration of aminoglycosides are considered under "Neomycin" below.

NEOMYCIN

Neomycin is a broad-spectrum antibiotic. Susceptible microorganisms usually are inhibited by concentrations of 5 to 10 $\mu\text{g/ml}$ or less. Gram-negative species that are highly sensitive are *E. coli*, *Enterobacter aerogenes*, *Klebsiella pneumoniae*, and *Proteus vulgaris*. Gram-

positive microorganisms that are inhibited include *S. aureus* and *E. faecalis*. *M. tuberculosis* also is sensitive to neomycin. Strains of *P. aeruginosa* are resistant to neomycin.

Neomycin sulfate is available for topical and oral administration. Neomycin and *polymyxin B* have been used for irrigation of the bladder. For this purpose, 1 ml of a preparation (NEOSPORIN G.U. IRRIGANT) containing 40 mg neomycin and 200,000 units polymyxin B per milliliter is diluted in 1 L of 0.9% sodium chloride solution and is used for continuous irrigation of the urinary bladder through appropriate catheter systems. The goal is to prevent bacteriuria and bacteremia associated with the use of indwelling catheters. The bladder usually is irrigated at the rate of 1 L every 24 hours.

Neomycin currently is available in many brands of creams, ointments, and other products alone and in combination with polymyxin, *bacitracin*, other antibiotics and a variety of corticosteroids. There is no evidence that these topical preparations shorten the time required for healing of wounds or that those containing a steroid are more effective.

Therapeutic Uses. Neomycin has been used widely for topical application in a variety of infections of the skin and mucous membranes caused by microorganisms susceptible to the drug. These include infections associated with burns, wounds, ulcers, and infected dermatoses. However, such treatment does not eradicate bacteria from the lesions.

The oral administration of neomycin (usually in combination with erythromycin base) has been employed primarily for "preparation" of the bowel for surgery. For therapy of hepatic encephalopathy, a daily dose of 4 to 12 g (in divided doses) by mouth is given, provided that renal function is normal. Because renal insufficiency is a complication of hepatic failure and neomycin is nephrotoxic, it is used rarely for this indication. *Lactulose* is a much less toxic agent and is preferred (see Chapter 37).

Absorption and Excretion. Neomycin is poorly absorbed from the gastrointestinal tract and is excreted by the kidney, as are the other aminoglycosides. An oral dose of 3 g produces a peak plasma concentration of 1 to 4 $\mu\text{g/ml}$; a total daily intake of 10 g for 3 days yields a blood concentration below that associated with systemic toxicity if renal function is normal. Patients with renal insufficiency may accumulate the drug. About 97% of an oral dose of neomycin is not absorbed and is eliminated unchanged in the feces.

Untoward Effects. Hypersensitivity reactions, primarily skin rashes, occur in 6% to 8% of patients when neomycin is applied topically. Individuals sensitive to this agent may develop cross-reactions when exposed to other aminoglycosides. The most important toxic effects of neomycin are renal damage and nerve deafness; this is why the drug is no longer available for parenteral administration. Toxicity has been reported in patients with normal renal function after topical application or irrigation of wounds with 0.5% neomycin solution. Neuromuscular blockade with respiratory paralysis also has occurred after irrigation of wounds or serosal cavities.

The most important adverse effects resulting from the oral administration of neomycin are intestinal malabsorption and superinfection. Individuals treated with 4 to 6 g/day of the drug by mouth sometimes develop a spruelike syndrome with diarrhea, steatorrhea, and azotorrhea. Overgrowth of yeasts in the intestine also may

occur; this is not associated with diarrhea or other symptoms in most cases.

CLINICAL SUMMARY

The role of aminoglycosides in the treatment of bacterial infections has diminished steadily as alternative drugs have become available. The aminoglycosides are narrow-spectrum agents, with their activity limited mainly to gram-negative aerobes. Compared with other antibacterials, aminoglycosides are among the most toxic, particularly if used for prolonged periods of time; serum concentrations must be monitored to avoid drug accumulation. These agents are first-line therapy for only a limited number of very specific, often historically prominent infections, such as plague, tularemia, and tuberculosis. Gentamicin or amikacin may have a role as a backup agent in the treatment of nosocomial infections caused by multidrug-resistant gram-negative pathogens such as *Pseudomonas* or *Acinetobacter*. Gentamicin also may be useful for the treatment of serious urinary tract infections caused by enteric organisms that have acquired resistance to sulfa drugs, penicillins, cephalosporins, and fluoroquinolones. Although gentamicin has been recommended for use in combination with vancomycin or a β -lactam to enhance bactericidal effect (*i.e.*, synergism), the clinical benefit of such combinations is unproven for most infections. Because more effective and less toxic alternatives usually are available, aminoglycosides should be used sparingly and reserved for specific indications, as noted earlier. If an aminoglycoside must be used, the duration of therapy should be kept to a minimum to avoid toxicity, and serum concentrations should be monitored.

PROTEIN SYNTHESIS INHIBITORS AND MISCELLANEOUS ANTIBACTERIAL AGENTS

Henry F. Chambers

The antimicrobial agents discussed in this chapter are: (1) bacteriostatic, protein-synthesis inhibitors that target the ribosome, such as *tetracyclines*, *chloramphenicol*, macrolides, ketolides, *clindamycin*, *quinupristin/dalfopristin*, *linezolid*, and *spectinomycin*; (2) glycopeptides (*vancomycin* and *teicoplanin*) and lipopeptides (*daptomycin*); and (3) miscellaneous compounds acting by diverse mechanisms with limited indications: *bacitracin*, *polymyxin*, and *mupirocin*.

TETRACYCLINES

History. *Chlortetracycline*, the prototype of this class, was introduced in 1948, but is no longer marketed in the United States. Because of their activity against *Rickettsia*, gram-positive and gram-negative bacteria, aerobes, anaerobes, and *Chlamydia*, tetracyclines became known as “broad-spectrum” antibiotics. They are sufficiently similar to permit discussion as a group.

Source and Chemistry. *Oxytetracycline* is a natural product elaborated by *Streptomyces rimosus*. Tetracycline is a semisynthetic derivative of chlortetracycline. *Demeclocycline* is the product of a mutant strain of *Strep. aureofaciens*, and *methacycline* (not available in the United States), *doxycycline*, and *minocycline* all are semisynthetic derivatives. The tetracyclines are close congeners of polycyclic naphthacene-carboxamide. Their structural formulas are shown in Table 46-1.

Effects on Pathogenic Microorganisms. Tetracyclines are bacteriostatic antibiotics with activity against a wide range of aerobic and anaerobic gram-positive and gram-negative bacteria. They also are effective against some microorganisms, such as *Rickettsia*, *Coxiella burnetii*, *Mycoplasma pneumoniae*, *Chlamydia* spp., *Legionella*

spp., *Ureaplasma*, some atypical mycobacteria, and *Plasmodium* spp., that are resistant to cell-wall-active antimicrobial agents. They are not active against fungi. Demeclocycline, tetracycline, oxytetracycline, minocycline, and doxycycline are available in the United States for systemic use. Chlortetracycline and oxytetracycline are used in ophthalmic preparations. Methacycline is not available. Other derivatives are available in other countries. The more lipophilic drugs, minocycline and doxycycline, usually are the most active by weight, followed by tetracycline. Resistance of a bacterial strain to any one member of the class may result in cross-resistance to other tetracyclines. Bacterial strains with tetracycline minimum inhibitory concentrations (MICs) $\leq 4 \mu\text{g/ml}$ are considered susceptible except for *Haemophilus influenzae* and *Streptococcus pneumoniae*, whose susceptibility breakpoints (defined as the upper limit of the concentration at which bacteria are still considered susceptible to a given drug) are $\leq 2 \mu\text{g/ml}$, and *Neisseria gonorrhoeae*, with a breakpoint of $\leq 0.25 \mu\text{g/ml}$.

Bacterial Susceptibilities. Tetracyclines intrinsically are more active against gram-positive than gram-negative microorganisms, but acquired resistance is common. The prevalence of resistant strains varies in different regions. For example, approximately 10% of *Streptococcus pneumoniae* isolates in the United States are resistant to tetracycline versus 40% in the Asia-Pacific region (Hoban *et al.*, 2001). Susceptibilities of staphylococci, enterococci, and hemolytic streptococci are variable: *Bacillus anthracis* and *Listeria monocytogenes* are susceptible, *H. influenzae* is generally susceptible, but many Enterobacteriaceae have acquired resistance. Although all strains of *Pseudomonas aeruginosa* are resistant, 90% of strains of *Burkholderia pseudomallei* (the cause of melioidosis) are sensitive. Most strains of *Brucella* also are susceptible. Tetracyclines remain useful for infections caused by *Haemophilus ducreyi* (chancroid), *Brucella*, *Vibrio cholerae* and

Table 46–1
Structural Formulas of the Tetracyclines

CONGENER	SUBSTITUENT(S)	POSITION(S)
Chlortetracycline	–Cl	7
Oxytetracycline	–OH, –H	5
Demeclocycline	–OH, –H; –Cl	6; 7
Methacycline	–OH, –H; CH ₂	5; 6
Doxycycline	–OH, –H; –CH ₃ , –H	5; 6
Minocycline	–H, –H; –N(CH ₃) ₂	6; 7

V. vulnificus, and inhibit the growth of *Legionella pneumophila*, *Campylobacter jejuni*, *Helicobacter pylori*, *Yersinia pestis*, *Yersinia enterocolitica*, *Francisella tularensis*, and *Pasteurella multocida*. Strains of *Neisseria gonorrhoeae* no longer are predictably susceptible to tetracycline, which is not recommended for treatment of gonococcal infections. The tetracyclines are active against many anaerobic and facultative microorganisms. The MIC breakpoint for susceptible anaerobic bacteria is 8 µg/ml. A variable number of anaerobes (e.g., *Bacteroides* spp., *Propionibacterium*, *Peptococcus*) are sensitive to doxycycline, but other antibiotics (e.g., chloramphenicol, clindamycin, metronidazole, and certain β-lactam antibiotics) have better activity. Tetracycline is active against *Actinomyces* and is a drug of choice for treating actinomycosis.

Rickettsiae. All tetracyclines are highly effective against the rickettsiae responsible for Rocky Mountain spotted fever, murine typhus, epidemic typhus, scrub typhus, rickettsialpox, and Q fever (*C. burnetii*).

Miscellaneous Microorganisms. The tetracyclines are active against many spirochetes, including *Borrelia recurrentis*, *Borrelia burgdorferi* (Lyme disease), *Treponema pallidum* (syphilis), and *Treponema pertenue*. Tetracyclines are active against *Chlamydia* and *Mycoplasma*. Some nontuberculosis strains of mycobacteria (e.g., *M. marinum*) also are susceptible.

Effects on Intestinal Flora. Many of the tetracyclines are incompletely absorbed from the gastrointestinal tract, and high concentrations in the bowel can markedly alter enteric flora. Sensitive aerobic and anaerobic coliform microorganisms and gram-positive spore-forming bacteria are suppressed markedly during long-term tetracycline regimens. As the fecal coliform count declines, overgrowth of tetracycline-resistant microorganisms occurs, particularly of yeasts (*Candida* spp.), enterococci, *Proteus*, and *Pseudomonas*. Tetracycline occasionally produces pseudomembranous colitis caused by *Clostridium difficile*.

Figure 46–1. Inhibition of bacterial protein synthesis by tetracyclines. Messenger RNA (mRNA) attaches to the 30S subunit of bacterial ribosomal RNA. The P (peptidyl) site of the 50S ribosomal RNA subunit contains the nascent polypeptide chain; normally, the aminoacyl tRNA charged with the next amino acid (aa) to be added to the chain moves into the A (acceptor) site, with complementary base pairing between the anticodon sequence of tRNA and the codon sequence of mRNA. Tetracyclines inhibit bacterial protein synthesis by binding to the 30S subunit and blocking tRNA binding to the A site.

Mechanism of Action. Tetracyclines inhibit bacterial protein synthesis by binding to the 30S bacterial ribosome and preventing access of aminoacyl tRNA to the acceptor (A) site on the mRNA-ribosome complex (Figure 46–1). These drugs enter gram-negative bacteria by passive diffusion through the hydrophilic channels formed by the porin proteins of the outer cell membrane and by active transport *via* an energy-dependent system that pumps all tetracyclines across the cytoplasmic membrane. Entry of these drugs into gram-positive bacteria requires metabolic energy, but is not as well understood.

Resistance to the Tetracyclines. Resistance is primarily plasmid-mediated and often is inducible. The three main resistance mechanisms are: (1) decreased accumulation of tetracycline as a result of either decreased antibiotic influx or acquisition of an energy-dependent efflux pathway; (2) production of a ribosomal protection protein that displaces tetracycline from its target, a “protection” that also may occur by mutation; and (3) enzymatic inactivation of tetracyclines. Cross resistance, or lack thereof, among tetracyclines depends on which mechanism is operative. For example, *S. aureus* strains that are tetracycline-resistant on the basis of efflux mediated by *tetK* still may be susceptible to minocycline. Tetracycline resistance due to a ribosomal protection mechanism (*tetM*) produces cross-resis-

tance to doxycycline and minocycline because the target site protected is the same for all tetracyclines.

The glycylicyclines are synthetic analogues of the tetracyclines, with the most promising compound being the 9-*tert*-butyl-glycyamido derivative of minocycline, *tigecycline*. The glycylicyclines exhibit antibacterial activities typical of earlier tetracyclines, and also display activity against tetracycline-resistant organisms containing genes responsible for efflux mechanisms or ribosomal protection. The glycylicyclines also appear to be active against other resistant pathogens including methicillin-resistant *S. aureus* and *S. epidermidis*, penicillin-resistant *S. pneumoniae*, and vancomycin-resistant enterococci.

Absorption, Distribution, and Excretion. Absorption. Oral absorption of most tetracyclines is incomplete. The percentage of an oral dose that is absorbed with an empty stomach is low for chlortetracycline (30%); intermediate for oxytetracycline, demeclocycline, and tetracycline (60% to 80%); and high for doxycycline (95%) and minocycline (100%). The percentage of unabsorbed drug rises as the dose increases. Absorption mostly takes place in the stomach and upper small intestine and is greater in the fasting state. Absorption of tetracyclines is impaired by the concurrent ingestion of dairy products; aluminum hydroxide gels; calcium, magnesium, and iron or zinc salts; and bismuth subsalicylate. Thus, milk, milk products, antacids, Pepto-Bismol, and dietary Fe and Zn supplements will interfere with tetracycline absorption. The decreased absorption apparently results from chelation of divalent and trivalent cations.

Variable absorption of orally administered tetracyclines leads to a wide range of plasma concentrations in different individuals. Oxytetracycline and tetracycline are incompletely absorbed. After a single oral dose, the peak plasma concentration is attained in 2 to 4 hours. These drugs have half-lives in the range of 6 to 12 hours and frequently are administered two to four times daily. The administration of 250 mg every 6 hours produces peak plasma concentrations of 2 to 2.5 $\mu\text{g/ml}$. Increasing the dosage above 1 g every 6 hours does not further increase plasma concentrations. Demeclocycline, which also is incompletely absorbed, can be administered in lower daily dosages than the above-mentioned congeners because its half-life of 16 hours provides effective plasma concentrations for 24 to 48 hours.

Oral doses of oxycycline and minocycline are well absorbed (90% to 100%) and have half-lives of 16 to 18 hours; they therefore can be administered less frequently and at lower doses than tetracycline, oxytetracycline, or demeclocycline. After an oral dose of 200 mg of doxycycline, a maximum plasma concentration of 3 $\mu\text{g/ml}$ is achieved at 2 hours, and the plasma concentration remains above 1 $\mu\text{g/ml}$ for 8 to 12 hours. Plasma concentrations are equivalent whether doxycycline is given orally or parenterally. Food, including dairy products, does not interfere with the absorption of doxycycline or minocycline.

Distribution. Tetracyclines distribute widely throughout the body and into tissues and secretions, including urine and prostate. They accumulate in reticuloendothelial cells of the liver, spleen, and bone marrow, and in bone, dentine, and enamel of unerupted teeth (*see below*).

Inflammation of the meninges is not required for the passage of tetracyclines into the cerebrospinal fluid (CSF). Penetration of these drugs into most other fluids and tissues is excellent. Concentrations in synovial fluid and the mucosa of the maxillary sinus approach that in plasma. Tetracyclines cross the placenta and enter the fetal circulation and amniotic fluid. Relative to the maternal circulation, tetracycline concentrations in umbilical cord plasma and amniotic fluid are 60% and 20%, respectively. Relatively high concentrations of these drugs also are found in breast milk.

Excretion. With the exception of doxycycline, the primary route of elimination for most tetracyclines is the kidney, although they also are concentrated in the liver and excreted in bile. After biliary excretion, they are partially reabsorbed *via* enterohepatic recirculation. Elimination *via* the intestinal tract occurs even when the drugs are given parenterally. Minocycline is an exception and is significantly metabolized by the liver. Comparable amounts of tetracycline (*i.e.*, 20% to 60%) are excreted in the urine within 24 hours following oral or intravenous administration. Approximately 10% to 35% of a dose of oxytetracycline is excreted in active form in the urine, where it can be detected within 30 minutes and reaches a peak concentration about 5 hours after administration. The rate of renal clearance of demeclocycline is less than half that of tetracycline. Decreased hepatic function or obstruction of the common bile duct reduces the biliary excretion of these agents, resulting in longer half-lives and higher plasma concentrations. Because of their enterohepatic circulation, these drugs may remain in the body for a long time after cessation of therapy.

Minocycline is recovered from urine and feces in significantly lower amounts than are the other tetracyclines, and it appears to be metabolized to a considerable extent. Renal clearance of minocycline is low. The drug persists in the body long after its administration is stopped, possibly due to retention in fatty tissues. Nonetheless, the half-life of minocycline is not prolonged in patients with hepatic failure.

Doxycycline at recommended doses does not accumulate significantly in patients with renal failure and thus is one of the safest of the tetracyclines for use in patients with renal impairment. The drug is excreted in the feces. Its half-life may be significantly shortened by concurrent

therapy with barbiturates, phenytoin, rifampin, or other inducers of hepatic microsomal enzymes.

Routes of Administration and Dosage. A wide variety of tetracyclines are available for oral, parenteral, and topical administration. As indicated earlier, only tetracycline, oxytetracycline (TERRAMYCIN, others), demeclocycline (DECLOMYCIN), minocycline (MINOCIN, others), and doxycycline (VIBRAMYCIN, others) are available in the United States.

Oral Administration. The oral dose of tetracycline ranges from 1 to 2 g per day in adults. Children older than 8 years of age should receive 25 to 50 mg/kg daily in two to four divided doses. The recommended dose of demeclocycline is 150 mg every 6 hours or 300 mg every 12 hours for adults and 6 to 12 mg/kg in two to four divided doses for children older than 8 years of age. Demeclocycline is used rarely as an antimicrobial agent because of its higher risks of photosensitivity reactions and nephrogenic diabetes insipidus (*see* Untoward Effects, below). The dose of doxycycline for adults is 100 mg 12 hours apart on the first day and then 100 mg once a day, or twice daily when severe infection is present; for children older than 8 years of age the dose is 4 to 5 mg/kg per day in two divided doses the first day, then 2 to 2.5 mg/kg given once or twice daily. The dose of minocycline for adults is 200 mg initially, followed by 100 mg every 12 hours; for children, it is 4 mg/kg initially followed by 2 mg/kg every 12 hours.

Gastrointestinal distress, nausea, and vomiting can be minimized by administration of tetracyclines with food. As mentioned previously, dairy products; antacids containing calcium, aluminum, zinc, magnesium, or silicate; vitamins with iron; sulcralfate (which contains aluminum); and bismuth subsalicylate will interfere with tetracycline absorption and should be avoided (*see* Chapter 36). Cholestyramine and colestipol also bind orally administered tetracyclines and interfere with their absorption. Generally, tetracyclines should be administered 2 hours before or 2 hours after meals and other drugs that interfere with their absorption.

Parenteral Administration. Doxycycline, the preferred parenteral tetracycline in the United States, is indicated in severe illness, in patients unable to ingest medication, or when the oral drug causes significant nausea and vomiting. Tetracyclines should not be administered intramuscularly because of local irritation and poor absorption.

The usual intravenous dose of doxycycline is 200 mg in one or two infusions on the first day and 100 mg once or twice daily on subsequent days. For children who weigh less than 45 kg, the dose is 4.4 mg/kg on the first

day, after which it is reduced by half. The total daily dose of intravenous tetracycline (no longer available in the United States) for most acute infections is 1 g (or 2 g for severe infection), divided into equal doses and administered at 6- or 12-hour intervals. This dose, which should not be exceeded, may cause adverse effects in some patients (*see* Toxic Effects). The low pH of tetracycline, but not doxycycline or minocycline, invariably causes phlebitis if infused into a peripheral vein. The intravenous dose of minocycline for adults is 200 mg, followed by 100 mg every 12 hours. Children older than 8 years of age should receive an initial dose of 4 mg/kg, followed by 2 mg/kg every 12 hours. Each 100 mg of minocycline must be diluted with 500 to 1000 ml of compatible fluid and slowly infused over 6 hours to minimize toxicity.

Local Application. Except for local use in the eye, topical use of the tetracyclines is not recommended. Their use in ophthalmic therapy is discussed in Chapter 63. Minocycline sustained-release microspheres for subgingival administration are used in dentistry as an adjunct to scaling and root planing procedures to reduce pocket depth in patients with adult periodontitis.

Therapeutic Uses. The tetracyclines have been used extensively to treat infectious diseases and as an additive to animal feeds to facilitate growth. These uses have increased bacterial resistance to tetracyclines, but the drugs remain useful for infections caused by rickettsiae, mycoplasmas, and chlamydiae. Doxycycline is useful for treatment of respiratory tract infections because it covers atypical organisms and because respiratory pathogens increasingly are resistant to other drug classes.

Rickettsial Infections. Tetracyclines are effective and may be life-saving in rickettsial infections, including Rocky Mountain spotted fever, recrudescent epidemic typhus (Brill's disease), murine typhus, scrub typhus, rickettsialpox, and Q fever. Clinical improvement often is evident within 24 hours after initiation of therapy. Doxycycline is the drug of choice for treatment of suspected or proven Rocky Mountain spotted fever in adults and in children, including those younger than 9 years of age, in whom the risk of staining of permanent teeth is outweighed by the seriousness of this potentially fatal infection (Masters *et al.*, 2003).

Mycoplasma Infections. *Mycoplasma pneumoniae* is sensitive to the tetracyclines. Treatment of pneumonia with tetracycline shortens the duration of fever, cough, malaise, fatigue, pulmonary rales, and radiological abnormalities in the lungs. Mycoplasma may persist in the sputum after cessation of therapy, despite rapid resolution of the active infection.

Chlamydia. *Lymphogranuloma Venereum.* Doxycycline (100 mg twice daily for 21 days) is first-line therapy for treatment of this infection. The size of buboes decreases within 4 days, and inclusion and elementary bodies entirely disappear from the lymph nodes within one week. Rectal pain, discharge, and bleeding of lymphogranulomatous proctitis are decreased markedly. When relapses occur, treatment is resumed with full doses and is continued for longer periods.

Pneumonia, bronchitis, or sinusitis caused by *Chlamydia pneumoniae* responds to tetracycline therapy. The tetracyclines also are of value in cases of psittacosis. Drug therapy for 10 to 14 days usually is adequate.

Trachoma. Doxycycline (100 mg twice daily for 14 days) or tetracycline (250 mg four times daily for 14 days) is effective for this infection. However, this disease is important in early childhood before the complete calcification of the permanent teeth, and tetracyclines therefore often are contraindicated (see “Untoward Effects,” below). *Azithromycin* (see section on macrolides), which is effective as a single dose, is preferred.

Nonspecific Urethritis. Nonspecific urethritis is often due to *Chlamydia trachomatis*. Doxycycline, 100 mg every 12 hours for 7 days, is effective; however, azithromycin is usually preferred because it can be given as a single 1-g dose.

Sexually Transmitted Diseases. Because of resistance, doxycycline no longer is recommended for gonococcal infections. If coinfection with *C. trachomatis* has not been excluded, then either doxycycline or azithromycin should be administered in addition to an agent effective for gonococcal urethritis (Centers for Disease Control and Prevention, 2002).

C. trachomatis often is a coexistent pathogen in acute pelvic inflammatory disease, including endometritis, salpingitis, parametritis, and/or peritonitis. Doxycycline, 100 mg intravenously twice daily, is recommended for at least 48 hours after substantial clinical improvement, followed by oral therapy at the same dosage to complete a 14-day course. Doxycycline usually is combined with *cefoxitin* or *cefotetan* (see Chapter 44) to cover anaerobes and facultative aerobes.

Acute epididymitis is caused by infection with *C. trachomatis* or *N. gonorrhoeae* in men less than 35 years of age. Effective regimens include a single injection of ceftriaxone (250 mg) plus doxycycline, 100 mg orally twice daily for 10 days. Sexual partners of patients with any of the above conditions also should be treated.

Nonpregnant, penicillin-allergic patients who have primary, secondary, or latent syphilis can be treated with a tetracycline regimen such as doxycycline 100 mg orally

twice daily for 2 weeks. Tetracyclines should not be used for treatment of neurosyphilis.

Anthrax. Doxycycline 100 mg every 12 hours (2.2 mg/kg every 12 hours for children weighing less than 45 kg) is indicated for prevention or treatment of anthrax. It should be used in combination with another agent when treating inhalational or gastrointestinal infection. The recommended duration of therapy is 60 days for exposures occurring as an act of bioterrorism.

Bacillary Infections. *Brucellosis.* Tetracyclines in combination with rifampin or streptomycin are effective for acute and chronic infections caused by *Brucella melitensis*, *Brucella suis*, and *Brucella abortus*. Effective regimens are doxycycline, 200 mg per day, plus rifampin, 600 to 900 mg daily for 6 weeks, or the usual dose of doxycycline plus streptomycin 1 g daily, intramuscularly. Relapses usually respond to a second course of therapy.

Tularemia. Although streptomycin is preferable, tetracyclines also are effective in tularemia (Ellis *et al.*, 2002). Both the ulceroglandular and typhoidal types of the disease respond well.

Cholera. Doxycycline (300 mg as a single dose) is effective in reducing stool volume and eradicating *Vibrio cholerae* from the stool within 48 hours. Antimicrobial agents, however, are not substitutes for fluid and electrolyte replacement in this disease. In addition, some strains of *V. cholerae* are resistant to tetracyclines.

Other Bacillary Infections. Therapy with the tetracyclines is often ineffective in infections caused by *Shigella*, *Salmonella*, or other Enterobacteriaceae because of a high prevalence of drug-resistant strains in many areas. Resistance limits the usefulness of tetracyclines for travelers' diarrhea.

Coccal Infections. Because of resistance, tetracyclines fell into disuse for infections caused by staphylococci, streptococci, or meningococci. However, community strains of methicillin-resistant *S. aureus* often are susceptible to tetracycline, doxycycline, or minocycline, which appear to be effective for uncomplicated skin and soft-tissue infections. Approximately 85% of strains of *S. pneumoniae* are susceptible to tetracyclines, and doxycycline remains an effective agent for empirical therapy of community-acquired pneumonia (Bartlett *et al.*, 1998).

Urinary Tract Infections. Tetracyclines are no longer recommended for routine treatment of urinary tract infections because many enteric organisms that cause these infections, including *E. coli*, are resistant.

Other Infections. Actinomycosis, although most responsive to penicillin G, may be successfully treated with a tetracycline. Minocycline is an alternative for the treatment of nocardiosis, but a sulfonamide should be used

concurrently. Yaws and relapsing fever respond favorably to the tetracyclines. Tetracyclines are useful in the acute treatment and for prophylaxis of leptospirosis (*Leptospira* spp.). *Borrelia* spp., including *B. recurrentis* (relapsing fever) and *B. burgdorferi* (Lyme disease), respond to therapy with a tetracycline. The tetracyclines have been used to treat susceptible atypical mycobacterial pathogens, including *M. marinum*.

Acne. Tetracyclines have been used to treat acne. They may act by inhibiting propionibacteria, which reside in sebaceous follicles and metabolize lipids into irritating free fatty acids. The relatively low doses of tetracycline used for acne (e.g., 250 mg orally twice a day) apparently are associated with few side effects.

Untoward Effects. Toxic Effects. Gastrointestinal. All tetracyclines can produce gastrointestinal irritation, most commonly after oral administration. Epigastric burning and distress, abdominal discomfort, nausea, vomiting, and diarrhea may occur. Tolerability can be improved by administering the drug with food, but tetracyclines should not be taken with dairy products or antacids. Tetracycline has been associated with esophagitis, esophageal ulcers, and pancreatitis. *Pseudomembranous colitis caused by overgrowth of Clostridium difficile is a potentially life-threatening complication (see below).*

Photosensitivity. Demeclocycline, doxycycline, and other tetracyclines to a lesser extent may produce mild-to-severe photosensitivity reactions in the skin of treated individuals exposed to sunlight. Onycholysis and pigmentation of the nails may develop with or without accompanying photosensitivity.

Hepatic Toxicity. Oxytetracycline and tetracycline are the least hepatotoxic of these agents. Hepatic toxicity typically develops in patients receiving 2 g or more of drug per day parenterally, but this effect also may occur when large quantities are administered orally. Pregnant women are particularly susceptible to tetracycline-induced hepatic damage.

Renal Toxicity. Tetracyclines may aggravate azotemia in patients with renal disease because of their catabolic effects. Doxycycline has fewer renal side effects than do other tetracyclines. Nephrogenic diabetes insipidus has been observed in some patients receiving demeclocycline, and this phenomenon has been exploited for the treatment of the syndrome of inappropriate secretion of antidiuretic hormone (see Chapter 29).

Fanconi syndrome, characterized by nausea, vomiting, polyuria, polydipsia, proteinuria, acidosis, glycosuria, and aminoaciduria, has been observed in patients ingesting outdated and degraded tetracycline. These

symptoms presumably result from a toxic effect on proximal renal tubules.

Effects on Teeth. Children receiving long- or short-term therapy with a tetracycline may develop permanent brown discoloration of the teeth. The larger the drug dose relative to body weight, the more intense the enamel discoloration. The duration of therapy appears to be less important than the total quantity of antibiotic administered. The risk of this untoward effect is highest when a tetracycline is given to neonates and babies before the first dentition. However, pigmentation of the permanent teeth may develop if the drug is given between the ages of 2 months and 5 years, when these teeth are being calcified. The deposition of the drug in the teeth and bones probably is due to its chelating property and the formation of a tetracycline–calcium orthophosphate complex.

Treatment of pregnant patients with tetracyclines may produce discoloration of the teeth in their children. The period of greatest danger to the teeth is from midpregnancy to about 4 to 6 months of the postnatal period for the deciduous anterior teeth, and from a few months to 5 years of age for the permanent anterior teeth, when the crowns are being formed. However, children up to 8 years old may be susceptible to this complication of tetracycline therapy.

Miscellaneous Effects. Tetracyclines are deposited in the skeleton during gestation and throughout childhood and may depress bone growth in premature infants. This is readily reversible if the period of exposure to the drug is short.

Thrombophlebitis frequently follows intravenous administration. This irritative effect of tetracyclines has been used therapeutically in patients with malignant pleural effusions, where drug is instilled into the pleural space in a procedure called pleurodesis.

Long-term tetracycline therapy may produce leukocytosis, atypical lymphocytes, toxic granulation of granulocytes, and thrombocytopenic purpura.

The tetracyclines may cause increased intracranial pressure (pseudotumor cerebri) in young infants, even when given in the usual therapeutic doses. Except for the elevated pressure, the spinal fluid is normal. The pressure promptly returns to normal when therapy is discontinued, and this complication rarely occurs in older individuals.

Patients receiving minocycline may experience vestibular toxicity, manifested by dizziness, ataxia, nausea, and vomiting. The symptoms occur soon after the initial dose and generally disappear within 24 to 48 hours after drug administration is stopped. Long-term use of minocycline can pigment the skin, producing a brownish discoloration. Doxycycline currently is being studied as an inhibitor of matrix metalloproteinases (Villareal *et al.*, 2003), an action unrelated to its effects on bacterial protein synthesis.

Hypersensitivity Reactions. Various skin reactions, including morbilliform rashes, urticaria, fixed drug eruptions, and generalized exfoliative dermatitis, rarely may follow the use of any of the tetracyclines. Among the more severe allergic responses are angioedema and anaphylaxis; anaphylactoid reactions can occur even after the

oral use of these agents. Other hypersensitivity reactions are burning of the eyes, cheilosis, atrophic or hypertrophic glossitis, pruritus ani or vulvae, and vaginitis. Although the exact cause of these reactions is unknown, they can persist for weeks or months after cessation of tetracycline therapy. Fever of varying degrees and eosinophilia may occur when these agents are administered. Asthma also has been observed. Cross-sensitization among the various tetracyclines is common.

Biological Effects Other Than Allergic or Toxic. Like all antimicrobial agents, the tetracyclines administered orally or parenterally may lead to the development of superinfections caused by strains of bacteria or fungi resistant to these agents. Vaginal, oral, and even systemic infections are observed. The incidence of these infections appears to be much higher with the tetracyclines than with the penicillins.

Pseudomembranous colitis, caused by an overgrowth of toxin-producing *C. difficile*, is characterized by severe diarrhea, fever, and stools containing shreds of mucous membrane and a large number of neutrophils. The toxin is cytotoxic to mucosal cells and causes shallow ulcerations that can be seen by sigmoidoscopy. Discontinuation of the drug, combined with the oral administration of metronidazole, usually is curative.

To decrease the incidence of toxic effects, observe the following precautions in the use of the tetracyclines: Do not administer them to pregnant patients; do not use them for treatment of common infections in children younger than 8 years of age; and discard unused supplies of these antibiotics. Inform patients of these precautions.

CHLORAMPHENICOL

History and Source. Chloramphenicol, an antibiotic produced by *Streptomyces venezuelae*, was introduced into clinical practice in 1948. With the drug's wide use, it became evident that chloramphenicol could cause serious and fatal blood dyscrasias. For this reason, chloramphenicol is now reserved for treatment of life-threatening infections (*e.g.*, meningitis, rickettsial infections) in patients who cannot take safer alternatives because of resistance or allergies (Wareham and Wilson, 2002).

Chemistry. Chloramphenicol has the following structural formula:

The antibiotic is unique among natural compounds in that it contains a nitrobenzene moiety and is a derivative of dichloroacetic acid. The biologically active form is levorotatory.

Mechanism of Action. Chloramphenicol inhibits protein synthesis in bacteria, and to a lesser extent, in eukaryotic cells. The drug readily penetrates bacterial cells, probably by facilitated diffusion. Chloramphenicol acts primarily by binding reversibly to the 50S ribosomal sub-

Figure 46–2. Inhibition of bacterial protein synthesis by chloramphenicol. Chloramphenicol binds to the 50S ribosomal subunit at the peptidyltransferase site and inhibits the transpeptidation reaction. Chloramphenicol binds to the 50S ribosomal subunit near the site of action of clindamycin and the macrolide antibiotics. These agents interfere with the binding of chloramphenicol and thus may interfere with each other's actions if given concurrently. See Figure 46–1 and its legend for additional information.

unit (near the binding site for the macrolide antibiotics and clindamycin, which chloramphenicol inhibits competitively). Although binding of tRNA at the codon recognition site on the 30S ribosomal subunit is undisturbed, the drug apparently prevents the binding of the amino acid-containing end of the aminoacyl tRNA to the acceptor site on the 50S ribosomal subunit. The interaction between peptidyltransferase and its amino acid substrate cannot occur, and peptide bond formation is inhibited (Figure 46–2).

Chloramphenicol also can inhibit mitochondrial protein synthesis in mammalian cells, perhaps because mitochondrial ribosomes resemble bacterial ribosomes (both are 70S) more than they do the 80S cytoplasmic ribosomes of mammalian cells. The peptidyltransferase of mitochondrial ribosomes, but not of cytoplasmic ribosomes, is inhibited by chloramphenicol. Mammalian erythropoietic cells are particularly sensitive to the drug.

Antimicrobial Actions. Chloramphenicol possesses a broad spectrum of antimicrobial activity. Strains are considered sensitive if they are inhibited by concentrations of 8 $\mu\text{g}/\text{ml}$ or less, except *N. gonorrhoeae*, *S. pneumoniae*, and *H. influenzae*, which have lower MIC breakpoints. Chloramphenicol is bacteriostatic against most species, although it may be bactericidal against *H. influenzae*, *Neisseria meningitidis*, and *S. pneumoniae*. More than 95% of strains of the following gram-negative bacteria are inhibited *in vitro* by 8 $\mu\text{g}/\text{ml}$

or less of chloramphenicol: *H. influenzae*, *N. meningitidis*, *N. gonorrhoeae*, *Brucella* spp., and *Bordetella pertussis*. Likewise, most anaerobic bacteria, including gram-positive cocci and *Clostridium* spp., and gram-negative rods including *B. fragilis*, are inhibited by this concentration of the drug. Some aerobic gram-positive cocci, including *Streptococcus pyogenes*, *Streptococcus agalactiae* (group B streptococci), and *S. pneumoniae*, are sensitive to 8 µg/ml. Strains of *S. aureus* tend to be less susceptible, with MICs greater than 8 µg/ml. Chloramphenicol is active against *Mycoplasma*, *Chlamydia*, and *Rickettsia*.

The Enterobacteriaceae are variably sensitive to chloramphenicol. Most strains of *Escherichia coli* (75% or more) and *Klebsiella pneumoniae* are susceptible. *Proteus mirabilis* and indole-positive *Proteus* spp. are susceptible. *P. aeruginosa* is resistant to even very high concentrations of chloramphenicol. Strains of *V. cholerae* have remained largely susceptible to chloramphenicol. Strains of *Shigella* and *Salmonella* resistant to multiple drugs, including chloramphenicol, are prevalent. Of special concern is the increasing prevalence of multiple-drug-resistant strains of *Salmonella* serotype typhi, particularly for strains acquired outside the United States.

Resistance to Chloramphenicol. Resistance to chloramphenicol usually is caused by a plasmid-encoded acetyltransferase that inactivates the drug. Resistance also can result from decreased permeability and from ribosomal mutation. Acetylated derivatives of chloramphenicol fail to bind to bacterial ribosomes.

Absorption, Distribution, Fate, and Excretion. Chloramphenicol (CHLOROMYCETIN) is absorbed rapidly from the gastrointestinal tract, and peak concentrations of 10 to 13 µg/ml occur within 2 to 3 hours after the administration of a 1-g dose. The preparation of chloramphenicol for parenteral use is the water-soluble, inactive prodrug sodium succinate. Similar concentrations of chloramphenicol succinate in plasma are achieved after intravenous and intramuscular administration. Hydrolysis of chloramphenicol succinate by esterases occurs *in vivo*. Chloramphenicol succinate is rapidly cleared from plasma by the kidneys; this may reduce overall bioavailability of the drug, since as much as 30% of the dose may be excreted before hydrolysis. Poor renal function in the neonate and other states of renal insufficiency result in increased plasma concentrations of chloramphenicol succinate. Decreased esterase activity has been observed in the plasma of neonates and infants, prolonging time to peak concentrations of active chloramphenicol (up to 4 hours) and extending the period over which renal clearance of chloramphenicol succinate can occur.

Chloramphenicol is widely distributed in body fluids and readily reaches therapeutic concentrations in CSF, where values are approximately 60% of those in plasma (range, 45% to 99%) in the presence or absence of meningitis. The drug actually may accumulate in the brain. Chloramphenicol is present in bile, milk, and placental fluid. It also is found in the aqueous humor after subconjunctival injection.

Hepatic metabolism to the inactive glucuronide is the major route of elimination. This metabolite and chloramphenicol itself are excreted in the urine following filtration and secretion. Patients with cirrhosis or otherwise impaired hepatic function have decreased metabolic clearance, and dosage should be adjusted in these individuals. The half-life of chloramphenicol correlates with plasma bilirubin concentrations. About 50% of chloramphenicol is bound to plasma proteins; such binding is reduced in cirrhotic patients and in neonates. Half-life is not altered significantly by renal insufficiency or hemodialysis, and dosage adjustment usually is not required. However, if the dose of chloramphenicol has been reduced because of cirrhosis, clearance by hemodialysis may be significant. This effect can be minimized by administering the drug at the end of hemodialysis. Significant variability in the metabolism and pharmacokinetics of chloramphenicol in neonates, infants, and children necessitates monitoring of drug concentrations in plasma.

Therapeutic Uses. *Therapy with chloramphenicol must be limited to infections for which the benefits of the drug outweigh the risks of the potential toxicities. When other antimicrobial drugs that are equally effective and potentially less toxic are available, they should be used instead of chloramphenicol* (Wareham and Wilson, 2002).

Typhoid Fever. Third-generation cephalosporins and quinolones are drugs of choice for the treatment of typhoid fever because they are less toxic and because many strains of *Salmonella typhi* often are resistant to chloramphenicol (Parry, 2003).

The adult dose of chloramphenicol for typhoid fever is 1 g every 6 hours for 4 weeks. Although intravenous and oral routes have been used, the response is more rapid with oral administration. Provided that the primary isolate is sensitive, relapses respond satisfactorily to retreatment.

Bacterial Meningitis. Third-generation cephalosporins have replaced chloramphenicol in the therapy of bacterial meningitis (Quagliarello and Scheld, 1997). Chloramphenicol remains an alternative drug for the treatment of meningitis caused by *H. influenzae*, *N. meningitidis*, and *S. pneumoniae* in patients who have severe allergy to β-lactams and in developing countries (Fuller *et al.*, 2003). The total daily dose for children should be 50 to 75 mg/kg of body weight, divided into four equal doses given intravenously every 6 hours for 2 weeks. Results with chloramphenicol used for pneumococcal meningitis may be unsatisfactory, because some strains are inhibited but not killed. Moreover, penicillin-resistant strains frequently also are resistant to chloramphenicol (Hoban *et al.*, 2001). In the rare situation in which chloramphenicol must be used to treat pneumococcal meningitis, lumbar puncture should be repeated 2 to 3 days after treatment is initiated to ensure that an adequate response has occurred. Higher doses of chloramphenicol (100 mg/kg per day) sometimes may be required.

Anaerobic Infections. Chloramphenicol is quite effective against most anaerobic bacteria, including *Bacteroides* spp., and it is effective for treatment of serious intra-abdominal infections or brain

abscesses. However, equally effective and less toxic alternatives are available, and chloramphenicol is rarely indicated.

Rickettsial Diseases. The tetracyclines usually are the preferred agents for the treatment of rickettsial diseases. However, in patients allergic to these drugs, in those with reduced renal function, in pregnant women, and in children younger than 8 years of age who require prolonged or repeated courses of therapy, chloramphenicol may be the drug of choice. Rocky Mountain spotted fever, epidemic, murine, scrub, and recrudescent typhus, and Q fever respond well to chloramphenicol. For adults, a dose of 50 mg/kg per day is recommended for all the rickettsial diseases. The daily dose of chloramphenicol for children with these diseases is 75 mg/kg, divided into equal portions and given every 6 to 8 hours; if chloramphenicol palmitate is used (not available in the United States), the daily maintenance dose may be as high as 100 mg/kg, given at the same intervals. Therapy should be continued until the general condition has improved and the patient is afebrile for 24 to 48 hours.

Brucellosis. Chloramphenicol is not as effective as the tetracyclines in the treatment of brucellosis. When a tetracycline is contraindicated, 750 to 1000 mg of chloramphenicol orally every 6 hours is recommended. Relapses usually respond to retreatment.

Untoward Effects. Chloramphenicol inhibits the synthesis of proteins of the inner mitochondrial membrane, probably by inhibiting the ribosomal peptidyltransferase. These include subunits of cytochrome *c* oxidase, ubiquinone-cytochrome *c* reductase, and the proton-translocating ATPase critical for aerobic metabolism. Much of the toxicity observed with this drug can be attributed to these effects.

Hypersensitivity Reactions. Although relatively uncommon, macular or vesicular skin rashes result from hypersensitivity to chloramphenicol. Fever may appear simultaneously or be the sole manifestation. Angioedema is a rare complication. Jarisch-Herxheimer reactions may occur after institution of chloramphenicol therapy for syphilis, brucellosis, and typhoid fever.

Hematological Toxicity. The most important adverse effect of chloramphenicol is on the bone marrow. Chloramphenicol affects the hematopoietic system in two ways: a dose-related toxicity that presents as anemia, leukopenia, or thrombocytopenia; and an idiosyncratic response manifested by aplastic anemia, leading in many cases to fatal pancytopenia. Pancytopenia seems to occur more commonly in individuals who undergo prolonged therapy and especially in those who are exposed to the drug on more than one occasion. A genetic predisposition is suggested by the occurrence of pancytopenia in identical twins. Although the incidence of the reaction is low—1 in approximately 30,000 or more courses of therapy—the fatality rate is high when bone-marrow aplasia is complete, and there is an increased incidence of acute leukemia in those who recover. Aplastic anemia accounts for approximately 70% of cases of blood dyscrasias due to chloramphenicol, while hypoplastic anemia, agranulocytosis, and thrombocytopenia make up the remainder. The exact biochemical mechanism has not yet been elucidated but is hypothesized to involve conversion of the nitro group to a toxic intermediate by intestinal bacteria.

The risk of aplastic anemia does not contraindicate the use of chloramphenicol in situations in which it may be life-saving. The drug should never be used, however, in undefined situations or in diseases readily, safely, and effectively treatable with other antimicrobial agents.

Dose-related, reversible erythroid suppression probably reflects an inhibitory action of chloramphenicol on mitochondrial protein synthesis in erythroid precursors, which in turn impairs iron incorporation into heme. Leukopenia and thrombocytopenia also may occur. Bone marrow suppression occurs regularly when plasma concentrations are 25 $\mu\text{g/ml}$ or higher and is observed with the use of large doses of chloramphenicol, prolonged treatment, or both. Dose-related suppression of the bone marrow may progress to fatal aplasia if treatment is continued, but most cases of bone marrow aplasia develop suddenly, without prior dose-related marrow suppression. Some patients who developed chronic bone marrow hypoplasia after chloramphenicol treatment subsequently developed acute myeloblastic leukemia.

The administration of chloramphenicol in the presence of hepatic disease frequently depresses erythropoiesis. About one-third of patients with severe renal insufficiency exhibit the same reaction.

Toxic and Irritative Effects. Nausea and vomiting, unpleasant taste, diarrhea, and perineal irritation may follow the oral administration of chloramphenicol. Among the rare toxic effects produced by this antibiotic are blurring of vision and digital paresthesias. Tissues that have a high rate of oxygen consumption may be particularly susceptible to chloramphenicol effects on mitochondrial enzyme systems; encephalopathy and cardiomyopathy have been reported.

Neonates, especially if premature, may develop a serious illness termed *gray baby syndrome* if exposed to excessive doses of chloramphenicol. This syndrome usually begins 2 to 9 days (average of 4 days) after treatment is started. Within the first 24 hours, vomiting, refusal to suck, irregular and rapid respiration, abdominal distention, periods of cyanosis, and passage of loose, green stools occur. The children all are severely ill by the end of the first day, and in the next 24 hours turn an ashen-gray color and become flaccid and hypothermic. A similar “gray syndrome” has been reported in adults who were accidentally overdosed with the drug. Death occurs in about 40% of patients within 2 days of initial symptoms. Those who recover usually exhibit no sequelae.

Neonates, especially if premature, may develop a serious illness termed *gray baby syndrome* if exposed to excessive doses of chloramphenicol. This syndrome usually begins 2 to 9 days (average of 4 days) after treatment is started. Within the first 24 hours, vomiting, refusal to suck, irregular and rapid respiration, abdominal distention, periods of cyanosis, and passage of loose, green stools occur. The children all are severely ill by the end of the first day, and in the next 24 hours turn an ashen-gray color and become flaccid and hypothermic. A similar “gray syndrome” has been reported in adults who were accidentally overdosed with the drug. Death occurs in about 40% of patients within 2 days of initial symptoms. Those who recover usually exhibit no sequelae.

Two mechanisms apparently are responsible for chloramphenicol toxicity in neonates: (1) a developmental deficiency of glucuronyl transferase, the hepatic enzyme that metabolizes chloramphenicol, in the first 3 to 4 weeks of life; and (2) inadequate renal excretion of unconjugated drug. At the onset of the clinical syndrome, chloramphenicol concentrations in plasma usually exceed 100 $\mu\text{g}/\text{ml}$, although they may be as low as 75 $\mu\text{g}/\text{ml}$. Children 2 weeks of age or younger should receive chloramphenicol in a daily dose no larger than 25 mg/kg of body weight; after this age, full-term infants may be given daily quantities up to 50 mg/kg. Toxic effects have not been observed in the newborns when as much as 1 g of the antibiotic has been given every 2 hours to the mothers during labor.

Chloramphenicol is removed only minimally from the blood by either peritoneal dialysis or traditional hemodialysis. Thus, exchange transfusion and charcoal hemoperfusion have been used to treat overdose with chloramphenicol in infants.

Drug Interactions. Chloramphenicol inhibits hepatic cytochrome P450 isozymes (CYPs) and thereby prolongs the half-lives of drugs that are metabolized by this system, including *warfarin*, *dicumarol*, *phenytoin*, *chlorpropamide*, antiretroviral protease inhibitors, *rifabutin*, and *tolbutamide*. Severe toxicity and death have occurred because of failure to recognize such effects.

Conversely, other drugs may alter the elimination of chloramphenicol. Concurrent administration of *phenobarbital* or *rifampin*, which potently induce CYPs, shortens the half-life of the antibiotic and may result in subtherapeutic drug concentrations.

MACROLIDES (ERYTHROMYCIN, CLARITHROMYCIN, AND AZITHROMYCIN)

History and Source. *Erythromycin* was discovered in 1952 by McGuire and coworkers in the metabolic products of a strain of *Streptomyces erythreus*. *Clarithromycin* and azithromycin are semi-synthetic derivatives of erythromycin.

Chemistry. Macrolide antibiotics contain a many-membered lactone ring (14-membered rings for erythromycin and clarithromycin and a 15-membered ring for azithromycin) to which are attached one or more deoxy sugars. Clarithromycin differs from erythromycin only by methylation of the hydroxyl group at the 6 position, and azithromycin differs by the addition of a methyl-substituted nitrogen atom into the lactone ring. These structural modifications improve acid stability and tissue penetration and broaden the spectrum of activity. The structural formulas of the macrolides are as follows:

Antibacterial Activity. Erythromycin usually is bacteriostatic, but may be bactericidal in high concentrations against very susceptible organisms. The antibiotic is most active *in vitro* against aerobic gram-positive cocci and bacilli. Susceptible strains of *S. pyogenes*, *S. pneumoniae*, and viridans streptococci have MICs that range from 0.015 to 1 $\mu\text{g}/\text{ml}$. Macrolide resistance is common among streptococci. Because the mechanisms producing resistance to erythromycin affect all macrolides, cross-resistance among them is complete. The prevalence of macrolide resistance among group A streptococcal isolates, which can be as high as 40%, is related to consumption of macrolide antibiotics within the population. Macrolide resistance among *S. pneumoniae* often coexists with penicillin resistance. Only 5% of penicillin-susceptible strains are macrolide-resistant, whereas 50% or more of penicillin-resistant strains may be macrolide-resistant. Staphylococci are not reliably sensitive to erythromycin. Macrolide-resistant strains of *S. aureus* are potentially

cross-resistant to clindamycin and streptogramin B (quinupristin). Gram-positive bacilli also are sensitive to erythromycin; typical MICs are 1 $\mu\text{g/ml}$ for *Clostridium perfringens*, from 0.2 to 3 $\mu\text{g/ml}$ for *Corynebacterium diphtheriae*, and from 0.25 to 4 $\mu\text{g/ml}$ for *Listeria monocytogenes*.

Erythromycin is inactive against most aerobic enteric gram-negative bacilli. It has modest activity *in vitro* against other gram-negative organisms, including *H. influenzae* (MIC, 1 to 32 $\mu\text{g/ml}$) and *N. meningitidis* (MIC, 0.4 to 1.6 $\mu\text{g/ml}$), and good activity against most strains of *N. gonorrhoeae* (MIC, 0.12 to 2 $\mu\text{g/ml}$). Useful antibacterial activity also is observed against *Pasteurella multocida*, *Borrelia* spp., and *Bordetella pertussis*. Resistance is common for *B. fragilis* (the MIC ranging from 2 to 32 $\mu\text{g/ml}$). Macrolides are usually active against *Campylobacter jejuni* (MIC, 0.5 to 4 $\mu\text{g/ml}$). Erythromycin is active against *M. pneumoniae* (MIC, 0.004 to 0.02 $\mu\text{g/ml}$) and *Legionella pneumophila* (MIC, 0.01 to 2 $\mu\text{g/ml}$). Most strains of *C. trachomatis* are inhibited by 0.06 to 2 $\mu\text{g/ml}$ of erythromycin. Some of the atypical mycobacteria, including *M. scrofulaceum*, are sensitive to erythromycin *in vitro*; *M. kansasii* and *M. avium-intracellulare* vary in sensitivity. *M. fortuitum* is resistant. Macrolides have no effect on viruses, yeasts, or fungi.

Clarithromycin is slightly more potent than erythromycin against sensitive strains of streptococci and staphylococci, and has modest activity against *H. influenzae* and *N. gonorrhoeae*. Clarithromycin has good activity against *M. catarrhalis*, *Chlamydia* spp., *L. pneumophila*, *B. burgdorferi*, *Mycoplasma pneumoniae*, and *H. pylori*.

Azithromycin generally is less active than erythromycin against gram-positive organisms and slightly more active than either erythromycin or clarithromycin against *H. influenzae* and *Campylobacter* spp. Azithromycin is very active against *M. catarrhalis*, *P. multocida*, *Chlamydia* spp., *M. pneumoniae*, *L. pneumophila*, *B. burgdorferi*, *Fusobacterium* spp., and *N. gonorrhoeae*.

In general, organisms are considered susceptible to clarithromycin and azithromycin at MICs ≤ 2 $\mu\text{g/ml}$. An exception is *H. influenzae*, with MIC breakpoints of ≤ 8 $\mu\text{g/ml}$ and ≤ 4 $\mu\text{g/ml}$ for clarithromycin and azithromycin, respectively.

Azithromycin and clarithromycin have enhanced activity against *M. avium-intracellulare*, as well as against some protozoa (e.g., *Toxoplasma gondii*, *Cryptosporidium*, and *Plasmodium* spp.). Clarithromycin has good activity against *Mycobacterium leprae*.

Mechanism of Action. Macrolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to 50S ribosomal subunits of sensitive microorganisms (Figure 46–3), at or very near the site that binds chloramphenicol (Figure 46–2). Erythromycin does not inhibit peptide bond formation *per se*, but rather inhibits the translocation step wherein a newly synthesized peptidyl tRNA molecule moves from the acceptor site on the ribosome to the peptidyl donor site. Gram-positive bacteria accumulate about 100 times more erythromycin than do gram-negative bacteria. Cells are considerably more permeable to the un-ionized form of the drug, which probably explains the increased antimicrobial activity at alkaline pH.

Figure 46–3. Inhibition of bacterial protein synthesis by the macrolide antibiotics erythromycin, clarithromycin, and azithromycin. Macrolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to the 50S ribosomal subunits of sensitive organisms. Erythromycin appears to inhibit the translocation step wherein the nascent peptide chain temporarily residing at the A site of the transferase reaction fails to move to the P, or donor, site. Alternatively, macrolides may bind and cause a conformational change that terminates protein synthesis by indirectly interfering with transpeptidation and translocation. See Figure 46–1 and its legend for additional information.

Resistance to macrolides usually results from one of four mechanisms: (1) drug efflux by an active pump mechanism (encoded by *mrsA*, *mefA*, or *mefE* in staphylococci, group A streptococci, or *S. pneumoniae*, respectively); (2) ribosomal protection by inducible or constitutive production of methylase enzymes, mediated by expression of *ermA*, *ermB*, and *ermC*, which modify the ribosomal target and decrease drug binding; (3) macrolide hydrolysis by esterases produced by Enterobacteriaceae (Lina *et al.*, 1999; Nakajima, 1999); and (4) chromosomal mutations that alter a 50S ribosomal protein (found in *B. subtilis*, *Campylobacter* spp., mycobacteria, and gram-positive cocci).

The MLS_B (macrolide-lincosamide-streptogramin B) phenotype is conferred by *erm* genes, which encode methylases that modify the macrolide binding of the ribosome. Because macrolides, lincosamides, and type B streptogramins share the same ribosomal binding site, constitutive expression of *erm* confers cross-resistance to all three drug classes. If resistance is due to inducible expression of *erm*, there is resistance to the macrolides, which are inducers of *erm*, but not to lincosamides and streptogramin B, which are not inducers. Cross-resistance can still occur if constitutive mutants are selected by exposure to lincosamides or streptogramin B. Efflux-mediated resistance to macrolides

may not result in cross-resistance to lincosamides or streptogramin B because they are structurally dissimilar to macrolides and are not substrates of the macrolide pump.

Absorption, Distribution, and Excretion. Absorption.

Erythromycin base is incompletely but adequately absorbed from the upper small intestine. Because it is inactivated by gastric acid, the drug is administered as enteric-coated tablets, as capsules containing enteric-coated pellets that dissolve in the duodenum, or as an ester. Food, which increases gastric acidity, may delay absorption.

Peak serum concentrations are 0.3 to 0.5 $\mu\text{g/ml}$, 4 hours after oral administration of 250 mg of the base, and 0.3 to 1.9 $\mu\text{g/ml}$ after a single dose of 500 mg. Esters of erythromycin base (e.g., stearate, estolate, and ethylsuccinate) have improved acid stability, and their absorption is less altered by food. A single, oral 250-mg dose of erythromycin estolate produces peak serum concentrations of approximately 1.5 $\mu\text{g/ml}$ after 2 hours, and a 500-mg dose produces peak concentrations of 4 $\mu\text{g/ml}$. Peak serum concentrations of erythromycin ethylsuccinate are 1.5 $\mu\text{g/ml}$ (0.5 $\mu\text{g/ml}$ of base) 1 to 2 hours after administration of a 500-mg dose. These peak values include the inactive ester and the free base, the latter of which comprises 20% to 35% of the total. The concentration of microbiologically active erythromycin base in serum therefore is similar for the various preparations.

Higher concentrations of erythromycin can be achieved by intravenous administration. Values are approximately 10 $\mu\text{g/ml}$ 1 hour after intravenous administration of 500 to 1000 mg of erythromycin lactobionate.

Clarithromycin is absorbed rapidly from the gastrointestinal tract after oral administration, but first-pass metabolism reduces its bioavailability to 50% to 55%. Peak concentrations occur approximately 2 hours after drug administration. Clarithromycin may be given with or without food, but the extended-release form, typically given once-daily as a 1-g dose, should be administered with food to improve bioavailability. Steady-state peak concentrations in plasma of 2 to 3 $\mu\text{g/ml}$ are achieved after 2 hours with a regimen of 500 mg every 12 hours, or after 2 to 4 hours with two 500-mg extended-release tablets given once daily.

Azithromycin administered orally is absorbed rapidly and distributes widely throughout the body, except to the brain and CSF. Concomitant administration of aluminum and magnesium hydroxide antacids decreases the peak serum drug concentrations but not overall bioavailability. Azithromycin should not be administered with food. A 500-mg loading dose will produce a peak plasma drug concentration of approximately 0.4 $\mu\text{g/ml}$. When this loading dose is followed by 250-mg once-daily for 4 days, the steady-state peak drug concentration is 0.24 $\mu\text{g/ml}$. Azithromycin also can be administered intravenously, producing plasma concentrations of 3 to 4 $\mu\text{g/ml}$ after a 1-hour infusion of 500 mg.

Distribution. Erythromycin diffuses readily into intracellular fluids, achieving antibacterial activity in essentially all sites except the brain and CSF. Erythromycin penetrates into prostatic fluid, achieving concentrations approximately 40% of those in plasma. Concentrations in middle ear exudate reach only 50% of serum

concentrations and thus may be inadequate for the treatment of otitis media caused by *H. influenzae*. Protein binding is approximately 70% to 80% for erythromycin base and even higher, 96%, for the estolate. Erythromycin traverses the placenta, and drug concentrations in fetal plasma are about 5% to 20% of those in the maternal circulation. Concentrations in breast milk are 50% of those in serum.

Clarithromycin and its active metabolite, 14-hydroxyclearithromycin, distribute widely and achieve high intracellular concentrations throughout the body. Tissue concentrations generally exceed serum concentrations. Concentrations in middle-ear fluid are 50% higher than simultaneous serum concentrations for clarithromycin and the active metabolite. Protein binding of clarithromycin ranges from 40% to 70% and is concentration dependent.

Azithromycin's unique pharmacokinetic properties include extensive tissue distribution and high drug concentrations within cells (including phagocytes), resulting in much greater concentrations of drugs in tissue or secretions compared to simultaneous serum concentrations. Tissue fibroblasts act as the natural reservoir for the drug *in vivo*. Protein binding is 50% at very low plasma concentrations and less at higher concentrations.

Elimination. Only 2% to 5% of orally administered erythromycin is excreted in active form in the urine; this value is from 12% to 15% after intravenous infusion. The antibiotic is concentrated in the liver and is excreted in the bile, which may contain as much as 250 $\mu\text{g/ml}$ when serum concentrations are very high. The serum elimination half-life of erythromycin is approximately 1.6 hours. Although the half-life may be prolonged in patients with anuria, dosage reduction is not routinely recommended in renal-failure patients. The drug is not removed significantly by either peritoneal dialysis or hemodialysis.

Clarithromycin is eliminated by renal and nonrenal mechanisms. It is metabolized in the liver to several metabolites, the active 14-hydroxy metabolite being the most significant. Primary metabolic pathways are oxidative *N*-demethylation and hydroxylation at the 14 position. The elimination half-lives are 3 to 7 hours for clarithromycin and 5 to 9 hours for 14-hydroxyclearithromycin. Metabolism is saturable, resulting in nonlinear pharmacokinetics with higher dosages; longer half-lives are observed after larger doses. The amount of clarithromycin excreted unchanged in the urine ranges from 20% to 40%, depending on the dose administered and the formulation (tablet *versus* oral suspension). An additional 10% to 15% of a dose is excreted in the urine as 14-hydroxyclearithromycin. Although the pharmacokinetics of clarithromycin are altered in patients with either

hepatic or renal dysfunction, dose adjustment is not necessary unless the creatinine clearance is less than 30 ml per minute.

Azithromycin undergoes some hepatic metabolism to inactive metabolites, but biliary excretion is the major route of elimination. Only 12% of drug is excreted unchanged in the urine. The elimination half-life, 40 to 68 hours, is prolonged because of extensive tissue sequestration and binding.

Therapeutic Uses. Depending on the nature and severity of the infection, the usual oral dose of erythromycin (*erythromycin base*; E-MYCIN, others) for adults ranges from 1 to 2 g per day, in equally divided and spaced amounts, usually given every 6 hours. Daily doses of erythromycin as large as 8 g orally, given for 3 months, have been well tolerated. Food should not be taken concurrently, if possible, with erythromycin base or the stearate formulations, but this is not necessary with *erythromycin estolate* or *erythromycin ethylsuccinate* (E.E.S., others). The oral dose of erythromycin for children is 30 to 50 mg/kg per day, divided into four portions; this dose may be doubled for severe infections. Intramuscular administration of erythromycin is not recommended because of pain upon injection. Intravenous administration is generally reserved for the therapy of severe infections, such as legionellosis. The usual dose is 0.5 to 1 g every 6 hours; 1 g of erythromycin gluceptate has been given intravenously every 6 hours for as long as 4 weeks with no adverse effects except for thrombophlebitis at the site of injection. *Erythromycin lactobionate* (ERYTHROCIN LACTOBIONATE-I.V.) is available for intravenous injection.

Clarithromycin (BIAXIN FILMTABS, BIAXIN XL FILMTABS, and BIAXIN granules for suspension) usually is given twice daily at a dose of 250 mg for children older than 12 years and adults with mild to moderate infection. Larger doses (e.g., 500 mg twice daily) are indicated for more severe infection such as pneumonia or when infection is caused by more resistant organisms such as *H. influenzae*. Children younger than 12 years old have received 7.5 mg/kg twice daily in clinical studies. The 500-mg, extended-release formulation is given as two tablets once daily. Clarithromycin (500 mg) is also packaged with *lansoprazole* (30 mg) and *amoxicillin* (1 g) as a combination regimen (PREVPAC) that is administered twice daily for 14 days to eradicate *H. pylori* and to reduce the associated risk of duodenal ulcer recurrence (see Chapter 36).

Azithromycin (ZITHROMAX tablet, oral suspension, and powder for intravenous injection) should be given 1 hour before or 2 hours after meals when administered orally.

For outpatient therapy of community-acquired pneumonia, pharyngitis, or skin and skin-structure infections, a loading dose of 500 mg is given on the first day, then 250 mg per day is given for days 2 through 5. Treatment or prophylaxis of *M. avium-intracellulare* infection in AIDS patients requires higher doses: 500 mg daily in combination with one or more other agents for treatment, or 1200 mg once weekly for primary prevention (Kovacs and Masur, 2000). Azithromycin is useful in treatment of sexually transmitted diseases, especially during pregnancy when tetracyclines are contraindicated. The treatment of uncomplicated nongonococcal urethritis presumed to be caused by *C. trachomatis* consists of a single 1-g dose of azithromycin. This dose also is effective for chancroid. Azithromycin (1 g a week for 3 weeks) is an alternative regimen for treatment of granuloma inguinale or lymphogranuloma venereum.

In children, the recommended dose of azithromycin oral suspension for acute otitis media and pneumonia is 10 mg/kg on the first day (maximum 500 mg) and 5 mg/kg (maximum 250 mg per day) on days 2 through 5. The dose for tonsillitis or pharyngitis is 12 mg/kg per day, up to 500 mg total, for 5 days.

***Mycoplasma pneumoniae* Infections.** A macrolide or tetracycline is the drug of choice for mycoplasma infections. Erythromycin reduces the duration of fever caused by *M. pneumoniae* and accelerates the rate of clearing of the chest radiographs.

Legionnaires' Disease. Erythromycin has been considered as the drug of choice for treatment of pneumonia caused by *L. pneumophila*, *L. micdadei*, or other *Legionella* spp. Because of excellent *in vitro* activity, superior tissue concentration, the ease of administration as a single daily dose, and better tolerability compared to erythromycin, azithromycin (or a fluoroquinolone) has supplanted erythromycin as the first-line agent for treatment of legionellosis (Garey and Amsden, 1999). The recommended dose is 500 mg daily, intravenously or orally, for a total of 10 to 14 days.

Chlamydial Infections. Chlamydial infections can be treated effectively with any of the macrolides. A single 1-g dose of azithromycin is recommended for patients with uncomplicated urethral, endocervical, rectal, or epididymal infections because of the ease of compliance. During pregnancy, erythromycin base, 500 mg four times daily for 7 days, is recommended as first-line therapy for chlamydial urogenital infections. Azithromycin, 1 g orally as a single dose, is a suitable alternative. Erythromycin base is preferred for chlamydial pneumonia of infancy and ophthalmia neonatorum (50 mg/kg per day in four divided doses for 10 to 14 days). Azithromycin, 1 g a week for 3 weeks, may be effective for lymphogranuloma venereum.

Pneumonia caused by *Chlamydia pneumoniae* responds to macrolides, fluoroquinolones, and tetracyclines in standard doses for community-acquired pneumonia. No comparative trials have been conducted to determine which agent, if any, is most efficacious. Duration of therapy also is ill defined. In practice, a specific etiological diagnosis rarely is made and length of treatment, typically 7 to 10 days, often is determined empirically based on clinical response.

Diphtheria. Erythromycin 250 mg four times daily for 7 days is very effective for acute infections or for eradicating the carrier state. The other macrolides also are likely to be effective; because clinical experience with them is lacking, they are not FDA approved for this indication. The presence of an antibiotic does not alter the course of an acute infection with the diphtheria bacillus or the risk of complications. Antitoxin is indicated in the treatment of acute infection.

Pertussis. Erythromycin is the drug of choice for treating persons with *B. pertussis* disease and for postexposure prophylaxis of household members and close contacts. A 7-day regimen of erythromycin estolate (40 mg/kg per day, maximum 1 g/day) is as effective as the 14-day regimens traditionally recommended (Halperin *et al.*, 1997). Clarithromycin and azithromycin also are effective (Bace *et al.*, 1999). If administered early in the course of whooping cough, erythromycin may shorten the duration of illness; it has little influence on the disease once the paroxysmal stage is reached, although it may eliminate the microorganisms from the nasopharynx. Nasopharyngeal cultures should be obtained from people with pertussis who do not improve with erythromycin therapy, since resistance has been reported.

Streptococcal Infections. Pharyngitis, scarlet fever, erysipelas, and cellulitis caused by *S. pyogenes* and pneumonia caused by *S. pneumoniae* respond to macrolides. They are valuable alternatives for treatment of patients who have a serious allergy to penicillin. Unfortunately, macrolide-resistant strains are increasingly encountered. Penicillin-resistant strains of *S. pneumoniae* also are very likely to be resistant to macrolides.

Staphylococcal Infections. Erythromycin has been an alternative agent for the treatment of relatively minor infections caused by either penicillin-sensitive or penicillin-resistant *S. aureus*. However, many strains of *S. aureus* are resistant to macrolides, and they no longer can be relied upon unless *in vitro* susceptibility has been documented.

Campylobacter Infections. The treatment of gastroenteritis caused by *C. jejuni* with erythromycin (250 to 500 mg orally four times a day for 7 days) hastens eradication of the microorganism from the stools and reduces the duration of symptoms. Availability of fluoroquinolones, which are highly active against *Campylobacter* species and other enteric pathogens, largely has replaced the use of erythromycin for this disease in adults. Erythromycin remains useful for treatment of *Campylobacter* gastroenteritis in children.

Helicobacter pylori Infection. Clarithromycin 500 mg, in combination with omeprazole, 20 mg, and amoxicillin, 1 g, each administered twice daily for 10 to 14 days, is effective for treatment of peptic ulcer disease caused by *H. pylori* (Peterson *et al.*, 2000). Numerous other regimens, some effective as 7-day treatments, have been studied and also are effective. The more effective regimens generally include three agents, one of which usually is clarithromycin (see Chapter 36).

Tetanus. Erythromycin (500 mg orally every 6 hours for 10 days) may be given to eradicate *Clostridium tetani* in patients with tetanus who are allergic to penicillin. However, the mainstays of therapy are débridement, physiological support, tetanus antitoxin, and drug control of convulsions.

Syphilis. Erythromycin has been used in the treatment of early syphilis in patients who are allergic to penicillin, but it no longer is recommended. Tetracyclines are the recommended alternative in penicillin-allergic patients. During pregnancy it is recommended that patients be desensitized to penicillin.

Mycobacterial Infections. Clarithromycin or azithromycin is recommended as first-line therapy for prophylaxis and treatment of dis-

seminated infection caused by *M. avium-intracellulare* in AIDS patients and for treatment of pulmonary disease in non-HIV-infected patients (Kovacs and Masur, 2000). Azithromycin (1.2 g once weekly) or clarithromycin (500 mg twice daily) is recommended for primary prevention for AIDS patients with fewer than 50 CD4 cells per mm³. Single-agent therapy should not be used for treatment of active disease or for secondary prevention in AIDS patients. Clarithromycin (500 mg twice daily) plus ethambutol (15 mg/kg once daily) with or without rifabutin is an effective combination regimen. Azithromycin (500 mg once daily) may be used instead of clarithromycin, but clarithromycin appears to be slightly more efficacious (Ward *et al.*, 1998). Clarithromycin also has been used with minocycline for the treatment of *Mycobacterium leprae* in lepromatous leprosy.

Other Infections. Clarithromycin and azithromycin have been used in the treatment of toxoplasmosis encephalitis and diarrhea due to *Cryptosporidium* in AIDS patients. Rigorous clinical trials demonstrating efficacy of macrolides for these infections are lacking.

Prophylactic Uses. Penicillin is the drug of choice for the prophylaxis of recurrences of rheumatic fever. Erythromycin is an effective alternative for individuals who are allergic to penicillin.

Erythromycin has been recommended as an alternative to penicillin in allergic patients for prevention of bacterial endocarditis after dental or respiratory-tract procedures. Clindamycin has replaced erythromycin for use in penicillin-allergic patients. Clarithromycin or azithromycin as a single 500-mg dose also may be used (Dajani *et al.*, 1997).

Untoward Effects. Serious untoward effects are rarely caused by erythromycin. Among the allergic reactions observed are fever, eosinophilia, and skin eruptions, which may occur alone or in combination; each disappears shortly after therapy is stopped. Cholestatic hepatitis is the most striking side effect. It is caused primarily by erythromycin estolate and rarely by the ethylsuccinate or the stearate. The illness starts after about 10 to 20 days of treatment and is characterized initially by nausea, vomiting, and abdominal cramps. The pain often mimics that of acute cholecystitis. These symptoms are followed shortly thereafter by jaundice, which may be accompanied by fever, leukocytosis, eosinophilia, and elevated transaminases in plasma. Biopsy of the liver reveals cholestasis, periportal infiltration by neutrophils, lymphocytes, and eosinophils, and occasionally, necrosis of neighboring parenchymal cells. Findings usually resolve within a few days after cessation of drug therapy and rarely are prolonged. The syndrome may represent a hypersensitivity reaction to the estolate ester.

Oral administration of erythromycin, especially of large doses, frequently is accompanied by epigastric distress, which may be quite severe. Intravenous administration of erythromycin may cause similar symptoms, with abdominal cramps, nausea, vomiting, and diarrhea. Erythromycin stimulates gastrointestinal motility by acting on motilin receptors. Because of this property, eryth-

romycin is used postoperatively to promote peristalsis; it has been exploited to speed gastric emptying in patients with gastroparesis (see Chapter 37). The gastrointestinal symptoms are dose-related and occur more commonly in children and young adults; they may be reduced by prolonging the infusion time to 1 hour or by pretreatment with glycopyrrolate (Bowler *et al.*, 1992). Intravenous infusion of 1-g doses, even when dissolved in a large volume, often is followed by thrombophlebitis. This can be minimized by slow rates of infusion.

Erythromycin has been reported to cause cardiac arrhythmias, including QT prolongation with ventricular tachycardia. Most patients have had underlying cardiac disease, or the arrhythmias were associated with combination drug therapies that included erythromycin (*e.g.*, *cisapride* or *terfenadine* plus erythromycin; see Chapter 34).

Transient auditory impairment is a potential complication of treatment with erythromycin; it has been observed to follow intravenous administration of large doses of the gluceptate or lactobionate (4 g per day) or oral ingestion of large doses of the estolate.

Drug Interactions. Erythromycin and clarithromycin inhibit CYP3A4 and are associated with clinically significant drug interactions (Periti *et al.*, 1992). Erythromycin potentiates the effects of *carbamazepine*, corticosteroids, *cyclosporine*, *digoxin*, ergot alkaloids, *theophylline*, *triazolam*, *valproate*, and *warfarin*, probably by interfering with CYP-mediated metabolism of these drugs (see Chapter 3). Clarithromycin, which is structurally related to erythromycin, has a similar drug interaction profile. Azithromycin, which differs from erythromycin and clarithromycin because of its 15-membered lactone ring structure, and *dirithromycin*, which is a longer-acting 14-membered lactone ring analog of erythromycin analog, appear to be free of these drug interactions. Caution is advised, nevertheless, when using azithromycin in conjunction with drugs known to interact with erythromycin.

KETOLIDES (TELITHROMYCIN)

Source and Chemistry. Ketolides, of which *telithromycin* (Ketek) is the only one currently approved, are semisynthetic derivatives of erythromycin (Ackermann and Rodloff, 2003). Telithromycin differs from erythromycin in that a 3-keto group replaces the α -L-cladinose of the 14-member macrolide ring, and there is a substituted carbamate at C11-C12. These modifications render ketolides less susceptible to methylase-mediated (*erm*) and efflux-mediated (*mef* or *msr*) mechanisms of resistance. Ketolides therefore are active against many macrolide-resistant gram-positive strains. The structural formula of telithromycin is:

TELITHROMYCIN

Antibacterial Activity. Ketolides and macrolides have very similar antibacterial properties. Telithromycin is active against staphylococci, streptococci, *S. pneumoniae*, *Haemophilus* spp., *Moraxella catarrhalis*, mycoplasma, chlamydia, and *Legionella*. It is slightly more active by weight than erythromycin. MIC breakpoints for telithromycin are ≤ 0.25 $\mu\text{g/ml}$ for *S. aureus*, ≤ 1 $\mu\text{g/ml}$ for *S. pneumoniae*, and ≤ 4 $\mu\text{g/ml}$ for *H. influenzae*.

Mechanism of Action and Resistance. Ketolides and macrolides have the same ribosomal target site. The principal difference between the two is that structural modifications within ketolides neutralize the common resistance mechanisms that make macrolides ineffective (Nilius and Ma, 2002). Introduction of the 3-keto function converts a methylase-inducing macrolide into a non-inducing ketolide. This moiety also prevents drug efflux, probably because it generates a less-desirable substrate. The carbamate substitution at C11-C12 enhances binding to the ribosomal target site, even when the site is methylated, by introducing an extra interaction of the ketolide with the ribosome. Inducible and constitutive methylase-producing strains of *S. pneumoniae* are therefore telithromycin-susceptible. However, constitutive methylase-producing strains of *S. aureus* and *S. pyogenes* are telithromycin-resistant because the strength of the ketolide interaction with the fully methylated ribosomal binding site is insufficient to overcome resistance. Constitutive methylase producers can be selected from strains with the inducible *erm* phenotype.

Absorption, Distribution, and Excretion. Telithromycin is formulated as a 400-mg tablet for oral administration. There is no parenteral form. It is well absorbed with approximately 60% bioavailability. Peak serum concentrations, averaging 2 $\mu\text{g/ml}$ following a single, 800-mg oral dose, are achieved within 30 minutes to 4 hours. With

a half-life of 9.8 hours, the drug can be given once daily. It is 60% to 70% bound by serum protein, principally albumin. It penetrates well into most tissues, exceeding plasma concentrations by approximately two- to tenfold or more. Telithromycin is concentrated into macrophages and white blood cells, where concentrations of 40 $\mu\text{g}/\text{ml}$ (500 times the simultaneous plasma concentration) are maintained 24 hours after dosing. The drug is cleared primarily by hepatic metabolism, 50% by CYP3A4 and 50% by CYP-independent metabolism. No adjustment of the dose is required for hepatic failure or mild-to-moderate renal failure. No dose has been established for patients in whom creatinine clearance is less than 30 ml/minute, although a reduction in dosage probably is advisable (Shi *et al.*, 2004).

Therapeutic Uses. Given its spectrum of activity and based on its noninferiority against a number of comparators, telithromycin is approved for treatment of respiratory tract infections, including acute exacerbation of chronic bronchitis (5-day regimen), acute bacterial sinusitis (5-day regimen), and community-acquired pneumonia (7- to 10-day regimen). Although telithromycin is not indicated for treatment of severe pneumonia or bacteremia, almost 90% of patients who proved to have pneumococcal bacteremia were clinically cured after taking it. In premarketing trials of telithromycin on patients with community-acquired pneumonia caused by multiple-drug-resistant strains of *S. pneumoniae* (resistant to penicillins, cephalosporins, macrolides, tetracyclines, or trimethoprim-sulfamethoxazole) over 90% of patients were cured.

Untoward Effects. Telithromycin generally is well tolerated. Nausea, vomiting, and diarrhea are the most common side effects, occurring in 3% to 10% of treatment courses. Visual disturbances due to slowed accommodation occur in about 1% of treatment courses, and include blurred vision, difficulty focusing, and diplopia. Reversible hepatic dysfunction with elevated transaminases or hepatitis has been reported. Pseudomembranous colitis has been reported. Telithromycin is not recommended for routine use in patients with myasthenia gravis due to reports of disease exacerbation in telithromycin-treated patients.

Telithromycin may cause clinically significant QTc prolongation and increased risk of ventricular arrhythmia in predisposed patients (*see* Chapter 34). It should not be used in patients with prolonged QT syndrome, uncorrected hypokalemia or hypomagnesemia, profound bradycardia, or in patients receiving certain antiarrhythmics (*e.g.*, *quinidine*, *procainamide*, *amiodarone*) or other agents that prolong QTc (*e.g.*, *cisapride*, *pimozide*).

Telithromycin has several clinically significant drug interactions similar to those for erythromycin. It is both a substrate and a strong inhibitor of CYP3A4. Coadministration of rifampin, a potent inducer of CYP, decreases the serum concentrations of telithromycin by 80%. CYP3A4 inhibitors (*e.g.*, *itraconazole*) increase peak serum concentrations of telithromycin. Serum concentrations of CYP3A4 substrates (*e.g.*, *pimozide*, *cisapride*, *midazolam*, *statins*, *cyclosporine*, *phenytoin*) are increased by telithromycin. Telithromycin also increases peak serum concentrations of *metoprolol* and *digoxin*.

CLINDAMYCIN

Chemistry. Clindamycin is a derivative of the amino acid *trans*-L-4-*n*-propylhygrinic acid, attached to a sulfur-containing derivative of an octose. It is a congener of *lincomycin*, and its structural formula is:

Mechanism of Action. Clindamycin binds exclusively to the 50S subunit of bacterial ribosomes and suppresses protein synthesis. Although clindamycin, erythromycin, and chloramphenicol are not structurally related, they act at sites in close proximity (Figures 46–2 and 46–3), and binding by one of these antibiotics to the ribosome may inhibit the interaction of the others. There are no clinical indications for the concurrent use of these antibiotics. Macrolide resistance due to ribosomal methylation by *erm*-encoded enzymes also may produce resistance to clindamycin. However, because clindamycin does not induce the methylase, there is cross-resistance only if the enzyme is produced constitutively. Clindamycin is not a substrate for macrolide efflux pumps; thus strains that are resistant to macrolides by this mechanism are susceptible to clindamycin. Altered metabolism occasionally causes clindamycin resistance (Bozdogan *et al.*, 1999).

Antibacterial Activity. Bacterial strains are susceptible to clindamycin at MICs of $\leq 0.5 \mu\text{g}/\text{ml}$. Clindamycin generally

is similar to erythromycin in its *in vitro* activity against susceptible strains of pneumococci, *S. pyogenes*, and viridans streptococci. Ninety percent or more of strains of streptococci, including some that are macrolide-resistant, remain susceptible to clindamycin, with MICs less than 0.5 µg/ml (Doern *et al.*, 1998). Methicillin-susceptible strains of *S. aureus* usually are susceptible to clindamycin, but methicillin-resistant strains of *S. aureus* and coagulase-negative staphylococci frequently are resistant.

Clindamycin is more active than erythromycin or clarithromycin against anaerobic bacteria, especially *B. fragilis*; some strains are inhibited by <0.1 µg/ml, and most are inhibited by 2 µg/ml. The MICs for other anaerobes are as follows: *Bacteroides melanogenicus*, 0.1 to 1 µg/ml; *Fusobacterium*, <0.5 µg/ml (although most strains of *Fusobacterium varium* are resistant); *Peptostreptococcus*, <0.1 to 0.5 µg/ml; *Peptococcus*, 1 to 100 µg/ml (with 10% of strains resistant); and *C. perfringens*, <0.1 to 8 µg/ml. From 10% to 20% of clostridial species other than *C. perfringens* are resistant. Resistance to clindamycin in *Bacteroides* spp. increasingly is encountered (Hedberg and Nord, 2003). Strains of *Actinomyces israelii* and *Nocardia asteroides* are sensitive. Essentially all aerobic gram-negative bacilli are resistant.

With regard to atypical organisms and parasites, *M. pneumoniae* is resistant. *Chlamydia* spp. are variably sensitive, although the clinical relevance is not established. Clindamycin plus primaquine and clindamycin plus pyrimethamine are second-line regimens for *Pneumocystis jirovecii* pneumonia and *T. gondii* encephalitis, respectively. Clindamycin has been used for treatment of babesiosis.

Absorption, Distribution, and Excretion. *Absorption.*

Clindamycin is nearly completely absorbed following oral administration. Peak plasma concentrations of 2 to 3 µg/ml are attained within 1 hour after the ingestion of 150 mg. The presence of food in the stomach does not reduce absorption significantly. The half-life of the antibiotic is about 2.9 hours, and modest accumulation of drug is thus expected if it is given every 6 hours.

Clindamycin palmitate, an oral preparation for pediatric use, is an inactive prodrug that is hydrolyzed rapidly *in vivo*. Its rate and extent of absorption are similar to those of clindamycin. After several oral doses at 6-hour intervals, children attain plasma concentrations of 2 to 4 µg/ml with the administration of 8 to 16 µg/kg.

The phosphate ester of clindamycin, which is given parenterally, also is rapidly hydrolyzed *in vivo* to the active parent compound. After intramuscular injection, peak concentrations in plasma are not attained until 3 hours in adults and 1 hour in children; these values approximate 6 µg/ml after a 300-mg dose and 9 µg/ml after a 600-mg dose in adults.

Distribution. Clindamycin is widely distributed in many fluids and tissues, including bone. Significant concentrations are not attained in CSF, even when the

meninges are inflamed. Concentrations sufficient to treat cerebral toxoplasmosis are achievable (Gatti *et al.*, 1998). The drug readily crosses the placental barrier. Ninety percent or more of clindamycin is bound to plasma proteins. Clindamycin accumulates in polymorphonuclear leukocytes, alveolar macrophages, and in abscesses.

Excretion. Only about 10% of the clindamycin administered is excreted unaltered in the urine, and small quantities are found in the feces. However, antimicrobial activity persists in feces for 5 or more days after parenteral therapy with clindamycin is stopped; growth of clindamycin-sensitive microorganisms in colonic contents may be suppressed for up to 2 weeks.

Clindamycin is inactivated by metabolism to *N*-demethylclindamycin and clindamycin sulfoxide, which are excreted in the urine and bile. Accumulation of clindamycin can occur in patients with severe hepatic failure, and dosage adjustments thus may be required.

Therapeutic Uses. The oral dose of clindamycin (*clindamycin hydrochloride*; CLEOCIN) for adults is 150 to 300 mg every 6 hours; for severe infections, it is 300 to 600 mg every 6 hours. Children should receive 8 to 12 mg/kg per day of *clindamycin palmitate hydrochloride* (CLEOCIN PEDIATRIC) in three or four divided doses (some physicians recommend 10 to 30 mg/kg per day in six divided doses) or for severe infections, 13 to 25 mg/kg per day. However, children weighing 10 kg or less should receive ½ teaspoonful of clindamycin palmitate hydrochloride (37.5 mg) every 8 hours as a minimal dose.

For serious infections due to aerobic gram-positive cocci and the more sensitive anaerobes (not generally including *B. fragilis*, *Peptococcus*, and *Clostridium* spp. other than *C. perfringens*), intravenous or intramuscular administration is recommended in dosages of 600 to 1200 mg per day, divided into three or four equal doses for adults. *Clindamycin phosphate* (CLEOCIN PHOSPHATE) is available for intramuscular or intravenous use. For more severe infections, particularly those proven or suspected to be caused by *B. fragilis*, *Peptococcus*, or *Clostridium* species other than *C. perfringens*, parenteral administration of 1.2 to 2.4 g per day of clindamycin is suggested. Daily doses as high as 4.8 g have been given intravenously to adults. Children should receive 10 to 40 mg/kg per day in three or four divided doses; in severe infections, a minimal daily dose of 300 mg is recommended, regardless of body weight.

Although a number of infections with gram-positive cocci will respond favorably to clindamycin, the high incidence of diarrhea and the occurrence of pseudomembranous colitis limit its use to infections in which it is clearly superior to other agents. Clindamycin is particularly valuable for the treatment of infections with anaerobes, especially those due to *B. fragilis*. Clindamycin is not predictably useful for the treatment of bacterial brain abscesses, since penetration into the CSF is poor; metronidazole, in combination with penicillin or a third-generation cephalosporin, is preferred.

On the basis of one clinical trial which found that clindamycin (600 mg intravenously every 8 hours) was superior to penicillin (1 million units intravenously every 4 hours; Levison *et al.*, 1983), clindamycin has replaced penicillin as the drug of choice for treatment of lung abscess and anaerobic lung and pleural space infections.

Clindamycin (600 to 1200 mg given intravenously every 6 hours) in combination with pyrimethamine (a 200-mg loading dose followed by 75 mg orally each day) and *leucovorin* (folinic acid, 10 mg/day) is effective for acute treatment of encephalitis caused by *T. gondii* in patients with AIDS. Clindamycin (600 mg intravenously every 8 hours, or 300 to 450 mg orally every 6 hours for less severe disease) in combination with primaquine (15 mg of base once daily) is useful for the treatment of mild to moderate cases of *P. jiroveci* pneumonia in AIDS patients.

Clindamycin also is available as a topical solution, gel, or lotion (CLEOCIN T, others) and as a vaginal cream (CLEOCIN). It is effective topically (or orally) for acne vulgaris and bacterial vaginosis.

Untoward Effects. The reported incidence of diarrhea associated with the administration of clindamycin ranges from 2% to 20%. A number of patients (variously reported as 0.01% to 10%) have developed pseudomembranous colitis caused by the toxin from the organism *C. difficile*. This colitis is characterized by abdominal pain, diarrhea, fever, and mucus and blood in the stools. Proctoscopic examination reveals white to yellow plaques on the mucosa of the colon. *This syndrome may be lethal.* Discontinuation of the drug, combined with administration of metronidazole orally or intravenously usually is curative, but relapses can occur. Agents that inhibit peristalsis, such as opioids, may prolong and worsen the condition.

Skin rashes occur in approximately 10% of patients treated with clindamycin and may be more common in patients with HIV infection. Other reactions, which are uncommon, include exudative erythema multiforme (Stevens-Johnson syndrome), reversible elevation of aspartate aminotransferase and alanine aminotransferase, granulocytopenia, thrombocytopenia, and anaphylactic reactions. Local thrombophlebitis may follow intravenous administration of the drug. Clindamycin can inhibit neuromuscular transmission and may potentiate the effect of a neuromuscular blocking agent administered concurrently.

QUINUPRISTIN/DALFOPRISTIN

Quinupristin/dalfopristin (SYNERCID) is a combination of quinupristin, a streptogramin B, with dalfopristin, a streptogramin A, in a 30:70 ratio. These compounds are semisynthetic derivatives of naturally occurring pristina-mycins, produced by *Streptomyces pristinaespiralis*. *Pristinamycin* has been available in France for more

than 30 years for oral treatment of staphylococcal infections. Quinupristin and dalfopristin are more soluble derivatives of pristinamycin IA and pristinamycin IIA, respectively, and therefore are suitable for intravenous administration. Their chemical structures are:

Antibacterial Activity. Quinupristin/dalfopristin is active against gram-positive cocci, including *S. pneumoniae*, beta- and alpha-hemolytic strains of streptococci, *E. faecium* (but not *E. faecalis*), and coagulase-positive and coagulase-negative strains of staphylococci. The combination is largely inactive against gram-negative organisms, although *Moraxella catarrhalis* and *Neisseria* spp. are susceptible. It also is active against organisms responsible for atypical pneumonia, *M. pneumoniae*, *Legionella* spp., and *Chlamydia pneumoniae*. The combination is bactericidal against streptococci and many strains of staphylococci, but bacteriostatic against *E. faecium*. MICs for strains of streptococci, including penicillin-susceptible and penicillin-resistant strains of *S. pneumoniae*, are 0.25 to 1 $\mu\text{g/ml}$. MICs typically are <1 $\mu\text{g/ml}$ for both methicillin-susceptible and methicillin-resistant strains of staphylococci and for vancomycin-intermediate *S. aureus* strains. MICs for *E. faecium* are 1 $\mu\text{g/ml}$ or less for both

vancomycin-susceptible and vancomycin-resistant strains, but for *E. faecalis* are 8 µg/ml or higher.

Mechanism of Action. Quinupristin and dalbapristin are protein synthesis inhibitors that bind the 50S ribosomal subunit. Quinupristin binds at the same site as macrolides and has a similar effect, with inhibition of polypeptide elongation and early termination of protein synthesis. Dalbapristin binds at a site nearby, resulting in a conformational change in the 50S ribosome, synergistically enhancing the binding of quinupristin at its target site. Dalbapristin directly interferes with polypeptide-chain formation. In many bacterial species, the net result of the cooperative and synergistic binding of these two molecules to the ribosome is bactericidal activity.

Resistance to quinupristin is mediated by MLS type B resistance determinants (e.g., *ermA* and *ermC* in staphylococci and *ermB* in enterococci), encoding a ribosomal methylase that prevents binding of drug to its target; or *vgb* or *vgbB*, which encode lactonases that inactivate type B streptogramins (Allignet *et al.*, 1998; Bozdogan and Leclercq, 1999). Resistance to dalbapristin is mediated by *vat*, *vatB*, *vatC*, *vatD*, and *sata*, which encode acetyltransferases that inactivate type A streptogramins (Allignet *et al.*, 1998; Allignet and El Solh, 1999; Soltani *et al.*, 2000); or staphylococcal genes *vga* and *vgaB*, which encode ATP-binding efflux proteins that pump type A streptogramins out of the cell (Allignet *et al.*, 1998; Bozdogan and Leclercq, 1999). These resistance determinants are located on plasmids that may be transferable by conjugative mobilization (Allignet *et al.*, 1998). Resistance to quinupristin/dalbapristin always is associated with a resistance gene for type A streptogramins. Genes encoding resistance to type B streptogramins also may be present, but are not sufficient by themselves to produce resistance. Methylase-encoding *erm* genes, however, can render the combination bacteriostatic instead of bactericidal, making it ineffective in certain infections in which bactericidal activity is necessary for cure, such as endocarditis.

Absorption, Distribution, and Excretion. The combination of quinupristin/dalbapristin is administered only by intravenous infusion over at least 1 hour. It is incompatible with saline and heparin and should be dissolved in 5% dextrose in water. Steady-state peak serum concentrations in healthy male volunteers are approximately 3 µg/ml of quinupristin and 7 µg/ml of dalbapristin with a 7.5-mg/kg dose administered every 8 hours. The half-life is 0.85 hour for quinupristin and 0.7 hour for dalbapristin. The volume of distribution is 0.87 L/kg for quinupristin and 0.71 L/kg for dalbapristin. Hepatic metabolism by conjugation is the prin-

cipal means of clearance for both compounds, with 80% of an administered dose eliminated by biliary excretion. Renal elimination of active compound accounts for most of the remainder. No dosage adjustment is necessary for renal insufficiency. Pharmacokinetics are not significantly altered by peritoneal dialysis or hemodialysis. The area under the plasma concentration curve of active component and its metabolites is increased by 180% for quinupristin and 50% for dalbapristin by hepatic insufficiency. No adjustment is recommended unless the patient is unable to tolerate the drug, in which case the dosing frequency should be reduced from 8 hours to 12 hours.

Therapeutic Uses. Quinupristin/dalbapristin is approved in the United States for treatment of infections caused by vancomycin-resistant strains of *E. faecium* and complicated skin and skin-structure infections caused by methicillin-susceptible strains of *S. aureus* or *S. pyogenes* (Nichols *et al.*, 1999). In Europe it also is approved for treatment of nosocomial pneumonia and infections caused by methicillin-resistant strains of *S. aureus* (Fagon *et al.*, 2000). In open-label, nonrandomized studies, clinical and microbiological cure rates for a variety of infections caused by vancomycin-resistant *E. faecium* were approximately 70% with quinupristin/dalbapristin at a dose of 7.5 mg/kg every 8 to 12 hours (Moellering *et al.*, 1999). Quinupristin/dalbapristin should be reserved for treatment of serious infections caused by multiple-drug-resistant gram-positive organisms such as vancomycin-resistant *E. faecium*.

Untoward Effects. The most common side effects are infusion-related events, such as pain and phlebitis at the infusion site and arthralgias and myalgias. Phlebitis and pain can be minimized by infusion of drug through a central venous catheter. Arthralgias and myalgias, which are more likely to be a problem in patients with hepatic insufficiency and may be due to accumulation of metabolites, are managed by reducing the infusion frequency to every 12 hours. Quinupristin/dalbapristin inhibits CYP3A4. The concomitant administration of other CYP3A4 substrates (see Chapter 3) with quinupristin/dalbapristin may raise blood pressure and/or result in significant toxicity. Examples include antihistamines (e.g., *azelastine* and *clemastine*); some anticonvulsants (e.g., *fosphenytoin* and *felbamate*); macrolide antibiotics; some fluoroquinolones (e.g., *moxifloxacin* and *ketoconazole*); some antimalarials (e.g., *chloroquine*, *mefloquine*, and *quinine*); some antidepressants (e.g., *fluoxetine*, *imipramine*, *venlafaxine*); some antipsychotics (e.g., *haloperidol*, *risperidone*, and *quetiapine*); *tacrolimus*; and *doxepin*. Appropriate caution and monitoring are recommended for drugs in which the

toxic therapeutic window is narrow or for drugs that prolong the QTc interval.

LINEZOLID

Linezolid (ZYVOX) is a synthetic antimicrobial agent of the oxazolidinone class (Clemett and Markham, 2000; Diekema and Jones, 2000; Hamel *et al.*, 2000). Its chemical structure is:

Antibacterial Activity. Linezolid is active against gram-positive organisms including staphylococci, streptococci, enterococci, gram-positive anaerobic cocci, and gram-positive rods such as *Corynebacterium* spp. and *Listeria monocytogenes*. It has poor activity against most gram-negative aerobic or anaerobic bacteria. It is bacteriostatic against enterococci and staphylococci and bactericidal against streptococci. MICs are ≤ 2 $\mu\text{g/ml}$ against strains of *E. faecium*, *E. faecalis*, *S. pyogenes*, *S. pneumoniae*, and viridans strains of streptococci. MICs are ≤ 4 $\mu\text{g/ml}$ for strains of *S. aureus* and coagulase-negative staphylococci. *Mycobacterium tuberculosis* is moderately susceptible, with MICs of 2 $\mu\text{g/ml}$. Because of its unique mechanism of action, linezolid is active against strains that are resistant to multiple other agents, including penicillin-resistant strains of *S. pneumoniae*; methicillin-resistant, vancomycin-intermediate, and vancomycin-resistant strains of staphylococci; and vancomycin-resistant strains of enterococci.

Mechanism of Action. Linezolid inhibits protein synthesis by binding to the P site of the 50S ribosomal subunit and preventing formation of the larger ribosomal-fMet-tRNA complex that initiates protein synthesis. As mentioned above, there is no cross-resistance with other drug classes. Resistance in enterococci and staphylococci is due to point mutations of the 23S rRNA (Wilson *et al.*, 2003). Since multiple copies of 23S rRNA genes are present in bacteria, resistance generally requires mutations in two or more copies.

Absorption, Distribution, and Excretion. Linezolid is well absorbed after oral administration and may be administered without regard to food. With oral bioavail-

ability approaching 100%, dosing for oral and intravenous preparations is the same. Peak serum concentrations average 12 to 14 $\mu\text{g/ml}$ 1 to 2 hours after a single 600-mg dose in adults and approximately 20 $\mu\text{g/ml}$ at steady state with dosing every 12 hours. The half-life is approximately 4 to 6 hours. Linezolid is 30% protein-bound and distributes widely to well-perfused tissues, with a 0.6 to 0.7 L/kg volume of distribution.

Linezolid is broken down by nonenzymatic oxidation to aminoethoxyacetic acid and hydroxyethyl glycine derivatives. Approximately 80% of the dose of linezolid appears in the urine, 30% as active compound, and 50% as the two primary oxidation products. Ten percent of the administered dose appears as oxidation products in feces. Although serum concentrations and half-life of the parent compound are not appreciably altered by renal insufficiency, oxidation products accumulate in renal insufficiency, with half-lives increasing by approximately 50% to 100%. The clinical significance of this is unknown, and no dose adjustment in renal insufficiency is currently recommended. Linezolid and its breakdown products are eliminated by dialysis; therefore the drug should be administered after hemodialysis. One case report noted sustained therapeutic concentrations of linezolid in peritoneal dialysis fluid with oral administration of 600 mg of linezolid twice daily (DePestel *et al.*, 2003).

Therapeutic Uses. Linezolid is FDA approved for treatment of infections caused by vancomycin-resistant *E. faecium*; nosocomial pneumonia caused by methicillin-susceptible and-resistant strains of *S. aureus*; community-acquired pneumonia caused by penicillin-susceptible strains of *S. pneumoniae*; complicated skin and skin-structure infections caused by streptococci and methicillin-susceptible and -resistant strains of *S. aureus*; and uncomplicated skin and skin-structure infections (Clemett and Markham, 2000). In noncomparative studies, linezolid (600 mg twice daily) has had clinical and microbiological cure rates in the range of 85% to 90% in treatment of a variety of infections (soft tissue, urinary tract, and bacteremia) caused by vancomycin-resistant *E. faecium*. A 200-mg, twice-daily dose was less effective, with a clinical and microbiological cure rates of approximately 75% and 59%, respectively. The 600-mg, twice-daily dose therefore should be used for treatment of infections caused by enterococci. A 400-mg, twice-daily dosage regimen is recommended only for treatment of uncomplicated skin and skin-structure infections.

In randomized, comparative studies, cure rates with linezolid (~60%) were similar to those with vancomycin for nosocomial pneumonia caused by methicillin-resistant or -susceptible *S. aureus* (Rubinstein *et al.*, 2001; Wunderink *et al.*, 2003a). A post-hoc analysis suggested that linezolid may be superior to vancomycin for nosocomial pneumonia caused by methicillin-resistant *S. aureus*, but this needs to be confirmed in a prospective randomized trial (Wunderink *et al.*, 2003b). Efficacy of linezolid also was similar to that of either oxacillin or vancomycin for skin and skin-structure infections, the majority of microbiologically documented cases being caused by *S. aureus*. Although relatively few patients with *S.*

aureus bacteremia have been treated, linezolid appears to be comparable in efficacy to vancomycin for methicillin-resistant strains. Linezolid also may be an effective alternative for patients with methicillin-resistant *S. aureus* infections who are failing vancomycin therapy or whose isolates have reduced susceptibility to vancomycin (Howden *et al.*, 2004). Linezolid is bacteriostatic for staphylococci and enterococci; it probably should not be used for treatment of suspected endocarditis.

Linezolid should be reserved as an alternative agent for treatment of infections caused by multiple-drug-resistant strains. It should not be used when other agents are likely to be effective (e.g., community-acquired pneumonia, even though it has the indication). Indiscriminant use and overuse will hasten selection of resistant strains and the eventual loss of this valuable new agent.

Untoward Effects. The drug seems to be well tolerated, with generally minor side effects (*e.g.*, gastrointestinal complaints, headache, rash). Myelosuppression, including anemia, leukopenia, pancytopenia, and thrombocytopenia, has been reported in patients receiving linezolid. Thrombocytopenia or a significant reduction in platelet count has been associated with linezolid in 2.4% of treated patients, and its occurrence is related to duration of therapy. Platelet counts should be monitored in patients with risk of bleeding, preexisting thrombocytopenia, or intrinsic or acquired disorders of platelet function (including those potentially caused by concomitant medication) and in patients receiving courses of therapy lasting beyond 2 weeks. Linezolid is a weak, nonspecific inhibitor of monoamine oxidase. Patients receiving concomitant therapy with an adrenergic or serotonergic agent or consuming more than 100 mg of tyramine a day may experience palpitations, headache, or hypertensive crisis. Peripheral and optic neuropathy, which seem to be reversible upon drug discontinuation, have been reported with prolonged use. Linezolid is neither a substrate nor an inhibitor of CYPs.

SPECTINOMYCIN

Source and Chemistry. Spectinomycin is an antibiotic produced by *Streptomyces spectabilis*. The drug is an aminocyclitol; its structural formula is as follows:

Antibacterial Activity and Mechanism. Spectinomycin is active against a number of gram-negative bacterial species, but it is inferior to other drugs to which such microorganisms are suscep-

tible. *Its only therapeutic use is in the treatment of gonorrhea caused by strains resistant to first-line drugs, or if there are contraindications to the use of these drugs.*

Spectinomycin selectively inhibits protein synthesis in gram-negative bacteria. The antibiotic binds to and acts on the 30S ribosomal subunit. Its action is similar to that of the aminoglycosides, but spectinomycin is not bactericidal and does not cause misreading of messenger RNA. Bacterial resistance may be mediated by mutations in the 16S ribosomal RNA or by modification of the drug by adenylyltransferase (Clark *et al.*, 1999).

Absorption, Distribution, and Excretion. Spectinomycin is rapidly absorbed after intramuscular injection. A single dose of 2 g produces peak serum concentrations of 100 $\mu\text{g/ml}$ at 1 hour. Eight hours after injection, the concentration is approximately 15 $\mu\text{g/ml}$. The drug is not significantly bound to plasma protein, and all of an administered dose is recovered in the urine within 48 hours.

Therapeutic Uses. The Centers for Disease Control and Prevention recommends *ceftriaxone*, *cefixime*, *ciprofloxacin*, *ofloxacin*, or *levofloxacin* for the treatment of uncomplicated gonococcal infection (Centers for Disease Control, 2002). However, spectinomycin is recommended as an alternative regimen in patients who are intolerant or allergic to β -lactam antibiotics and quinolones. Spectinomycin also is useful in pregnancy when patients are intolerant to β -lactams and when quinolones are contraindicated. The recommended dose for men and women is a single, deep intramuscular injection of 2 g. One of the disadvantages of this regimen is that spectinomycin has no effect on incubating or established syphilis, and it is not active against *Chlamydia* spp. It also is less effective for pharyngeal infections, and follow-up cultures to document cure should be obtained.

Untoward Effects. Spectinomycin, when given as a single intramuscular injection, produces few significant untoward effects. Urticaria, chills, and fever have been noted after single doses, as have dizziness, nausea, and insomnia. The injection may be painful.

POLYMYXIN B AND COLISTIN

Because of the extreme nephrotoxicity associated with parenteral administration of these drugs, they are rarely if ever used except topically.

Source and Chemistry. The polymyxins, discovered in 1947, are a group of closely related antibiotics elaborated by various strains of *Bacillus polymyxa*. *Colistin* is produced by *Bacillus (Aerobacillus) colistinus*. These drugs, which are cationic detergents, are relatively simple, basic peptides with molecular masses of about 1000 daltons. The structural formula for polymyxin B, which is a mixture of polymyxins B₁ and B₂, is:

Colistin (polymyxin E) has a similar structure; it is available as colistin sulfate for oral use and as colistimethate sodium for parenteral administration (not recommended).

Antibacterial Activity and Mechanism of Action. The antimicrobial activities of polymyxin B and colistin are similar and are restricted to gram-negative bacteria, including *Enterobacter*, *E. coli*, *Klebsiella*, *Salmonella*, *Pasteurella*, *Bordetella*, and *Shigella*, which usually are sensitive to concentrations of 0.05 to 2 $\mu\text{g}/\text{ml}$. Most strains of *P. aeruginosa* are inhibited by less than 8 $\mu\text{g}/\text{ml}$ *in vitro*. *Proteus* spp. are intrinsically resistant.

Polymyxins are surface-active, amphipathic agents. They interact strongly with phospholipids and disrupt the structure of cell membranes. The permeability of the bacterial membrane changes immediately on contact with the drug. Sensitivity to polymyxin B apparently is related to the phospholipid content of the cell wall-membrane complex. The cell walls of certain resistant bacteria may prevent access of the drug to the cell membrane.

Polymyxin B binds to the lipid A portion of endotoxin (the lipopolysaccharide of the outer membrane of gram-negative bacteria) and inactivates this molecule. Polymyxin B attenuates pathophysiological consequences of the release of endotoxin in several experimental systems, but the clinical utility of polymyxin B for this indication has not yet been established.

Absorption, Distribution, and Excretion. Polymyxin B and colistin are not absorbed when given orally and are poorly absorbed from mucous membranes and the surfaces of large burns. They are cleared renally, and modification of the dose is required in patients with impaired renal function.

Therapeutic Uses. Polymyxin B sulfate is available for ophthalmic, otic, and topical use in combination with a variety of other compounds. Colistin is available as otic drops. Parenteral preparations are still marketed, but they generally are not recommended and are rarely used. However, colistin may be useful as a salvage regimen for treatment of infections caused by multiple-drug-resistant organisms such as *Stenotrophomonas maltophilia*, *Acinetobacter* spp., or *P. aeruginosa*, when other alternatives have been exhausted (Linden *et al.*, 2003; San Gabriel *et al.*, 2004).

Infections of the skin, mucous membranes, eye, and ear due to polymyxin B-sensitive microorganisms respond to local application of the antibiotic in solution or ointment. External otitis, frequently due to *Pseudomonas*, may be cured by the topical use of the drug. *P. aeruginosa* is a common cause of infection of corneal ulcers; local application or subconjunctival injection of polymyxin B often is curative.

Untoward Effects. Polymyxin B applied to intact or denuded skin or mucous membranes produces no systemic reactions because of its almost complete lack of absorption from these sites. Hypersensitization is uncommon with topical application. Polymyxins interfere with neurotransmission at the neuromuscular junction, resulting in muscle weakness and apnea. Other neurological reactions include paresthesias, vertigo, and slurred speech. Polymyxins are nephrotoxic, and administration with aminoglycosides should be avoided if possible.

VANCOMYCIN

History and Source. Vancomycin is a glycopeptide antibiotic produced by *Streptococcus orientalis*. Teicoplanin, also a glycopeptide, is available in Europe (Biavasco *et al.*, 1997).

Chemistry. Vancomycin is a complex and unusual tricyclic glycopeptide with a molecular mass of about 1500 daltons. Its structural formula is:

Antibacterial Activity. Vancomycin is primarily active against gram-positive bacteria. Strains are considered susceptible at MICs of ≤ 4 $\mu\text{g}/\text{ml}$. *S. aureus* and *S. epidermidis*, including strains resistant to methicillin, usually are inhibited by concentrations of 1 to 4 $\mu\text{g}/\text{ml}$. *S. pyogenes*, *S. pneumoniae*, and viridans streptococci are highly susceptible to vancomycin. *Bacillus* spp., including *B. anthracis*, are inhibited by 2 $\mu\text{g}/\text{ml}$ or less. *Corynebacterium* spp. (diphtheroids) are inhibited by less than 0.04 to 3.1 $\mu\text{g}/\text{ml}$ of vancomycin; most species of *Actinomyces*, by 5 to 10 $\mu\text{g}/\text{ml}$; and *Clostridium* spp., by 0.39 to 6 $\mu\text{g}/\text{ml}$. Essentially all species of gram-negative bacilli and mycobacteria are resistant to vancomycin.

Mechanisms of Action and Resistance. Vancomycin inhibits the synthesis of the cell wall in sensitive bacteria by binding with high affinity to the D-alanyl-D-alanine terminus of cell wall precursor units (Figure 46-4). The drug is bactericidal for dividing microorganisms.

Strains of enterococci once were uniformly susceptible to vancomycin. Vancomycin-resistant strains of enterococci, primarily *Enterococcus faecium*, have emerged as major nosocomial pathogens in hospitals in the United States. Vancomycin resistance determinants in *E. faecium* and *E. faecalis* are located on a transposon that is part of a conjugative plasmid, rendering it readily transferable among enterococci, and potentially, other gram-positive bacteria. These strains typically are resistant to multiple antibiotics, including streptomycin, gentamicin, and ampicillin, effectively eliminating these as alternative therapeutic agents. Resistance to streptomycin and gentamicin

Figure 46–4. Inhibition of bacterial cell wall synthesis. Vancomycin inhibits the polymerization or transglycosylase reaction (A) by binding to the D-alanyl-D-alanine terminus of the cell wall precursor unit attached to its lipid carrier and blocks linkage to the glycopeptide polymer (indicated by the subscript n). These $(\text{NAM-NAG})_n$ peptidoglycan polymers are located within the cell wall. *Van A*-type resistance is due to expression of enzymes that modify cell wall precursor by substituting a terminal D-lactate for D-alanine, reducing vancomycin binding affinity by 1000 times. β -Lactam antibiotics inhibit the cross-linking or transpeptidase reaction (B) that links glycopeptide polymer chains by formation of a cross-bridge with the stem peptide (the five glycines in this example) of one chain, displacing the terminal D-alanine of an adjacent chain.

is of special concern, because the combination of an aminoglycoside with a cell-wall-synthesis inhibitor is the only reliably bactericidal regimen for treatment of enterococcal endocarditis.

Enterococcal resistance to vancomycin is the result of alteration of the D-alanyl-D-alanine target to D-alanyl-D-lactate or D-alanyl-D-serine (Arias *et al.*, 2000), which bind vancomycin poorly, due to the lack of a critical site for hydrogen bonding. Several enzymes within the *van* gene cluster are required for this target alteration to occur.

Several phenotypes of resistance to vancomycin have been described. The *Van A* phenotype confers inducible resistance to teicoplanin and vancomycin in *E. faecium* and *E. faecalis*. The *Van B* phenotype, which tends to be a lower level of resistance, also has been identified in *E. faecium* and *E. faecalis*. The trait is inducible by vancomycin but not teicoplanin, and consequently, many strains remain susceptible to teicoplanin. The *Van C* phenotype, the least important clinically and least well characterized, confers resistance only to vancomycin, is constitutive, and is present in no species of enterococci other than *E. faecalis* and *E. faecium*. *Van D* and *Van E* gene clusters also have been identified, and presumably others will follow.

S. aureus and coagulase-negative staphylococci may express reduced or “intermediate” susceptibility to vancomycin (MIC, 8 to 16

$\mu\text{g/ml}$) (Hiramatsu *et al.*, 1997; Smith *et al.*, 1999; Garrett *et al.*, 1999) or high-level resistance (MIC $\geq 32 \mu\text{g/ml}$; Centers for Disease Control, 2004). Intermediate resistance is associated with (and may be preceded by) a heterogeneous phenotype in which a small proportion of cells within the population (1 in 10^5 to 1 in 10^6) will grow in the presence of vancomycin concentrations above $4 \mu\text{g/ml}$. The genetic and biochemical basis of the intermediate phenotype is not well understood. Intermediate strains produce an abnormally thick cell wall, and resistance may be due to false targets for vancomycin. Several genetic elements and multiple mutations are involved, and many of the genes that have been implicated encode enzymes of the cell-wall biosynthetic pathway (Sieradzki and Tomasz, 1999; Sieradzki *et al.*, 1999).

The first high-level vancomycin-resistant *S. aureus* strain (MIC $\geq 32 \mu\text{g/ml}$) was isolated in June 2002 (Weigel *et al.*, 2003). This strain, like others that have subsequently been isolated, harbored a conjugative plasmid into which the *Van A* transposon, Tn1546, was integrated as a consequence of an interspecies horizontal gene transfer from *E. faecalis* to a methicillin-resistant strain of *S. aureus*.

Infections caused by intermediate strains have failed to respond to vancomycin clinically and in animal models (Climo *et al.*, 1999; Moore *et al.*, 2003). Prior treatment courses and low vancomycin levels may predispose patients to infection and treatment failure with vancomycin-intermediate strains. These strains typically are resistant to methicillin and multiple other antibiotics; their emergence is a major concern because until recently vancomycin has been the only antibiotic to which staphylococci were reliably susceptible.

Absorption, Distribution, and Excretion. Vancomycin is poorly absorbed after oral administration. For parenteral therapy, the drug should be administered intravenously, never intramuscularly. A single intravenous dose of 1 g in adults produces plasma concentrations of 15 to 30 $\mu\text{g/ml}$ 1 hour after a 1- to 2-hour infusion. The drug has a serum elimination half-life of about 6 hours. Approximately 30% of vancomycin is bound to plasma protein. Vancomycin appears in various body fluids, including the CSF when the meninges are inflamed (7% to 30%); bile; and pleural, pericardial, synovial, and ascitic fluids. About 90% of an injected dose is excreted by glomerular filtration. The drug accumulates if renal function is impaired, and dosage adjustments must be made under these circumstances. The drug can be cleared rapidly from plasma with high-flux methods of hemodialysis.

Therapeutic Uses. Vancomycin hydrochloride (VANCO-CIN, others) is marketed for *intravenous* use as a sterile powder for solution. It should be diluted and infused over at least a 60-minute period to avoid infusion-related adverse reactions (*see below*). The usual dose of vancomycin for adults is 30 mg/kg per day in 2 to 3 divided doses. This dose will yield average steady-state serum concentrations of 15 $\mu\text{g/ml}$. The “therapeutic range” for this agent is somewhat controversial. A target trough serum concentration of 5 to 15 $\mu\text{g/ml}$, 10 to 20 $\mu\text{g/ml}$ for more serious infections such as endocarditis or meningitis, is recommended. Doses above 30 mg/kg per day may be required to achieve these trough concentrations, and up to 60 mg/kg per day has been suggested for use in meningitis (Quagliarello and Scheld, 1997). *The “peak” concentration, which need not be monitored routinely, as the distribution phase of the drug is long, should generally remain below 60 $\mu\text{g/ml}$ to avoid ototoxicity.*

Pediatric doses are as follows: for newborns during the first week of life, 15 mg/kg initially, followed by 10 mg/kg every 12 hours; for infants 8 to 30 days old, 15 mg/kg followed by 10 mg/kg every 8 hours; for older infants and children, 10 mg/kg every 6 hours.

Alteration of dosage is required for patients with impaired renal function. The drug has been used effectively in functionally anephric patients and dialysis patients by the administration of 1 g (approximately 15 mg/kg) every 5 to 7 days. Because there is so much variation in how well vancomycin is dialyzed with different membranes, it is recommended that blood levels be monitored to decide how frequently the drug needs to be administered to maintain therapeutic concentrations.

Vancomycin can be administered orally to patients with pseudomembranous colitis, although metronidazole is preferred.

The dose for adults is 125 to 250 mg every 6 hours; the total daily dose for children is 40 mg/kg, given in three to four divided doses. *Vancomycin hydrochloride for oral solution* is available for this purpose, as are capsules.

Vancomycin should be employed only to treat serious infections and is particularly useful in the management of infections due to methicillin-resistant staphylococci, including pneumonia, empyema, endocarditis, osteomyelitis, and soft-tissue abscesses and in severe staphylococcal infections in patients who are allergic to penicillins and cephalosporins. However, vancomycin is less rapidly bactericidal than any of the antistaphylococcal β -lactams (*e.g., nafcillin or cefazolin*) and therefore may be less efficacious clinically (Levine *et al.*, 1991). Treatment with vancomycin is effective and convenient when there is disseminated staphylococcal infection or localized infection of a shunt in a patient with irreversible renal disease who is being maintained by hemodialysis or peritoneal dialysis, because the drug can be administered once weekly or in the dialysis fluid. Intraventricular administration of vancomycin (*via* a shunt or reservoir) has been necessary in a few cases of CNS infections due to susceptible microorganisms that did not respond to intravenous therapy alone.

Administration of vancomycin is an effective alternative for the treatment of endocarditis caused by viridans streptococci in patients who are allergic to penicillin. In combination with an aminoglycoside, it may be used for enterococcal endocarditis in patients with serious penicillin allergy. Vancomycin also is effective for the treatment of infections caused by *Corynebacterium* spp. Vancomycin has become an important antibiotic in the management of known or suspected penicillin-resistant pneumococcal infections (Friedland and McCracken, 1994).

Untoward Effects. Among the hypersensitivity reactions produced by vancomycin are macular skin rashes and anaphylaxis. Phlebitis and pain at the site of intravenous injection are relatively uncommon. Chills, rash, and fever may occur. Rapid intravenous infusion may cause erythematous or urticarial reactions, flushing, tachycardia, and hypotension. The extreme flushing that can occur is sometimes called “red-neck” or “red-man” syndrome. This is not an allergic reaction but a direct toxic effect of vancomycin on mast cells, causing them to release histamine.

Auditory impairment, sometimes permanent, may follow the use of this drug. Ototoxicity is associated with excessively high concentrations of the drug in plasma (60 to 100 $\mu\text{g/ml}$). Nephrotoxicity, formerly quite common probably because of less pure formulations of the drug, has become an unusual side effect when appropriate doses are used, as judged by renal function and determinations of blood levels of the drug. Caution must be exercised, however, when ototoxic or nephrotoxic drugs, such as aminoglycosides, are administered concurrently or in patients with impaired renal function.

TEICOPLANIN

Source and Chemistry. Teicoplanin is a glycopeptide antibiotic produced by *Actinoplanes teichomyetius*. The drug actually is a mixture

of six closely related compounds: one compound has a terminal hydrogen at the oxygen indicated by an asterisk; five compounds have an R substituent of either a decanoic acid [*n*-, 8-methyl-, 9-methyl-, (Z)-4-] or of a nonanoic acid [8-methyl]. Although not FDA approved for use in the United States, it is available in Europe. It is similar to vancomycin in chemical structure, mechanism of action, spectrum of activity, and route of elimination (*i.e.*, primarily renal). Its structure is:

Mechanisms of Action and Resistance. Teicoplanin, like vancomycin, inhibits cell-wall synthesis by binding with high affinity to the D-alanyl-D-alanine terminus of cell wall precursor units (Figure 46-4), and it is active only against gram-positive bacteria. It is reliably bactericidal against susceptible strains, except for enterococci. It is active against methicillin-susceptible and methicillin-resistant staphylococci, which typically have MICs of $<4 \mu\text{g/ml}$. The MICs for *Listeria monocytogenes*, *Corynebacterium* spp., *Clostridium* spp., and anaerobic gram-positive cocci range from 0.25 to $2 \mu\text{g/ml}$. Non-*viridans* and *viridans* streptococci, *S. pneumoniae*, and enterococci are inhibited by concentrations ranging from 0.01 to $1 \mu\text{g/ml}$. Some strains of staphylococci, coagulase-positive and coagulase-negative, as well as enterococci and other organisms that are intrinsically resistant to vancomycin (*i.e.*, *Lactobacillus* spp. and *Leuconostoc* spp.), are resistant to teicoplanin.

The mechanisms of resistance to teicoplanin in strains of staphylococci have not been elucidated, but resistance can emerge in a previously susceptible strain during a course of therapy. The *Van A* phenotype of vancomycin-resistant enterococci also determines resistance to teicoplanin. The mechanism is the same as for vancomycin: alteration of the cell-wall target so that the glycopeptide does not bind. Strains of enterococci with *Van B* resistance often are susceptible to teicoplanin, which is a poor inducer of the enzymes responsible for the cell-wall alteration. *Van C* strains of enterococci, which in general are not human pathogens, are susceptible to teicoplanin.

Absorption, Distribution, and Excretion. The primary differences between vancomycin and teicoplanin are: teicoplanin can be administered safely by intramuscular injection; it is highly bound by plasma proteins (90% to 95%); and it has an extremely long serum elimination half-life (up to 100 hours in patients with normal renal function). The dose of teicoplanin in adults is 6 to 30 mg/kg per day, with the higher dosages reserved for treatment of serious staphylococcal infec-

tions. Once-daily dosing is possible for the treatment of most infections because of the prolonged serum elimination half-life. As with vancomycin, teicoplanin doses must be adjusted in patients with renal insufficiency. For functionally anephric patients, administration once weekly has been appropriate, but serum drug concentrations should be monitored to determine that the therapeutic range has been maintained (*e.g.*, trough concentration of 15 to $20 \mu\text{g/ml}$).

Therapeutic Uses. Teicoplanin has been used to treat a wide variety of infections, including osteomyelitis and endocarditis, caused by methicillin-resistant and methicillin-susceptible staphylococci, streptococci, and enterococci. Teicoplanin has been found to be comparable to vancomycin in efficacy, except for treatment failures from low doses used for such serious infections as endocarditis. Teicoplanin is not as efficacious as antistaphylococcal penicillins for treating bacteremia and endocarditis caused by methicillin-susceptible *S. aureus*, with teicoplanin cure rates of 60% to 70% versus 85% to 90% for the penicillins. The efficacy of teicoplanin against *S. aureus* may be improved by the addition of an aminoglycoside (*e.g.*, gentamicin 1 mg/kg every 8 hours in patients with normal renal function) to provide a synergistic effect. Strains of streptococci are uniformly susceptible to teicoplanin. This drug has been very effective in a once-daily regimen for patients with streptococcal osteomyelitis or endocarditis. Teicoplanin is among the most active drugs against enterococci. Limited experience indicates that it is effective, although only bacteriostatic, for serious enterococcal infections. It should be combined with gentamicin to achieve a bactericidal effect in the treatment of enterococcal endocarditis.

Untoward Effects. The main side effect reported for teicoplanin is skin rash, which is more common in higher dosages. Hypersensitivity reactions, drug fever, and neutropenia also have been reported. Ototoxicity has occurred rarely.

DAPTOMYCIN

Source and Chemistry. Daptomycin (CUBICIN) is a cyclic lipopeptide antibiotic derived from *Streptomyces roseosporus*. Discovered more than 20 years ago, its clinical development has been resumed in response to increasing need for bactericidal antibiotics effective against vancomycin-resistant gram-positive bacteria (Carpenter and Chambers, 2004). Its structural formula is:

Antibacterial Activity. Daptomycin is a bactericidal antibiotic selectively active against aerobic, facultative, and anaerobic gram-posi-

tive bacteria (Jevitt *et al.*, 2003; Streit *et al.*, 2004). The MIC susceptibility breakpoint for staphylococci and streptococci is $\leq 1 \mu\text{g/ml}$; for enterococci it is $\leq 4 \mu\text{g/ml}$. Approximately 90% of strains of staphylococci and streptococci are inhibited at concentrations of 0.25 to 0.5 $\mu\text{g/ml}$; the corresponding values for *E. faecalis* and *E. faecium* are 0.5 to 1 and 2 to 4 $\mu\text{g/ml}$, respectively. Daptomycin may be active against vancomycin-resistant strains, although MICs tend to be higher for these organisms than for their vancomycin-susceptible counterparts. MICs of *Corynebacterium* spp., *Peptostreptococcus*, propionibacteria, and *Clostridium perfringens* are ≤ 0.5 to 1 $\mu\text{g/ml}$ (Goldstein *et al.*, 2004). *Actinomyces* spp. are inhibited over the concentration range of 4 to 32 $\mu\text{g/ml}$. *In vitro* activity of daptomycin is Ca^{2+} -dependent, and MIC tests should be performed in medium containing 50 mg/L calcium.

Mechanisms of Action and Resistance. Daptomycin binds to bacterial membranes resulting in depolarization, loss of membrane potential, and cell death. It has concentration-dependent bactericidal activity. Due to its unique mechanism of action, cross-resistance with other antibiotic classes seems not occur, and there are no known resistance mechanisms. There were two cases (one *S. aureus* and one *E. faecalis*) among more than 1000 cases treated in which resistance emerged during therapy. Staphylococci with decreased susceptibility to vancomycin have higher daptomycin MICs than fully susceptible strains (Jevitt *et al.*, 2003).

Absorption, Fate, and Excretion. Daptomycin is poorly absorbed orally and should only be administered intravenously. Direct toxicity to muscle precludes intramuscular injection. The steady-state peak serum concentration following intravenous administration of 4 mg/kg in healthy volunteers is approximately 58 $\mu\text{g/ml}$. Daptomycin displays linear pharmacokinetics at doses up to 8 mg/kg. It is reversibly bound to albumin; protein binding is 92%. The serum half-life is 8 to 9 hours in normal subjects, permitting once-daily dosing. Approximately 80% of the administered dose is recovered in urine; a small amount is excreted in feces. Dosage adjustment is required for creatinine clearance below 30 ml/minute; this is accomplished by administering the recommended dose every 48 hours. For hemodialysis patients the dose should be administered immediately after dialysis.

Daptomycin neither inhibits nor induces CYPs, and there are no important drug-drug interactions. However, caution is recommended when administering daptomycin in conjunction with aminoglycosides or statins because of potential risks of nephrotoxicity and myopathy, respectively.

Therapeutic Uses. Daptomycin is indicated for treatment of complicated skin and skin-structure infections caused by methicillin-susceptible and methicillin-resistant strains of *S. aureus*, hemolytic streptococci, and vancomycin-susceptible *E. faecalis* (Carpenter and Chambers, 2004). Its efficacy is comparable to that of vancomycin. Efficacy in more serious infections, such as endocarditis or complicated bacteremia, has not been demonstrated, although clinical trials are under way. Daptomycin was inferior to comparators for treatment of community-acquired pneumonia and is not indicated for this infection.

Untoward Effects. Skeletal muscle damage occurs in dogs given daptomycin at doses above 10 mg/kg. Peripheral neuropathic effects with axonal degeneration occurred at higher doses. In humans, ele-

vations of creatine kinase may occur; this does not require discontinuation of the drug unless there are findings of an otherwise unexplained myopathy. In Phase 1 and 2 clinical trials, a few patients had evidence of possible neuropathy, although this was not observed in Phase 3 studies.

BACITRACIN

Source and Chemistry. Bacitracin is an antibiotic produced by the Tracy-I strain of *Bacillus subtilis*. The bacitracins are a group of polypeptide antibiotics; multiple components have been demonstrated in the commercial products. The major constituent is bacitracin A. Its probable structural formula is:

A unit of the antibiotic is equivalent to 26 μg of the USP standard.

Mechanism of Action; Antibacterial Activity. Bacitracin inhibits the synthesis of the bacterial cell wall. A variety of gram-positive cocci and bacilli, *Neisseria*, *H. influenzae*, and *Treponema pallidum* are sensitive to 0.1 unit or less of bacitracin per milliliter. *Actinomyces* and *Fusobacterium* are inhibited by concentrations of 0.5 to 5 units/ml. Enterobacteriaceae, *Pseudomonas*, *Candida* spp., and *Nocardia* are resistant to the drug.

Therapeutic Uses. While bacitracin previously has been employed parenterally, current use is restricted to topical application.

Bacitracin is available in ophthalmic and dermatologic ointments; the antibiotic also is available as a powder for the preparation of topical solutions. The ointments are applied directly to the involved surface one or more times daily. A number of topical preparations of bacitracin, to which *neomycin* or polymyxin or both have been added, are available, and some contain the three antibiotics plus hydrocortisone.

Topical bacitracin alone or in combination with other antimicrobial agents has no established value in the treatment of furunculosis, pyoderma, carbuncle, impetigo, and superficial and deep abscesses. For open infections such as infected eczema and infected dermal ulcers, the local application of the antibiotic may be of some help in eradicating sensitive bacteria. Unlike several other antibiotics used topically, bacitracin rarely produces hypersensitivity. Suppurative conjunctivitis and infected corneal ulcer respond well to the topical use of bacitracin when caused by susceptible bacteria. Bacitracin has been used with limited success for eradication of nasal carriage of staphylococci. Oral bacitracin has been used with some success for the treatment of antibiotic-associated diarrhea caused by *C. difficile*. Bacitracin is used by neurosurgeons to irrigate the meninges intraoperatively as an alternative to vancomycin. It has no direct toxicity on neurons.

Untoward Effects. Serious nephrotoxicity results from the parenteral use of this antibiotic. Hypersensitivity reactions rarely result from topical application.

MUPIROCIN

Source and Chemistry. Mupirocin (BACTROBAN) is derived from a fermentation product of *Pseudomonas fluorescens*. It is for topical use only. Its structural formula is:

Antibacterial Activity. Mupirocin is active against many gram-positive and selected gram-negative bacteria. It has good activity with MICs ≤ 1 $\mu\text{g/ml}$ against *Streptococcus pyogenes* and methicillin-susceptible and methicillin-resistant strains of *S. aureus*. It is bactericidal at concentrations achieved with topical application.

Mechanism of Action and Resistance. Mupirocin inhibits bacterial protein synthesis by reversible binding and inhibition of isoleucyl transfer-RNA synthetase. There is no cross-resistance with other classes of antibiotics. Low-level resistance, which is not clinically significant, is due to mutations of the host gene encoding isoleucyl transfer-RNA synthetase or an extra chromosomal copy of a gene encoding a modified isoleucyl transfer-RNA synthetase (Ramsey *et al.*, 1996; Udo *et al.*, 2001). High-level resistance (MIC >1 mg/ml) is mediated by a plasmid or chromosomal copy of *mupA*, which encodes a “bypass” synthetase that binds mupirocin poorly (Udo *et al.*, 2001).

Absorption, Fate, and Excretion. Systemic absorption through intact skin or skin lesions is minimal. Any mupirocin that is absorbed is rapidly metabolized to inactive monic acid.

Therapeutic Uses. Mupirocin is available as a 2% cream and a 2% ointment for dermatologic use and as a 2% ointment for intranasal use. The dermatologic preparations are indicated for treatment of traumatic skin lesions and impetigo secondarily infected with *S. aureus* or *S. pyogenes*.

The nasal ointment is approved for eradication of *S. aureus* nasal carriage. Mupirocin is highly effective in eradicating *S. aureus* carriage (Laupland and Conly, 2003). Because *S. aureus* colonization often precedes infection, eradication of carriage by intranasal application of mupirocin might reduce the risk of later infection. However, two clinical trials failed to demonstrate that mupirocin prophylaxis reduces nosocomial *S. aureus* infections (Kalmeijer *et al.*, 2002; Wertheim *et al.*, 2004).

A third large study found that *S. aureus* nasal carriers had fewer *S. aureus* nosocomial infections of any site, but failed to show a reduction in *S. aureus* surgical site infections, the primary endpoint of the study (Perl *et al.*, 2002). The accumulated evidence indicates that patients who stand to benefit from mupirocin prophylaxis are those with proven *S. aureus* nasal colonization plus risk factors for

distant infection or a history of skin or soft tissue infections. General inpatient populations and individuals lacking specific risk factors for *S. aureus* infection are not likely to benefit from mupirocin prophylaxis.

Untoward Effects. Mupirocin may cause irritation and sensitization at the site of application. Contact with the eyes should be avoided because mupirocin causes tearing, burning, and irritation that may take several days to resolve. Systemic reactions to mupirocin occur rarely, if at all. Polyethylene glycol present in the ointment can be absorbed from damaged skin. Application of the ointment to large surface areas should be avoided in patients with moderate to severe renal failure to avoid accumulation of polyethylene glycol.

CLINICAL SUMMARY

Doxycycline, the most important member of the tetracyclines, is useful as a broad-spectrum agent that treats sexually transmitted diseases, rickettsial infections, plague, brucellosis, tularemia, and spirochetal infections. The emergence of resistance to other antibiotic classes among common bacterial pathogens has enhanced the utility of doxycycline for respiratory tract infections, given its activity against *S. pneumoniae*, *Haemophilus* spp., and atypical pneumonia pathogens; and for skin and soft-tissue infections caused by community strains of methicillin-resistant *S. aureus*, for which minocycline also is particularly active.

Macrolides and ketolides are useful for treatment of respiratory tract infections because they are active against the common pathogens of community-acquired pneumonia, including *S. pneumoniae*, *Haemophilus* spp., *Chlamydia*, mycoplasma, and *Legionella*. They generally are well-tolerated, orally bioavailable, and except for erythromycin, effective in once- or twice-daily dosing. All except azithromycin have important drug interactions because they inhibit hepatic CYPs.

Chloramphenicol is rarely used in the United States and Europe because it can cause irreversible bone marrow toxicity and because less-toxic drugs are readily available. However, it continues to be an important antibiotic in developing nations because it is inexpensive and highly effective for a broad range of infections.

Spectinomycin is indicated only for the treatment of gonococcal infection when a β -lactam or fluoroquinolone cannot be used. Clindamycin has excellent activity against gram-positive cocci, but principally is used to treat anaerobic infections. Vancomycin, daptomycin, quinupristin/dalfopristin, and linezolid are indicated for the treatment of gram-positive infections caused by drug-resistant organisms such as penicillin-resistant

pneumococci and methicillin-resistant staphylococci. Quinupristin/dalfopristin and linezolid are indicated for the treatment of vancomycin-resistant *E. faecium* infections. These drugs, along with daptomycin, also are active against vancomycin-insensitive strains of *S. aureus*, although sufficient data demonstrating clinical efficacy are lacking.

Polymyxins, bacitracin, and mupirocin are useful for the topical treatment of minor skin infections. Colistin (polymyxin E) can be administered systemically and is active against drug-resistant gram-negative bacteria, including *Pseudomonas*, *Stenotrophomonas*, and *Acinetobacter*; its significant toxicity makes it an agent of last resort. Mupirocin is effective for eradication of *S. aureus* nasal colonization.

CHEMOTHERAPY OF TUBERCULOSIS, MYCOBACTERIUM AVIUM COMPLEX DISEASE, AND LEPROSY

William A. Petri, Jr.

Mycobacterial organisms cause tuberculosis, *Mycobacterium avium* complex (MAC) disease, and leprosy. Tuberculosis remains the primary worldwide cause of death due to infectious disease. A number of characteristics of mycobacteria make these diseases chronic and necessitate prolonged treatment. Mycobacteria grow slowly and may be dormant in the host for long periods; thus, they are relatively resistant to the effects of antibiotics. Many antibacterial agents do not penetrate the cell walls of mycobacteria, and a portion of mycobacteria can reside inside macrophages, adding another permeability barrier that effective agents must cross. Mycobacteria are agile in developing resistance to single chemotherapeutic agents. As a consequence, effective therapy of mycobacterial infections requires a prolonged course (months to years) of multiple drugs. Issues of patient compliance and drug toxicity are important, as are drug interactions, especially in patients being treated concurrently for HIV and tuberculosis or MAC infection. This chapter provides an overview of drugs used for first- and second-line treatment of tuberculosis and discusses therapeutic strategies evolving as resistance to available agents increases. Prophylaxis and treatment of *M. avium* infection in the setting of HIV coinfection are also discussed. In addition, this chapter covers the five clinically recognized forms of leprosy and the drug combinations used for their treatment.

The essential elements of the treatment of mycobacterial disease are to always treat with at least 2 different drugs to which the organism is susceptible and to treat for sufficient duration to prevent relapse (Leibert and Rom, 2004).

Drugs used in the treatment of tuberculosis can be divided into two major categories (Table 47–1). “First-line”

agents combine the greatest level of efficacy with an acceptable degree of toxicity; these include *isoniazid*, *rifampin*, *ethambutol*, *streptomycin*, and *pyrazinamide*. The large majority of patients with tuberculosis can be treated successfully with these drugs. Excellent results for patients with non–drug-resistant tuberculosis can be obtained with a 6-month course of treatment; for the first 2 months, isoniazid, rifampin, ethambutol, and pyrazinamide are given, followed by isoniazid and rifampin for the remaining 4 months. Administration of rifampin in combination with isoniazid for 9 months also is effective therapy for all forms of disease caused by strains of *Mycobacterium tuberculosis* susceptible to both agents (Bass *et al.*, 1994). Occasionally, because of microbial resistance, it may be necessary to resort to “second-line” drugs in addition; thus, treatment may be initiated with 5 to 6 drugs. This category of agents includes *moxifloxacin* or *gatifloxacin*, *ethionamide*, *aminosalicylic acid*, *cycloserine*, *amikacin*, *kanamycin*, *capreomycin*, and *linezolid* (Iseman, 1993). In HIV-infected patients receiving protease inhibitors and/or nonnucleoside reverse transcriptase inhibitors, drug interactions with the rifamycins (rifampin, *rifapentine*, *rifabutin*) are an important concern. Directly observed therapy, in which a health care worker actually witnesses the ingestion of medications, improves the outcome of tuberculosis treatment regimens (Havlir and Barnes, 1999).

Isoniazid is ineffective in the treatment of leprosy or *M. avium* complex infection. Lepromatous (multibacillary) leprosy is treated with *dapsone*, *clofazimine*, and rifampin for a minimum of 2 years, while tuberculoid (paucibacillary) leprosy is treated with dapsone and rifampin for 6 months.

Table 47-1

Drugs Used in the Treatment of Tuberculosis, Mycobacterium avium Complex, and Leprosy

MYCOBACTERIAL SPECIES	FIRST-LINE THERAPY	ALTERNATIVE AGENTS
<i>M. tuberculosis</i>	Isoniazid + rifampin*+ pyrazinamide + ethambutol or streptomycin	Moxifloxacin or gatifloxacin; cycloserine; capreomycin; kanamycin; amikacin; ethionamide; clofazimine; aminosalicyclic acid
<i>M. avium</i> complex	Clarithromycin or azithromycin + ethambutol with or without rifabutin	Rifabutin; rifampin; ethionamide; cycloserine; moxifloxacin or gatifloxacin
<i>M. kansasii</i>	Isoniazid + rifampin*+ ethambutol	Trimethoprim-sulfamethoxazole; ethionamide; cycloserine; clarithromycin; amikacin; streptomycin; moxifloxacin or gatifloxacin
<i>M. fortuitum</i> complex	Amikacin + doxycycline	Cefoxitin; rifampin; a sulfonamide; moxifloxacin or gatifloxacin; clarithromycin; trimethoprim-sulfamethoxazole; imipenem
<i>M. marinum</i>	Rifampin + ethambutol	Trimethoprim-sulfamethoxazole; clarithromycin; minocycline; doxycycline
<i>M. leprae</i>	Dapsone + rifampin ± clofazimine	Minocycline; moxifloxacin or gatifloxacin; clarithromycin; ethionamide

*In HIV-infected patients, the substitution of rifabutin for rifampin minimizes drug interactions with the HIV protease inhibitors and nonnucleoside reverse transcriptase inhibitors.

Antimicrobial agents with activity against MAC include rifabutin, *clarithromycin*, *azithromycin*, streptomycin, and fluoroquinolones. Clarithromycin and azithromycin are more effective than rifabutin for prophylaxis of *M. avium* complex infection in patients with AIDS. Clarithromycin or azithromycin, in combination with ethambutol (to prevent development of resistance), is effective treatment for *M. avium* complex infection in HIV-infected individuals.

History. The discovery of isoniazid was fortuitous; in 1945 Chorine reported that nicotinamide possesses tuberculostatic action. Examination of the compounds related to nicotinamide revealed that many pyridine derivatives possess tuberculostatic activity; among these were congeners of isonicotinic acid. Because the thiosemicarbazones were known to inhibit *M. tuberculosis*, the thiosemicarbazone of isonicotinaldehyde was synthesized and studied. The starting material for this synthesis was the methyl ester of isonicotinic acid, and the first intermediate was isonicotinylhydrazide (isoniazid).

Chemistry. Isoniazid is the hydrazide of isonicotinic acid; the structural formula is:

The isopropyl derivative of isoniazid, iproniazid (1-isonicotinyl-2-isopropylhydrazide), also inhibits the multiplication of the tubercle bacillus. This compound, which potently inhibits monoamine oxidase, is too toxic for use in human beings. However, its study led to the use of monoamine oxidase inhibitors for the treatment of depression (see Chapter 17).

Antibacterial Activity. Isoniazid is bacteriostatic for “resting” bacilli, but is bactericidal for rapidly dividing microorganisms. The minimal

I. DRUGS FOR TUBERCULOSIS

ISONIAZID

Isoniazid (isonicotinic acid hydrazide; NYDRAZID, others) is still considered the primary drug for the chemotherapy of tuberculosis. All patients with disease caused by isoniazid-sensitive strains of the tubercle bacillus should receive the drug if they can tolerate it.

tuberculostatic concentration is 0.025 to 0.05 $\mu\text{g/ml}$. The bacteria undergo one or two divisions before multiplication is arrested. The drug is remarkably selective for mycobacteria, and concentrations in excess of 500 $\mu\text{g/ml}$ are required to inhibit the growth of other microorganisms.

Isoniazid is highly effective for the treatment of experimentally induced tuberculosis in animals and is strikingly superior to streptomycin. Unlike streptomycin, isoniazid penetrates cells with ease and is just as effective against bacilli growing within cells as it is against those growing in culture media.

Among the various nontuberculous (atypical) mycobacteria, only *M. kansasii* is sometimes susceptible to isoniazid. However, sensitivity always must be tested *in vitro*, since the inhibitory concentration required may be rather high.

Bacterial Resistance. When tubercle bacilli are grown *in vitro* in increasing concentrations of isoniazid, mutants are readily selected that are resistant to the drug, even when the drug is present in enormous concentrations. However, cross-resistance between isoniazid and other agents used to treat tuberculosis (except ethionamide, which is structurally related to isoniazid) does not occur. The most common mechanism of isoniazid resistance is mutations in catalase-peroxidase (*katG*) that decrease its activity, preventing conversion of the prodrug isoniazid to its active metabolite (Blanchard, 1996). Another mechanism of resistance is related to a mutation in the mycobacterial *inhA* and *KasA* genes involved in mycolic acid biosynthesis (Banerjee *et al.*, 1994). Mutations in NADH dehydrogenase (*ndh*) also confer isoniazid resistance (Miesel *et al.*, 1998). Interestingly, isoniazid-resistant strains of *M. tuberculosis* appear to be less virulent in animal models (Zhang, 2004).

As with the other agents described, treatment with isoniazid alone selects for isoniazid-resistant bacteria and leads to the emergence *in vivo* of resistant strains. The shift from primarily sensitive to mainly insensitive microorganisms occasionally occurs within a few weeks after therapy is started; however, the time of appearance of isoniazid resistance varies considerably from one case to another. Approximately 1 in 10^6 tubercle bacilli will be genetically resistant to isoniazid; since tuberculous cavities may contain as many as 10^7 to 10^9 microorganisms, it is not surprising that treatment with isoniazid alone selects for these resistant bacteria. The incidence of primary resistance to isoniazid in the United States until recently had been fairly stable at 2% to 5% of isolates of *M. tuberculosis*. Resistance currently is estimated at 8% of isolates, but may be much higher in certain populations, including Asian and Hispanic immigrants and in large urban areas and coastal or border communities (Centers for Disease Control, 1999; Iseman, 1993).

Mechanism of Action. Isoniazid is a prodrug; mycobacterial catalase-peroxidase converts isoniazid into an active metabolite. A primary action of isoniazid is to inhibit the biosynthesis of mycolic acids—long, branched lipids that are attached to a unique polysaccharide, arabinogalactan, to form part of the mycobacterial cell wall. The mechanism of action of isoniazid is complex, with resistance mapping to mutations in at least five different genes (*katG* [coding for the catalase-peroxidase that activates the prodrug isoniazid], *inhA*, *ahpC*, *kasA*, and *ndh*) (see above). The preponderance of evidence points to *inhA* as the primary drug target. Indeed, the catalase-peroxidase-activated isoniazid, but not the prodrug, binds to the *inhA* gene product enoyl-ACP reductase of

fatty acid synthase II, which converts Δ^2 -unsaturated fatty acids to saturated fatty acids in the mycolic acid biosynthetic pathway (Vilcheze *et al.*, 2000). Mycolic acids are unique to mycobacteria, explaining the high degree of selectivity of the antimicrobial activity of isoniazid. Mutations of the *katG* gene that result in an inactive catalase-peroxidase cause high-level isoniazid resistance, since the prodrug cannot be activated by the catalase-peroxidase (Blanchard, 1996). Isoniazid also inhibits mycobacterial catalase-peroxidase (the isoniazid-activating enzyme), which may increase the likelihood of damage to the mycobacteria from reactive oxygen species and H_2O_2 . Exposure to isoniazid leads to a loss of acid-fastness and a decrease in the quantity of methanol-extractable lipids in the microorganisms.

Absorption, Distribution, and Excretion. Isoniazid is readily absorbed when administered either orally or parenterally. Aluminum-containing antacids may interfere with absorption. Peak plasma concentrations of 3 to 5 $\mu\text{g/ml}$ develop 1 to 2 hours after oral ingestion of usual doses.

Isoniazid diffuses readily into all body fluids and cells. The drug is detectable in significant quantities in pleural and ascitic fluids; concentrations in the cerebrospinal fluid (CSF) with inflamed meninges are similar to those in the plasma (Holdiness, 1985). Isoniazid penetrates well into caseous material. The concentration of the agent is initially higher in the plasma and muscle than in the infected tissue, but the latter retains the drug for a long time in quantities well above those required for bacteriostasis.

From 75% to 95% of a dose of isoniazid is excreted in the urine within 24 hours, mostly as metabolites. The main excretory products in humans result from enzymatic acetylation (acetylisoniazid) and enzymatic hydrolysis (isonicotinic acid). Small quantities of an isonicotinic acid conjugate (probably isonicotinyl glycine), one or more isonicotinyl hydrazones, and traces of *N*-methylisoniazid also are detectable in the urine.

The distribution of slow and rapid inactivators of the drug is bimodal owing to differences in the levels and activity of the genetically polymorphic arylamine *N*-acetyltransferase type 2 (NAT2) (Figure 47–1). The activity of NAT2 enzyme translated from variant alleles is decreased mostly by the impaired stability or a decrease in V_{max} . At least 36 NAT2 alleles have been identified, although many may not be clinically important (Kinzig-Schippers *et al.*, 2005). As an autosomal recessive trait, only individuals bearing two variant alleles are expected to be prone to impaired acetylation capacity (Meisel, 2002). The rate of acetylation significantly alters the concentrations of the drug that are achieved in plasma and its half-life in the circulation. The half-life of the drug may be prolonged by hepatic insufficiency.

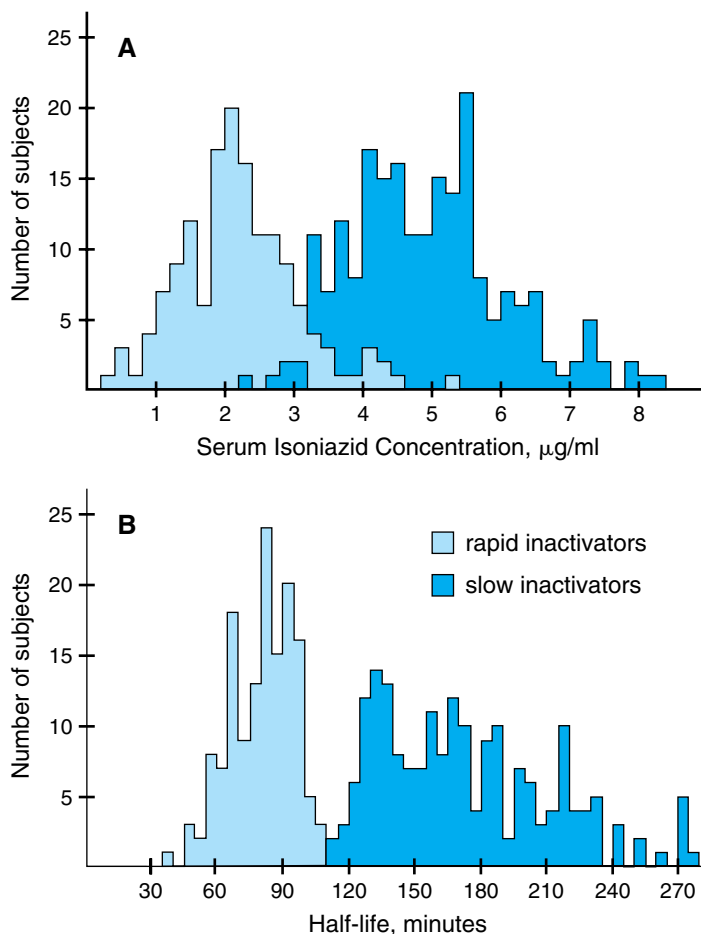

Figure 47-1. Bimodal distribution of serum isoniazid concentrations and half-lives in a large group of Finnish patients. More than 300 patients were given intravenous injections of 5 mg/kg of isoniazid. Serum drug concentrations were assayed at multiple times after injection. **A.** The distribution of the serum concentrations of isoniazid 180 minutes after injection; the light blue histograms represent rapid inactivators, and the dark blue histograms, slow inactivators. **B.** The distribution of serum half-lives of isoniazid for patients of each group. (Reproduced with permission from Tiitinen, 1969.)

The frequency of each acetylation phenotype is dependent upon race but is not influenced by sex or age. Fast acetylation is found in Inuit and Japanese. Slow acetylation is the predominant phenotype in most Scandinavians, Jews, and North African Caucasians. The incidence of “slow acetylators” among various racial types in the United States is about 50%. Since high acetyltransferase activity (fast acetylation) is inherited as an autosomal dominant trait, “fast acetylators” of isoniazid are either heterozygous or homozygous. The average concentration of active isoniazid in the circulation of fast acetylators is about 30% to 50% of that in slow acetylators. In the whole population, the half-life of isoniazid varies from less than 1 to more than 4 hours (Figure 47-1). The mean half-life in fast acetylators is approximately 70 minutes, whereas 2 to 5 hours is characteristic of slow acetylators. Because isoniazid is relatively nontoxic, a sufficient amount of drug can be administered to fast acetylators to achieve a therapeutic effect equal to that seen in slow acetylators. A dosage reduction is recommended for slow acetylators with hepatic failure. The clearance of isoniazid is dependent only to a small degree on the status of renal function, but patients

who are slow inactivators of the drug may accumulate toxic concentrations if their renal function is impaired.

Therapeutic Uses. Isoniazid is still the most important drug worldwide for the treatment of all types of tuberculosis. Toxic effects can be minimized by prophylactic therapy with *pyridoxine* and careful surveillance of the patient. For treatment of active infections, the drug must be used concurrently with another agent, although it is used alone for prophylaxis.

Isoniazid is available for oral and parenteral administration. The commonly used total daily dose of isoniazid is 5 mg/kg, with a maximum of 300 mg; oral and intramuscular doses are identical. Isoniazid usually is given orally in a single daily dose but may be given in two divided doses. Although doses of 10 to 20 mg/kg, with a maximum of 600 mg, occasionally are used in severely ill patients, there is no evidence that this regimen is more effective. Children

should receive 10 to 20 mg/kg per day (300 mg maximum). Isoniazid may be used as intermittent therapy for tuberculosis; after a minimum of 2 months of daily therapy with isoniazid, rifampin, and pyrazinamide, for sensitive strains of *M. tuberculosis*, patients may be treated with twice-weekly doses of isoniazid (15 mg/kg orally) plus rifampin (10 mg/kg, up to 600 mg per dose) for 4 months.

Pyridoxine, vitamin B₆, (10 to 50 mg per day) should be administered with isoniazid to minimize the risks of peripheral neuropathy and central nervous system toxicity (see below) in malnourished patients and those predisposed to neuropathy (e.g., the elderly, pregnant women, HIV-infected individuals, diabetics, alcoholics, and uremics) (Snider, 1980).

Untoward Effects. The incidence of adverse reactions to isoniazid was estimated to be 5.4% among more than 2000 patients treated with the drug; the most prominent of these reactions were rash (2%), fever (1.2%), jaundice (0.6%), and peripheral neuritis (0.2%). Hypersensitivity to isoniazid may result in fever, various skin eruptions, hepatitis, and morbilliform, maculopapular, purpuric, and urticarial rashes. Hematological reactions also may occur (agranulocytosis, eosinophilia, thrombocytopenia, anemia). Vasculitis associated with antinuclear antibodies may appear during treatment but disappears when the drug is stopped. Arthritic symptoms (back pain; bilateral proximal interphalangeal joint involvement; arthralgia of the knees, elbows, and wrists; and the “shoulder-hand” syndrome) have been attributed to this agent.

If pyridoxine is not given concurrently, peripheral neuritis (most commonly paresthesias of feet and hands) is the most common reaction to isoniazid and occurs in about 2% of patients receiving 5 mg/kg of the drug daily. Higher doses may result in peripheral neuritis in 10% to 20% of patients. Neuropathy is more frequent in slow acetylators and in individuals with diabetes mellitus, poor nutrition, or anemia. The prophylactic administration of pyridoxine prevents the development not only of peripheral neuritis, but also of most other nervous system disorders in practically all instances, even when therapy lasts as long as 2 years.

Isoniazid may precipitate convulsions in patients with seizure disorders, and rarely, in patients with no history of seizures. Optic neuritis and atrophy also have occurred during therapy with the drug. Muscle twitching, dizziness, ataxia, paresthesias, stupor, and toxic encephalopathy that may be fatal are other manifestations of the neurotoxicity of isoniazid. A number of mental abnormalities may appear during the use of this drug, including euphoria, transient impairment of memory, separation of ideas and reality, loss of self-control, and florid psychoses.

Isoniazid is known to inhibit the parahydroxylation of *phenytoin*, and signs and symptoms of toxicity occur in approximately 27% of patients given both drugs, particularly in those who are slow acetylators (Miller *et al.*, 1979). Concentrations of phenytoin in plasma should be monitored and adjusted if necessary. The dosage of isoniazid should not be changed.

Although jaundice has been known for some time to be an untoward effect of exposure to isoniazid, not until the early 1970s did it become apparent that severe hepatic injury leading to death may occur in some individuals receiving this drug (Garibaldi *et al.*,

1972). Additional studies in adults and children have confirmed this observation; the characteristic pathological process is bridging and multilobular necrosis. Continuation of the drug after symptoms of hepatic dysfunction have appeared tends to increase the severity of damage. The mechanisms responsible for this toxicity are unknown, although acetylhydrazine, which is a metabolite of isoniazid, causes hepatic damage in adults. Hence, patients who are rapid acetylators of isoniazid might be expected to be more likely to develop hepatotoxicity than slow acetylators; whether this is true, however, is unresolved. A contributory role of alcoholic hepatitis has been noted, but chronic carriers of the hepatitis B virus tolerate isoniazid (McGlynn *et al.*, 1986). Age appears to be the most important factor in determining the risk of isoniazid-induced hepatotoxicity. Hepatic damage is rare in patients less than 20 years old; the complication is observed in 0.3% of those 20 to 34 years old, and the incidence increases to 1.2% and 2.3% in individuals 35 to 49 and older than 50 years of age, respectively (Bass *et al.*, 1994; Comstock, 1983). Up to 12% of patients receiving isoniazid may have elevated plasma aspartate and alanine transaminase activities (Bailey *et al.*, 1974). Patients receiving isoniazid should be carefully evaluated at monthly intervals for symptoms of hepatitis (anorexia, malaise, fatigue, nausea, and jaundice) and warned to discontinue the drug if such symptoms occur. Some clinicians also prefer to determine serum aspartate aminotransferase activities at monthly intervals in high-risk individuals (ages 7 to 35, excessive alcohol intake, history of liver disease, etc.) (Byrd *et al.*, 1979), and recommend that an elevation greater than five times normal is cause for drug discontinuation. Most hepatitis occurs 4 to 8 weeks after the start of therapy. Isoniazid should be administered with great care to those with preexisting hepatic disease.

Among miscellaneous reactions associated with isoniazid therapy are dryness of the mouth, epigastric distress, methemoglobinemia, tinnitus, and urinary retention. In persons predisposed to pyridoxine-deficiency anemia, the administration of isoniazid may result in dramatic anemia, but treatment with large doses of vitamin B₆ gradually returns the blood to normal in such cases. A drug-induced syndrome resembling systemic lupus erythematosus has also been reported. Overdose of isoniazid, as in attempted suicide, may result in nausea, vomiting, dizziness, slurred speech, and visual hallucinations followed by coma, seizures, metabolic acidosis, and hyperglycemia. Pyridoxine is an antidote in this setting; it should be given in a dose that approximates the amount of isoniazid ingested.

RIFAMPIN AND OTHER RIFAMYCINS

The rifamycins (rifampin, rifabutin, rifapentine) are a group of structurally similar, complex macrocyclic antibiotics produced by *Amycolatopsis mediterranei* (Farr, 2000); rifampin (RIFADIN; RIMACTANE) is a semisynthetic derivative of one of these—rifamycin B. Rifamycins were first isolated by Lepetit Research Laboratories from cultures obtained from a pine forest near Nice, France (Ver-non, 2004).

Chemistry. Rifampin is soluble in organic solvents and in water at acidic pH. It has the following structure:

Antibacterial Activity. Rifampin inhibits the growth of most gram-positive bacteria as well as many gram-negative microorganisms such as *Escherichia coli*, *Pseudomonas*, indole-positive and indole-negative *Proteus*, and *Klebsiella*. Rifampin is very active against *Staphylococcus aureus* and coagulase-negative staphylococci. The drug also is highly active against *Neisseria meningitidis* and *Haemophilus influenzae*; minimal inhibitory concentrations range from 0.1 to 0.8 $\mu\text{g/ml}$. Rifampin inhibits the growth of *Legionella* species in cell culture and in animal models.

Rifampin in concentrations of 0.005 to 0.2 $\mu\text{g/ml}$ inhibits the growth of *M. tuberculosis in vitro*. Among nontuberculous mycobacteria, *M. kansasii* is inhibited by 0.25 to 1 $\mu\text{g/ml}$. The majority of strains of *Mycobacterium scrofulaceum*, *Mycobacterium intracellulare*, and *M. avium* are suppressed by concentrations of 4 $\mu\text{g/ml}$, but certain strains may be resistant to 16 $\mu\text{g/ml}$. *Mycobacterium fortuitum* is highly resistant to the drug. Rifampin increases the *in vitro* activity of streptomycin and isoniazid, but not that of ethambutol, against *M. tuberculosis*.

Bacterial Resistance. Microorganisms, including mycobacteria, may develop resistance to rifampin rapidly *in vitro* as a one-step process, and one of every 10^7 to 10^8 tubercle bacilli is resistant to the drug. Microbial resistance to rifampin is due to an alteration of the target of this drug, DNA-dependent RNA polymerase, with resistance in most cases being due to mutations between codons 507 and 533 of the polymerase *rpoB* gene (Blanchard, 1996); the mutations reduce binding of the drug to the polymerase. As a consequence, the antibiotic must not be used alone in the chemotherapy of tuberculosis. When rifampin has been used to eradicate the meningococcal carrier state, failures have been due to the appearance of drug-resistant bacteria after treatment for as few as 2 days. Certain rifampin-resistant bacterial mutants have decreased virulence. Tuberculosis caused by rifampin-resistant mycobacteria has been described in patients who had not received prior chemotherapy, but this is very rare (usually less than 1%; Cauthen *et al.*, 1988).

Mechanism of Action. Rifampin inhibits DNA-dependent RNA polymerase of mycobacteria and other microorganisms by forming a stable drug–enzyme complex, leading to suppression of initiation of chain formation (but not chain elongation) in RNA synthesis. More specifically, the β subunit of this complex enzyme is the site of action of the drug, although rifampin binds only to the holoenzyme. Nuclear RNA polymerases from a variety of eukaryotic cells do not bind rifampin, and RNA synthesis is correspondingly unaffected in eukaryotic cells.

High concentrations of rifamycin antibiotics can inhibit RNA synthesis in mammalian mitochondria, viral DNA-dependent RNA polymerases, and reverse transcriptases. Rifampin is bactericidal for both intracellular and extracellular microorganisms.

Absorption, Distribution, and Excretion. The oral administration of rifampin produces peak concentrations in plasma in 2 to 4 hours; after ingestion of 600 mg, this value is about 7 $\mu\text{g/ml}$, but there is considerable variability. Aminosalicilyc acid may delay the absorption of rifampin and cause a failure to reach adequate plasma concentrations. If aminosalicilate and rifampin are used concurrently, they should be given separately at an interval of 8 to 12 hours.

Following absorption from the gastrointestinal tract, rifampin is eliminated rapidly in the bile, and an enterohepatic circulation ensues. During this time, the drug is progressively deacetylated, such that after 6 hours, nearly all of the antibiotic in the bile is in the deacetylated form, which retains essentially full antibacterial activity. Intestinal reabsorption is reduced by deacetylation (as well as by food), and thus metabolism facilitates elimination of the drug. The half-life of rifampin varies from 1.5 to 5 hours and is increased by hepatic dysfunction; the half-life may be decreased in patients receiving isoniazid concurrently who are slow inactivators of isoniazid. The half-life of rifampin is progressively shortened by about 40% during the first 14 days of treatment, owing to induction of hepatic microsomal enzymes that accelerate rifampin deacetylation. Up to 30% of a dose of the drug is excreted in the urine and 60% to 65% in the feces; less than half of this may be unaltered antibiotic. Adjustment of dosage is not necessary in patients with impaired renal function.

Rifampin is distributed throughout the body and is present in effective concentrations in many organs and body fluids, including the CSF. This is perhaps best exemplified by the fact that the drug may impart an orange-red color to the urine, feces, saliva, sputum, tears, and sweat; patients should be so warned. (For various aspects of rifampin metabolism, *see* Furesz, 1970; Farr, 2000.)

Therapeutic Uses. Rifampin for oral administration is available alone and as a fixed-dose combination with isoniazid (150 mg of isoniazid, 300 mg of rifampin; RIFAMATE) or with isoniazid and pyrazinamide (50 mg of isoniazid, 120 mg of rifampin, and 300 mg pyrazinamide; RIFATER). A parenteral form of rifampin is available for use when the drug cannot be taken by mouth. *Rifampin and isoniazid are the most effective drugs available for the treatment of tuberculosis.*

The dose of rifampin for treatment of tuberculosis in adults is 600 mg, given once daily, either 1 hour before or 2 hours after a meal. Children should receive 10 mg/kg given in the same way. Doses of 15 mg/kg or higher are associated with increased hepatotoxicity in children (Centers for Disease Control, 1980). Rifampin, like isoniazid, should never be used alone for the treatment of tuberculosis because of the rapidity with which resistance may develop. Despite the long list of untoward effects from rifampin, their incidence is low, and treatment seldom has to be interrupted.

The use of rifampin in the chemotherapy of tuberculosis is detailed below. Rifampin also is indicated for the prophylaxis of meningococcal disease and *H. influenzae* meningitis. To prevent meningococcal disease, adults may be treated with 600 mg twice daily for 2 days or 600 mg once daily for 4 days; children should receive 10 to 15 mg/kg, to a maximum of 600 mg.

Untoward Effects. Rifampin generally is well tolerated. When given in usual doses, fewer than 4% of patients with tuberculosis have significant adverse reactions; the most common are rash (0.8%), fever (0.5%), and nausea and vomiting (1.5%) (Grosset and Leventis, 1983). Rarely, hepatitis and deaths due to liver failure have been observed in patients who received other hepatotoxic agents in addition to rifampin, or who had preexisting liver disease. Hepatitis from rifampin rarely occurs in patients with normal hepatic function; likewise, the combination of isoniazid and rifampin appears generally safe in such patients (Gangadharam, 1986). However, chronic liver disease, alcoholism, and old age appear to increase the incidence of severe hepatic problems when rifampin is given alone or concurrently with isoniazid.

Rifampin should not be administered on an intermittent schedule (less than twice weekly) and/or in daily doses of 1.2 g or greater because this is associated with frequent side effects. A flulike syndrome with fever, chills, and myalgias develops in 20% of patients so treated. The syndrome also may include eosinophilia, interstitial nephritis, acute tubular necrosis, thrombocytopenia, hemolytic anemia, and shock.

Because rifampin potently induces CYP1A2, 2C9, 2C19, and 3A4, its administration results in a decreased half-life for a number of compounds, including HIV protease and non-nucleoside reverse transcriptase inhibitors, *digitoxin*, *digoxin*, *quinidine*, *disopyramide*, *mexiletine*, *tocainide*, *ketoconazole*, *propranolol*, *metoprolol*, *clofibrate*, *verapamil*, *methadone*, *cyclosporine*, corticosteroids, oral anticoagulants, *theophylline*, barbiturates, oral contraceptives, *halothane*, *fluconazole*, and the sulfonylureas (Farr, 2000).

Rifabutin (*see below*) has less effect on the metabolism of many of the HIV protease inhibitors. The significant interaction between rifampin and oral anticoagulants of the *coumarin* type leads to a decrease in efficacy of these agents. This effect appears about 5 to 8

days after rifampin administration is started and persists for 5 to 7 days after it is stopped (*see Chapter 54*). The ability of rifampin to enhance the catabolism of a variety of steroids leads to the decreased effectiveness of oral contraceptives, and can induce adrenal insufficiency in patients with marginal adrenocortical reserve (*see Chapter 59*). The increased metabolism of methadone and other narcotics has led to reports of precipitation of withdrawal syndromes and inadequate pain control unless the dose is increased. Rifampin may reduce biliary excretion of contrast media used for visualization of the gallbladder (Baciewicz *et al.*, 1987).

Gastrointestinal disturbances produced by rifampin (epigastric distress, nausea, vomiting, abdominal cramps, diarrhea) have occasionally required discontinuation of the drug. Various symptoms related to the nervous system also have been noted, including fatigue, drowsiness, headache, dizziness, ataxia, confusion, inability to concentrate, generalized numbness, pain in the extremities, and muscular weakness. Hypersensitivity reactions include fever, pruritus, urticaria, various types of skin eruptions, eosinophilia, and soreness of the mouth and tongue. Hemolysis, hemoglobinuria, hematuria, renal insufficiency, and acute renal failure have been observed rarely; these also are thought to be hypersensitivity reactions. Thrombocytopenia, transient leukopenia, and anemia have occurred during therapy. Since the potential teratogenicity of rifampin is unknown and the drug is known to cross the placenta, it is best to avoid the use of this agent during pregnancy.

Graber and associates (1973) noted immunoglobulin light-chain proteinuria (either kappa, lambda, or both) in about 85% of patients with tuberculosis treated with rifampin. None of the patients had symptoms or electrophoretic patterns compatible with myeloma. However, renal failure has been associated with light-chain proteinuria (Warrington *et al.*, 1977).

Rifampin is effective for chemoprophylaxis of meningococcal disease and meningitis due to *H. influenzae* in household contacts of patients with such infections. Combined with a β -lactam antibiotic or vancomycin, rifampin may be useful for therapy in selected cases of staphylococcal endocarditis (on both natural and prosthetic valves) or osteomyelitis, especially those caused by staphylococci "tolerant" to penicillin. Rifampin may be indicated for treatment of infections in patients with inadequate leukocytic bactericidal activity and for eradication of the staphylococcal nasal carrier state in patients with chronic furunculosis.

Rifabutin (MYCOBUTIN) is a rifampin derivative used in tuberculosis-infected HIV patients treated concurrently with protease inhibitors because rifabutin is a less potent inducer of CYPs. It has the same mechanism of action as rifampin and is discussed further in the section on drugs for *Mycobacterium avium* complex. Unique side effects of rifabutin include polymyalgia, pseudojaundice, and anterior uveitis (Vernon, 2004). About one-fourth of rifampin-resistant *M. tuberculosis* isolates are rifabutin-sensitive, so it may have a role in the treatment of multidrug-resistant tuberculosis.

Rifapentine (PRIFTIN) has a longer half-life than rifampin and rifabutin, which allows once-weekly dosing.

Compared to rifabutin and rifampin, it is intermediate in its induction of CYPs (Vernon, 2004). Its use in the treatment of tuberculosis in HIV-infected patients was associated with the selection of rifamycin resistance; rifabutin is therefore preferred in this situation (Vernon, 2004).

ETHAMBUTOL

Chemistry. Ethambutol is a water-soluble and heat-stable compound; its structural formula is:

Antibacterial Activity, Mechanism of Action, Resistance. Nearly all strains of *M. tuberculosis* and *M. kansasii* as well as a number of strains of MAC are sensitive to ethambutol (Pablos-Méndez *et al.*, 1998). The sensitivities of other nontuberculous organisms are variable. Ethambutol has no effect on other bacteria. It suppresses the growth of most isoniazid- and streptomycin-resistant tubercle bacilli. Resistance to ethambutol develops very slowly *in vitro*.

Mycobacteria take up ethambutol rapidly when the drug is added to cultures that are in the exponential growth phase. However, growth is not significantly inhibited before about 24 hours. Ethambutol inhibits arabinosyl transferases involved in cell wall biosynthesis. Bacterial resistance to the drug develops *in vivo* via single amino acid mutations in the *embA* gene when ethambutol is given in the absence of other effective agents (Belanger *et al.*, 1996).

Absorption, Distribution, and Excretion. About 75% to 80% of an orally administered dose of ethambutol is absorbed from the gastrointestinal tract. Concentrations in plasma are maximal in humans 2 to 4 hours after the drug is taken and are proportional to the dose. A single dose of 25 mg/kg produces a plasma concentration of 2 to 5 $\mu\text{g/ml}$ at 2 to 4 hours. The drug has a half-life of 3 to 4 hours. Within 24 hours, 75% of an ingested dose of ethambutol is excreted unchanged in the urine; up to 15% is excreted in the form of two metabolites, an aldehyde and a dicarboxylic acid derivative. Renal clearance of ethambutol is approximately 7 $\text{ml}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$; thus it is evident that the drug is excreted by tubular secretion in addition to glomerular filtration.

Therapeutic Uses. Ethambutol (*ethambutol hydrochloride*; MYAMBUTOL) has been used with notable success in the therapy of tuberculosis of various forms when given concurrently with isoniazid. Because of a lower incidence of toxic effects and better acceptance by patients, ethambutol has essentially replaced aminosalicylic acid.

Ethambutol is available for oral administration in tablets containing the D isomer. The usual adult dose of ethambutol is 15 mg/kg given once a day. Some physicians prefer to treat with 25 mg/kg

per day for the first 60 days and then to reduce the dose to 15 mg/kg per day, particularly for those who have received previous therapy. Ethambutol accumulates in patients with impaired renal function, and adjustment of dosage is necessary.

Ethambutol is not recommended for children under 5 years of age, in part because of concern about the ability to test their visual acuity (*see below*). Children from ages 6 to 12 years should receive 10 to 15 mg/kg per day.

The use of ethambutol in the chemotherapy of tuberculosis is described below.

Untoward Effects. The most important side effect is optic neuritis, resulting in decreased visual acuity and loss of ability to differentiate red from green. The incidence of this reaction is proportional to the dose of ethambutol and is observed in 15% of patients receiving 50 mg/kg per day, in 5% of patients receiving 25 mg/kg per day, and in fewer than 1% of patients receiving daily doses of 15 mg/kg (the recommended dose for treatment of tuberculosis). The intensity of the visual difficulty is related to the duration of therapy after the decreased visual acuity first becomes apparent and may be unilateral or bilateral. Tests of visual acuity and red-green discrimination prior to the start of therapy and periodically thereafter are thus recommended. Recovery usually occurs when ethambutol is withdrawn; the time required is a function of the degree of visual impairment.

Ethambutol produces very few untoward reactions. Fewer than 2% of nearly 2000 patients who received daily doses of 15 mg/kg of ethambutol had adverse reactions: 0.8% experienced diminished visual acuity, 0.5% had a rash, and 0.3% developed drug fever. Other side effects that have been observed are pruritus, joint pain, gastrointestinal upset, abdominal pain, malaise, headache, dizziness, mental confusion, disorientation, and possible hallucinations. Numbness and tingling of the fingers owing to peripheral neuritis are infrequent. Anaphylaxis and leukopenia are rare.

Therapy with ethambutol results in an increased concentration of urate in the blood in about 50% of patients, owing to decreased renal excretion of uric acid. The effect may be detectable as early as 24 hours after a single dose or as late as 90 days after treatment is started. This untoward effect is possibly enhanced by isoniazid and pyridoxine (Postlethwaite *et al.*, 1972).

STREPTOMYCIN

The pharmacology of streptomycin, including its adverse effects and its uses in infections other than tuberculosis, are discussed in Chapter 45. Only features of the drug related to its antibacterial activity and therapeutic effects in the management of mycobacterial diseases are considered here.

History. Streptomycin was the first clinically available effective drug for the treatment of tuberculosis. At first it was given in large

doses, but problems related to toxicity and the development of resistant microorganisms seriously limited its usefulness. The antibiotic was then administered in smaller quantities, but streptomycin administered alone still proved to be far from ideal for the management of all forms of the disease. However, the discovery of other compounds that, when administered concurrently with streptomycin, reduced the rate at which microorganisms became drug-resistant enabled physicians to treat tuberculosis effectively with streptomycin. It is now the least used of the first-line agents in the therapy of tuberculosis.

Antibacterial Activity. Streptomycin is bactericidal for the tubercle bacillus *in vitro*. Concentrations as low as 0.4 $\mu\text{g/ml}$ may inhibit growth. The vast majority of strains of *M. tuberculosis* are sensitive to 10 $\mu\text{g/ml}$. *M. kansasii* is frequently sensitive, but other nontuberculous mycobacteria are only occasionally susceptible.

The activity of streptomycin *in vivo* is essentially suppressive. When the antibiotic is administered to experimental animals prior to inoculation with the tubercle bacillus, the development of disease is not prevented. Infection progresses until the animals' immunological mechanisms respond. The presence of viable microorganisms in abscesses and in the regional lymph nodes adds support to the concept that the activity of streptomycin *in vivo* is to suppress, not to eradicate, the tubercle bacillus. This property of streptomycin may be related to the observation that the drug does not readily enter living cells and thus cannot kill intracellular microbes.

Bacterial Resistance. Large populations of all strains of tubercle bacilli include a number of cells that are markedly resistant to streptomycin because of mutation. However, primary resistance to the antibiotic is found in only 2% to 3% of isolates of *M. tuberculosis*. Selection for resistant tubercle bacilli occurs *in vivo* as it does *in vitro*. In general, the longer therapy is continued, the greater the incidence of resistance to streptomycin. When streptomycin was used alone, as many as 80% of patients harbored insensitive tubercle bacilli after 4 months of treatment; many of these microorganisms were not inhibited by concentrations of drug as high as 1 mg/ml.

Therapeutic Uses. Since other effective agents have become available, the use of streptomycin for the treatment of pulmonary tuberculosis has been sharply reduced. Many clinicians prefer to give 4 drugs, of which streptomycin may be one, for the most serious forms of tuberculosis, such as disseminated disease or meningitis.

For tuberculosis, adults should be given 15 mg/kg per day in divided doses given by intramuscular injection every 12 hours, not to exceed 1 g per day. Children should receive 20 to 40 mg/kg per day in divided doses every 12 to 24 hours, not to exceed 1 g per day. Therapy usually is discontinued after 2 to 3 months, or sooner if cultures become negative.

Untoward Effects. Untoward effects of streptomycin are considered in detail in Chapter 45. In one series of 515 patients with tuberculosis who were treated with this aminoglycoside, 8.2% had adverse reactions; half of these involved the auditory and vestibular functions of the

eighth cranial nerve. Other relatively frequent problems included rash (in 2%) and fever (in 1.4%).

PYRAZINAMIDE

Chemistry. Pyrazinamide is the synthetic pyrazine analog of nicotinamide. It has the following structural formula:

PYRAZINAMIDE

Antibacterial Activity. Pyrazinamide exhibits bactericidal activity *in vitro* only at a slightly acidic pH. Activity at acid pH is ideal, since *M. tuberculosis* resides in an acidic phagosome within the macrophage (Jacobs, 2000). Tubercle bacilli within monocytes *in vitro* are inhibited or killed by the drug at a concentration of 12.5 $\mu\text{g/ml}$. Resistance develops rapidly if pyrazinamide is used alone. The target of pyrazinamide appears to be the mycobacterial fatty acid synthase I gene involved in mycolic acid biosynthesis (Zimhony *et al.*, 2000).

Absorption, Distribution, and Excretion. Pyrazinamide is well absorbed from the gastrointestinal tract and widely distributed throughout the body. The oral administration of 500 mg produces plasma concentrations of about 9 to 12 $\mu\text{g/ml}$ at 2 hours and 7 $\mu\text{g/ml}$ at 8 hours. The plasma half-life is 9 to 10 hours in patients with normal renal function. The drug is excreted primarily by renal glomerular filtration. Pyrazinamide is distributed widely—including to the CNS, lungs, and liver—after oral administration. Penetration of the drug into the CSF is excellent. Pyrazinamide is hydrolyzed to pyrazinoic acid and subsequently hydroxylated to 5-hydroxypyrazinoic acid, the major excretory product.

Therapeutic Uses. Pyrazinamide has become an important component of short-term (6-month) multiple-drug therapy of tuberculosis (British Thoracic Association, 1982; Bass *et al.*, 1994). Pyrazinamide is available in tablets for oral administration. The daily dose for adults is 15 to 30 mg/kg orally, given as a single dose. The maximum quantity to be given is 2 g per day, regardless of weight. Children should receive 15 to 30 mg/kg per day; daily doses also should not exceed 2 g. Pyrazinamide has been safe and effective when administered twice or thrice weekly (at increased dosages).

Untoward Effects. Injury to the liver is the most serious side effect of pyrazinamide. When a dose of 40 to 50 mg/kg is administered orally, signs and symptoms of hepatic disease appear in about 15% of patients, with jaundice in 2% to 3% and death due to hepatic necrosis in rare instances. Elevations of plasma alanine and aspartate aminotransferases are the earliest abnormalities produced by the drug. Regimens employed currently (15 to 30 mg/kg per day) are much safer. Prior to pyrazinamide administration all patients should undergo studies of hepatic function and these studies should be repeated at frequent intervals during the entire period of treatment. If evidence of significant hepatic damage becomes apparent, therapy must be stopped. Pyrazinamide should not be given to individuals with any degree of hepatic dysfunction unless this is absolutely unavoidable.

The drug inhibits excretion of urate, resulting in hyperuricemia in nearly all patients; acute episodes of gout have occurred. Other untoward effects that have been observed with pyrazinamide are arthralgias, anorexia, nausea and vomiting, dysuria, malaise, and fever. While some international organizations recommend the use of pyrazinamide in pregnancy, this is not the case in the United States because of inadequate data on teratogenicity (Bass *et al.*, 1994).

QUINOLONES

The fluoroquinolones, which are discussed in Chapter 43, are highly active against *M. tuberculosis* as well as nontuberculous mycobacteria and are important components of treatment regimens of multidrug-resistant tuberculosis (Drlica *et al.*, 2004) (Table 47–1). The C-8-methoxy-fluoroquinolones, such as gatifloxacin (TEQUIN) and moxifloxacin (AVELOX), are the most active and therefore least likely to result in the development of quinolone resistance. Unfortunately, when resistance develops to one fluoroquinolone in mycobacteria, cross-resistance develops within this entire class of antibiotics. Thus the most active fluoroquinolones should be used, and only in combination with other antimycobacterial agents, to prevent resistance from developing (Ginsberg *et al.*, 2003).

LINEZOLID

Linezolid (ZYVOX), which is discussed in Chapter 46, is highly active *in vitro* against *M. tuberculosis* and some nontuberculous mycobacteria (Wallace *et al.*, 2001; Alcalá *et al.*, 2003). Clinical experience with its use to treat these infections is limited at present.

INTERFERON- γ

Interferon- γ (IFN- γ) (ACTIMMUNE) activates macrophages to kill *M. tuberculosis*. Aerosol delivery of IFN- γ to the lungs of patients with multidrug-resistant tuberculosis results in wide pulmonary distribution and enhanced local immune stimulation (Condos *et al.*, 2004). IFN- γ is discussed further in Chapter 52.

ETHIONAMIDE

Chemistry. Synthesis and study of a variety of congeners of thioisonicotinamide revealed that an α -ethyl derivative—ethionamide

(TRECATOR-SC)—is considerably more effective than the parent compound. It has the following structural formula:

Antibacterial Activity, Resistance. The multiplication of *M. tuberculosis* is suppressed by concentrations of ethionamide ranging from 0.6 to 2.5 $\mu\text{g/ml}$. Resistance can develop rapidly *in vitro* and *in vivo* when ethionamide is used as a single-agent treatment, and can include low-level cross-resistance to isoniazid. A concentration of 10 $\mu\text{g/ml}$ or less will inhibit approximately 75% of photochromogenic mycobacteria; the scotochromogens are more resistant. Ethionamide is very effective in the treatment of experimental tuberculosis in animals, although its activity varies greatly with the animal model studied.

Mechanism of Action. In the manner of isoniazid, ethionamide is also an inactive prodrug that is activated by a mycobacterial reductase system. EtaA, an NADPH-specific, FAD-containing monooxygenase, converts ethionamide to a sulfoxide, and thence to 2-ethyl-4-aminopyridine (Vannelli *et al.*, 2002). Although these products are not toxic to mycobacteria, it is believed that a closely related and transient intermediate is the active antibiotic. Ethionamide inhibits mycobacterial growth by inhibiting the activity of the *inhA* gene product, the enoyl-ACP reductase of fatty acid synthase II (Larsen *et al.*, 2002). This is the same enzyme that activated isoniazid inhibits. Although the exact mechanisms of inhibition may differ, the results are the same: inhibition of mycolic acid biosynthesis and consequent impairment of cell-wall synthesis. Recent advances in understanding the mechanisms of activation and action of thioamides (Fraaije, *et al.*, 2004) may suggest new agents for treating mycobacterial infections.

Absorption, Distribution, and Excretion. The oral administration of 1 g of ethionamide yields peak concentrations in plasma of about 20 $\mu\text{g/ml}$ in 3 hours; the concentration at 9 hours is 3 $\mu\text{g/ml}$. The half-life of the drug is about 2 hours. Approximately 50% of patients are unable to tolerate a single dose larger than 500 mg because of gastrointestinal disturbance. Ethionamide is rapidly and widely distributed; the concentrations in the blood and various organs are approximately equal. Significant concentrations are present in CSF. Ethionamide is cleared by hepatic metabolism; like aminosalicylic acid, ethionamide inhibits the acetylation of isoniazid *in vitro*. Less than 1% of ethionamide is excreted in an active form in the urine.

Therapeutic Uses. *Ethionamide is a secondary agent, to be used concurrently with other drugs only when therapy with primary agents is ineffective or contraindicated.*

Ethionamide is administered only orally. The initial dosage of ethionamide for adults is 250 mg twice daily; it is increased by 125 mg per day every 5 days until a dose of 15 to 20 mg/kg per day is achieved. The maximal dose is 1 g daily. The drug is best taken with meals in divided doses in order to minimize gastric irritation. Children should receive 15 to 20 mg/kg per day in two divided doses, not to exceed 1 g per day.

Untoward Effects. The most common reactions to ethionamide are anorexia, nausea and vomiting, gastric irritation, and a variety of neurologic symptoms. Severe postural hypotension, mental depression, drowsiness, and asthenia are common. Convulsions and peripheral neuropathy are rare. Other reactions referable to the nervous system include olfactory disturbances, blurred vision, diplopia, dizziness, paresthesias, headache, restlessness, and tremors. Pyridoxine (vitamin B₆) relieves the neurologic symptoms and its concomitant administration is recommended. Severe allergic skin rashes, purpura, stomatitis, gynecomastia, impotence, menorrhagia, acne, and alopecia also have been observed. A metallic taste also may be noted. Hepatitis has been associated with the use of the drug in about 5% of cases. The signs and symptoms of hepatotoxicity clear when treatment is stopped. Hepatic function should be assessed at regular intervals in patients receiving ethionamide.

AMINOSALICYLIC ACID

Chemistry. The structural formula of aminosalicylic acid (*p*-aminosalicylic acid, PAS) is:

Antibacterial Activity. Aminosalicylic acid is bacteriostatic. *In vitro*, most strains of *M. tuberculosis* are sensitive to a concentration of 1 µg/ml. The antimicrobial activity of aminosalicylic acid is highly specific, and microorganisms other than *M. tuberculosis* are unaffected. Most nontuberculous mycobacteria are not inhibited by the drug. Aminosalicylic acid alone is of little value in the treatment of tuberculosis in humans.

Bacterial Resistance. Strains of tubercle bacilli insensitive to several hundred times the usual bacteriostatic concentration of aminosalicylic acid can be produced *in vitro*. Resistant strains of tubercle bacilli also emerge in patients treated with aminosalicylic acid, but much more slowly than with streptomycin.

Mechanism of Action. Aminosalicylic acid is a structural analog of *para*-aminobenzoic acid, and its mechanism of action appears to be very similar to that of the sulfonamides (see Chapter 43). Nonetheless, the sulfonamides are ineffective against *M. tuberculosis*, and aminosalicylic acid is inactive against sulfonamide-susceptible bacteria. This differential sensitivity presumably reflects differences in the enzymes responsible for folate biosynthesis in the various microorganisms.

Absorption, Distribution, and Excretion. Aminosalicylic acid is readily absorbed from the gastrointestinal tract. A single oral dose of 4 g of the free acid produces maximal concentrations in plasma of about 75 µg/ml within 1.5 to 2 hours. The sodium salt is absorbed even more rapidly. The drug appears to be distributed throughout the total body water and reaches high concentrations in pleural fluid

and caseous tissue but CSF levels are low. The drug has a half-life of about 1 hour, and concentrations in plasma are negligible within 4 to 5 hours after a single conventional dose. Over 80% of the drug is excreted in the urine; more than 50% is in the form of the acetylated compound; the largest portion of the remainder is made up of the free acid. Excretion of aminosalicylic acid is greatly retarded by renal dysfunction, and the use of the drug is not recommended in such patients. Probenecid decreases the renal excretion of this agent.

Therapeutic Uses. Aminosalicylic acid (PASER) is a second-line agent. Its importance in the management of pulmonary and other forms of tuberculosis has markedly decreased since more active and better-tolerated drugs, such as rifampin and ethambutol, have been developed (see Chemotherapy of Tuberculosis, below).

It is administered orally in a daily dose of 10 to 12 g. Because it is a gastric irritant, the drug is best administered after meals, with the daily dose being divided into 2 to 4 equal portions. Children should receive 150 to 300 mg/kg per day in 3 to 4 divided doses.

Untoward Effects. The incidence of untoward effects associated with the use of aminosalicylic acid is approximately 10% to 30%. Gastrointestinal problems—including anorexia, nausea, epigastric pain, abdominal distress, and diarrhea—are predominant and often limit patient adherence. Patients with peptic ulcers tolerate the drug especially poorly. Hypersensitivity reactions to aminosalicylic acid are seen in 5% to 10% of patients. High fever may develop abruptly, with intermittent spiking, or it may appear gradually and be low-grade. Generalized malaise, joint pains, and sore throat may be present at the same time. Skin eruptions of various types appear as isolated reactions or accompany the fever. Among the hematological abnormalities that have been observed are leukopenia, agranulocytosis, eosinophilia, lymphocytosis, an atypical mononucleosis syndrome, and thrombocytopenia. Acute hemolytic anemia may appear in some instances.

CYCLOSERINE

Cycloserine (SEROMYCIN) is a broad-spectrum antibiotic produced by *Streptococcus orchidaceus*. It was first isolated from a fermentation brew in 1955 and was later synthesized. Currently, cycloserine is used in conjunction with other tuberculostatic drugs in the treatment of pulmonary or extrapulmonary tuberculosis when primary agents (isoniazid, rifampin, ethambutol, pyrazinamide, streptomycin) have failed.

Chemistry. Cycloserine is D-4-amino-3-isoxazolidone; the structural formula is:

The drug is stable in alkaline solution but is rapidly destroyed when exposed to neutral or acidic pH.

Antibacterial Activity. Cycloserine is inhibitory for *M. tuberculosis* in concentrations of 5 to 20 µg/ml *in vitro*. There is no cross-resis-

tance between cycloserine and other tuberculostatic agents. While the antibiotic is effective in experimental infections caused by other microorganisms, studies *in vitro* reveal no suppression of growth in cultures made in conventional media, which contain D-alanine; this amino acid blocks the antibacterial activity of cycloserine.

Mechanism of Action. Cycloserine and D-alanine are structural analogs; thus, cycloserine inhibits reactions in which D-alanine is involved in bacterial cell-wall synthesis (*see* Chapter 44). The use of medium free of D-alanine reveals that the antibiotic inhibits the growth *in vitro* of enterococci, *E. coli*, *S. aureus*, *Nocardia* species, and *Chlamydia*.

Absorption, Distribution, and Excretion. When given orally, 70% to 90% of cycloserine is rapidly absorbed. Peak concentrations in plasma are reached 3 to 4 hours after a single dose and are in the range of 20 to 35 $\mu\text{g/ml}$ in children who receive 20 mg/kg; only small quantities are present after 12 hours. Cycloserine is distributed throughout body fluids and tissues. There is no appreciable blood-brain barrier to the drug, and CSF concentrations are approximately the same as those in plasma. About 50% of a parenteral dose of cycloserine is excreted unchanged in the urine in the first 12 hours; a total of 65% is recoverable in the active form over a period of 72 hours. Very little of the antibiotic is metabolized. The drug may accumulate to toxic concentrations in patients with renal insufficiency; it may be removed from the circulation by dialysis.

Therapeutic Uses. Cycloserine should be used only when retreatment is necessary or when microorganisms are resistant to other drugs. When cycloserine is employed to treat tuberculosis, it must be given together with other effective agents. Cycloserine is available for oral administration. The usual dose for adults is 250 to 500 mg twice daily.

Untoward Effects. Reactions to cycloserine most commonly involve the central nervous system. Symptoms tend to appear within the first 2 weeks of therapy and usually disappear when the drug is withdrawn. Among the central manifestations are somnolence, headache, tremor, dysarthria, vertigo, confusion, nervousness, irritability, psychotic states with suicidal tendencies, paranoid reactions, catatonic and depressed reactions, twitching, ankle clonus, hyperreflexia, visual disturbances, paresis, and tonic-clonic or absence seizures. Large doses of cycloserine or the concomitant ingestion of alcohol increases the risk of seizures. Cycloserine is contraindicated in individuals with a history of epilepsy and should be used with caution in individuals with a history of depression, as suicide is a risk.

OTHER DRUGS

The agents in this section are similar in several aspects. They are all second-line drugs that are used only for treatment of disease caused by resistant *M. tuberculosis* or by nontuberculous mycobacteria. They all must be given parenterally, and they have similar pharmacokinetics and toxicity. *Since these agents are potentially ototoxic and nephrotoxic, no two drugs from this group should be employed simultaneously, and these drugs should not be*

used in combination with streptomycin. Streptomycin, an aminoglycoside that is discussed in Chapter 45, inhibits the growth of *M. tuberculosis in vitro* at a concentration of 10 $\mu\text{g/ml}$ or less.

Amikacin also is an aminoglycoside (*see* Chapter 45). It is extremely active against several mycobacterial species and has a role in the treatment of disease caused by nontuberculous mycobacteria (Brown and Wallace, 2000).

Capreomycin (CAPASTAT) is an antimycobacterial cyclic peptide elaborated by *Streptococcus capreolus*. It consists of 4 active components—capreomycins IA, IB, IIA, and IIB. The agent used clinically contains primarily IA and IB. Bacterial resistance to capreomycin develops when it is given alone; such microorganisms show cross-resistance with kanamycin and *neomycin*. Capreomycin is used only in conjunction with other appropriate antitubercular drugs in treatment of pulmonary tuberculosis when bactericidal agents cannot be tolerated or when causative organisms have become resistant.

Capreomycin must be given intramuscularly. The recommended daily dose is 15 to 30 mg/kg per day or up to 1 g for 60 to 120 days, followed by 1 g two to three times a week. The adverse reactions associated with the use of capreomycin are hearing loss, tinnitus, transient proteinuria, cylindruria, and nitrogen retention. Severe renal failure is rare. Eosinophilia is common. Leukocytosis, leukopenia, rashes, and fever have also been observed. Injections of the drug may be painful.

CHEMOTHERAPY OF TUBERCULOSIS

The availability of effective agents has so altered the treatment of tuberculosis that most patients are now treated in the ambulatory setting, often after diagnosis and initial therapy in a general hospital. Prolonged bed rest is not necessary or even helpful in speeding recovery. Patients must, however, be seen at frequent intervals to follow the course of their disease and treatment. The local health department must be notified of all cases. Contacts should be investigated for the possibility of disease and for the appropriateness of prophylactic therapy with isoniazid.

The majority of cases of previously untreated tuberculosis in the United States is caused by microorganisms that are sensitive to isoniazid, rifampin, ethambutol, and pyrazinamide. *To prevent the development of resistance to these agents that frequently occurs, treatment must include at least 2 drugs to which the bacteria are sensitive.* The preferred standard 6-month treatment program for drug-sensitive tuberculosis in adults and children consists of isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin (for sensitive organisms) for 4 additional months. The combination of isoniazid and rifampin for 9 months is equally effective for drug-sensitive tuberculosis. Because of the increasing frequency of drug resistance, the Centers for Disease Control and Pre-

vention (CDC) has recommended that initial therapy should be with a 4-drug regimen (isoniazid, rifampin, pyrazinamide, and ethambutol or streptomycin) pending sensitivity results. Directly observed therapy is the most effective approach to ensure treatment completion rates of about 90% (Chaulk and Kazandjian, 1998).

Drug interactions are a special concern in patients receiving highly active antiretroviral therapy. The rifamycins accelerate the metabolism of protease inhibitors and non-nucleoside reverse transcriptase inhibitors. Of the rifamycins, rifabutin has the least effect on *indinavir* and *nelfinavir* serum levels, and is therefore the current agent of choice in this setting.

Patients infected with the human immunodeficiency virus (HIV) may benefit from longer (9- to 12-month) treatment regimens (Havlir and Barnes, 1999). Treatment should be initiated with at least a 4-drug regimen consisting of isoniazid, rifabutin, pyrazinamide, and ethambutol or streptomycin. In patients with a high likelihood of infection with multidrug-resistant strains, an initial 5- or 6-drug regimen may be appropriate (Lane *et al.*, 1994; Gallant *et al.*, 1994). Treatment should be continued for at least 6 months after three negative cultures have been obtained. If isoniazid or rifampin cannot be used, therapy should be continued for at least 18 months (12 months after cultures become negative). Chemoprophylaxis (*see* below) should be undertaken if a patient with HIV infection has a positive tuberculin test (induration ≥ 5 mm), a history of a positive tuberculin skin test that was not treated with chemoprophylaxis, or recent close contact with a potentially infectious patient with tuberculosis. Isoniazid does not reduce the incidence of tuberculosis in anergic patients with HIV, so the earlier recommendation to treat such patients with chemoprophylaxis has been abandoned (Gordin *et al.*, 1997).

Therapy of Specific Types of Tuberculosis. Therapy for uncomplicated drug-sensitive pulmonary tuberculosis consists of isoniazid (5 mg/kg, up to 300 mg per day), rifampin (10 mg/kg per day, up to 600 mg daily), pyrazinamide (15 to 30 mg/kg per day or a maximum of 2 g per day), and a fourth agent. The fourth agent may be either ethambutol (usual adult dose of 15 mg/kg once per day) or streptomycin (1 g daily). The dosage of streptomycin is reduced to 1 g twice weekly after 2 months. Some physicians prefer to institute ethambutol therapy with a dose of 25 mg/kg per day for the first 60 days, and then to reduce the dose to 15 mg/kg per day, particularly for those who have received previous therapy. Pyridoxine, 15 to 50 mg per day, also should be included for most adults to minimize adverse reactions to isoniazid (Snider, 1980). Isoniazid, rifampin, pyrazinamide, and ethambutol or streptomycin are given for 2 months; isoniazid and rifampin are then continued for 4 additional months. Children are treated similarly; doses are isoniazid, 10 mg/kg per day (300 mg maximum); rifampin, 10 to 20 mg/kg per day (600 mg maximum); pyrazinamide, 15 to 30 mg/kg per day (2 g

maximum; Bass *et al.*, 1994). The multidrug regimen of isoniazid, rifampin, and ethambutol is considered safe during pregnancy.

Clinical improvement is readily discernible in the vast majority of patients with pulmonary tuberculosis if the treatment is appropriate. Efficacy usually becomes obvious within the first 2 weeks of therapy and is evidenced by a reduction of fever, decrease in cough, weight gain, and increase in the sense of well-being. Progressive radiological improvement also is evident. Over 90% of patients who receive optimal treatment will have negative cultures within 3 to 6 months, depending on the severity of the disease. Cultures that remain positive after 6 months frequently yield resistant microorganisms; the value of using an alternative therapeutic program should then be considered.

Failure of chemotherapy may be due to (1) irregular or inadequate therapy (resulting in persistent or resistant mycobacteria) caused by poor patient adherence to the protracted therapeutic regimen; (2) the use of a single drug, with interruption necessitated by toxicity or hypersensitivity; (3) an inadequate initial regimen; or (4) the primary resistance of the microorganism.

Problems in Chemotherapy. Bacterial Resistance to Drugs. One of the more important problems in the chemotherapy of tuberculosis is bacterial resistance. The primary reason for development of drug resistance is poor patient adherence. To prevent noncompliance and the attendant development of drug-resistant tuberculosis, directly observed therapy is advisable for most patients, in which a health care provider observes the patient ingest the medications 2 to 5 times weekly (Barnes and Barrows, 1993; Chaulk and Kazandjian, 1998).

Where drug resistance is suspected but sensitivities are not yet known (as in patients who have undergone several courses of treatment), therapy should be instituted with 5 or 6 drugs, including 2 or 3 that the patient has not received in the past. Such a regimen might include isoniazid, rifampin, pyrazinamide, ethambutol, streptomycin, and ethionamide. Some physicians include isoniazid in the therapeutic regimen, even if microorganisms are resistant, because of some evidence that disease with isoniazid-resistant mycobacteria does not “progress” during such therapy. Others prefer to discontinue isoniazid to lessen the possibility of toxicity. Therapy should be continued for at least 24 months.

Nontuberculous (Atypical) Mycobacteria. These microorganisms (not including *M. avium* complex, which is discussed later) have been recovered from a variety of lesions in humans (Brown and Wallace, 2000). Because they frequently are resistant to many of the commonly used agents, they must be examined for sensitivity *in vitro* and drug therapy selected on this basis (Table 47-1). In some instances, surgical removal of the infected tissue followed by long-term treatment with effective agents is necessary.

M. kansasii causes disease similar to that caused by *M. tuberculosis*, but it may be milder. The microorganisms may be resistant to isoniazid. Therapy with isoniazid, rifampin, and ethambutol has been successful (Lane *et al.*, 1994). *M. marinum* causes skin lesions. A combination of rifampin and ethambutol is probably effective; *minocycline* (Loria, 1976) or tetracycline is active *in vitro* and is used by some physicians (Izumi *et al.*, 1977). *M. scrofulaceum* is an uncommon cause of cervical lymphadenitis. Surgical excision still seems to be the therapy of choice (Lincoln and Gilberg, 1972). Microbes of the *M. fortuitum* complex (including *Mycobacterium chelonae*) are usually saprophytes, but they may cause chronic lung disease and infections of skin and soft tissues. The microorganisms are highly resistant to most drugs, but amikacin, *cefoxitin*, and tetracyclines are active *in vitro* (Sanders *et al.*, 1977; Sanders, 1982).

Chemoprophylaxis of Tuberculosis. The chemoprophylaxis of tuberculosis is the practice of treating latent infection to prevent progression to active disease. Latent infection may be diagnosed by a positive delayed-type hypersensitivity reaction to a purified protein derivative (PPD) of tuberculosis injected intradermally (the “tuberculin test”). There are several approaches to the chemoprophylaxis of tuberculosis. The classical prophylaxis with 12 months of isoniazid resulted in a 75% reduction in the risk of active tuberculosis (from an incidence of 14.3% to 3.6% over 5 years). A 6-month course of isoniazid therapy was nearly as effective, with a 65% risk reduction and a lower incidence of isoniazid-induced hepatitis (International Union Against Tuberculosis, 1982). Currently the CDC recommends isoniazid for 6 to 9 months or rifampin for 4 months if isoniazid cannot be used (Centers for Disease Control, 2001). A 2-month regimen of daily rifampin and pyrazinamide was shown to be as effective as 12 months of isoniazid in one study of HIV-infected individuals (Halsey *et al.*, 1998). However, severe hepatotoxicity resulting in the deaths of 5 of the estimated 10,000 non-HIV-infected individuals has resulted in the rifampin-plus-pyrazinamide regimen being used only in exceptional circumstances (*e.g.*, PPD conversion after exposure to isoniazid-resistant *M. tuberculosis*) and only with intensive monitoring for liver injury during treatment (Centers for Disease Control, 2001; Leibert and Rom, 2004).

Prophylactic therapy can effectively prevent the development of active tuberculosis in certain instances (Haas, 2000). There are 4 categories of patients for whom prophylactic therapy should be considered: those exposed to tuberculosis but who have no evidence of infection; those with infection (positive tuberculin test: induration >5 mm [HIV infected or other immunosuppressed patients and recent contacts of TB patients]); those with infection positive tuberculin test (induration >10 mm reaction to 5 units of PPD [not immunocompromised but with risk factors for TB]) and no apparent disease; and those with a history of tuberculosis but in whom the disease is currently “inactive” (Centers for Disease Control, 2001; Bass *et al.*, 1994; Wilkinson *et al.*, 1998; Gordin *et al.*, 1997; Gallant *et al.*, 1994). The main risk of chemoprophylaxis is isoniazid-induced hepatitis, which is much less common (as low as 1/100,000 for severe isoniazid hepatitis) (Nolan *et al.*, 1999) with current approaches to monitoring patients for liver injury due to isoniazid. Monitored isoniazid prophylaxis minimizes the risk of toxicity even in patients over the age of 35 (Salpeter *et al.*, 1997; Centers for Disease Control, 2001).

Household contacts and other close associates of patients with tuberculosis who have negative tuberculin tests should receive isoniazid for at least 6 months after

the contact has been broken, regardless of age. This is especially important for children. If the tuberculin skin test becomes positive, therapy should be continued for 12 months.

Patients with old “inactive” tuberculosis who have not received adequate chemotherapy in the past should be considered for 1 year of treatment with isoniazid (Comstock, 1983). HIV-infected intravenous drug abusers with a positive skin test have an approximately 8% chance per year of developing active tuberculosis (Selwyn *et al.*, 1989). Isoniazid prophylaxis in HIV-infected persons appears to be as effective as in nonimmunocompromised persons (Wilkinson *et al.*, 1998). The CDC recommends that isoniazid prophylaxis be continued for 12 months. Persons infected with HIV who are exposed to multidrug-resistant tuberculosis should receive prophylaxis with rifampin and pyrazinamide (with close monitoring for hepatic toxicity; Centers for Disease Control, 2001) or high-dose ethambutol and pyrazinamide, with or without a fluoroquinolone (Gallant *et al.*, 1994).

Prophylaxis with isoniazid is contraindicated for patients who have active hepatic disease or who have had reactions to the drug. In these individuals rifampin for 4 months can be given (Centers for Disease Control, 2001). In pregnant women, prophylaxis usually should be delayed until after delivery. For prophylaxis, isoniazid generally is given to adults in a daily dose of 300 mg. Children should receive 10 mg/kg to a maximal daily dose of 300 mg. Pyridoxine should be coadministered in individuals susceptible to isoniazid-induced neuropathy (*see above*).

II. DRUGS FOR *MYCOBACTERIUM AVIUM* COMPLEX

Before the advent of highly active antiretroviral therapy (HAART, *see* Chapter 50) and the use of prophylactic regimens, disseminated infection with MAC bacteria occurred in 15% to 40% of patients with HIV infection. Infections with MAC now are greatly reduced (Benson, 1997–98). Patients with *M. avium* complex infection usually are in advanced stages of HIV disease, with CD4 T-lymphocyte counts below 100/mm³ and symptoms of fever, night sweats, weight loss, and anemia at the time of diagnosis. In non-HIV-infected persons, MAC infection usually is limited to the lungs and presents with a chronic

productive cough and chest roentgenograms showing evidence of limited, diffuse, and/or cavitary disease (Havlr and Ellner, 2000). Although standard antimycobacterial agents have little activity against MAC, new antimicrobial agents with activity against MAC recently have become available. These agents currently are in use for both the prevention and treatment of MAC in patients with AIDS.

RIFABUTIN

Rifabutin is a derivative of rifamycin, which shares a common mechanism of action (inhibition of mycobacterial RNA polymerase), but is more active than rifampin *in vitro* and in experimental murine tuberculosis.

Chemistry. Rifabutin is soluble in organic solvents and at low concentrations (0.19 mg/ml) in water. It has the following structure:

Antibacterial Activity. Rifabutin has better activity against the MAC organisms than does rifampin. Rifabutin is active *in vitro* against MAC bacteria isolated from both HIV-infected (where the majority of MAC infections are *M. avium*) and non-HIV-infected individuals (in whom approximately 40% of MAC infections are *M. intracellulare*). Rifabutin inhibits the growth of most MAC isolates at concentrations ranging from 0.25 to 1 $\mu\text{g/ml}$. Rifabutin also inhibits the growth of many strains of *M. tuberculosis* at concentrations of $\leq 0.125 \mu\text{g/ml}$.

Bacterial Resistance. Cross-resistance between rifampin and rifabutin is common in *M. tuberculosis*, although some strains have been identified that are resistant to rifampin yet sensitive to rifabutin. Of 225 *M. avium* strains that were resistant to 10 $\mu\text{g/ml}$ of rifampin, 80% were sensitive to 1 $\mu\text{g/ml}$ rifabutin (Heifets *et al.*, 1985).

Absorption, Distribution, Metabolism, and Excretion. The oral administration of 300 mg of rifabutin produces a peak plasma concentration of approximately 0.4 $\mu\text{g/ml}$ at 2 to 3 hours. The drug is metabolized by hepatic CYPs and eliminated in a biphasic manner with a mean

terminal half-life of 45 hours (range of 16 to 96 hours). Because rifabutin is a lipophilic drug, concentrations are substantially higher (five- to tenfold) in tissue than in plasma. Following absorption from the GI tract, rifabutin is eliminated in the urine and bile. Adjustment of dosage is not necessary in patients with impaired renal function. Rifabutin is a weaker inducer of hepatic CYPs than is rifampin.

Therapeutic Uses. Rifabutin is effective for the prevention of MAC infection in HIV-infected individuals. At a dose of 300 mg per day, rifabutin decreased the frequency of MAC bacteremia (2%) (Nightingale *et al.*, 1993). However, azithromycin or clarithromycin are more effective and less likely to interact with HAART drugs. Rifabutin also is commonly substituted for rifampin in the treatment of tuberculosis in HIV-infected patients, as it has a less profound CYP-dependent interaction with indinavir and nelfinavir (Haas, 2000). Rifabutin also is used in combination with clarithromycin and ethambutol for the therapy of MAC disease (Shafran *et al.*, 1996).

Untoward Effects. Rifabutin generally is well tolerated in persons with HIV infection; primary reasons for discontinuation of therapy include rash (4%), gastrointestinal intolerance (3%), and neutropenia (2%) (Nightingale *et al.*, 1993). Overall, neutropenia occurred in 25% of patients with severe HIV infection who received rifabutin. Uveitis and arthralgias have occurred in patients receiving rifabutin doses greater than 450 mg daily in combination with clarithromycin or fluconazole. Patients should be cautioned to discontinue the drug if visual symptoms (pain or blurred vision) occur. Like rifampin, the drug causes an orange-tan discoloration of skin, urine, feces, saliva, tears, and contact lenses. Rarely, thrombocytopenia, a flulike syndrome, hemolysis, myositis, chest pain, and hepatitis have occurred in patients treated with rifabutin.

Although a less potent inducer of CYPs than rifampin, rifabutin does induce hepatic microsomal enzymes, with its administration decreasing the half-life of a number of different compounds, including *zidovudine*, *prednisone*, *digitoxin*, *quinidine*, *ketoconazole*, *propranolol*, *phenytoin*, *sulfonylureas*, and *warfarin*. It has less effect than does rifampin on serum levels of indinavir and nelfinavir.

MACROLIDES

The macrolides clarithromycin and azithromycin are extremely valuable agents for the treatment of MAC and

other nontuberculous mycobacteria. Clarithromycin alters the metabolism of many other drugs that are metabolized at the cytochrome P450 system, leading to many potential drug interactions. A discussion of the pharmacology of the macrolides is presented in Chapter 46. Only features of the macrolides related to their use in the treatment of MAC infections are considered here.

Antibacterial Activity. Clarithromycin is approximately fourfold more active than azithromycin against MAC bacteria *in vitro* and is active against most nontuberculous mycobacteria with the exception of *Mycobacterium simiae* at ≤ 4 $\mu\text{g/ml}$. Azithromycin's lower potency may be compensated for *in vivo* by its greater intracellular penetration: Tissue levels generally exceed plasma levels by one hundredfold.

Bacterial Resistance. Use of clarithromycin or azithromycin alone in the therapy of MAC infection is associated with the development of resistance after prolonged treatment. For this reason, these drugs should not be used as monotherapy of MAC infection.

Therapeutic Uses. Clarithromycin (500 mg twice daily) or azithromycin (500 mg daily) is used in combination with ethambutol, with or without rifabutin, for treatment of MAC infection (Shafran *et al.*, 1996). Treatment should be continued throughout the lifetime of an HIV-infected individual (U.S. Public Health Service, 1999). Azithromycin has minimal potential for affecting drugs metabolized by CYP3A4.

Untoward Effects. The high doses used to treat MAC infections can occasionally cause tinnitus, dizziness, and reversible hearing loss.

QUINOLONES

The quinolones (*e.g.*, ciprofloxacin, levofloxacin, moxifloxacin, and gatifloxacin) are discussed in detail in Chapter 43. These drugs have inhibitory activity against MAC bacteria *in vitro* (at concentrations of ≤ 100 $\mu\text{g/ml}$). Minimal inhibitory concentrations for *M. fortuitum* and *M. kansasii* are ≤ 3 $\mu\text{g/ml}$ for these quinolones but *M. chelonae* usually are resistant. Single-agent therapy of *M. fortuitum* infection with ciprofloxacin has been associated with the development of resistance. Ciprofloxacin, 750 mg twice daily or 500 mg three times daily, has been used as part of a 4-drug regimen (with clarithromycin, rifabutin, and amikacin) as salvage therapy for MAC infections in HIV-infected patients, with improvement in symptoms (Havlr and Ellner, 2000). Multidrug-resistant tuberculosis has been treated with ofloxacin, 300 or 800 mg each day, in combination with second-line agents. Moxifloxacin and gatifloxacin are more active *in vitro* than the older fluoroquinolones and would be expected to be useful agents clinically.

AMIKACIN

The antibacterial activity and pharmacology of amikacin are discussed fully in Chapter 45. Amikacin may have a role as a third or fourth agent in a multiple-drug regimen for MAC treatment. Most isolates of MAC are inhibited *in vitro* by 8 to 32 $\mu\text{g/ml}$ of amikacin.

CHEMOTHERAPY OF MYCOBACTERIUM AVIUM COMPLEX

Initial pessimism about the treatment of MAC infection has lifted with the availability of clarithromycin and azithromycin. Both of these agents have excellent activity against many strains of MAC, with clinical responses (decrease or elimination of bacteremia, resolution of fever and night sweats) demonstrated even with single-drug therapy. Single-agent therapy, however, has been associated with the emergence of resistant strains. Most clinicians treat disseminated MAC infections with clarithromycin or azithromycin plus ethambutol (Haas, 2000; Shafran *et al.*, 1996). In some situations, and with unclear benefits, rifabutin, clofazimine, and/or a quinolone are added to the above regimen. Drug interactions and adverse drug reactions are common with multiple-drug regimens and necessitated drug discontinuation in 46% of patients in one study (Kemper *et al.*, 1992). Clinical improvement should be expected in the first 1 to 2 months of treatment, with sterilization of blood cultures seen as late as 3 months into therapy. Therapy of MAC infection in HIV-infected individuals should continue for life if the therapy is associated with clinical and microbiological improvement (U.S. Public Health Service, 1999). Isoniazid and pyrazinamide have no role in the treatment of MAC infection.

Prophylaxis of MAC infection with clarithromycin or azithromycin should be strongly considered for HIV-infected persons whose CD4 cell count is less than 50/mm³. Clarithromycin and azithromycin are well-tolerated medications that have proven effective at reducing the incidence of MAC infection in this population. With the advent of HAART, it would be a reasonable decision to stop prophylaxis in a patient who responds to anti-HIV therapy with a sustained CD4⁺ T-lymphocyte count greater than 100/mm³ and a sustained suppression of HIV plasma RNA (U.S. Public Health Service, 1999).

III. DRUGS FOR LEPROSY

Largely due to a World Health Organization global initiative to eliminate leprosy (Hansen's disease) as a public health problem by 2005, between 1985 and 2003 the number of leprosy patients worldwide plummeted by nearly 90% to around 534,000. The cornerstone of the WHO's global elimination strategy is the provision of effective

multidrug chemotherapy, namely dapsone, rifampin, and clofazimine (Table 47–1), free of charge, to all leprosy patients in the world. The ongoing success of the strategy is evident; by the end of 2003, all but 10 of the 22 countries considered endemic for leprosy in 1985 had achieved elimination (defined as a prevalence rate of <1 case per 10,000 inhabitants) of the disease (World Health Organization, 2004). The history of the development of multidrug therapy against leprosy has been published by the WHO (Sansarricq, 2004).

SULFONES

The sulfones are derivatives of 4,4'-diaminodiphenylsulfone (dapsone), all of which have certain pharmacological properties in common. They are discussed here as a class; only dapsone and *sulfoxone* are considered individually.

History. The sulfones first attracted interest because of their chemical relationship to the sulfonamides. In the 1940s, sulfones were found to be effective in suppressing experimental infections with the tubercle bacillus and for rat leprosy; this finding was soon followed by successful clinical trials in human leprosy. The sulfones are currently the most important drugs for the treatment of this disorder.

Chemistry. All clinically useful sulfones are derivatives of dapsone. Despite the study and development of a large variety of sulfones, dapsone remains the agent most useful clinically.

Antibacterial Activity, Mechanism of Action, and Resistance. Because *Mycobacterium leprae* does not grow on artificial media, conventional methods cannot be applied to determine its susceptibility to potential therapeutic agents *in vitro*. Therefore, *in vivo* assays with rat footpads have been used to test agents. Dapsone is bacteriostatic, but not bactericidal, for *M. leprae*, and the estimated sensitivity to the drug is between 1 and 10 $\mu\text{g/ml}$ for microorganisms recovered from untreated patients (Levy and Peters, 1976). *M. leprae* may become resistant to the drug during therapy.

The mechanism of action of the sulfones is the same as that of the sulfonamides: they are competitive inhibitors of dihydropteroate synthase and prevent the normal bacterial utilization of *para*-amino-benzoic acid. Both possess approximately the same range of antibacterial activity and both are antagonized by *para*-aminobenzoic acid.

Dapsone-resistant strains of *M. leprae* are termed *secondary* if they emerge during therapy. Secondary resistance usually is seen in lepromatous (multibacillary) patients treated with a single drug. The incidence is as high as 19% (WHO Expert Committee on Leprosy, 1998). Partial-to-complete primary resistance (seen in previously untreated patients) has been described in 2.5% to 40% of patients, depending on geographical location (Centers for Disease Control, 1982); some authorities question the clinical significance of primary resistance (Gelber *et al.*, 1990; Gelber and Rea, 2000).

Therapeutic Uses. Dapsone is available for oral administration. Several dosage schedules have been recommended (Gelber and Rea, 2000). Daily therapy with 100 mg has been successful in adults. Therapy usually is begun with smaller amounts, and doses are increased to those recommended over 1 to 2 months. Therapy

should be continued for at least 3 years and may be necessary for the lifetime of the patient.

Untoward Effects. The untoward reactions induced by various sulfones are very similar, with the most common being hemolysis of varying degree. This develops in almost every individual treated with 200 to 300 mg of dapsone per day. Doses of 100 mg or less in normal healthy persons and 50 mg or less in healthy individuals with a glucose-6-phosphate dehydrogenase deficiency do not cause hemolysis. Methemoglobinemia also is common, and Heinz-body formation may occur. A genetic deficiency in the NADH-dependent methemoglobin reductase can result in severe methemoglobinemia after administration of dapsone. While diminished red-cell survival usually occurs during the use of sulfones and is presumed to be a dose-related effect of their oxidizing activity, hemolytic anemia is unusual unless the patient also has a disorder of either the erythrocytes or the bone marrow. The hemolysis may be so severe that manifestations of hypoxia become striking.

Anorexia, nausea, and vomiting may follow the oral administration of sulfones. Isolated instances of headache, nervousness, insomnia, blurred vision, paresthesias, reversible peripheral neuropathy (thought to be due to axonal degeneration), drug fever, hematuria, pruritus, psychosis, and a variety of skin rashes have been reported (Rapoport and Guss, 1972). An infectious mononucleosis-like syndrome, which may be fatal, occurs occasionally. The sulfones may induce an exacerbation of lepromatous leprosy by a process thought to be analogous to the Jarisch-Herxheimer reaction. This "sulfone syndrome" may develop 5 to 6 weeks after initiation of treatment in malnourished people. Its manifestations include fever, malaise, exfoliative dermatitis, jaundice with hepatic necrosis, lymphadenopathy, methemoglobinemia, and anemia.

If proper precautions are observed, the sulfones may be given safely for many years in doses adequate for the successful therapy of leprosy. Treatment should be initiated with a small dose and the quantity then increased gradually. Patients must be under consistent and prolonged laboratory and clinical supervision. The reactions induced by the sulfones, especially those related to exacerbation of the leprosy, may be very severe and may require the cessation of treatment as well as the institution of specific measures to reduce the threat to life.

Absorption, Distribution, and Excretion. Dapsone is absorbed rapidly and nearly completely from the gastrointestinal tract. The disubstituted sulfones, such as sulfoxone, are absorbed incompletely when administered orally, and large amounts are excreted in the feces. Peak concentrations of dapsone in plasma are reached within 2 to 8 hours after administration; the mean half-life of elimination is about 20 to 30 hours. Twenty-four hours after oral ingestion of 100 mg, plasma concentrations range from 0.4 to 1.2 $\mu\text{g/ml}$, and a dose of 100 mg of dapsone per day produces an average of 2 μg of "free" dapsone per gram of blood or nonhepatic tissue. About 70% of the drug is bound to plasma protein. Concentrations in plasma following conventional doses of sulfoxone sodium are 10 to 15 $\mu\text{g/ml}$. These values fall relatively rapidly; however, appreciable quantities are still present at 8 hours.

The sulfones are distributed throughout total body water and are present in all tissues. They tend to be retained in skin and muscle and especially in liver and kidney; traces of the drug are present in these organs up to 3 weeks after therapy is stopped. The sulfones are retained in the circulation for a long time because of intestinal reabsorption from the bile; periodic interruption of treatment is advised

able for this reason. Dapsone is acetylated in the liver, and the rate of acetylation is genetically determined; the same enzyme carries out the acetylation of isoniazid. Daily administration of 50 to 100 mg results in serum levels exceeding the usual minimal inhibitory concentrations, even in rapid acetylators, in whom the serum half-life of dapsone is shorter than usual.

Approximately 70% to 80% of a dose of dapsone is excreted in the urine. The drug is present in urine as an acid-labile mono-*N*-glucuronide and mono-*N*-sulfamate in addition to an unknown number of unidentified metabolites. *Probenecid* decreases the urinary excretion of the acid-labile dapsone metabolites significantly and that of free dapsone to a lesser extent (Goodwin and Sparell, 1969).

RIFAMPIN

Rifampin has been discussed above with regard to its use in tuberculosis. This antibiotic is rapidly bactericidal for *M. leprae*, and the minimal inhibitory concentration is <1 µg/ml. Infectivity of patients is reversed rapidly by therapy that includes rifampin. Because of the prevalence of resistance to dapsone, the WHO Expert Committee on Leprosy (1998) now recommends a regimen of multiple drugs, including rifampin.

CLOFAZIMINE

Clofazimine (LAMPRENE) is a phenazine dye with the following structural formula:

The biochemical basis for the antimicrobial actions of clofazimine remains to be established. Clofazimine appears to preferentially bind to GC-rich mycobacterial DNA (Morrison and Marley, 1976) and also increase mycobacterial phospholipase A₂ activity and inhibit microbial K⁺ transport (Steel *et al.*, 1999). It is weakly bactericidal against *M. intracellulare*. The drug also exerts an anti-inflammatory effect and prevents the development of erythema nodosum leprosum. Clofazimine is now recommended as a component of multiple-drug therapy for leprosy (*see below*). The compound also is useful for treatment of chronic skin ulcers (Buruli ulcer) produced by *Mycobacterium ulcerans*.

Clofazimine is absorbed by the oral route and appears to accumulate in tissues. Human leprosy from which dapsone-resistant bacilli have been recovered has been treated with clofazimine with good results. However, unlike dapsone-sensitive microorganisms, in which killing occurs immediately after dapsone is administered, dapsone-resistant strains do not exhibit an appreciable effect until 50 days after initiation of therapy with clofazimine. The daily dose of clofazimine is usually 100 mg. Patients treated with clofazimine may develop red discoloration of the skin, which may be very distressing to light-skinned individuals. Eosinophilic enteritis has also been described as an adverse reaction to the drug.

MISCELLANEOUS AGENTS

Thalidomide has been shown effective for the treatment of erythema nodosum leprosum (Okafor, 2003). It has immunomodulatory actions and inhibits tumor necrosis factor- α (*see Chapter 52*), but the mechanism of action against leprosy is not established. Doses of 100 to 300 mg per day have been effective. *Because of the marked teratogenicity of thalidomide, its prescribing and dispensing is restricted to physicians and patients enrolled in the System for Thalidomide Education and Prescribing Safety (STEPS) oversight program.* This oversight program is designed to help ensure a zero-tolerance policy for thalidomide exposure during pregnancy.

Ethionamide has been discussed above as an agent for treatment of tuberculosis. It can be used as a substitute for clofazimine in oral doses of 250 to 375 mg per day. Newer agents that appear promising based on animal trials and limited experience in patients include minocycline, clarithromycin, *pefloxacin* (an investigational fluoroquinolone in the United States), and *ofloxacin* (Gelber and Rea, 2000).

CHEMOTHERAPY OF LEPROSY

Five clinical types of leprosy are recognized. At one end of the spectrum is *tuberculoid leprosy*. This form of the disease is characterized by skin macules with clear centers and well-defined margins; these are almost always anesthetic. *M. leprae* is rarely found in smears made from quiescent lesions but may appear during activity. Virchow cells are not demonstrable. Noncaseating foci with giant cells of the Langhans variety are present. The patient's cell-mediated immune responses are normal, and the lepromin test (intradermal injection of a suspension of heat-killed, bacillus-laden tissue) is invariably positive. The disease is characterized by prolonged remissions with periodic reactivation.

At the other end of the spectrum is the widely disseminated *lepromatous* form of the disease. Patients with this disease have markedly impaired cell-mediated immunity and are frequently anergic; the lepromin test causes no reaction. Lepromatous disease is characterized by diffuse or ill-defined, localized infiltration of the skin, which becomes thickened, glossy, and corrugated; areas of decreased sensation may appear. *M. leprae* is demonstrable in smears, and granulomas containing bacteria-laden histiocytes (Virchow cells) are present. As the disease progresses, large nerve trunks are involved and anesthesia, atrophy of skin and muscle, absorption of small bones, ulceration, and spontaneous amputations may occur. Three intermediate forms of the disease are recognized: borderline tuberculoid disease, borderline lepromatous disease, and borderline disease (Gelber and Rea, 2000).

Patients with tuberculoid leprosy may develop "reversal reactions," which are manifestations of delayed hypersensitivity to antigens of *M. leprae*. Cutaneous ulcerations and deficits of peripheral nerve function may occur. Early therapy with corticosteroids or clofazimine is effective.

Reactions in the lepromatous form of the disease (erythema nodosum leprosum) are characterized by the appearance of raised, tender, intracutaneous nodules, severe constitutional symptoms, and high fever. This reaction may be triggered by several conditions, but is often associated with therapy. It is thought to be an Arthus-type reaction related to release of microbial antigens in patients harboring large numbers of bacilli. Treatment with clofazimine or thalidomide is effective.

The outlook for persons with leprosy has been remarkably altered by successful chemotherapy, surgical procedures that help to restore function and repair disfigurement, and a striking change in

the attitude of the public toward patients who have this infection. The social stigma of individuals with this affliction gradually is being replaced by the attitude that considers leprosy a disease caused by a bacterium. Patients with leprosy can be classified as “infectious” or “noninfectious” on the basis of the type and duration of disease and effects of therapy. Thus, even “infectious” patients need not be hospitalized provided that adequate medical supervision and therapy are maintained, the home environment meets specific conditions, and the local health officer concurs in the disposition of the case.

Therapy, when effective, heals ulcers and mucosal lesions in months. Cutaneous nodules respond more slowly, and it may take years to eradicate bacteria from mucous membranes, skin, and nerves. The degree of residual pigmentation or depigmentation, atrophy, and scarring depends upon the extent of the initial involvement. Severe ocular lesions show little response to the sulfones. If treatment is initiated before ocular disease is evident, the latter may be prevented. Keratoconjunctivitis and corneal ulceration may be secondary to nerve involvement.

The World Health Organization now recommends therapy with multiple drugs for all patients with leprosy (WHO Expert Committee on Leprosy, 1998). The reasons for using combinations of agents include reduction in the development of resistance, the need for adequate therapy when primary resistance already exists, and reduction in the duration of therapy. Dosage recommendations for control programs take a number of practical constraints into account. For patients with large populations of bacteria (multibacillary forms)—including lepromatous disease, borderline lepromatous disease, and borderline disease—the following regimen is suggested: dapson, 100 mg daily; plus clofazimine, 50 mg daily (unsupervised); plus rifampin, 600 mg, and clofazimine, 300 mg, once a month under supervision for 1 to 5 years. Some prefer to treat lepromatous leprosy with daily dapson (100 mg) and daily rifampin (450 to 600 mg) (Gelber and Rea, 2000). All drugs are given orally. The minimal duration of therapy is 2 years, and treatment should continue until acid-fast bacilli are not detected in lesions.

Patients with a small population of bacteria (paucibacillary disease), including those with tuberculoid, borderline tuberculoid, and indeterminate disease, should be treated with dapson, 100 mg daily, plus rifampin, 600 mg once monthly (under supervision), for a minimum of 6 months. Relapses are treated by repeating the regimen. A recent clinical trial suggests that single-dose multidrug therapy with rifampin (600 mg), ofloxacin (400 mg), and minocycline (100 mg) may be as effective (Single Lesion Multicentre Trial Group, 1997). More prolonged treatment programs are recommended for patients in the United States (Gelber and Rea, 2000).

CLINICAL SUMMARY

Combination therapy is almost always the desirable approach for mycobacterial disease to ensure effective eradication and to prevent the emergence of resistance. Isoniazid, rifampin, ethambutol, streptomycin, and pyrazinamide are first-line agents for the treatment of tuberculosis. The use of immunomodulators such as interferon- γ to increase macrophage killing of the intracellular bacterium is a potentially interesting new avenue for treatment. Antimi-

crobial agents with excellent activity against *Mycobacterium avium* complex include rifabutin, clarithromycin, azithromycin, and fluoroquinolones. Drug interactions and adverse drug reactions, however, are common with multiple-drug regimens, and clinical monitoring is important. Considerable progress has been achieved in eliminating leprosy through the use of multiple-drug chemotherapy including dapson, rifampin, and clofazimine. Thalidomide also has been found to have activity in patients with leprosy.

Table 48-1
Treatment of Mycoses

DEEP MYCOSES	DRUGS	SUPERFICIAL MYCOSES	DRUGS
<i>Invasive aspergillosis</i>		<i>Candidiasis</i>	
Immunosuppressed	Voriconazole, amphotericin B	<i>Vulvovaginal</i>	<i>Topical</i> Butoconazole, clotrimazole, miconazole, nystatin, terconazole, tioconazole
Nonimmunosuppressed	Voriconazole, amphotericin B, itraconazole		<i>Oral</i> Fluconazole
<i>Blastomycosis</i>		<i>Oropharyngeal</i>	<i>Topical</i> Clotrimazole, nystatin
Rapidly progressive or CNS	Amphotericin B		<i>Oral (systemic)</i> Fluconazole, itraconazole
Indolent and non-CNS	Itraconazole	<i>Cutaneous</i>	<i>Topical</i> Amphotericin B, clotrimazole, ciclopirox, econazole, ketoconazole, miconazole, nystatin
<i>Candidiasis</i>		<i>Ringworm</i>	<i>Topical</i> Butenafine, ciclopirox, clotrimazole, econazole, haloprogin, ketoconazole, miconazole, naftifine, oxiconazole, sertaconazole, sulconazole, terbinafine, tolnaftate, undecylenate
Deeply invasive or esophageal	Amphotericin B, fluconazole, caspofungin		<i>Systemic</i> Griseofulvin, itraconazole, terbinafine
<i>Coccidioidomycosis</i>			
Rapidly progressing	Amphotericin B		
Indolent	Itraconazole, fluconazole		
Meningeal	Fluconazole, intrathecal amphotericin B		
<i>Cryptococcosis</i>			
Non-AIDS and initial AIDS	Amphotericin B, flucytosine		
Maintenance AIDS	Fluconazole		
<i>Histoplasmosis</i>			
<i>Chronic pulmonary</i>	Itraconazole		
<i>Disseminated</i>			
Rapidly progressing or CNS	Amphotericin B		
Indolent non-CNS	Itraconazole		
Maintenance AIDS	Itraconazole		
<i>Mucormycosis</i>	Amphotericin B		
<i>Pseudallescheriasis</i>	Voriconazole, itraconazole		
<i>Sporotrichosis</i>			
Cutaneous	Itraconazole		
Extracutaneous	Amphotericin B, itraconazole		

Drug Formulations. Amphotericin B is insoluble in water but was formulated for intravenous infusion by complexing it with the bile salt deoxycholate. The complex is marketed as a lyophilized powder (FUNGIZONE) containing 50 mg of amphotericin B, 41 mg of deoxycholate, and a small amount of sodium phosphate buffer. The amphotericin B–deoxycholate complex (C-AMB) forms a colloid in water, with particles largely below 0.4 μm in diameter. Filters in intravenous infusion lines that trap particles above 0.22 μm in diameter will remove significant amounts of drug. Addition of electrolytes to infusion solutions causes the colloid to aggregate.

The amphipathic nature of amphotericin B has made it possible to create lipid formulations for intravenous infusion. Three such formulations of amphotericin B are marketed in the United States. Amphotericin B colloidal dispersion (ABCD, AMPHOTEC, AMPHOCIL) contains roughly equimolar amounts of amphotericin B and cholesteryl sulfate. Like C-AMB, ABCD forms a colloidal solution when dispersed in aqueous solution. In aqueous solution, ABCD particles are disk-shaped; they are 115 nm wide by 4 nm thick. ABCD provides much lower blood levels than C-AMB in mice and human beings. In mice, 41% to 80% of 14 daily doses can be recovered in the liver. In a randomized, double-blind study in patients

with neutropenic fever comparing daily ABCD (4 mg/kg) with C-AMB (0.8 mg/kg), chills and hypoxia were significantly more common with ABCD (79.8% and 12%, respectively) than with C-AMB (65.4% and 2.9%), requiring withdrawal of 4.6% of the study patients receiving ABCD, compared with only 0.9% of those receiving C-AMB (White *et al.*, 1998). Hypoxia was associated with severe febrile reactions. In a randomized, double-blind comparison of ABCD (6 mg/kg) and C-AMB (1 to 1.5 mg/kg) in invasive aspergillosis patients, the 95% confidence limits on the difference in efficacy between the two drugs was within 20% (Bowden *et al.*, 2002). ABCD was less nephrotoxic than C-AMB (49% vs. 15%) but caused more fever (27% vs. 16%) and chills (53% vs. 30%). Administration of the recommended ABCD dose over 3 to 4 hours and use of premedication to reduce febrile reactions are advised, particularly with initial infusions. ABCD is approved only for patients with invasive aspergillosis who are not responding to or are unable to tolerate C-AMB.

A small, unilamellar vesicle formulation of amphotericin B (AMBISOME) also is available. Amphotericin B (50 mg) is combined with 350 mg of lipid in an approximately 10% molar ratio. The lipid contains hydrogenated soy lecithin (phosphatidylcholine), cholesterol, and distearoylphosphatidylglycerol in a 10:5:4 molar ratio. The drug is supplied as a lyophilized powder, which is reconstituted with sterile water for injection. With complete dispersion, particle size is about 80 nm. Blood levels following intravenous infusion are almost equivalent to those obtained with C-AMB, and because AMBISOME can be given at higher doses, blood levels have been achieved that exceed those obtained with C-AMB. Amphotericin B accumulation in the liver and spleen is higher with AMBISOME than with C-AMB. In a series of 23 patients receiving 3 mg/kg daily for an average of 27 days, the average serum creatinine rise was 34%, with nephrotoxicity requiring dose reduction in only one patient (Coker *et al.*, 1993). Adverse effects include nephrotoxicity, hypokalemia, and infusion-related reactions, such as fever, chills, hypoxia, hypotension, and hypertension, but these uncommonly lead to drug discontinuation. Infusion-related pain in the back, abdomen, or chest occurs in occasional patients, usually with the first few doses. Anaphylaxis also has been reported. Most of the information about the efficacy of AMBISOME comes from open studies that make comparisons difficult. Blinded, randomized trials of C-AMB and AMBISOME as empirical therapy or prophylaxis in febrile neutropenic patients have found equivalent results, but these studies cast no light on efficacy in established infections. Studies comparing AMBISOME with C-AMB for disseminated histoplasmosis or cryptococcal meningitis in AIDS patients, using either drug as a short course followed by prolonged azole therapy, have not yet established efficacy against those mycoses. AMBISOME is approved for empiric therapy of fever in the neutropenic host not responding to appropriate antibacterial agents, as well as for salvage therapy of aspergillosis, cryptococcosis, and candidiasis. The recommended daily intravenous dose for empiric therapy is 3 mg/kg; for treatment of mycoses, the dosage is 3 to 5 mg/kg. AMBISOME also is effective in visceral leishmaniasis at doses of 3 to 4 mg/kg daily. The drug is administered in 5% dextrose in water, with initial doses being infused over 2 hours. If well tolerated, infusion duration can be shortened to 1 hour. Doses of 7.5 to 10 mg/kg have been used in small numbers of patients but are associated with a higher rate of azotemia and hypokalemia.

The third lipid formulation is amphotericin B lipid complex (ABLC, ABELCET). This preparation of dimyristoylphosphatidylcholine and dimyristoylphosphatidylglycerol in a 7:3 mixture with

approximately 35 mol% amphotericin B forms ribbonlike sheets that range in size from 1.6 to 11 μm . Blood levels of amphotericin B are much lower with ABLC than with the same dose of C-AMB. In open, noncomparative trials, ABLC has seemed to be effective in a variety of mycoses, with the possible exception of cryptococcal meningitis (Sharkey *et al.*, 1996). ABLC is given in a dose of 5 mg/kg in 5% dextrose in water, infused once daily over 2 hours. The drug is approved for salvage therapy of deep mycoses.

The cost of the lipid formulations of amphotericin B is 20 to 50 times that of C-AMB, raising formidable cost-benefit issues. A systematic review of the literature concluded that the three lipid formulations collectively reduced the risk of the patient's serum creatinine doubling during therapy by 58% (Barrett *et al.*, 2003). In patients at high risk for nephrotoxicity, ABLC is more nephrotoxic than AMBISOME (Wingard *et al.*, 2000). In some patients, the additive burden of amphotericin B nephrotoxicity can help precipitate advanced renal failure, with attendant morbidity and financial burden. Infusion-related reactions are not consistently reduced with the use of lipid preparations. ABCD causes more infusion-related reactions than C-AMB. Although AMBISOME reportedly causes fewer infusion-related reactions than ABLC during the first dose (Wingard *et al.*, 2000), the difference depends on whether premedication is given and varies considerably between patients. Infusion-related reactions typically decrease with subsequent infusions.

Antifungal Activity. Amphotericin B has useful clinical activity against *Candida* spp., *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Sporothrix schenckii*, *Coccidioides immitis*, *Paracoccidioides braziliensis*, *Aspergillus* spp., *Penicillium marneffeii*, and the agents of mucormycosis.

Amphotericin B has limited activity against the protozoa *Leishmania braziliensis* and *Naegleria fowleri*. The drug has no antibacterial activity.

Mechanism of Action. The antifungal activity of amphotericin B depends principally on its binding to a sterol moiety, primarily ergosterol that is present in the membrane of sensitive fungi. By virtue of their interaction with these sterols, polyenes appear to form pores or channels that increase the permeability of the membrane, allowing leakage of a variety of small molecules (Figure 48-1).

Fungal Resistance. Some isolates of *Candida lusitanae* have appeared to be relatively resistant to amphotericin B. *Aspergillus terreus* may be more resistant to amphotericin B than other *Aspergillus* species, although the host's immune response is the most significant factor in determining outcome in invasive aspergillosis (Steinbach *et al.*, 2004). Mutants selected *in vitro* for nystatin or amphotericin B resistance replace ergosterol with certain precursor sterols. The rarity of significant amphotericin B resistance arising during therapy has left it unclear whether ergosterol-deficient mutants retain sufficient pathogenicity to survive in deep tissue.

Absorption, Distribution, and Excretion. Gastrointestinal absorption of all amphotericin B formulations is negligible. Repeated daily intravenous infusions to adults of 0.5 mg/kg of C-AMB result in concentrations in plasma of about 1 to 1.5 $\mu\text{g/ml}$ at the end of the infusion; these concentrations fall to about 0.5 to 1 $\mu\text{g/ml}$ within 24 hours. The drug is released from its complex with deoxycholate

Figure 48–1. Mechanism of action of amphotericin, imidazoles, triazoles, and allylamines in fungi. Amphotericin B and other polyenes, such as nystatin, bind to ergosterol in fungal cell membranes and increase membrane permeability. The imidazoles and triazoles, such as itraconazole and fluconazole, inhibit 14- α -sterol demethylase, prevent ergosterol synthesis, and lead to the accumulation of 14- α -methylsterols. The allylamines, such as naftifine and terbinafine, inhibit squalene epoxidase and prevent ergosterol synthesis. The echinocandins, such as caspofungin, inhibit the formation of glucans in the fungal cell wall.

in the bloodstream, and the amphotericin B that remains in plasma is more than 90% bound to proteins, largely β -lipoprotein. Approximately 2% to 5% of each dose appears in the urine when patients are on daily therapy. Drug elimination apparently is unchanged in anephric patients and in patients receiving hemodialysis. Hepatic or biliary disease has no known effect on metabolism of the drug in humans. At least one-third of an injected dose can be recovered unchanged by methanolic extraction of tissue at autopsy; the highest concentrations are found in liver and spleen, with lesser amounts in kidney and lung. Concentrations of amphotericin B (C-AMB) in fluids from inflamed pleura, peritoneum, synovium, and aqueous humor are approximately two-thirds of trough concentrations in plasma. Little amphotericin B penetrates into cerebrospinal fluid (CSF), vitreous humor, or normal amniotic fluid. Because of extensive binding to tissues, there is a terminal phase of elimination with a half-life of about 15 days.

Therapeutic Uses. The usual therapeutic dose of C-AMB is 0.5 to 0.6 mg/kg, administered in 5% glucose over 4 hours. *Candida* esophagitis in adults responds to 0.15 to 0.2 mg/kg daily. Rapidly progressive mucormycosis or invasive aspergillosis is treated with doses of 1 to 1.2 mg/kg daily until progression is arrested. Double-dose alternate-day therapy may be more convenient but is not less toxic and therefore is rarely indicated.

Intrathecal infusion of amphotericin B (C-AMB) is useful in patients with meningitis caused by *Coccidioides*. The drug can be injected into the CSF of the lumbar spine, cisterna magna, or lateral cerebral ventricle. Regardless of the injection site, treatment is initiated with 0.05 to 0.1 mg and increased on a three-times-weekly schedule to 0.5 mg, as tolerated. Therapy is then continued on a twice-weekly schedule. Fever and headache are common reactions that may be decreased by intrathecal administration of 10 to 15 mg of hydrocortisone. Other less common but more serious problems that attend the use of intrathecal injections depend at least partially on the injection site. Local injections of amphotericin B into a joint or peritoneal dialysate fluid commonly produce irritation and pain. Intraocular injection following pars plana vitrectomy has been used successfully for fungal endophthalmitis.

Intravenous administration of amphotericin B is the treatment of choice for mucormycosis and is used for initial treatment of cryptococcal meningitis, severe or rapidly progressing histoplasmosis, blastomycosis, coccidioidomycosis, and penicilliosis marneffeii, as well as in patients not responding to azole therapy of invasive aspergillosis, extracutaneous sporotrichosis, fusariosis, alternariosis, and trichosporonosis. Amphotericin B (C-AMB or AMBISOME) is often given to selected patients with profound neutropenia who have fever that does not respond to broad-spectrum antibacterial agents over 5 to 7 days. Amphotericin B given once weekly has been used to prevent relapse in patients with AIDS who have been treated successfully for cryptococcosis or histoplasmosis.

Bladder irrigation with 50 μ g/ml of amphotericin B in sterile water is effective for *Candida* cystitis. Relapse is common if the catheter remains in the bladder or there is significant postvoiding residual urine. Inhalational administration of amphotericin B has not been successful in treatment of pulmonary mycoses. Topical amphotericin B is useful only in cutaneous candidiasis (see below).

Untoward Effects. The major acute reaction to intravenous amphotericin B formulations is fever and chills. Tachypnea and respiratory stridor or modest hypotension also may occur, but true bronchospasm or anaphylaxis is rare. Patients with preexisting cardiac or pulmonary disease may tolerate the metabolic demands of the reaction poorly and develop hypoxia or hypotension. Although the reaction ends spontaneously in 30 to 45 minutes, meperidine may shorten it. Pretreatment with oral acetaminophen or use of intravenous hydrocortisone hemisuccinate, 0.7 mg/kg, at the start of the infusion decreases reactions. Febrile reactions abate with subsequent infusions. Infants, children, and patients receiving therapeutic doses of glucocorticoids are less prone to reactions.

Azotemia occurs in 80% of patients who receive C-AMB for deep mycoses (Carlson and Condon, 1994). Toxicity is dose-dependent and transient and is increased by concurrent therapy with other nephrotoxic agents, such as aminoglycosides or cyclosporine. Although permanent histological changes in renal tubules occur even during short courses of C-AMB, permanent functional impairment is uncommon in adults with normal renal function prior to treatment unless the cumulative dose exceeds 3 to 4 g. Renal tubular acidosis and renal wasting of K^+ and Mg^{2+} also may be seen during and for several weeks after therapy. Supplemental K^+ is required in one-third of patients on prolonged therapy. An increase in intrarenal vascular resistance is the major cause of nephrotoxicity in amphotericin B-treated rats. In patients and experimental animals, saline loading has decreased nephrotoxicity, even in the absence of water or salt deprivation. Administration of 1 L of normal saline intravenously on the day that C-AMB is to be given has been recommend-

ed for adults who are able to tolerate the Na^+ load and who are not already receiving that amount in intravenous fluids. Azotemia occurs much less frequently with lipid preparations of amphotericin, and saline loading is not recommended.

Hypochromic, normocytic anemia is usual with C-AMB; the average hematocrit declined to 27% in one study. Decreased production of erythropoietin is the probable mechanism. Patients with low plasma erythropoietin may respond to administration of recombinant erythropoietin. Anemia reverses slowly following cessation of therapy. Headache, nausea, vomiting, malaise, weight loss, and phlebitis at peripheral infusion sites are common side effects. Thrombocytopenia or mild leukopenia is observed rarely. Hepatotoxicity is not firmly established with any amphotericin B formulation. Arachnoiditis has been observed as a complication of injection C-AMB into the CSF.

Flucytosine

Chemistry. *Flucytosine* is a fluorinated pyrimidine related to *flourouracil* and *flouxuridine*. It is 5-fluorocytosine, the formula of which is as follows:

FLUCYTOSINE

Antifungal Activity. Flucytosine has clinically useful activity against *Cryptococcus neoformans*, *Candida* spp., and the agents of chromoblastomycosis. Within these species, determination of susceptibility *in vitro* has been extremely dependent on the method employed, and susceptibility testing performed on isolates obtained prior to treatment has not correlated with clinical outcome.

Mechanism of Action. All susceptible fungi are capable of deaminating flucytosine to 5-fluorouracil, a potent antimetabolite that is used in cancer chemotherapy (Figure 48–2) (*see* Chapter 51). Fluorouracil is metabolized first to 5-fluorouracil-ribose monophosphate (5-FUMP) by the enzyme uracil phosphoribosyl transferase (UPRTase, also called uridine monophosphate pyrophosphorylase). As in mammalian cells, 5-FUMP then is either incorporated into RNA (*via* synthesis of 5-fluorouridine triphosphate) or metabolized to 5-fluoro-2'-deoxyuridine-5'-monophosphate (5-FdUMP), a potent inhibitor of thymidylate synthetase. DNA synthesis is impaired as the ultimate result of this latter reaction. The selective action of flucytosine is due to the lack or low levels of cytosine deaminase in mammalian cells, which prevents metabolism to fluorouracil.

Fungal Resistance. Drug resistance arising during therapy (secondary resistance) is an important cause of therapeutic failure when flucytosine is used alone for cryptococcosis and candidiasis. In chromoblastomycosis, resurgence of lesions after an initial response has led to the presumption of secondary drug resistance. In isolates of *Cryptococcus* and *Candida* species, secondary drug resistance has been accompanied by a change in the minimal inhibitory concentration from less than 2.5 $\mu\text{g}/\text{ml}$ to more than 360 $\mu\text{g}/\text{ml}$. The

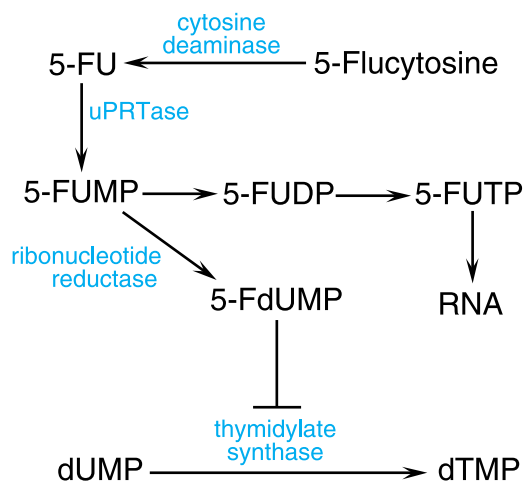

Figure 48–2. Action of flucytosine in fungi. 5-Flucytosine is transported by cytosine permease into the fungal cell, where it is deaminated to 5-fluorouracil (5-FU). The 5-FU is then converted to 5-fluorouracil-ribose monophosphate (5-FUMP) and then is either converted to 5-fluorouridine triphosphate (5-FUTP) and incorporated into RNA or converted by ribonucleotide reductase to 5-fluoro-2'-deoxyuridine-5'-monophosphate (5-FdUMP), which is a potent inhibitor of thymidylate synthase. 5-FUDP, 5-fluorouridine-5'-diphosphate; dUMP, deoxyuridine-5'-monophosphate; dTMP, deoxyuridine-5'-monophosphate.

mechanism for this resistance can be loss of the permease necessary for cytosine transport or decreased activity of either UPRTase or cytosine deaminase (Figure 48–2). In *Candida albicans*, substitution of thymine for cytosine at nucleotide 301 in the gene encoding UPRTase (*FURI*) causes a cysteine to become an arginine, modestly increasing flucytosine resistance (Dodgson *et al.*, 2004). Flucytosine resistance is further increased if both *FURI* alleles in the diploid fungus are mutated. This specific mutation has been found only in a group of genetically related isolates called “Clade 1,” and its clinical significance is unknown.

Absorption, Distribution, and Excretion. Flucytosine is absorbed rapidly and well from the gastrointestinal tract. It is widely distributed in the body, with a volume of distribution that approximates total body water, and is minimally bound to plasma proteins. The peak plasma concentration in patients with normal renal function is approximately 70 to 80 $\mu\text{g}/\text{ml}$, achieved 1 to 2 hours after a dose of 37.5 mg/kg. Approximately 80% of a given dose is excreted unchanged in the urine; concentrations in the urine range from 200 to 500 $\mu\text{g}/\text{ml}$. The half-life of the drug is 3 to 6 hours in normal individuals. In renal failure, the half-life may be as long as 200 hours. The clearance of flucytosine is approximately equivalent to that of creatinine. Because of its obligate renal excretion, modification of dosage is necessary in patients with decreased renal function, and concentrations of drug in plasma should be measured periodically. Peak concentrations should range between 50 and 100 $\mu\text{g}/\text{ml}$. Flucytosine is cleared by hemodialysis, and patients undergoing such treatment should receive a single dose of 37.5 mg/kg after dialysis; the drug also is removed by peritoneal dialysis.

Flucytosine concentration in CSF is about 65% to 90% of that found simultaneously in the plasma. The drug also appears to penetrate into the aqueous humor.

Therapeutic Uses. Flucytosine (ANCOBON) is given orally at 100 mg/kg per day, in four divided doses at 6-hour intervals. Dosage must be adjusted for decreased renal function. Flucytosine is used predominantly in combination with amphotericin B. Flucytosine caused no added toxicity when added to 0.7 mg/kg of amphotericin B for the initial 2 weeks of therapy of cryptococcal meningitis in AIDS patients. Although the CSF colony count diminished more rapidly with combination therapy, there was no apparent impact on mortality or morbidity (van der Horst *et al.*, 1997; Brouwer *et al.*, 2004). An all-oral regimen of flucytosine plus *fluconazole* also has been advocated for therapy of AIDS patients with cryptococcosis, but the combination has substantial gastrointestinal toxicity with no evidence that flucytosine adds benefit to the regimen (Larsen *et al.*, 1994). In cryptococcal meningitis of non-AIDS patients, the role of flucytosine is more conjectural. The addition of flucytosine to 6 weeks or more of therapy with C-AMB runs the risk of substantial bone marrow suppression or colitis if the flucytosine dose is not promptly adjusted downward as amphotericin B-induced azotemia occurs. It is now common practice in HIV-negative patients with cryptococcal meningitis is to begin with C-AMB or AMBISOME plus flucytosine and change to fluconazole after the patient has improved (Pappas *et al.*, 2001). Prospective study of this regimen is needed in HIV-negative patients, where the goal is cure and not just suppression of symptoms.

Untoward Effects. Flucytosine may depress the bone marrow and lead to leukopenia and thrombocytopenia; patients are more prone to this complication if they have an underlying hematological disorder, are being treated with radiation or drugs that injure the bone marrow, or have a history of treatment with such agents. Other untoward effects—including rash, nausea, vomiting, diarrhea, and severe enterocolitis—have been noted. In approximately 5% of patients, plasma levels of hepatic enzymes are elevated, but this effect reverses when therapy is stopped. Toxicity is more frequent in patients with AIDS or azotemia (including those who are receiving amphotericin B concurrently) and when plasma drug concentrations exceed 100 $\mu\text{g/ml}$. Toxicity may result from conversion of flucytosine to 5-fluorouracil by the microbial flora in the intestinal tract of the host.

Imidazoles and Triazoles

The azole antifungals include two broad classes, imidazoles and triazoles, which share the same antifungal spectrum and mechanism of action. The systemic triazoles are metabolized more slowly and have less effect on human sterol synthesis than do the imidazoles. Because of these advantages, new congeners under development are mostly triazoles. Of the drugs now on the market in the United States, *clotrimazole*, *miconazole*, *ketoconazole*, *econazole*, *buto-*

conazole, *oxiconazole*, *sertaconazole*, and *sulconazole* are imidazoles; *terconazole*, *itraconazole*, *fluconazole*, *voriconazole*, and *posaconazole* (an experimental drug) are triazoles. The topical use of azole antifungals is described in the second section of this chapter. The structure of a triazole is as follows:

Antifungal Activity. Azoles as a group have clinically useful activity against *Candida albicans*, *Candida tropicalis*, *Candida parapsilosis*, *Candida glabrata*, *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Coccidioides* species, *Paracoccidioides brasiliensis*, and ringworm fungi (dermatophytes). *Aspergillus* spp., *Scedosporium apiospermum* (*Pseudallescheria boydii*), *Fusarium*, and *Sporothrix schenckii* are intermediate in susceptibility. *Candida krusei* and the agents of mucormycosis are resistant. Thus, these drugs do not have any useful antibacterial or antiparasitic activity, with the possible exception of antiprotozoal effects against *Leishmania major* and the investigational azole, posaconazole, which has some *in vitro* activity against mucormycosis.

Mechanism of Action. At concentrations achieved following systemic administration, the major effect of imidazoles and triazoles on fungi is inhibition of 14- α -sterol demethylase, a microsomal cytochrome P450 (CYP) enzyme (Figure 48–1). Imidazoles and triazoles thus impair the biosynthesis of ergosterol for the cytoplasmic membrane and lead to the accumulation of 14- α -methylsterols. These methylsterols may disrupt the close packing of acyl chains of phospholipids, impairing the functions of certain membrane-bound enzyme systems such as ATPase and enzymes of the electron transport system and thus inhibiting growth of the fungi.

Some azoles (*e.g.*, clotrimazole) directly increase permeability of the fungal cytoplasmic membrane, but the concentrations required are likely only obtained with topical use.

Azole resistance has emerged gradually during prolonged azole therapy, causing clinical failure in patients with far-advanced HIV infection and oropharyngeal or esophageal candidiasis. The primary mechanism of resistance in *C. albicans* is accumulation of mutations in *ERG11*, the gene coding for the 14- α -sterol demethylase. These mutations protect heme in the enzyme pocket from binding to the azole, but allow access of the natural substrate for the enzyme, lanosterol. Cross resistance is conferred to all azoles. Increased azole efflux by both ATP-binding cassette (ABC) and major facilitator superfamily transporters can add to fluconazole resistance in

C. albicans and *C. glabrata*. Increased production of 14- α -sterol demethylase is another potential cause of resistance. Mutation of the C5,6 sterol reductase gene *ERG3* also can increase azole resistance in some species.

Ketoconazole

Ketoconazole, administered orally, has been replaced by itraconazole for the treatment of all mycoses except when the lower cost of ketoconazole outweighs the advantage of itraconazole. Itraconazole lacks ketoconazole's corticosteroid suppression, while retaining most of ketoconazole's pharmacological properties and expanding the antifungal spectrum. Ketoconazole sometimes is used to inhibit excessive production of glucocorticoids in patients with Cushing's syndrome (see Chapter 59).

Itraconazole

This synthetic triazole is an equimolar racemic mixture of four diastereoisomers (two enantiomeric pairs), each possessing three chiral centers. The structural formula, which is shown below, is closely related to the imidazole ketoconazole:

Absorption, Distribution, and Excretion. Itraconazole (SPORONOX) is available as a capsule and two solution formulations, one for oral and one for intravenous administration. The capsule form of the drug is best absorbed in the fed state, but the oral solution is better absorbed in the fasting state, providing peak plasma concentrations that are more than 150% of those obtained with the capsule. Both the oral solution and intravenous formulation are solubilized in a 40:1 weight ratio of itraconazole hydroxypropyl- β -cyclodextrin, so that administration of 200 mg of itraconazole provides 8 g of this excipient. Itraconazole is metabolized in the liver. It is both a substrate for and a potent inhibitor of CYP3A4. Itraconazole is present in plasma with an approximately equal concentration of a biologically active metabolite, hydroxy-itraconazole. Bioassays may report up to 3.3 times as much itraconazole in plasma as do physical methods such as high-performance liquid chromatography, depending on the susceptibility of

the bioassay organism to hydroxy-itraconazole. The native drug and metabolite are >99% bound to plasma proteins. Neither appears in urine or CSF. The half-life of itraconazole at steady state is approximately 30 to 40 hours. Steady-state levels of itraconazole are not reached for 4 days and those of hydroxy-itraconazole for 7 days; thus, loading doses are recommended when treating deep mycoses. Severe liver disease will increase itraconazole plasma concentrations, but azotemia and hemodialysis have no effect. Some 80% to 90% of intravenously administered hydroxypropyl- β -cyclodextrin is excreted in the urine, and the compound accumulates in the presence of azotemia. Intravenous administration of itraconazole is contraindicated in patients with a creatinine clearance below 30 ml/min because of concern about potential hydroxypropyl- β -cyclodextrin toxicity. Itraconazole is not carcinogenic but is teratogenic in rats, and is contraindicated for the treatment of onychomycosis during pregnancy or for women contemplating pregnancy (category C).

Drug Interactions. Table 48–2 lists known interactions of itraconazole with other drugs, a list that is still expanding. Many of the interactions can result in serious toxicity from the companion drug, inducing potentially fatal cardiac arrhythmias when used with *quinidine* or *cisapride* (only available under a restricted program in the United States). Other interactions may decrease itraconazole concentrations below therapeutic levels.

Therapeutic Uses. Itraconazole given as a capsule is the drug of choice for patients with indolent, nonmeningeal infections due to *B. dermatitidis*, *H. capsulatum*, *P. brasiliensis*, and *C. immitis*. This dosage form also is useful in therapy of indolent invasive aspergillosis outside the CNS, particularly after the infection has been stabilized with amphotericin B. The intravenous formulation is approved for the initial 2 weeks of therapy with blastomycosis, histoplasmosis, and indolent aspergillosis, and for empirical therapy of febrile neutropenic patients not responding to antibacterial antibiotics and at high risk of fungal infections. The intravenous route would be most appropriate for patients unable to tolerate the oral formulation or unable to absorb itraconazole because of decreased gastric acid production. Approximately half the patients with distal subungual onychomycosis respond to itraconazole (Evans and Sigurgeirsson, 1999). Although not an approved use, itraconazole is a reasonable choice for treatment of pseudallescheriasis, an infection not responding to amphotericin B therapy, as well as cutaneous and extracutaneous sporotrichosis, tinea corporis, and extensive tinea versicolor. HIV-infected patients with disseminated histoplasmosis or *Penicillium marneffei* infections have a decreased incidence of relapse if given prolonged itraconazole “maintenance” therapy. It is as yet unclear whether patients responding to highly active antiretroviral therapy (HAART) will require less than lifelong therapy for *P. marneffei* and disseminated histoplasmosis (see Chapter 50). Itraconazole is not recommended for maintenance therapy of cryptococcal meningitis in HIV-infected patients because of a high incidence of relapse. Long-term therapy has been used in non-HIV-infected patients with allergic bronchopulmonary aspergillosis to decrease the dose of glucocorticoids and reduce attacks of acute bronchospasm (Salez *et al.*, 1999).

Itraconazole solution is effective and approved for use in oropharyngeal and esophageal candidiasis. Because the oral solution preparation has more gastrointestinal side effects than do fluconazole tablets, itraconazole solution usually is reserved for patients not responding to fluconazole who are not receiving protease inhibitors or other drugs that make itraconazole contraindicated. Itraconazole capsules and oral solution are not bioequivalent and should not be used interchangeably.

Untoward Effects. Adverse effects of itraconazole therapy can occur as a result of interactions with many other drugs (Table 48–2). Serious hepatotoxicity has rarely led to hepatic failure and death. If symptoms of hepatotoxicity occur, the drug should be discontinued and liver function assessed. Itraconazole causes a dose-dependent inotropic effect that can lead to congestive heart failure in patients with impaired ventricular function. In the absence of interacting drugs, itraconazole capsules are well tolerated at 200 mg daily. Gastrointestinal distress occasionally prevents use of 400 mg per day. In one series of patients receiving 50 to 400 mg per day, nausea and vomiting were recorded in 10%, hypertriglyceridemia in 9%, hypokalemia in 6%, increased serum aminotransferase in 5%, rash in 2%, and at least one side effect in 39%. Occasionally, rash necessitates drug discontinuation, but most adverse effects can be handled with dose reduction. Profound hypokalemia has been seen in patients receiving 600 mg or more daily and in those who recently have received prolonged amphotericin B therapy. Doses of 300 mg twice daily have led to other side effects, including adrenal insufficiency, lower limb edema, hypertension, and in at least one case, rhabdomyolysis. Doses above 400 mg per day are not recommended for long-term use.

Intravenous itraconazole has all the adverse effects of capsules but generally is well tolerated, except for chemical phlebitis. A dedicated catheter port is required, and infusion durations less than 1 hour are not recommended. Toxicity from high plasma levels of hydroxypropyl- β -cyclodextrin in azotemic patients has not been reported, but pending further studies, the intravenous formulation is contraindicated in patients with a creatinine clearance below 30 ml/min.

The oral solution of itraconazole is well tolerated but has all the adverse effects of itraconazole capsules. Anaphylaxis has been observed rarely, as well as severe rash, including Stevens-Johnson syndrome. Some patients complain of the taste, and gastrointestinal side effects are common, although adherence is generally unimpaired. Diarrhea, abdominal cramps, anorexia, and nausea are more common than with the capsules.

Dosage. In treating deep mycoses, a loading dose of 200 mg of itraconazole is administered three times daily for the first 3 days. For maintenance therapy, two 100-mg capsules are given twice daily with food. The divided doses are alleged to increase the area under the plasma concentration *versus* time curve (AUC), even though the half-life is about 30 hours. For maintenance therapy of HIV-infected patients with disseminated histoplasmosis, 200 mg once daily is used. Onychomycosis can be treated with either 200 mg once daily for 12 weeks or 200 mg twice daily for 1 week out of each month—so-called pulse therapy (Evans and Sigurgeirsson, 1999). Retention of active drug in the nail keratin permits intermittent treat-

ment. Daily therapy is preferred by some authorities for infections likely to be more refractory, but costs twice as much as pulse therapy. Once-daily *terbinafine* (250 mg), however, is slightly superior to pulse therapy with itraconazole (*see below*). A loading dose of itraconazole is given as a 200-mg intravenous infusion over 1 hour twice daily for 2 days, followed by 200 mg once daily for 12 days. Itraconazole oral solution should be taken fasting in a dose of 100 mg (10 ml) once daily and swished vigorously in the mouth before swallowing to optimize any topical effect. Patients with oropharyngeal or esophageal thrush are given 100 mg of the solution twice a day for 2 to 4 weeks.

Fluconazole

Fluconazole is a fluorinated bistriazole. Its structure is as follows:

FLUCONAZOLE

Absorption, Distribution, and Excretion. Fluconazole is almost completely absorbed from the gastrointestinal tract. Plasma concentrations are essentially the same whether the drug is given orally or intravenously, and its bioavailability is unaltered by food or gastric acidity. Peak plasma concentrations are 4 to 8 $\mu\text{g/ml}$ after repetitive doses of 100 mg. Renal excretion accounts for over 90% of elimination, and the elimination half-time is 25 to 30 hours. Fluconazole diffuses readily into body fluids, including breast milk, sputum, and saliva; concentrations in CSF can reach 50% to 90% of the simultaneous values in plasma. The dosage interval should be increased from 24 to 48 hours with a creatinine clearance of 21 to 40 ml/min and to 72 hours at 10 to 20 ml/min. A dose of 100 to 200 mg should be given after each hemodialysis. About 11% to 12% of drug in the plasma is protein bound.

Drug Interactions. Fluconazole is an inhibitor of CYP3A4 and CYP2C9. Fluconazole significantly increases plasma concentrations of *amprenavir*, *cisapride*, *cyclosporine*, *phenytoin*, sulfonyleureas (*glipizide*, *tolbutamide*, others), *tacrolimus*, *theophylline*, *telithromycin*, and *warfarin*. Patients who receive more than 400 mg daily or azotemic patients who have elevated fluconazole blood levels may experience drug interactions not otherwise seen. Rifampin decreases the fluconazole AUC by about 25%, which ordinarily

would not be significant. Drugs that decrease gastric acidity do not significantly lower fluconazole blood levels.

Therapeutic Uses. Candidiasis. Fluconazole, 200 mg on the first day and then 100 mg daily for at least 2 weeks, is effective in oropharyngeal candidiasis. Esophageal candidiasis responds to 100 to 200 mg daily, and this dose also has been used to decrease candiduria in high-risk patients. A single dose of 150 mg is effective in uncomplicated vaginal candidiasis. A dose of 400 mg daily decreases the incidence of deep candidiasis in allogeneic bone marrow transplant recipients and is useful in treating candidemia of nonimmunosuppressed patients. Fluconazole is not proven to be effective treatment for deep candidiasis in profoundly neutropenic patients. In patients who have not been receiving fluconazole prophylaxis, the drug has been used successfully as empirical treatment of febrile neutropenia in patients not responding to antibacterial agents and who are not judged to be at high risk of fungal infections. Based on resistance *in vitro*, *Candida krusei* would not be expected to respond to fluconazole or other azoles.

Cryptococcosis. Fluconazole, 400 mg daily, is used for the initial 8 weeks in the treatment of cryptococcal meningitis in patients with AIDS after the patient's clinical condition has been stabilized with intravenous amphotericin B. After 8 weeks, the dose is decreased to 200 mg daily and continued indefinitely. If the patient responds to HAART, has a CD4 count maintained above 100 to 200/mm³ for at least 6 months, and is asymptomatic from cryptococcal meningitis, it is reasonable to discontinue maintenance fluconazole as long as the CD4 response is maintained. A lumbar CSF with negative culture and no cryptococcal antigen provides additional assurance that the infection is inactive. For AIDS patients with cryptococcal meningitis who are alert and oriented and have other favorable prognostic signs, initial therapy with 400 mg daily may be considered. Fluconazole 400 mg daily has been recommended as continuation therapy in non-AIDS patients with cryptococcal meningitis who have responded to an initial course of C-AMB or AMBISOME and for patients with pulmonary cryptococcosis (Saag *et al.*, 2000).

Other Mycoses. Fluconazole is the drug of choice for treatment of coccidioid meningitis because of much less morbidity than with intrathecal amphotericin B. In other forms of coccidioidomycosis, fluconazole is comparable to itraconazole. Fluconazole has activity against histoplasmosis, blastomycosis, sporotrichosis, and ringworm, but response is less than with equivalent doses of itraconazole. Fluconazole is not effective in the prevention or treatment of aspergillosis. As with other azoles, with the possible exception of posaconazole, there is no activity in mucormycosis.

Untoward Effects. Nausea and vomiting may occur at doses above 200 mg daily. Patients receiving 800 mg daily may require parenteral antiemetics. Side effects in patients receiving more than 7 days of drug, regardless of dose, include the following: nausea 3.7%, headache 1.9%, skin rash 1.8%, vomiting 1.7%, abdominal pain 1.7%, and diarrhea 1.5%. Reversible alopecia may occur with prolonged therapy at 400 mg daily. Rare cases of deaths due to hepatic failure or Stevens-Johnson syndrome have been reported. Fluconazole is teratogenic in rodents and has been associated with skeletal and cardiac deformities in three infants born to two women taking high doses during pregnancy. Thus the drug should be avoided during pregnancy (category C).

Dosage. Fluconazole (DIFLUCAN, others) is marketed in the United States as tablets of 50, 100, 150, and 200 mg for oral administration, powder for oral suspension providing 10 and 40 mg/ml, and intrave-

nous solutions containing 2 mg/ml in saline and in dextrose solution. Dosage is 50 to 800 mg once daily and is identical for oral and intravenous administration. Children are treated with 3 to 6 mg/kg once daily.

Voriconazole

Voriconazole (VFEND; UK-109,495) is a triazole with a structure similar to fluconazole but has increased activity *in vitro*, an expanded spectrum, and poor aqueous solubility (pregnancy risk category C). The structure is shown below:

VORICONAZOLE

Absorption, Distribution, and Excretion. Oral bioavailability is 96% and protein binding 56% (Jeu *et al.*, 2003). Gastric acid is not necessary for absorption. Volume of distribution is high (4.6 L/kg), with extensive drug distribution in tissues. Metabolism occurs through the hepatic CYPs, particularly CYP2C19 and to a lesser extent CYP2C9. CYP3A4 plays a limited role. Less than 2% of native drug is recovered from urine, though 80% of the inactive metabolites are secreted in the urine. The oral dose does not have to be adjusted for azotemia or hemodialysis. Peak plasma concentrations after oral doses of 200 mg orally twice daily are about 3 $\mu\text{g/ml}$. CSF concentrations of 1 to 3 $\mu\text{g/ml}$ have been reported in a patient with fungal meningitis.

Plasma elimination half-life is 6 hours. Voriconazole exhibits nonlinear metabolism so that higher doses cause greater-than-linear increases in drug exposure. Genetic polymorphisms in CYP2C19 can cause up to fourfold differences in drug exposure; 15% to 20% of Asians are homozygous poor metabolizers, compared to 2% of Caucasians and African-Americans. Patients older than 65 years had 86% higher plasma AUC than patients aged 18 to 45. Patients with mild or moderate hepatic insufficiency had an average AUC that was 223% of age- and weight-matched controls. Patients with cirrhosis should receive the same loading dose of voriconazole but half the maintenance dose. There are no data to guide dosing in patients with severe hepatic insufficiency.

The intravenous formulation of voriconazole contains sulfobutyl ether β -cyclodextrin (SBECD). When voriconazole is given intravenously, SBECD is excreted completely by the kidney. Significant accumulation of SBECD occurs with a creatinine clearance below 50 ml/min. Because toxicity of SBECD at high plasma concentrations is unclear, oral voriconazole is preferred in azotemic patients.

Drug Interactions. Voriconazole is metabolized by, and inhibits, CYP2C19, CYP2C9, and CYP3A4. The affinity of voriconazole is highest for CYP2C19, followed in rank order by CYP2C9 and CYP3A4. The major metabolite of voriconazole, the voriconazole N-oxide, also inhibits the metabolic activity of CYP2C9, CYP3A4, and to a lesser extent, CYP2C19. Inhibitors or inducers of these three enzymes may increase or decrease voriconazole plasma concentrations, respectively. In addition, there is potential for voriconazole

and its major metabolite to increase the plasma concentrations of other drugs metabolized by these enzymes.

Coadministration with *rifampin*, *rifabutin*, or *ritonavir* is contraindicated because of accelerated voriconazole metabolism. *Efavirenz* and perhaps other nonnucleoside reverse transcriptase inhibitors (NNRTIs) significantly increase voriconazole metabolism and slow the metabolism of the NNRTI. When given with phenytoin, the voriconazole dose should be doubled. Drugs that significantly accumulate in patients receiving voriconazole include cyclosporine, tacrolimus, phenytoin, rifabutin, warfarin, and *sirolimus*. Because the sirolimus AUC increases elevenfold when voriconazole is given, coadministration is contraindicated. *Omeprazole* dose should be reduced by half if 40 mg or more per day is given. Until more experience with voriconazole is gained, it is prudent to be observant for the drug interactions known to occur with other azoles (Table 48–2).

Therapeutic Uses. In an open, randomized trial, voriconazole provided superior efficiency to C-AMB in the primary therapy of invasive aspergillosis (Herbrecht *et al.*, 2002). In a secondary analysis, survival also was superior in the voriconazole arm. Voriconazole was compared to AMBISOME in an open randomized trial in the empirical therapy of neutropenic patients whose fever did not respond to more than 96 hours of antibacterial therapy. Because the 95% confidence interval in this noninferiority trial permitted the possibility that voriconazole might be more than 10% worse than AMBISOME, the FDA did not approve voriconazole for this use (Walsh *et al.*, 2002). However, in a secondary analysis, there were fewer breakthrough infections with voriconazole (1.9%) than with AMBISOME (5%). Voriconazole is approved for use in esophageal candidiasis on the basis of a double-blind, randomized comparison with fluconazole (Ally *et al.*, 2001). Voriconazole is also approved for use as salvage therapy in patients with *Pseudallescheria boydii* (*Scedosporium apiospermum*) and *Fusarium* infections.

Untoward Effects. Voriconazole is teratogenic in animals and contraindicated in pregnancy (class D). Although voriconazole is generally well tolerated, occasional cases of hepatotoxicity have been reported and liver function should be monitored. Voriconazole, like some other azoles, causes a prolongation of the QTc interval, which can become significant in patients with other risk factors for *torsades de pointes*. Patients must be warned about possible visual effects. Approximately 30% of patients note transient visual changes beginning about half an hour after administration and lasting for another half hour. Blurred vision, altered color perception, and photophobia have been reported. Activities that require keen vision should be avoided when vision is altered. No sequelae occur. Uncommonly, transient visual hallucinations or confusion occur. Patients receiving their first intravenous infusion have had anaphylactoid reactions, with faintness, nausea, flushing, feverishness, and rash. In such patients, the infusion should be stopped. Rash has been reported in 5.8% of patients.

Dosage. Voriconazole for intravenous infusion is packaged as 200 mg with 3.2 g SBECD. Treatment is usually initiated with an intravenous infusion of 6 mg/kg every 12 hours for two doses, followed by 4 mg/kg every 12 hours. It should be administered at 3 mg/kg per hour, not as a bolus. As the patient improves, oral administration is continued as 200 mg every 12 hours. Patients failing to respond may be given 300 mg every 12 hours. Voriconazole is available as 50- or 200-mg tablets or a suspension of 40 mg/ml when hydrated. The tablets, but not the suspension, contain lactose. Because high-fat

meals reduce voriconazole bioavailability, oral drug should be given either 1 hour before or 1 hour after meals.

Echinocandins

Screening natural products of fungal fermentation in the 1970s led to the discovery that *echinocandins* had activity against *Candida* and that the biologic activity was directed against formation of $\beta(1,3)$ D-glucans in the cell wall (Wiederhold and Lewis, 2003). Selection of different echinocandins and their chemical modifications led first to the discovery of *cilofungin*. Clinical trials were stopped because of toxicity from the solubilizing agent. Further research has led to one drug approved for clinical use, *caspofungin*, and two compounds that are in development: *anidulafungin* and *micafungin*. All have the same mechanism of action but differing pharmacologic properties. Susceptible fungi include *Candida* species and *Aspergillus* species. *In vitro* resistance can be conferred in *C. albicans* by mutation in one of the genes that encodes $\beta(1,3)$ D-glucan synthase. Azole-resistant isolates of *C. albicans* remain susceptible to echinocandins.

Caspofungin Acetate. Caspofungin acetate (cancidas, MK-0991) is a water-soluble, semisynthetic lipopeptide synthesized from the fermentation product of *Glarea lozoyensis* (Keating and Figgitt, 2003; Johnson and Perfect, 2003). The chemical structure for caspofungin is shown below. The fermentation product is called pneumocandin B₀ because of its activity against cysts of *Pneumocystis jiroveci*. In susceptible yeasts, caspofungin causes lysis. In *Aspergillus*, hyphal tips become bulbous and may rupture, but hyphal growth continues sufficiently to negate use of the usual growth-inhibition endpoints for MIC estimation. It is not known if other endpoints correlate with *in vivo* activity, making it unwise to refer to caspofungin's *in vitro* activity against molds. Animal models have shown promising activity against *Aspergillus* species as well as many species of *Candida*. These models do not suggest activity against *Cryptococcus neoformans* or *Histoplasma capsulatum*.

Absorption, Distribution, and Excretion. Caspofungin is not absorbed through the gastrointestinal tract. After intravenous injection, caspofungin is eliminated from the bloodstream with a half-life of 9 to 11

hours. Catabolism is largely by hydrolysis and *N*-acetylation, with excretion of the metabolites in the urine and feces. Mild and moderate hepatic insufficiency increases the AUC by 55% and 76%, respectively. About 97% of serum drug is bound to albumin. Only clinically insignificant amounts of bioactive drug are present in urine, and no dose adjustment is necessary for renal insufficiency or hemodialysis.

Drug Interactions. The only potentially significant interaction yet found was a 35% increase in the caspofungin AUC by cyclosporine. Some subjects also developed increased serum aminotransferases, but it is unclear whether the modest increase in caspofungin AUC was responsible. Repeated administration of caspofungin (100 mg per day) has been well tolerated.

Therapeutic Use. Caspofungin is approved for patients with invasive aspergillosis who are failing or intolerant of approved drugs, such as amphotericin B formulations or voriconazole. Approval was based on a study of 63 patients in a noncomparative salvage trial. Caspofungin is also approved for esophageal candidiasis, based on randomized trials that found noninferiority to fluconazole and C-AMB (Villanueva *et al.*, 2001). Efficacy in fluconazole failures has not been reported but would be anticipated because there is no cross resistance. A blinded, randomized clinical trial of caspofungin in deeply invasive candidiasis found noninferiority to C-AMB, leading to approval for that indication (Mora-Duarte *et al.*, 2002). Most patients in that multicenter study were not neutropenic and had catheter-acquired candidemia. Too few patients were infected with *C. glabrata* to judge activity against that species. Efficacy was comparable to that of fluconazole in the same patient population. Caspofungin is also approved for the treatment of persistently febrile neutropenic patients with suspected fungal infections.

Untoward Effects. Caspofungin has been remarkably well tolerated, with the exception of phlebitis at the infusion site. Histamine-like effects have been reported with rapid infusions. Other symptoms have been equivalent to those observed in patients receiving fluconazole in the comparator arm.

Dosage. Caspofungin is administered intravenously once daily over 1 hour. In candidemia and salvage therapy of aspergillosis, the initial dose is 70 mg, followed by 50 mg daily. The dose may be increased to 70 mg daily in patients failing to respond. Esophageal candidiasis is treated with 50 mg daily.

Griseofulvin

Chemistry. The structural formula of *griseofulvin* is as follows:

The drug is practically insoluble in water.

Antifungal Activity. Griseofulvin is fungistatic *in vitro* for various species of the dermatophytes *Microsporum*, *Epidermophyton*, and *Trichophyton*. The drug has no effect on bacteria or on other fungi.

Resistance. Although failure of ringworm lesions to improve is not rare, isolates from these patients usually are still susceptible to griseofulvin *in vitro*.

Mechanism of Action. A prominent morphological manifestation of the action of griseofulvin is the production of multinucleate cells as the drug inhibits fungal mitosis. In mammalian cells treated with high concentrations, griseofulvin causes disruption of the mitotic spindle by interacting with polymerized microtubules. Although the effects of the drug are thus similar to those of *colchicine* and the vinca alkaloids, its binding sites on the microtubular protein are distinct. In addition to its binding to tubulin, griseofulvin also may bind to a microtubule-associated protein.

Absorption, Distribution, and Excretion. The oral administration of a 0.5-g dose of griseofulvin produces peak plasma concentrations of approximately 1 $\mu\text{g}/\text{ml}$ in about 4 hours. Blood levels are quite variable, however. Some studies have shown improved absorption when the drug is taken with a fatty meal. Since the rates of dissolution and disaggregation limit the bioavailability of griseofulvin, microsized and ultramicrosized powders are now used in preparations (FULVICIN U/F and GRIS-PEG, respectively). Although the bioavailability of the ultramicrocrystalline preparation is said to be 50% greater than that of the conventional microsized powder, this may not always be true. Griseofulvin has a half-life in plasma of about 1 day, and approximately 50% of the oral dose can be detected in the urine within 5 days, mostly in the form of metabolites. The primary metabolite is 6-methylgriseofulvin. Barbiturates decrease griseofulvin absorption from the gastrointestinal tract.

Griseofulvin is deposited in keratin precursor cells; when these cells differentiate, the drug is tightly bound to, and persists in, keratin, providing prolonged resistance to fungal invasion. For this reason, the new growth of hair or nails is the first to become free of disease. As the fungus-containing keratin is shed, it is replaced by normal tissue. Griseofulvin is detectable in the stratum corneum of the skin within 4 to 8 hours of oral administration. Sweat and trans-epidermal fluid loss play an important role in the transfer of the drug in the stratum corneum. Only a very small fraction of a dose of the drug is present in body fluids and tissues.

Therapeutic Uses. Mycotic disease of the skin, hair, and nails due to *Microsporum*, *Trichophyton*, or *Epidermophyton* responds to griseofulvin therapy. Infections that are readily treatable with this agent include infections of the hair (tinea capitis) caused by *Microsporum canis*, *Microsporum audouinii*, *Trichophyton schoenleinii*, and *Trichophyton verrucosum*; “ringworm” of the glabrous skin; tinea cruris and tinea corporis caused by *M. canis*, *Trichophyton rubrum*, *T. verrucosum*, and *Epidermophyton floccosum*; and tinea of the hands (*T. rubrum* and *T. mentagrophytes*) and beard (*Trichophyton* species). Griseofulvin also is highly effective in “athlete’s foot” or epidermophytosis involving the skin and nails, the vesicular form of which is most commonly due to *T. mentagrophytes* and the hyperkeratotic type to *T. rubrum*. However, topical therapy is preferred (see below). *T. rubrum* and *T. mentagrophytes* infections may require higher-than-conventional doses. Since very high doses of griseofulvin are carcinogenic and teratogenic in laboratory animals, the drug should not be used systemically to treat trivial infections that respond to topical therapy.

Dosage. The recommended daily dose of griseofulvin is 5 to 15 mg/kg for children and 500 mg to 1 g for adults. Doses of 1.5 to 2 g daily may be used for short periods in severe or extensive infec-

tions. Best results are obtained when the daily dose is divided and given at 6-hour intervals, although the drug often is given twice per day. Treatment must be continued until infected tissue is replaced by normal hair, skin, or nails, which requires 1 month for scalp and hair ringworm, 6 to 9 months for fingernails, and at least a year for toenails. Itraconazole or terbinafine is preferred for onychomycosis. Griseofulvin is not effective in treatment of subcutaneous or deep mycoses.

Untoward Effects. The incidence of serious reactions associated with the use of griseofulvin is very low. One of the minor effects is headache, which is sometimes severe and usually disappears as therapy is continued. The incidence of headache may be as high as 15%. Other nervous system manifestations include peripheral neuritis, lethargy, mental confusion, impairment of performance of routine tasks, fatigue, syncope, vertigo, blurred vision, transient macular edema, and augmentation of the effects of alcohol. Among the side effects involving the alimentary tract are nausea, vomiting, diarrhea, heartburn, flatulence, dry mouth, and angular stomatitis. Hepatotoxicity also has been observed. Hematologic effects include leukopenia, neutropenia, punctate basophilia, and monocytosis; these often disappear despite continued therapy. Blood studies should be carried out at least once a week during the first month of treatment or longer. Common renal effects include albuminuria and cylindruria without evidence of renal insufficiency. Reactions involving the skin are cold and warm urticaria, photosensitivity, lichen planus, erythema, erythema multiforme–like rashes, and vesicular and morbilliform eruptions. Serum sickness syndromes and severe angioedema develop rarely during treatment with griseofulvin. Estrogenlike effects have been observed in children. A moderate but inconsistent increase of fecal protoporphyrins has been noted with chronic use.

Griseofulvin induces hepatic CYPs, thus increasing the rate of metabolism of warfarin; adjustment of the dosage of the latter agent may be necessary in some patients. The drug may reduce the efficacy of low-estrogen oral contraceptive agents, probably by a similar mechanism.

Terbinafine

Terbinafine is a synthetic allylamine, structurally similar to the topical agent *naftifine*. Its structural formula is shown below:

Terbinafine is well absorbed, but bioavailability is decreased to about 40% because of first-pass metabolism in the liver. Proteins bind more than 99% of the drug in plasma. Drug accumulates in skin, nails, and fat. The initial half-life is about 12 hours but extends to 200 to 400 hours at steady state. Drug can be found in plasma for 4 to 8 weeks after prolonged therapy. Terbinafine is not recommended in patients with marked azotemia or hepatic failure, because in the latter condition, terbinafine plasma levels are increased by unpredictable amounts. Rifampin decreases and cimetidine increases plasma terbinafine concentrations. The drug is well tolerated, with a low incidence of gastrointestinal distress,

headache, or rash. Rarely, hepatotoxicity, severe neutropenia, Stevens-Johnson syndrome, or toxic epidermal necrolysis may occur. The drug is contraindicated in pregnancy (category B). It is recommended that systemic terbinafine therapy for onychomycosis be postponed until after pregnancy is complete. Its mechanism of action is probably inhibition of fungal squalene epoxidase, blocking ergosterol biosynthesis.

Terbinafine (LAMISIL), given as one 250-mg tablet daily, is at least as effective for nail onychomycosis as 200 mg daily of itraconazole, and slightly more effective than pulse itraconazole therapy (*see above*) (Evans, 1999). Duration of treatment varies with the site being treated but typically is 3 months. Although not approved for this use, terbinafine (250 mg daily) also is effective in ringworm elsewhere on the body. No pediatric formulation is available, so there is little experience with the drug in tinea capitis, usually a disease of children. The topical use of terbinafine is discussed in the following section.

Topical Antifungal Agents

Topical treatment is useful in many superficial fungal infections—*i.e.*, those confined to the stratum corneum, squamous mucosa, or cornea. Such diseases include dermatophytosis (ringworm), candidiasis, tinea versicolor, piedra, tinea nigra, and fungal keratitis. Topical administration of antifungal agents usually is not successful for mycoses of the nails (onychomycosis) and hair (tinea capitis) and has no place in the treatment of subcutaneous mycoses, such as sporotrichosis and chromoblastomycosis. The efficacy of topical agents in the treatment of superficial mycoses depends not only on the type of lesion and the mechanism of action of the drug, but also on the viscosity, hydrophobicity, and acidity of the formulation. Regardless of formulation, penetration of topical drugs into hyperkeratotic lesions often is poor. Removal of thick, infected keratin is sometimes a useful adjunct to therapy and is the principal mode of action of Whitfield's ointment (*see below*).

A plethora of topical agents is available for the treatment of superficial mycoses. Many of the older drugs—including *gentian violet*, *carbol-fuchsin*, *acrisorcin*, *triacetin*, *sulfur*, *iodine*, and *aminacrine*—are now rarely indicated and are not discussed here. Among the topical agents, the preferred formulation for cutaneous application usually is a cream or solution. Ointments are messy and are too occlusive for macerated or fissured intertriginous lesions. The use of powders, whether applied by shake containers or aerosols, is largely confined to the feet and moist lesions of the groin and other intertriginous areas.

The systemic agents used for the treatment of superficial mycoses are discussed above. Some of these agents also are administered topically; their uses are described here and also in Chapter 62.

Imidazoles and Triazoles for Topical Use

As discussed above, these closely related classes of drugs are synthetic antifungal agents that are used both topically and systemically. Indications for their topical use include ringworm, tinea versicolor, and mucocutaneous candidiasis. Resistance to imidazoles or triazoles is very rare among the fungi that cause ringworm. Selection of one of these agents for topical use should be based on cost and availability, since testing *in vitro* for fungal susceptibility to these drugs does not predict clinical responses.

Cutaneous Application. The preparations for cutaneous use described below are effective for tinea corporis, tinea pedis, tinea cruris, tinea versicolor, and cutaneous candidiasis. They should be applied twice a day for 3 to 6 weeks. Despite some activity *in vitro* against bacteria, this effect is not clinically useful. The cutaneous formulations are not suitable for oral, vaginal, or ocular use.

Vaginal Application. Vaginal creams, suppositories, and tablets for vaginal candidiasis are all used once a day for 1 to 7 days, preferably at bedtime to facilitate retention. None is useful in trichomoniasis, despite some activity *in vitro*. Most vaginal creams are administered in 5-g amounts. Three vaginal formulations—clotrimazole tablets, miconazole suppositories, and terconazole cream—come in both low- and high-dose preparations. A shorter duration of therapy is recommended for the higher dose of each. These preparations are administered for 3 to 7 days. Approximately 3% to 10% of the vaginal dose is absorbed. Although some imidazoles are teratogenic in rodents, no adverse effects on the human fetus have been attributed to the vaginal use of imidazoles or triazoles. The most common side effect is vaginal burning or itching. A male sexual partner may experience mild penile irritation. Cross-allergenicity among these compounds is assumed to exist, based on their structural similarities.

Oral Use. Use of the oral troche of clotrimazole is properly considered as topical therapy. The only indication for this 10-mg troche is oropharyngeal candidiasis. Antifungal activity is due entirely to the local concentration of the drug; there is no systemic effect.

Clotrimazole

Clotrimazole has the following structure:

CLOTRIMAZOLE

Absorption of clotrimazole is less than 0.5% after application to the intact skin; from the vagina, it is 3% to 10%. Fungicidal concentrations remain in the vagina for as long as 3 days after application of the drug. The small amount absorbed is metabolized in the liver and excreted in bile. In adults, an oral dose of 200 mg per day will give rise initially to plasma concentrations of 0.2 to 0.35 $\mu\text{g/ml}$, followed by a progressive decline.

In a small fraction of recipients, clotrimazole on the skin may cause stinging, erythema, edema, vesication, desquamation, pruritus, and

urticaria. When it is applied to the vagina, about 1.6% of recipients complain of a mild burning sensation, and rarely of lower abdominal cramps, a slight increase in urinary frequency, or skin rash. Occasionally, the sexual partner may experience penile or urethral irritation. By the oral route, clotrimazole can cause gastrointestinal irritation. In patients using troches, the incidence of this side effect is about 5%.

Therapeutic Uses. Clotrimazole is available as a 1% cream, lotion, and solution (LOTRIMIN, MYCELEX, others), 1% or 2% vaginal cream or vaginal tablets of 100, 200, or 500 mg (GYNE-LOTRIMIN, MYCELEX-G, others), and 10-mg troches (MYCELEX, others). On the skin, applications are made twice a day. For the vagina, the standard regimens are one 100-mg tablet once a day at bedtime for 7 days, one 200-mg tablet daily for 3 days, one 500-mg tablet inserted only once, or 5 g of cream once a day for 3 days (2% cream) or 7 days (1% cream). For nonpregnant females, one 200-mg tablet may be used once a day for 3 days. Troches are to be dissolved slowly in the mouth five times a day for 14 days.

Clotrimazole has been reported to cure dermatophyte infections in 60% to 100% of cases. The cure rates in cutaneous candidiasis are 80% to 100%. In vulvovaginal candidiasis, the cure rate is usually above 80% when the 7-day regimen is used. A 3-day regimen of 200 mg once a day appears to be similarly effective, as does single-dose treatment (500 mg). Recurrences are common after all regimens. The cure rate with oral troches for oral and pharyngeal candidiasis may be as high as 100% in the immunocompetent host.

Econazole

Econazole, the deschloro derivative of miconazole, has the following structure:

Econazole readily penetrates the stratum corneum and is found in effective concentrations down to the mid-dermis. However, less than 1% of an applied dose appears to be absorbed into the blood. Approximately 3% of recipients have local erythema, burning, stinging, or itching.

Econazole nitrate (SPECTAZOLE, others) is available as a water-miscible cream (1%) to be applied twice a day.

Miconazole

Miconazole is a very close chemical congener of econazole, with the following structure:

Miconazole readily penetrates the stratum corneum of the skin and persists there for more than 4 days after application. Less than 1% is absorbed into the blood. Absorption is no more than 1.3% from the vagina.

Adverse effects from topical application to the vagina include burning, itching, or irritation in about 7% of recipients, and infrequently, pelvic cramps (0.2%), headache, hives, or skin rash. Irritation, burning, and maceration are rare after cutaneous application. Miconazole is considered safe for use during pregnancy, although some authors avoid its vaginal use during the first trimester.

Therapeutic Uses. Miconazole nitrate is available as a dermatologic ointment, cream, solution, spray, or powder (MICATIN, MONISTAT-DERM, others). To avoid maceration, only the lotion should be applied to intertriginous areas. It is available as a 2% and 4% vaginal cream, and as 100-mg, 200-mg, or 1200-mg vaginal suppositories (MONISTAT 7, MONISTAT 3, others), to be applied high in the vagina at bedtime for 7, 3, or 1 day(s), respectively.

In the treatment of tinea pedis, tinea cruris, and tinea versicolor, the cure rate may be over 90%. In the treatment of vulvovaginal candidiasis, the mycologic cure rate at the end of 1 month is about 80% to 95%. Pruritus sometimes is relieved after a single application. Some vaginal infections caused by *Candida glabrata* also respond.

Terconazole and Butoconazole

Terconazole (TERAZOL, others) is a ketal triazole with structural similarities to ketoconazole. Its structure is as follows:

The mechanism of action of terconazole is similar to that of the imidazoles. The 80-mg vaginal suppository is inserted at bedtime for 3 days, while the 0.4% vaginal cream is used for 7 days and the 0.8% cream for 3 days. Clinical efficacy and patient acceptance of both preparations are at least as good as for clotrimazole in patients with vaginal candidiasis.

Butoconazole is an imidazole that is pharmacologically quite comparable to clotrimazole. Its structural formula is as follows:

Butoconazole nitrate (MYCELEX 3, others) is available as a 2% vaginal cream; it is used at bedtime in nonpregnant females. Because

of the slower response during pregnancy, a 6-day course is recommended (during the second and third trimester).

Tioconazole

Tioconazole (VAGISTAT 1, others) is an imidazole that is marketed for treatment of *Candida* vulvovaginitis. A single 4.6-g dose of ointment (300 mg) is given at bedtime.

Oxiconazole, Sulconazole, and Sertaconazole

These imidazole derivatives are used for the topical treatment of infections caused by the common pathogenic dermatophytes. Oxiconazole nitrate (OXISTAT) is available as a cream and lotion; sulconazole nitrate (EXELDERM) is supplied as a solution and cream. Sertaconazole (ERTACZO) is a 2% cream marketed for tinea pedis.

Ciclopirox Olamine

Ciclopirox olamine (LOPROX) has broad-spectrum antifungal activity. The chemical structure is as follows:

It is fungicidal to *C. albicans*, *E. floccosum*, *M. canis*, *T. mentagrophytes*, and *T. rubrum*. It also inhibits the growth of *Malassezia furfur*. After application to the skin, it penetrates through the epidermis into the dermis, but even under occlusion, less than 1.5% is absorbed into the systemic circulation. Because the half-life is 1.7 hours, no systemic accumulation occurs. The drug penetrates into hair follicles and sebaceous glands. It can sometimes cause hypersensitivity. It is available as a 0.77% cream and lotion for the treatment of cutaneous candidiasis and for tinea corporis, cruris, pedis, and versicolor. Cure rates in the dermatomycoses and candidal infections have been variously reported to be 81% to 94%. No topical toxicity has been noted.

Ciclopirox is also sold as a 0.77% gel and a 1% shampoo for the treatment of seborrheic dermatitis of the scalp, and an 8% topical solution (PENLAC NAIL LACQUER) is sold for the treatment of onychomycosis.

Haloprogin

Haloprogin is a halogenated phenolic ether with the following structure:

It is fungicidal to various species of *Epidermophyton*, *Pityrosporum*, *Microsporum*, *Trichophyton*, and *Candida*. During treatment with this drug, irritation, pruritus, burning sensations, vesiculation, increased maceration, and "sensitization" (or exacerbation of the lesion) occasionally occur, especially on the foot if occlusive

footgear is worn. Haloprogin is poorly absorbed through the skin; it is converted to trichlorophenol in the body. The systemic toxicity from topical application appears to be low.

Haloprogin (HALOTEX) cream or solution is applied twice a day for 2 to 4 weeks. Its principal use is against tinea pedis, for which the cure rate is about 80%; it is thus approximately equal in efficacy to *tolnaftate* (see below). It also is used against tinea cruris, tinea corporis, tinea manuum, and tinea versicolor. Haloprogin is no longer available in the United States.

Tolnaftate

Tolnaftate is a thiocarbamate with the following structure:

TOLNAFTATE

Tolnaftate is effective in the treatment of most cutaneous mycoses caused by *T. rubrum*, *T. mentagrophytes*, *T. tonsurans*, *E. floccosum*, *M. canis*, *M. audouinii*, *Microsporum gypseum*, and *M. furfur*, but it is ineffective against *Candida*. In tinea pedis, the cure rate is around 80%, compared with about 95% for miconazole. Toxic or allergic reactions to tolinaftate have not been reported.

Tolnaftate (AFTATE, TINACTIN, others) is available in a 1% concentration as a cream, gel, powder, aerosol powder, and topical solution, or as a topical aerosol liquid. The preparations are applied locally twice a day. Pruritus is usually relieved in 24 to 72 hours. Involution of interdigital lesions caused by susceptible fungi is very often complete in 7 to 21 days.

Naftifine

Naftifine is an allylamine with the following structure:

NAFTIFINE

Naftifine is representative of the allylamine class of synthetic agents that inhibit squalene-2,3-epoxidase and thus inhibit fungal biosynthesis of ergosterol. The drug has broad-spectrum fungicidal activity *in vitro*. Naftifine hydrochloride (NAFTIN) is available as a 1% cream or gel. It is effective for the topical treatment of tinea cruris and tinea corporis; twice-daily application is recommended. The drug is well tolerated, although local irritation has been observed in 3% of treated patients. Allergic contact dermatitis also has been reported. Naftifine also may be efficacious for cutaneous candidiasis and tinea versicolor, although the drug is not approved for these uses.

Terbinafine

Terbinafine 1% cream or spray is applied twice daily and is effective in tinea corporis, tinea cruris, and tinea pedis. Terbinafine is less active against *Candida* species and *Malassezia furfur*, but the

cream also can be used in cutaneous candidiasis and tinea versicolor. In European studies, oral terbinafine has appeared to be effective in treatment of ringworm, and in some cases of onychomycosis. The systemic use of terbinafine is discussed above.

Butenafine

Butenafine hydrochloride (MENTAX) is a benzylamine derivative with a mechanism of action similar to that of terbinafine and naftifine. Its spectrum of antifungal activity and use also are similar to those of the allylamines.

Polyene Antifungal Antibiotics

Nystatin. *Nystatin* was discovered in the New York State Health Laboratory and was named accordingly; it is a tetraene macrolide produced by *Streptomyces noursei*. Nystatin is structurally similar to amphotericin B and has the same mechanism of action. Nystatin is not absorbed from the gastrointestinal tract, skin, or vagina. A liposomal formulation (NYOTRAN) is in clinical trials for candidemia.

Nystatin (MYCOSTATIN, NILSTAT, others) is useful only for candidiasis and is supplied in preparations intended for cutaneous, vaginal, or oral administration for this purpose. Infections of the nails and hyperkeratinized or crusted skin lesions do not respond. Topical preparations include ointments, creams, and powders, all of which contain 100,000 units/g. Powders are preferred for moist lesions and are applied two or three times a day. Creams or ointments are used twice daily. Combinations of nystatin with antibacterial agents or corticosteroids also are available. Allergic reactions to nystatin are very uncommon.

Vaginal tablets containing 100,000 units of the drug are inserted once daily for 2 weeks. Although the tablets are well tolerated, imidazoles or triazoles are more effective agents than nystatin for vaginal candidiasis.

An oral suspension that contains 100,000 units/ml of nystatin is given four times a day. Premature and low-birth-weight neonates should receive 1 ml of this preparation, infants 2 ml, and children or adults 4 to 6 ml per dose. Older children and adults should be instructed to swish the drug around the mouth and then swallow. If not otherwise instructed, the patient may expectorate the bitter liquid and fail to treat the infected mucosa in the posterior pharynx or esophagus. Nystatin suspension is usually effective for oral candidiasis of the immunocompetent host. Other than the bitter taste and occasional complaints of nausea, adverse effects are uncommon. A 200,000-unit troche (mycostatin pastilles) is available for the treatment of oral candidiasis, and a 500,000-unit oral tablet is sold for the treatment of nonesophageal membrane gastrointestinal candidiasis.

Amphotericin B. Topical amphotericin B (FUNGIZONE) also is used for cutaneous candidiasis. A lotion, cream, and ointment are marketed; these preparations all contain 3% amphotericin B and are applied to the lesion two to four times daily. The systemic use of amphotericin B is discussed above.

Miscellaneous Antifungal Agents

Undecylenic Acid. *Undecylenic acid* is 10-undecenoic acid, an 11-carbon unsaturated compound. It is a yellow liquid with a characteristic rancid odor. It is primarily fungistatic, although fungicidal activity may be observed with long exposure to high concentrations of the agent. The drug is active against a variety of fungi, including

those that cause ringworm. Undecylenic acid (DESENEK, others) is available in a foam, ointment, cream, powder, spray powder, soap, and liquid. *Zinc undecylenate* is marketed in combination with other ingredients. The zinc provides an astringent action that aids in the suppression of inflammation. Compound undecylenic acid ointment contains both undecylenic acid (about 5%) and zinc undecylenate (about 20%). *Calcium undecylenate* (CALDESENE, CRUEX) is available as a powder.

Undecylenic acid preparations are used in the treatment of various dermatomycoses, especially tinea pedis. Concentrations of the acid as high as 10%, as well as those of the acid and salt in the compound ointment, may be applied to the skin. The preparations as formulated are usually not irritating to tissue, and sensitization to them is uncommon. It is of undoubted benefit in retarding fungal growth in tinea pedis, but the infection frequently persists despite intensive treatment with preparations of the acid and the zinc salt. At best, the clinical "cure" rate is about 50%, which is much lower than that obtained with the imidazoles, haloprogin, or tolnaftate. Efficacy in the treatment of tinea capitis is marginal, and the drug is no longer used for that purpose. Undecylenic acid preparations also are approved for use in the treatment of diaper rash, tinea cruris, and other minor dermatologic conditions.

Benzoic Acid and Salicylic Acid. An ointment containing benzoic and salicylic acids is known as *Whitfield's ointment*. It combines the fungistatic action of benzoate with the keratolytic action of salicylate. It contains benzoic acid and salicylic acid in a ratio of 2:1 (usually 6% to 3%) and is used mainly in the treatment of tinea pedis. Since benzoic acid is only fungistatic, eradication of the infection occurs only after the infected stratum corneum is shed, and continuous medication is required for several weeks to months. The salicylic acid accelerates the desquamation. The ointment also is sometimes used to treat tinea capitis. Mild irritation may occur at the site of application.

ANTIVIRAL AGENTS (NONRETROVIRAL)

Frederick G. Hayden

Viruses are obligate intracellular parasites that consist of either double- or single-stranded DNA or RNA enclosed in a protein coat called a *capsid*. Some viruses also possess a lipid envelope that, like the capsid, may contain antigenic glycoproteins. Most viruses contain or encode enzymes essential for viral replication inside a host cell, and they usurp the metabolic machinery of their host cell. The discovery of novel antiviral inhibitors often is linked to a better understanding of the molecular events in viral replication. Table 49–1 outlines the stages of viral replication and the classes of antiviral agents that could act at each stage of replication. Effective antiviral agents inhibit virus-specific replicative events or preferentially inhibit virus-directed rather than host cell-directed nucleic acid or protein synthesis. However, host cell molecules that are essential to viral replication also may offer targets for developing new short-term therapies. This chapter provides information about the antiviral activity, pharmacology, and clinical uses of specific antiviral agents for non-human immunodeficiency virus (non-HIV) infections.

Figure 49–1 provides a schematic diagram of the replicative cycle of a DNA virus (A) and an RNA virus (B). DNA viruses (and the diseases they cause) include poxviruses (smallpox), herpesviruses (chickenpox, shingles, oral and genital herpes), adenoviruses (conjunctivitis, sore throat), hepadnaviruses [hepatitis B (HBV)], and papillomaviruses (warts). Typically, DNA viruses enter into the host cell nucleus, where the viral DNA is transcribed into mRNA by host cell polymerase; mRNA is translated in the usual host cell fashion into virus-specific proteins. One exception to this strategy is poxvirus, which has its own RNA polymerase and consequently replicates in the host cell cytoplasm.

For RNA viruses, the replication strategy in the host cell relies either on enzymes in the virion (the whole

infective viral particle) to synthesize its mRNA or on the viral RNA serving as its own mRNA. The mRNA is translated into various viral proteins, including RNA polymerase, which directs the synthesis of more viral mRNA and genomic RNA (Figure 49–1B). Most RNA viruses complete their replication in the cytoplasm, but some, such as influenza, are transcribed in the host cell nucleus. Examples of RNA viruses (and the diseases they cause) include rubella virus (German measles), rhabdoviruses (rabies), picornaviruses (poliomyelitis, meningitis, colds, hepatitis A), arenaviruses (meningitis, Lassa fever), flaviviruses (West Nile meningoencephalitis, yellow fever, hepatitis C), orthomyxoviruses (influenza), paramyxoviruses (measles, mumps), and coronaviruses [colds, severe acute respiratory syndrome (SARS)].

One group of RNA viruses that deserves special mention is retroviruses, responsible for diseases such as acquired immunodeficiency syndrome (AIDS) (*see* Chapter 50) and T-cell leukemias [human T-cell lymphotropic virus I (HTLV-I)]. In retroviruses, the virus contains a reverse-transcriptase enzyme activity that makes a DNA copy of the viral RNA template. The DNA copy is then integrated into the host genome, at which point it is referred to as a *provirus* and is transcribed into both genomic RNA and mRNA for translation into viral proteins. The polymerase of hepadnaviruses possesses reverse-transcriptase activity, and nucleoside antiretroviral agents often are inhibitory for HBV.

Experiences from the development of antiviral agents have provided useful general insights with practical implications:

1. Although many compounds show antiviral activity *in vitro*, most affect some host cell function and are associated with unacceptable toxicity in human beings.

Table 49–1*Stages of Virus Replication and Possible Targets of Action of Antiviral Agents*

STAGE OF REPLICATION	CLASSES OF SELECTIVE INHIBITORS
Cell entry	
Attachment	Soluble receptor decoys, antireceptor antibodies, fusion protein inhibitors
Penetration	
Uncoating	Ion channel blockers, capsid stabilizers
Release of viral genome	
Transcription of viral genome*	Inhibitors of viral DNA polymerase, RNA polymerase, reverse transcriptase, helicase, primase, or integrase
Transcription of viral messenger RNA	
Replication of viral genome	
Translation of viral proteins	Interferons, antisense oligonucleotides, ribozymes
Regulatory proteins (early)	Inhibitors of regulatory proteins
Structural proteins (late)	
Posttranslational modifications	
Proteolytic cleavage	Protease inhibitors
Myristoylation, glycosylation	
Assembly of virion components	Interferons, assembly protein inhibitors
Release	Neuraminidase inhibitors, antiviral antibodies, cytotoxic lymphocytes
Budding, cell lysis	

*Depends on specific replication strategy of virus, but virus-specified enzyme required for part of process.

- Effective agents typically have a restricted spectrum of antiviral activity and target a specific viral protein, most often an enzyme involved in viral nucleic acid synthesis (polymerase or transcriptase) or viral protein processing (protease).
 - Single-nucleotide changes leading to critical amino acid substitutions in a target protein often are sufficient to cause antiviral drug resistance. Indeed, the selection of a drug-resistant variant indicates that a drug has a specific mechanism of antiviral action.
 - Current agents inhibit active replication, so viral replication may resume following drug removal. Effective host immune responses remain essential for recovery from infection. Clinical failures of antiviral therapy may occur with drug-sensitive virus in highly immunocompromised patients or following emergence of drug-resistant variants.
 - Most drug-resistant viruses are recovered from immunocompromised patients with high viral replicative loads and repeated or prolonged courses of antiviral treatment. (Influenza A virus is an exception.)
 - Current antiviral agents do not eliminate nonreplicating or latent virus, although some drugs have been used effectively for chronic suppression of disease reactivation.
 - Clinical efficacy depends on achieving inhibitory concentrations at the site of infection, usually within infected cells. For example, nucleoside analogs must be taken up and phosphorylated intracellularly for activity; consequently, concentrations of critical enzymes or competing substrates influence antiviral effects in cells of different types and in different metabolic states.
 - In vitro* sensitivity tests for antiviral agents are not standardized, except for selected viruses (*e.g.*, herpes simplex virus), and results depend on the assay system, cell type, viral inoculum, and laboratory. Therefore, clear relationships among drug concentrations active *in vitro*, those achieved in blood or other body fluids, and clinical response have not been established for most antiviral agents.
- Despite the clinical caveats implicit in these general principles, there are a number of useful antiviral agents and treatment strategies. Table 49–2 summarizes currently approved antiviral drugs. Their pharmacological properties are presented below, class by class, as listed in the table.

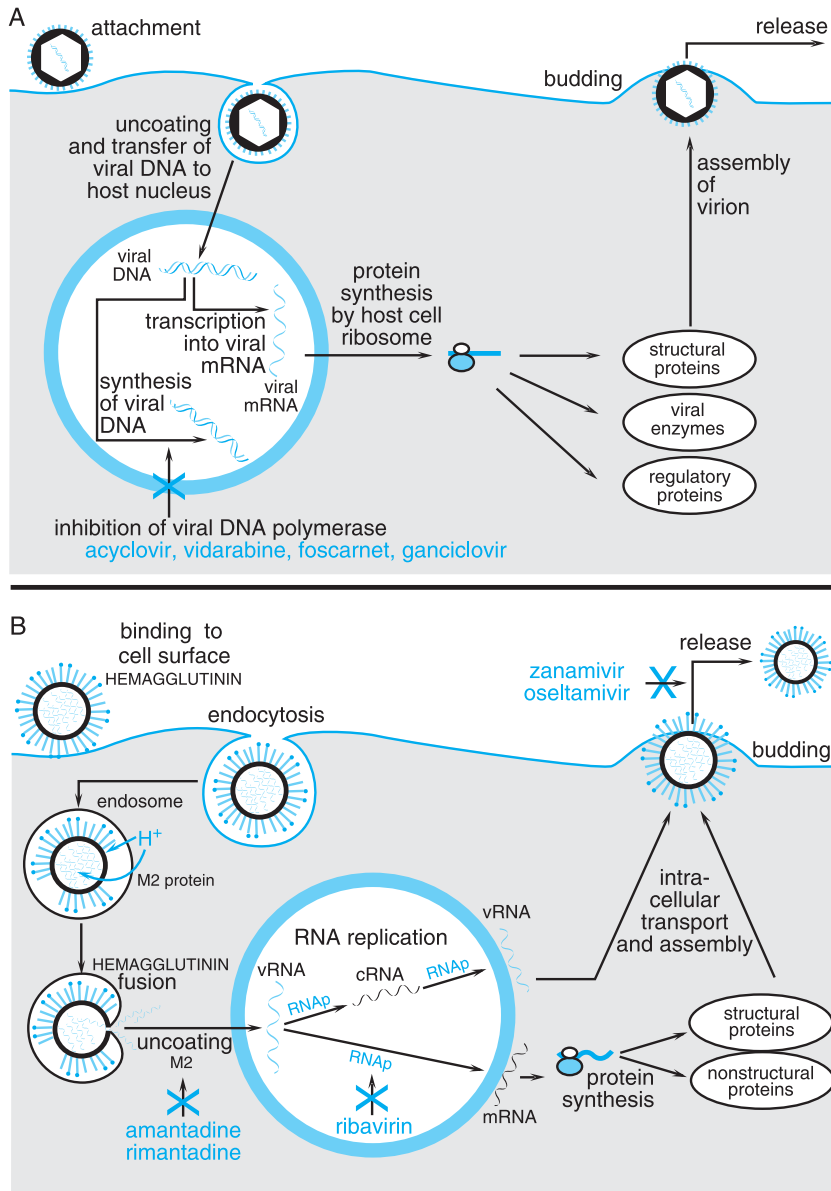

Figure 49–1. Replicative cycles of DNA (A) and RNA (B) viruses. The replicative cycles of herpesvirus (A) and influenza (B) are examples of DNA-encoded and RNA-encoded viruses, respectively. Sites of action of antiviral agents also are shown. Key: mRNA = messenger RNA; cDNA = complementary DNA; vRNA = viral RNA; DNAp = DNA polymerase; RNAp = RNA polymerase; cRNA = complementary RNA. An X on top of an arrow indicates a block to virus growth. **A.** Replicative cycles of herpes simplex virus, a DNA virus, and the probable sites of action of antiviral agents. Herpesvirus replication is a regulated multistep process. After infection, a small number of immediate-early genes are transcribed; these genes encode proteins that regulate their own synthesis and are responsible for synthesis of early genes involved in genome replication, such as thymidine kinases, DNA polymerases, etc. After DNA replication, the bulk of the herpesvirus genes (called *late genes*) are expressed and encode proteins that either are incorporated into or aid in the assembly of progeny virions. **B.** Replicative cycles of influenza, an RNA virus, and the loci for effects of antiviral agents. The mammalian cell shown is an airway epithelial cell. The M2 protein of influenza virus allows an influx of hydrogen ions into the virion interior, which in turn promotes dissociation of the RNP segments and release into the cytoplasm (uncoating). Influenza virus mRNA synthesis requires a primer cleared from cellular mRNA and used by the viral RNAP complex. The neuraminidase inhibitors zanamivir and oseltamivir specifically inhibit release of progeny virus. Small capitals indicate virus proteins.

Table 49–2

Nomenclature of Antiviral Agents

GENERIC NAME	OTHER NAMES	TRADE NAMES (USA)	DOSAGE FORMS AVAILABLE
Antiherpesvirus agents			
Acyclovir	ACV, acycloguanosine	ZOVIRAX	IV, O, T, ophth*
Cidofovir	HPMPC, CDV	VISTIDE	IV
Famciclovir	FCV	FAMVIR	O
Foscarnet	PFA, phosphonoformate	FOSCAVIR	IV, O*
Fomivirsen	ISIS 2922	VITRAVENE	Intravitreal
Ganciclovir	GCV, DHPG	CYTOVENE	IV, O, intravitreal
Idoxuridine	IDUR	HERPES, STOXIL, DENDRID	Ophth
Penciclovir	PCV	DENAVIR	T, IV*
Trifluridine	TFT, trifluorothymidine	VIROPTIC	Ophth
Valacyclovir		VALTREX	O
Valganciclovir		VALCYTE	O
Anti-influenza agents			
Amantadine		SYMMETREL	O
Oseltamivir	GS4104	TAMIFLU	O
Rimantadine		FLUMADINE	O
Zanamivir	GC167	RELENZA	Inhaled
Antihepatitis agents			
Adefovir dipivoxil	Bis-pom-PMEA	HEPSERA	O
Interferon-alfa		INTRON A, ROFERON A, INFERGEN, ALFERON N, WELLFERON*	Injected
Lamivudine	3TC	EPIVIR	O
Pegylated interferon alfa		PEGASYS, PEG-INTRON	SC
Other antiviral agents			
Ribavirin		VIRAZOLE, REBETOL, COPEGUS	O, inhaled, IV
Imiquimod		ALDARA	Topical

*Not currently approved for use in USA. ABBREVIATIONS: IV, intravenous; O, oral; T, topical; ophth, ophthalmic.

ANTIHERPESVIRUS AGENTS

Infection with herpes simplex virus type 1 (HSV-1) typically causes diseases of the mouth, face, skin, esophagus, or brain. Herpes simplex virus type 2 (HSV-2) usually causes infections of the genitals, rectum, skin, hands, or meninges. Both cause serious infections in neonates. HSV infection may be a primary one in a naive host, a nonprimary initial one in a host previously infected by other viruses, or the consequence of activation of a latent infection.

The first systemically administered antiherpesvirus agent, *vidarabine*, was approved by the Food and Drug

Administration (FDA) in 1977. However, its toxicities restricted its use to life-threatening infections of HSV and varicella-zoster virus (VZV). The discovery and development of *acyclovir*, approved in 1982, provided the first effective treatment for less severe HSV and VZV infections in ambulatory patients. Intravenous acyclovir is superior to vidarabine in terms of efficacy and toxicity in HSV encephalitis and in VZV infections of immunocompromised patients. Acyclovir is the prototype of a group of antiviral agents that are phosphorylated intracellularly by a viral kinase and subsequently by host cell enzymes to become inhibitors of viral DNA synthesis. Other agents employing this strategy include *penciclovir* and *ganciclovir*.

Acyclovir and Valacyclovir

Chemistry and Antiviral Activity. Acyclovir (9-[(2-hydroxy-ethoxy)methyl]-9H-guanine) is an acyclic guanine nucleoside analog that lacks a 3'-hydroxyl on the side chain. *Valacyclovir* is the L-valyl ester prodrug of acyclovir.

Acyclovir's clinically useful antiviral spectrum is limited to herpesviruses. *In vitro*, acyclovir is most active against HSV-1 (0.02 to 0.9 $\mu\text{g/ml}$), approximately half as active against HSV-2 (0.03 to 2.2 $\mu\text{g/ml}$), a tenth as potent against VZV (0.8 to 4.0 $\mu\text{g/ml}$) and Epstein-Barr virus (EBV), and least active against cytomegalovirus (CMV) (generally greater than 20 $\mu\text{g/ml}$) and human herpesvirus (HHV-6) (Wagstaff *et al.*, 1994). Uninfected mammalian cell growth generally is unaffected by high acyclovir concentrations (>50 $\mu\text{g/ml}$).

Mechanisms of Action and Resistance. Acyclovir inhibits viral DNA synthesis *via* a mechanism outlined in Figure 49-2 (Elion, 1986). Its selectivity of action depends on interaction with two distinct viral proteins: HSV thymidine kinase and DNA polymerase. Cellular uptake and initial phosphorylation are facilitated by HSV thymidine kinase. The affinity of acyclovir for HSV thymidine kinase is about 200 times greater than for the mammalian enzyme. Cellular enzymes convert the monophosphate to acyclovir triphosphate, which is present in forty- to one hundredfold higher concentrations in HSV-infected than in uninfected cells and competes for endogenous deoxyguanosine triphosphate (dGTP). The immunosuppressive agent *mycophenolate mofetil* (see Chapter 52) potentiates the antitherpes activity of acyclovir and related agents by depleting intracellular dGTP pools. Acyclovir triphosphate competitively inhibits viral DNA polymerases and, to a much smaller extent, cellular DNA polymerases. Acyclovir triphosphate also is incorporated into viral DNA, where it acts as a chain terminator because of the lack of a 3'-hydroxyl group. By a mechanism termed *suicide inactivation*, the terminated DNA template containing acyclovir binds the viral DNA polymerase and leads to its irreversible inactivation.

Acyclovir resistance in HSV has been linked to one of three mechanisms: absence or partial production of viral thymidine kinase, altered thymidine kinase substrate specificity (*e.g.*, phosphorylation of thymidine but not acyclo-

vir), or altered viral DNA polymerase. Alterations in viral enzymes are caused by point mutations and base insertions or deletions in the corresponding genes. Resistant variants are present in native virus populations, and heterogeneous mixtures of viruses occur in isolates from treated patients. The most common resistance mechanism in clinical HSV isolates is absent or deficient viral thymidine kinase activity; viral DNA polymerase mutants are rare. Phenotypic resistance typically is defined by *in vitro* inhibitory concentrations of greater than 2 to 3 $\mu\text{g/ml}$, which predict failure of therapy in immunocompromised patients.

Acyclovir resistance in VZV isolates is caused by mutations in VZV thymidine kinase and less often by mutations in viral DNA polymerase.

Absorption, Distribution, and Elimination. The oral bioavailability of acyclovir ranges from 10% to 30% and decreases with increasing dose (Wagstaff *et al.*, 1994). Peak plasma concentrations average 0.4 to 0.8 $\mu\text{g/ml}$ after 200-mg doses and 1.6 $\mu\text{g/ml}$ after 800-mg doses. Following intravenous dosing, peak and trough plasma concentrations average 9.8 and 0.7 $\mu\text{g/ml}$ after 5 mg/kg every 8 hours and 20.7 and 2.3 $\mu\text{g/ml}$ after 10 mg/kg every 8 hours, respectively.

Valacyclovir is converted rapidly and virtually completely to acyclovir after oral administration in healthy adults. This conversion is thought to result from first-pass intestinal and hepatic metabolism through enzymatic hydrolysis. Unlike acyclovir, valacyclovir is a substrate for intestinal and renal peptide transporters. The relative oral bioavailability of acyclovir increases three- to fivefold to approximately 70% following valacyclovir administration (Steingrimsdottir *et al.*, 2000). Peak acyclovir concentrations average 5 to 6 $\mu\text{g/ml}$ following single 1000-mg doses of oral valacyclovir and occur approximately 2 hours after dosing. Peak plasma concentrations of valacyclovir are only 4% of acyclovir levels. Less than 1% of an administered dose of valacyclovir is recovered in the urine, and most is eliminated as acyclovir.

Acyclovir distributes widely in body fluids, including vesicular fluid, aqueous humor, and cerebrospinal fluid. Compared with plasma, salivary concentrations are low, and vaginal secretion concentrations vary widely. Acyclovir is concentrated in breast milk, amniotic fluid, and placenta. Newborn plasma levels are similar to maternal ones. Percutaneous absorption of acyclovir after topical administration is low.

The mean plasma $t_{1/2}$ of elimination of acyclovir is about 2.5 hours, with a range of 1.5 to 6 hours in adults with normal renal function. The elimination $t_{1/2}$ of acyclovir is about 4 hours in neonates and increases to 20 hours in anuric patients (Wagstaff *et al.*, 1994). Renal excretion of unmetabolized acyclovir by glomerular filtration and tubular secretion is the principal route of elimination. Less than 15% is excreted as 9-carboxymethoxymethylguanine or minor metabolites. The pharmacokinetics of oral acyclovir and valacyclovir appear to be similar in pregnant and nonpregnant women (Kimberlin *et al.*, 1998).

Untoward Effects. Acyclovir generally is well tolerated. Topical acyclovir in a polyethylene glycol base may cause mucosal irritation and transient burning when applied to genital lesions.

Oral acyclovir has been associated infrequently with nausea, diarrhea, rash, or headache and very rarely with renal insufficiency

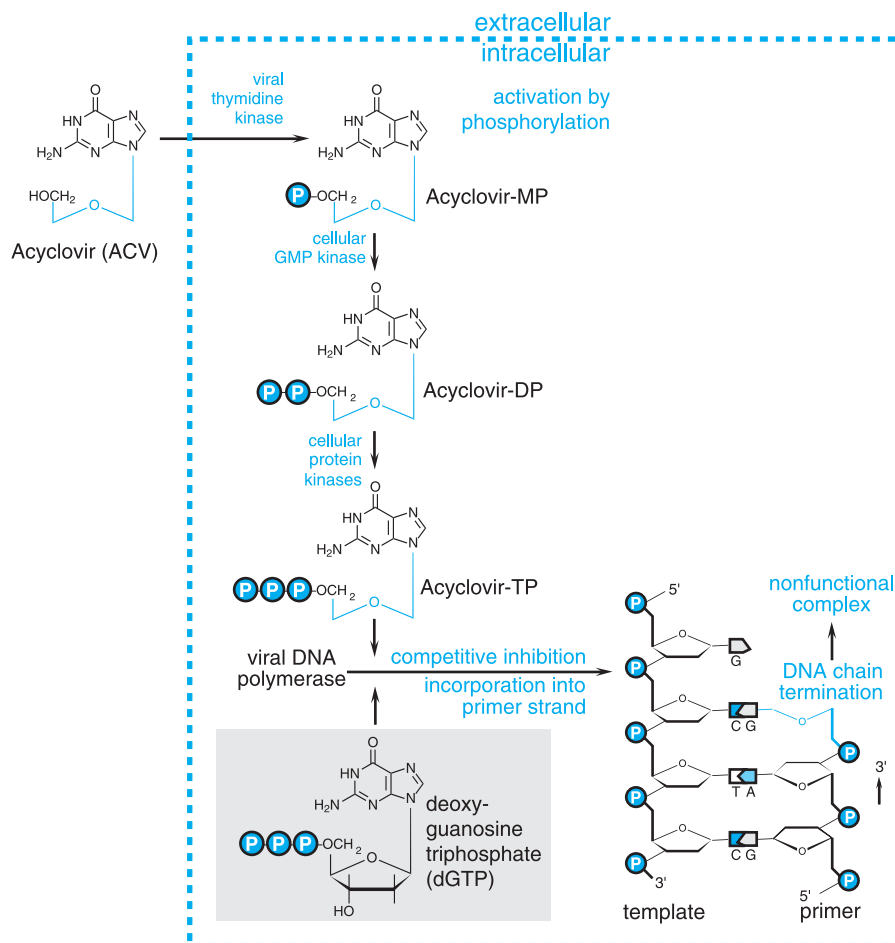

Figure 49-2. Conversion of acyclovir to acyclovir triphosphate leading to DNA chain termination. Acyclovir is converted to the monophosphate (MP) derivative by a herpesvirus thymidine kinase. Acyclovir-MP is then phosphorylated to acyclovir-DP and acyclovir-TP by cellular enzymes. Uninfected cells convert very little or no drug to the phosphorylated derivatives. Thus, acyclovir is selectively activated in cells infected with herpesviruses that code for appropriate thymidine kinases. Incorporation of acyclovir-MP from acyclovir-TP into the primer strand during viral DNA replication leads to chain termination and formation of an inactive complex with the viral DNA polymerase. (Adapted from Elion, 1986, with permission.)

or neurotoxicity. Valacyclovir also may be associated with headache, nausea, diarrhea, nephrotoxicity, and central nervous system (CNS) symptoms. High doses of valacyclovir have been associated with confusion and hallucinations, nephrotoxicity, and uncommonly, severe thrombocytopenic syndromes, sometimes fatal, in immunocompromised patients (Feinberg *et al.*, 1998). Acyclovir has been associated with neutropenia in neonates. Chronic acyclovir suppression of genital herpes has been used safely for up to 10 years. No excess frequency of congenital abnormalities has been recognized in infants born to women exposed to acyclovir during pregnancy (Ratanajamit *et al.*, 2003).

The principal dose-limiting toxicities of intravenous acyclovir are renal insufficiency and CNS side effects. Preexisting renal insufficiency, high doses, and high acyclovir plasma levels (>25 $\mu\text{g/ml}$) are risk factors for both. Reversible renal dysfunction occurs in approximately 5% of patients, probably related to high

urine levels causing crystalline nephropathy. Manifestations include nausea, emesis, flank pain, and increasing azotemia. Rapid infusion, dehydration, and inadequate urine flow increase the risk. Infusions should be given at a constant rate over at least an hour. Nephrotoxicity usually resolves with drug cessation and volume expansion. Neurotoxicity occurs in 1% to 4% of patients and may be manifested by altered sensorium, tremor, myoclonus, delirium, seizures, or extrapyramidal signs. Phlebitis following extravasation, rash, diaphoresis, nausea, hypotension, and interstitial nephritis also have been described. Hemodialysis may be useful in severe cases.

Severe somnolence and lethargy may occur with combinations of *zidovudine* and acyclovir. Concomitant *cyclosporine* and probably other nephrotoxic agents enhance the risk of nephrotoxicity. *Probenecid* decreases the acyclovir renal clearance and prolongs the plasma $t_{1/2}$ of elimination. Acyclovir may decrease the renal clear-

ance of other drugs eliminated by active renal secretion, such as *methotrexate*.

Therapeutic Uses. In immunocompetent persons, the clinical benefits of acyclovir and valacyclovir are greater in initial HSV infections than in recurrent ones, which typically are milder in severity (Whitley and Gnann, 1992). These drugs are particularly useful in immunocompromised patients because these individuals experience both more frequent and more severe HSV and VZV infections. Since VZV is less susceptible than HSV to acyclovir, higher doses must be used for treating varicella or zoster infections than for HSV infections. Oral valacyclovir is as effective as oral acyclovir in HSV infections and more effective for treating herpes zoster.

Herpes Simplex Virus Infections. In initial genital HSV infections, oral acyclovir (200 mg five times daily or 400 mg three times daily for 7 to 10 days) and valacyclovir (1000 mg twice daily for 7 to 10 days) are associated with significant reductions in virus shedding, symptoms, and time to healing (Kimberlin and Rouse, 2004). Intravenous acyclovir (5 mg/kg every 8 hours) has similar effects in patients hospitalized with severe primary genital HSV infections. Topical acyclovir is much less effective than systemic administration. None of these regimens reproducibly reduces the risk of recurrent genital lesions. Patient-initiated acyclovir (200 mg five times daily or 400 mg three times daily for 5 days or 800 mg three times daily for 2 days) or valacyclovir (500 mg twice daily for 3 or 5 days) shortens the manifestations of recurrent genital HSV episodes by 1 to 2 days. Frequently recurring genital herpes can be suppressed effectively with chronic oral acyclovir (400 mg twice daily or 200 mg three times daily) or with valacyclovir (500 mg or, for very frequent recurrences, 1000 mg once daily). During use, the rate of clinical recurrences decreases by about 90%, and subclinical shedding is markedly reduced, although not eliminated. Valacyclovir suppression of genital herpes reduces the risk of transmitting infection to a susceptible partner by about 50% over an 8-month period (Corey *et al.*, 2004). Chronic suppression may be useful in those with disabling recurrences of herpetic whitlow or HSV-related erythema multiforme.

Oral acyclovir is effective in primary herpetic gingivostomatitis (600 mg/m² four times daily for 10 days in children) but provides only modest clinical benefit in recurrent orolabial herpes. Short-term, high-dose valacyclovir (2 g twice over one day) shortens the duration of recurrent orolabial herpes by about one day (Anonymous, 2002). Topical acyclovir cream is modestly effective in recurrent labial (Spruance *et al.*, 2002) and genital herpes simplex virus infections. Preexposure acyclovir prophylaxis (400 mg twice daily for one week) reduces the overall risk of recurrence by 73% in those with sun-induced recurrences of HSV infections. Acyclovir during the last month of pregnancy reduces the likelihood of viral shedding and frequency of cesarean section in women with primary or recurrent genital herpes (Sheffield *et al.*, 2003).

In immunocompromised patients with mucocutaneous HSV infection, intravenous acyclovir (250 mg/m² every 8 hours for 7 days) shortens healing time, duration of pain, and the period of virus shedding. Oral acyclovir (800 mg five times per day) and valacyclovir (1000 mg twice daily) for 5 to 10 days are also effective. Recurrences

are common after cessation of therapy and may require long-term suppression. In those with very localized labial or facial HSV infections, topical acyclovir may provide some benefit. Intravenous acyclovir may be beneficial in viscerally disseminating HSV in immunocompromised patients and in patients with HSV-infected burn wounds.

Systemic acyclovir prophylaxis is highly effective in preventing mucocutaneous HSV infections in seropositive patients undergoing immunosuppression. Intravenous acyclovir (250 mg/m² every 8 to 12 hours) begun prior to transplantation and continuing for several weeks prevents HSV disease in bone marrow transplant recipients. For patients who can tolerate oral medications, oral acyclovir (400 mg five times daily) is effective, and long-term oral acyclovir (200 to 400 mg three times daily for 6 months) also reduces the risk of VZV infection (Steer *et al.*, 2000). In HSV encephalitis, acyclovir (10 mg/kg every 8 hours for a minimum of 10 days) reduces mortality by over 50% and improves overall neurologic outcome compared with vidarabine. Higher doses (15 to 20 mg/kg every 8 hours) and prolonged treatment (up to 21 days) are recommended by many experts. Intravenous acyclovir (20 mg/kg every 8 hours for 21 days) is more effective than lower doses in viscerally invasive neonatal HSV infections (Kimberlin *et al.*, 2001). In neonates and immunosuppressed patients and, rarely, in previously healthy persons, relapses of encephalitis following acyclovir may occur. The value of continuing long-term suppression with valacyclovir after completing intravenous acyclovir is under study.

An ophthalmic formulation of acyclovir (not available in the United States) is at least as effective as topical vidarabine or *trifluridine* in herpetic keratoconjunctivitis.

Infection owing to resistant HSV is rare in immunocompetent persons; however, in immunocompromised hosts, acyclovir-resistant HSV isolates can cause extensive mucocutaneous disease and, rarely, meningoencephalitis, pneumonitis, or visceral disease. Resistant HSV can be recovered from 6% to 17% of immunocompromised patients receiving acyclovir treatment (Bacon *et al.*, 2003). Recurrences after cessation of acyclovir usually are due to sensitive virus but may be due to acyclovir-resistant virus in AIDS patients. In patients with progressive disease, intravenous *foscarnet* therapy is effective, but vidarabine is not (Chilukuri and Rosen, 2003).

Varicella-Zoster Virus Infections. If begun within 24 hours of rash onset, oral acyclovir has therapeutic effects in varicella of children and adults. In children weighing up to 40 kg, acyclovir (20 mg/kg, up to 800 mg per dose, four times daily for 5 days) reduces fever and new lesion formation by about one day. Routine use in uncomplicated pediatric varicella is not recommended but should be considered in those at risk of moderate-to-severe illness (persons over 12 years old, secondary household cases, those with chronic cutaneous or pulmonary disorders, or those receiving *corticosteroids* or long-term *salicylates*) (Committee on Infectious Diseases American Academy of Pediatrics, 2003). In adults treated within 24 hours, oral acyclovir (800 mg five times daily for 7 days) reduces the time to crusting of lesions by approximately 2 days, the maximum number of lesions by one-half, and the duration of fever (Wallace *et al.*, 1992). Intravenous acyclovir appears to be effective in varicella pneumonia or encephalitis of previously healthy adults. Oral acyclovir (10 mg/kg four times daily) given between 7 and 14 days after exposure may reduce the risk of varicella.

In older adults with localized herpes zoster, oral acyclovir (800 mg five times daily for 7 days) reduces pain and healing times if treatment can be initiated within 72 hours of rash onset. A reduction in ocular complications, particularly keratitis and anterior uveitis, occurs with treatment of zoster ophthalmicus. Prolonged acyclovir

and concurrent *prednisone* for 21 days speed zoster healing and improve quality-of-life measures compared with each therapy alone. Valacyclovir (1000 mg three times daily for 7 days) provides more prompt relief of zoster-associated pain than acyclovir in older adults (≥ 50 years) with zoster (Beutner *et al.*, 1995).

In immunocompromised patients with herpes zoster, intravenous acyclovir (500 mg/m² every 8 hours for 7 days) reduces viral shedding, healing time, and the risks of cutaneous dissemination and visceral complications, as well as the length of hospitalization, in disseminating zoster. In immunosuppressed children with varicella, intravenous acyclovir decreases healing time and the risk of visceral complications.

Acyclovir-resistant VZV isolates uncommonly have been recovered from HIV-infected children and adults who may manifest chronic hyperkeratotic or verrucous lesions and sometimes meningoradiculitis. Intravenous foscarnet also appears to be effective for acyclovir-resistant VZV infections.

Other Viruses. Acyclovir is ineffective therapeutically in established cytomegalovirus (CMV) infections but has been used for CMV prophylaxis in immunocompromised patients. High-dose intravenous acyclovir (500 mg/m² every 8 hours for one month) in CMV-seropositive bone marrow transplant recipients is associated with about 50% lower risk of CMV disease and, when combined with prolonged oral acyclovir (800 mg four times daily through 6 months), improves survival (Prentice *et al.*, 1994). Following engraftment, valacyclovir (2000 mg four times daily to day 100) appears as effective as intravenous ganciclovir prophylaxis in such patients (Winston *et al.*, 2003). High-dose oral acyclovir or valacyclovir (2000 mg four times daily) suppression for 3 months may reduce the risk of CMV disease and its sequelae in certain solid-organ transplant recipients (Lowance *et al.*, 1999), but oral *valganciclovir* is the preferred agent for mismatched graft recipients (Pereyra and Rubin, 2004). Compared with acyclovir, high-dose valacyclovir reduces CMV disease in advanced HIV infection but is associated with greater toxicity and possibly shorter survival (Feinberg *et al.*, 1998).

In infectious mononucleosis, acyclovir is associated with transient antiviral effects but no clinical benefits. EBV-related oral hairy leukoplakia may improve with acyclovir. Oral acyclovir in conjunction with systemic corticosteroids appears beneficial in treating Bell's palsy, but valacyclovir is ineffective in acute vestibular neuritis.

Cidofovir

Chemistry and Antiviral Activity. *Cidofovir* (1-[(*S*)-3-hydroxy-2-(phosphonomethoxy)-propyl]cytosine dihydrate) is a cytidine nucleotide analog with inhibitory activity against human herpes, papilloma, polyoma, pox, and adenoviruses (Hitchcock *et al.*, 1996).

In vitro inhibitory concentrations range from greater than 0.2 to 0.7 $\mu\text{g/ml}$ for CMV, 0.4 to 33 $\mu\text{g/ml}$ for HSV, and 0.02 to 17 $\mu\text{g/ml}$ for adenoviruses. Because cidofovir is a phosphonate that is phosphorylated by cellular but not virus enzymes, it inhibits acyclovir-resistant thymidine kinase (TK)-deficient or TK-altered HSV or VZV strains, ganciclovir-resistant CMV strains with UL97 mutations but not those with DNA polymerase mutations, and some foscarnet-resistant CMV strains. Cidofovir synergistically inhibits CMV replication in combination with ganciclovir or foscarnet. Ether lipid esters of cidofovir are orally active in animal models of poxvirus and CMV infections (Kern *et al.*, 2004).

Mechanisms of Action and Resistance. Cidofovir inhibits viral DNA synthesis by slowing and eventually terminating chain elongation. Cidofovir is metabolized to its active diphosphate form by cellular enzymes; the levels of phosphorylated metabolites are similar in infected and uninfected cells. The diphosphate acts as both a competitive inhibitor with respect to dCTP and as an alternative substrate for viral DNA polymerase. The diphosphate has a prolonged intracellular half-life and competitively inhibits CMV and HSV DNA polymerases at concentrations one-eighth to one six-hundredth of those required to inhibit human DNA polymerases (Hitchcock *et al.*, 1996). A phosphocholine metabolite has a prolonged intracellular half-life (~87 hours) and may serve as an intracellular reservoir of drug. The prolonged intracellular half-life of cidofovir diphosphate allows infrequent dosing regimens, and single doses are effective in experimental HSV, varicella, and poxvirus infections.

Cidofovir resistance in CMV is due to mutations in viral DNA polymerase. Low-level resistance to cidofovir develops in up to about 30% of retinitis patients by 3 months of therapy. Highly ganciclovir-resistant CMV isolates that possess DNA polymerase and UL97 kinase mutations are resistant to cidofovir, and prior ganciclovir therapy may select for cidofovir resistance. Some foscarnet-resistant CMV isolates show cross-resistance to cidofovir, and triple-drug-resistant variants with DNA polymerase mutations occur.

Absorption, Distribution, and Elimination. Cidofovir is dianionic at physiological pH and has very low oral bioavailability (Cundy, 1999). The plasma levels after intravenous dosing decline in a biphasic pattern with a terminal half-life that averages about 2.6 hours. The volume of distribution approximates total-body water. Penetration into the CNS or eye has not been well characterized, but cerebrospinal fluid (CSF) levels are low. Extemporaneously compounded topical cidofovir gel may result in low plasma concentrations ($< 0.5 \mu\text{g/ml}$) in patients with large mucocutaneous lesions.

Cidofovir is cleared by the kidney *via* glomerular filtration and tubular secretion. Over 90% of the dose is recovered unchanged in the urine without significant metabolism in human beings. The probenecid-sensitive organic anion transporter 1 mediates uptake of cidofovir into proximal renal tubular epithelial cells (Ho *et al.*, 2000). High-dose probenecid (2 g 3 hours before and 1 g 2 and 8 hours after each infusion) blocks tubular transport of cidofovir and reduces renal clearance and associated nephrotoxicity. At cidofovir doses of 5 mg/kg, peak plasma concentrations increase from 11.5 to 19.6 $\mu\text{g/ml}$ with probenecid, and renal clearance is reduced to the level of glomerular filtration. Elimination relates linearly to creatinine clearance, and the half-life increases to 32.5 hours in patients on chronic ambulatory peritoneal dialysis (CAPD). Both CAPD and hemodialysis remove over 50% of the administered dose (Cundy, 1999).

Untoward Effects. Nephrotoxicity is the principal dose-limiting side effect of intravenous cidofovir. Proximal tubular dysfunction includes proteinuria, azotemia, glycosuria, metabolic acidosis, and uncommonly, Fanconi's syndrome. Concomitant oral probenecid (*see* above) and saline prehydration reduce the risk of renal toxicity. On maintenance doses of 5 mg/kg every 2 weeks, up to 50% of patients develop proteinuria, 10% to 15% show an elevated serum creatinine concentration, and 15% to 20% develop neutropenia. Anterior uveitis that is responsive to topical corticosteroids and cycloplegia occurs commonly and ocular hypotony occurs infrequently with intravenous cidofovir. Concurrent probenecid administration is associated with gastrointestinal upset, constitutional symptoms, and hypersensitivity reactions, including fever, rash, and uncommonly, anaphylactoid manifestations. Administration with food and pretreatment with *antiemetics*, *antihistamines*, and/or *acetaminophen* may improve tolerance.

Probenecid but not cidofovir alters zidovudine pharmacokinetics such that zidovudine doses should be reduced when probenecid is present, as should the doses of drugs similarly affected by probenecid [*e.g.*, β -lactam antibiotics, nonsteroidal antiinflammatory drugs (NSAIDs), acyclovir, lorazepam, furosemide, methotrexate, theophylline, and rifampin]. Concurrent nephrotoxic agents are contraindicated, and an interval of at least 7 days before beginning cidofovir treatment is recommended after prior exposure to an *aminoglycoside*, intravenous *pentamidine*, *amphotericin B*, foscarnet, NSAID, or contrast dye. Cidofovir and oral ganciclovir are poorly tolerated in combination at full doses.

Topical application of cidofovir is associated with dose-related application-site reactions (*e.g.*, burning, pain, and pruritus) in up to one-third of patients and occasionally ulceration. Intravitreal cidofovir may cause vitritis, hypotony, and visual loss and is contraindicated.

Preclinical studies indicate that cidofovir has mutagenic, gonadotoxic, embryotoxic, and teratogenic effects. Because cidofovir is carcinogenic in rats, it is considered a potential human carcinogen. It may cause infertility and is classified as pregnancy category C.

Therapeutic Uses. Intravenous cidofovir is approved for the treatment of CMV retinitis in HIV-infected patients. Intravenous cidofovir (5 mg/kg once a week for 2 weeks followed by dosing every 2 weeks) increases the time to progression of CMV retinitis in previously untreated patients and in those failing or intolerant of ganciclovir and foscarnet therapy. CMV viremia may persist during cido-

fovir administration. Maintenance doses of 5 mg/kg are more effective but less well tolerated than 3 mg/kg doses. Intravenous cidofovir has been used for treating acyclovir-resistant mucocutaneous HSV infection, adenovirus disease in transplant recipients (Ljungman *et al.*, 2003), and progressive multifocal leukoencephalopathy or extensive molluscum contagiosum in HIV patients. Reduced doses (0.25 to 1 mg/kg every 2 to 3 weeks) without probenecid may be beneficial in BK virus nephropathy in renal transplant patients (Vats *et al.*, 2003).

Extemporaneously compounded topical cidofovir gel eliminates virus shedding and lesions in some HIV-infected patients with acyclovir-resistant mucocutaneous HSV infections and has been used in treating anogenital warts and molluscum contagiosum in immunocompromised patients and cervical intraepithelial neoplasia in women. Intralesional cidofovir induces remissions in adults and children with respiratory papillomatosis.

Docosanol

Docosanol is a long-chain saturated alcohol that has been approved by the FDA as a 10% over-the-counter cream for the treatment of recurrent orolabial herpes. Docosanol inhibits the *in vitro* replication of many lipid-enveloped viruses, including HSV, at millimolar concentrations. It does not inactivate HSV directly but appears to block fusion between the cellular and viral envelope membranes and inhibit viral entry into the cell. Topical treatment beginning within 12 hours of prodromal symptoms or lesion onset reduces healing time by about one day and appears to be well tolerated (Anonymous, 2000). Treatment initiation at papular or later stages provides no benefit.

Famciclovir and Penciclovir

Chemistry and Antiviral Activity. *Famciclovir* is the diacetyl ester prodrug of 6-deoxy penciclovir and lacks intrinsic antiviral activity. *Penciclovir* (9-[4-hydroxy-3-hydroxymethylbut-1-yl] guanine) is an acyclic guanine nucleoside analog. The side chain differs structurally in that the oxygen has been replaced by a carbon, and an additional hydroxymethyl group is present. The structure of penciclovir is

Penciclovir is similar to acyclovir in its spectrum of activity and potency against HSV and VZV (Safrin *et al.*, 1997). The inhibitory concentrations of penciclovir

depend on cell type but are usually within twofold of those of acyclovir for HSV and VZV. It also is inhibitory for HBV.

Mechanisms of Action and Resistance. Penciclovir is an inhibitor of viral DNA synthesis. In HSV- or VZV-infected cells, penciclovir is phosphorylated initially by viral thymidine kinase. Penciclovir triphosphate serves as a competitive inhibitor of viral DNA polymerase (Safran *et al.*, 1997) (Figure 49–2). Although penciclovir triphosphate is approximately one one-hundredth times as potent as acyclovir triphosphate in inhibiting viral DNA polymerase, it is present in much higher concentrations and for more prolonged periods in infected cells than acyclovir triphosphate. The prolonged intracellular $t_{1/2}$ of penciclovir triphosphate, 7 to 20 hours, is associated with prolonged antiviral effects. Because penciclovir has a 3'-hydroxyl group, it is not an obligate chain terminator but does inhibit DNA elongation.

Resistant variants owing to thymidine kinase or DNA polymerase mutations can be selected by passage *in vitro*, but the occurrence of resistance during clinical use is currently low (Bacon *et al.*, 2003). Thymidine kinase-deficient, acyclovir-resistant herpes viruses are cross-resistant to penciclovir.

Absorption, Distribution, and Elimination. Oral penciclovir has low (5%) bioavailability. In contrast, famciclovir is well absorbed orally and converted rapidly to penciclovir by deacetylation of the side chain and oxidation of the purine ring during and following absorption from the intestine (Gill and Wood, 1996). The bioavailability of penciclovir is 65% to 77% following oral administration of famciclovir. Food slows absorption but does not reduce overall bioavailability. After single 250- or 500-mg doses of famciclovir, the peak plasma concentration of penciclovir averages 1.6 and 3.3 $\mu\text{g/ml}$, respectively. A small quantity of the 6-deoxy precursor but no famciclovir is detectable in plasma. After intravenous infusion of penciclovir at 10 mg/kg, peak plasma levels average 12 $\mu\text{g/ml}$. The volume of distribution is about twice the volume of total-body water. The plasma $t_{1/2}$ of elimination of penciclovir averages about 2 hours, and over 90% is excreted unchanged in the urine, probably by both filtration and active tubular secretion. Following oral famciclovir administration, nonrenal clearance accounts for about 10% of each dose, primarily through fecal excretion, but penciclovir (60% of dose) and its 6-deoxy precursor (<10% of dose) are eliminated primarily in the urine. The plasma half-life averages 9.9 hours in renal insufficiency ($\text{Cl}_{\text{cr}} < 30 \text{ ml/min}$); hemodialysis efficiently removes penciclovir. Lower peak plasma concentrations of penciclovir but no reduction in overall bioavailability occur in compensated chronic hepatic insufficiency (Boike *et al.*, 1994).

Untoward Effects. Oral famciclovir is well tolerated but may be associated with headache, diarrhea, and nausea. Urticaria, rash, and hallucinations or confusional states (predominantly in the elderly) have been reported. Topical penciclovir, which is formulated in

40% propylene glycol and a cetomacrogol base, is associated infrequently with application-site reactions (~1%). The short-term tolerance of famciclovir is comparable with that of acyclovir.

Penciclovir is mutagenic at high concentrations *in vitro*. Although studies in laboratory animals indicate that chronic famciclovir administration is tumorigenic and decreases spermatogenesis and fertility in rodents and dogs, long-term administration (1 year) does not affect spermatogenesis in men. No teratogenic effects have been observed in animals, but safety during pregnancy has not been established.

No clinically important drug interactions have been identified to date with famciclovir or penciclovir (Gill and Wood, 1996).

Therapeutic Uses. Oral famciclovir, topical penciclovir, and intravenous penciclovir are approved for managing HSV and VZV infections in various countries (Sacks and Wilson, 1999). Oral famciclovir (250 mg three times a day for 7 to 10 days) is as effective as acyclovir in treating first-episode genital herpes (Kimberlin and Rouse, 2004). In patients with recurrent genital HSV, patient-initiated famciclovir treatment (125 or 250 mg twice a day for 5 days) reduces healing time and symptoms by about one day. Famciclovir (250 mg twice a day for up to 1 year) is effective for suppression of recurrent genital HSV, but single daily doses are less effective. Higher doses (500 mg twice a day) reduce HSV recurrences in HIV-infected persons. Intravenous penciclovir (5 mg/kg every 8 or 12 hours for 7 days) is comparable with intravenous acyclovir for treating mucocutaneous HSV infections in immunocompromised hosts (Lazarus *et al.*, 1999). In immunocompetent persons with recurrent orolabial HSV, topical 1% penciclovir cream (applied every 2 hours while awake for 4 days) shortens healing time and symptoms by about one day (Raborn *et al.*, 2002).

In immunocompetent adults with herpes zoster of 3 days' duration or less, famciclovir (500 mg three times a day for 10 days) is at least as effective as acyclovir (800 mg five times daily) in reducing healing time and zoster-associated pain, particularly in those 50 years of age and older. Famciclovir is comparable with valacyclovir in treating zoster and reducing associated pain in older adults (Tyring *et al.*, 2000). Famciclovir (500 mg three times a day for 7 to 10 days) also is comparable with high-dose oral acyclovir in treating zoster in immunocompromised patients and in those with ophthalmic zoster (Tyring *et al.*, 2001).

Famciclovir is associated with dose-related reductions in HBV DNA and transaminase levels in patients with chronic HBV hepatitis but is less effective than lamivudine (Lai *et al.*, 2002). Famciclovir is also ineffective in treating lamivudine-resistant HBV infections owing to emergence of multiply resistant variants.

Fomivirsen

Fomivirsen, a 21-base phosphorothioate oligionucleotide, is the first FDA-approved antisense therapy for viral infections. It is complementary to the messenger RNA sequence for the major immediate-early transcriptional region of CMV and inhibits CMV replication through sequence-specific and nonspecific mechanisms, including inhibition of virus binding to cells. Fomivirsen is active against CMV strains resistant to ganciclovir, foscarnet, and cidofovir. CMV variants with tenfold

reduced susceptibility to fomivirsen have been selected by *in vitro* passage.

Fomivirsen is given by intravitreal injection in the treatment of CMV retinitis for patients intolerant of or unresponsive to other therapies. Following injection, it is cleared slowly from the vitreous ($t_{1/2}$ of approximately 55 hours) through distribution to the retina and probable exonuclease digestion (Geary *et al.*, 2002). Local metabolism by exonucleases accounts for elimination. In HIV-infected patients with refractory, sight-threatening CMV retinitis, fomivirsen injections (330 μg weekly for 3 weeks and then every 2 weeks or on days 1 and 15 followed by monthly) significantly delay time to retinitis progression (Vitravene Study Group, 2002). Ocular side effects include iritis in up to one-quarter of patients, which can be managed with topical corticosteroids; vitritis; cataracts; and increases in intraocular pressure in 15% to 20% of patients. Recent cidofovir use may increase the risk of inflammatory reactions.

Foscarnet

Chemistry and Antiviral Activity. Foscarnet (trisodium phosphonoformate) is an inorganic pyrophosphate analog that is inhibitory for all herpesviruses and HIV (Wagstaff and Bryson, 1994).

In vitro inhibitory concentrations are generally 100 to 300 μM for CMV and 80 to 200 μM for other herpesviruses, including most ganciclovir-resistant CMV and acyclovir-resistant HSV and VZV strains. Combinations of foscarnet and ganciclovir synergistically inhibit CMV replication *in vitro*. Concentrations of 500 to 1000 μM reversibly inhibit the proliferation and DNA synthesis of uninfected cells.

Mechanisms of Action and Resistance. Foscarnet inhibits viral nucleic acid synthesis by interacting directly with herpesvirus DNA polymerase or HIV reverse transcriptase (Chrisp and Clissold, 1991) (Figure 49–1B). It is taken up slowly by cells and does not undergo significant intracellular metabolism. Foscarnet reversibly blocks the pyrophosphate binding site of the viral polymerase in a noncompetitive manner and inhibits cleavage of pyrophosphate from deoxynucleotide triphosphates. Foscarnet has approximately one hundredfold greater inhibitory effects against herpesvirus DNA polymerases than against cellular DNA polymerase α .

Herpesviruses resistant to foscarnet have point mutations in the viral DNA polymerase and are associated with three- to sevenfold reductions in foscarnet activity *in vitro*.

Absorption, Distribution, and Elimination. Oral bioavailability of foscarnet is low. Following an intravenous infusion of 60 mg/kg every 8 hours, peak and trough plasma concentrations are approximately 450 to 575 and 80 to 150 μM , respectively. Vitreous levels approximate those in plasma, and CSF levels average 66% of those in plasma at steady state.

Over 80% of foscarnet is excreted unchanged in the urine by glomerular filtration and probably tubular secretion. Plasma clearance decreases proportionately with creatinine clearance, and dose adjustments are indicated for small decreases in renal function. Plasma elimination is complex, with initial bimodal half-lives totaling 4 to 8 hours and a prolonged terminal $t_{1/2}$ for elimination averaging 3 to 4 days. Sequestration in bone with gradual release accounts for the fate of an estimated 10% to 20% of a given dose. Foscarnet is cleared efficiently by hemodialysis (~50% of a dose).

Untoward Effects. Foscarnet's major dose-limiting toxicities are nephrotoxicity and symptomatic hypocalcemia. Increases in serum creatinine occur in up to one-half of patients but are reversible after cessation in most patients. High doses, rapid infusion, dehydration, prior renal insufficiency, and concurrent nephrotoxic drugs are risk factors. Acute tubular necrosis, crystalline glomerulopathy, nephrogenic diabetes insipidus, and interstitial nephritis have been described. Saline loading may reduce the risk of nephrotoxicity.

Foscarnet is highly ionized at physiological pH, and metabolic abnormalities are very common. These include increases or decreases in Ca^{2+} and phosphate, hypomagnesemia, and hypokalemia. Decreased serum ionized Ca^{2+} may cause paresthesia, arrhythmias, tetany, seizures, and other CNS disturbances. Concomitant intravenous *pentamidine* administration increases the risk of symptomatic hypocalcemia. Parenteral *magnesium sulfate* does not alter foscarnet-induced hypocalcemia or symptoms (Huycke *et al.*, 2000).

CNS side effects include headache in approximately 25% of patients, tremor, irritability, seizures, and hallucinosis. Other reported side effects are generalized rash, fever, nausea or emesis, anemia, leukopenia, abnormal liver function tests, electrocardiographic changes, infusion-related thrombophlebitis, and painful genital ulcerations. Topical foscarnet may cause local irritation and ulceration, and oral foscarnet may cause gastrointestinal disturbance. Preclinical studies indicate that high foscarnet concentrations are mutagenic and may cause tooth and skeletal abnormalities in developing laboratory animals. Safety in pregnancy or childhood is uncertain.

Therapeutic Uses. Intravenous foscarnet is effective for treatment of CMV retinitis, including ganciclovir-resistant infections, other types of CMV infection, and acyclovir-resistant HSV and VZV infections (Wagstaff and Bryson, 1994). Foscarnet is poorly soluble in aqueous solutions and requires large volumes for administration.

In CMV retinitis in AIDS patients, foscarnet (60 mg/kg every 8 hours or 90 mg/kg every 12 hours for 14 to 21 days followed by chronic maintenance at 90 to 120 mg/kg every day in one dose) is

associated with clinical stabilization in about 90% of patients (Wagstaff and Bryson, 1994). A comparative trial of foscarnet with ganciclovir found comparable control of CMV retinitis in AIDS patients but improved overall survival in the foscarnet-treated group (Anonymous, 1992). This improved survival with foscarnet may be related to the drug's intrinsic anti-HIV activity, but patients stop taking foscarnet over three times as often as ganciclovir because of side effects. A combination of foscarnet and ganciclovir is more effective than either drug alone in refractory retinitis; combinations may be useful in treating ganciclovir-resistant CMV infections in solid-organ transplant patients. Foscarnet benefits other CMV syndromes in AIDS or transplant patients but is ineffective as monotherapy in treating CMV pneumonia in bone marrow transplant patients. When used for preemptive therapy of CMV viremia in bone marrow transplant recipients, foscarnet (60 mg/kg every 12 hours for 2 weeks followed by 90 mg/kg daily for 2 weeks) is as effective as intravenous ganciclovir and causes less neutropenia (Reusser *et al.*, 2002). When used for CMV infections, foscarnet may reduce the risk of Kaposi's sarcoma in HIV-infected patients. Intravitreal injections of foscarnet also have been used.

In acyclovir-resistant mucocutaneous HSV infections, lower doses of foscarnet (40 mg/kg every 8 hours for 7 days or longer) are associated with cessation of viral shedding and with complete healing of lesions in about three-quarters of patients. Foscarnet also appears to be effective in acyclovir-resistant VZV infections. Topical foscarnet cream is ineffective in treating recurrent genital HSV in immunocompetent persons but appears to be useful in chronic acyclovir-resistant infections in immunocompromised patients.

Resistant clinical isolates of herpesviruses have emerged during therapeutic use and may be associated with poor clinical response to foscarnet treatment.

Ganciclovir and Valganciclovir

Chemistry and Antiviral Activity. Ganciclovir (9-[1,3-dihydroxy-2-propoxymethyl] guanine) is an acyclic guanine nucleoside analog that is similar in structure to acyclovir except in having an additional hydroxymethyl group on the acyclic side chain. Valganciclovir is the L-valyl ester prodrug of ganciclovir. The structure of ganciclovir is

This agent has inhibitory activity against all herpesviruses but is especially active against CMV (Noble and Faulds, 1998). Inhibitory concentrations are similar to those of acyclovir for HSV and VZV but 10 to 100 times lower for human CMV strains (0.2 to 2.8 $\mu\text{g/ml}$).

Inhibitory concentrations for human bone marrow progenitor cells are similar to those inhibitory for CMV replication, a finding predictive of ganciclovir's myelotoxicity during clinical use. Inhibition of human lymphocyte blastogenic responses also occurs at clinically achievable concentrations of 1 to 10 $\mu\text{g/ml}$.

Mechanisms of Action and Resistance. Ganciclovir inhibits viral DNA synthesis. It is monophosphorylated intracellularly by viral thymidine kinase during HSV infection and by a viral phosphotransferase encoded by the UL97 gene during CMV infection. Ganciclovir diphosphate and ganciclovir triphosphate are formed by cellular enzymes. At least tenfold higher concentrations of ganciclovir triphosphate are present in CMV-infected than in uninfected cells. The triphosphate is a competitive inhibitor of deoxyguanosine triphosphate incorporation into DNA and preferentially inhibits viral rather than host cellular DNA polymerases. Ganciclovir is incorporated into both viral and cellular DNA. Incorporation into viral DNA causes eventual cessation of DNA chain elongation (Figures 49-1B and 49-2).

Intracellular ganciclovir triphosphate concentrations are tenfold higher than those of acyclovir triphosphate and decline much more slowly with an intracellular $t_{1/2}$ of elimination exceeding 24 hours. These differences may account in part for ganciclovir's greater anti-CMV activity and provide the rationale for single daily doses in suppressing human CMV infections.

CMV can become resistant to ganciclovir by one of two mechanisms: reduced intracellular ganciclovir phosphorylation owing to mutations in the viral phosphotransferase encoded by the UL97 gene and mutations in viral DNA polymerase (Gilbert *et al.*, 2002). Resistant CMV clinical isolates have 4 to more than 20 times increases in inhibitory concentrations. Resistance has been associated primarily with impaired phosphorylation but sometimes only with DNA polymerase mutations. Highly resistant variants with dual UL97 and polymerase mutations are cross-resistant to cidofovir and variably to foscarnet. Ganciclovir also is much less active against acyclovir-resistant thymidine kinase-deficient HSV strains.

Absorption, Distribution, and Elimination. The oral bioavailability of ganciclovir averages 6% to 9% following ingestion with food. Peak and trough plasma levels are about 0.5 to 1.2 and 0.2 to 0.5 $\mu\text{g/ml}$, respectively, after 1000-mg doses every 8 hours. Oral valganciclovir is well absorbed and hydrolyzed rapidly to ganciclovir; the bioavailability of ganciclovir averages 61% following valganciclovir (Curran and Noble, 2001). Food increases the bio-

availability of valganciclovir by about 25%, and peak ganciclovir concentrations average 6.1 $\mu\text{g/ml}$ after 875-mg doses. High oral valganciclovir doses in the fed state provide ganciclovir exposures comparable with intravenous dosing (Brown *et al.*, 1999). Following intravenous administration of 5 mg/kg doses of ganciclovir, peak and trough plasma concentrations average 8 to 11 and 0.6 to 1.2 $\mu\text{g/ml}$, respectively. Following intravenous dosing, vitreous fluid levels are similar to or higher than those in plasma and average about 1 $\mu\text{g/ml}$. Vitreous levels decline with a half-life of 23 to 26 hours. Intraocular sustained-release ganciclovir implants provide vitreous levels of about 4.1 $\mu\text{g/ml}$.

The plasma half-life is about 2 to 4 hours in patients with normal renal function. Over 90% of ganciclovir is eliminated unchanged by renal excretion through glomerular filtration and tubular secretion. Consequently, the plasma $t_{1/2}$ increases almost linearly as creatinine clearance declines and may reach 28 to 40 hours in those with severe renal insufficiency.

Untoward Effects. Myelosuppression is the principal dose-limiting toxicity of ganciclovir. Neutropenia occurs in about 15% to 40% of patients and thrombocytopenia in 5% to 20% (Faulds and Heel, 1990). Neutropenia is observed most commonly during the second week of treatment and usually is reversible within 1 week of drug cessation. Persistent fatal neutropenia has occurred. Oral valganciclovir is associated with headache and gastrointestinal disturbance (*i.e.*, nausea, pain, and diarrhea) in addition to the toxicities associated with intravenous ganciclovir, including neutropenia. Recombinant *granulocyte colony-stimulating factor* (G-CSF, *filgrastim*, *lenograstim*) may be useful in treating ganciclovir-induced neutropenia (*see* Chapter 53).

CNS side effects occur in 5% to 15% of patients and range in severity from headache to behavioral changes to convulsions and coma. About one-third of patients have had to interrupt or prematurely stop intravenous ganciclovir therapy because of bone marrow or CNS toxicity. Infusion-related phlebitis, azotemia, anemia, rash, fever, liver function test abnormalities, nausea or vomiting, and eosinophilia also have been described.

Teratogenicity, embryotoxicity, irreversible reproductive toxicity, and myelotoxicity have been observed in animals at ganciclovir dosages comparable with those used in human beings. Ganciclovir is classified in pregnancy category C.

Zidovudine and probably other cytotoxic agents increase the risk of myelosuppression, as do nephrotoxic agents that impair ganciclovir excretion. Probenecid and possibly acyclovir reduce renal clearance of ganciclovir. *Zalcitabine* increases oral ganciclovir exposure by an average of 22%. Oral ganciclovir increases the absorption and peak plasma concentrations of *didanosine* by approximately twofold and that of zidovudine by about 20%.

Therapeutic Uses. Ganciclovir is effective for treatment and chronic suppression of CMV retinitis in immunocompromised patients and for prevention of CMV disease in transplant patients. In CMV retinitis, initial induction treatment (5 mg/kg intravenously every 12 hours for 10 to 21 days) is associated with improvement or stabilization in about 85% of patients (Faulds and Heel, 1990). Reduced viral excretion is usually evident by 1 week, and fundoscopic improvement is seen by 2 weeks. Because of the high risk of relapse, AIDS patients with retinitis require suppressive therapy with high doses of ganciclovir (30 to 35 mg/kg per week). Oral ganciclovir (1000 mg three times daily) is effective for suppression of retinitis after initial intravenous treat-

ment. Oral valganciclovir (900 mg twice daily for 21 days initial treatment) is comparable with intravenous dosing for initial control and sustained suppression (900 mg daily) of CMV retinitis (Martin *et al.*, 2002).

Intravitreal ganciclovir injections have been used in some patients, and an intraocular sustained-release ganciclovir implant (VITRASERT) is more effective than systemic dosing in suppressing retinitis progression.

Ganciclovir therapy (5 mg/kg every 12 hours for 14 to 21 days) may benefit other CMV syndromes in AIDS patients or solid-organ transplant recipients (Infectious Disease Community of Practice *et al.*, 2004). Response rates of 67% or higher have been found in combination with a decrease in immunosuppressive therapy. The duration of therapy depends on demonstrating clearance of viremia; early switch from intravenous ganciclovir to oral valganciclovir is feasible. Recurrent CMV disease occurs commonly after initial treatment. In bone marrow transplant recipients with CMV pneumonia, ganciclovir alone appears ineffective. However, ganciclovir combined with intravenous immunoglobulin or CMV immunoglobulin reduces the mortality of CMV pneumonia by about one-half. Ganciclovir treatment may benefit infants with congenital CMV disease (Michaels *et al.*, 2003), and further studies are in progress.

Ganciclovir has been used for both prophylaxis and preemptive therapy of CMV infections in transplant recipients (Pillay, 2000; Pereyra and Rubin, 2004). In bone marrow transplant recipients, preemptive ganciclovir treatment (5 mg/kg every 12 hours for 7 to 14 days followed by 5 mg/kg every day to days 100 to 120 after transplant) starting when CMV is isolated from bronchoalveolar lavage or from other sites is highly effective in preventing CMV pneumonia and appears to reduce mortality in these patients. Initiation of ganciclovir at the time of engraftment also reduces CMV disease rates but does not improve survival in part because of infections owing to ganciclovir-related neutropenia.

Intravenous ganciclovir, oral ganciclovir, and oral valganciclovir reduce the risk of CMV disease in solid-organ transplant recipients (Pereyra and Rubin, 2004; Infectious Disease Community of Practice *et al.*, 2004). Oral ganciclovir (1000 mg three times daily for 3 months) reduces CMV disease risk in liver transplant recipients, including high-risk patients with primary infection or those receiving antilymphocyte antibodies. Oral valganciclovir prophylaxis generally is more effective than high-dose oral acyclovir. Oral valganciclovir (900 mg once daily) provides somewhat greater antiviral effects and similar reductions in CMV disease as oral ganciclovir in mismatched solid-organ transplant recipients (Paya *et al.*, 2004).

In advanced HIV disease, oral ganciclovir (1000 mg three times daily) may reduce the risk of CMV disease and possibly mortality in those not receiving didanosine (Brosgart *et al.*, 1998). The addition of oral high-dose ganciclovir (1500 mg three times daily) to the intraocular ganciclovir implant further delays the time to retinitis progression and reduces the risk of new CMV disease and possibly the risk of Kaposi's sarcoma.

Ganciclovir resistance emerges in a minority of transplant patients, especially mismatched solid-organ recipients (Limaye *et al.*, 2000), and is associated with poorer prognosis. The use of antithymocyte globulin and prolonged ganciclovir exposure are risk factors. Recovery of ganciclovir-resistant CMV isolates has been associated with progressive CMV disease in AIDS and other immunocompromised patients. Over one-quarter of retinitis patients have resistant isolates by 9 months of therapy, and resis-

tant CMV has been recovered from CSF, vitreous fluid, and visceral sites.

A ganciclovir ophthalmic gel formulation appears to be effective in treating HSV keratitis (Colin *et al.*, 1997). Oral ganciclovir reduces HBV DNA levels and aminotransferase levels in chronic hepatitis B (Hadziyannis *et al.*, 1999).

Systemic ganciclovir has been studied in conjunction with suicide gene therapy expressing HSV thymidine kinase for treatment of brain tumors and a variety of other malignancies.

Idoxuridine

Idoxuridine (5-iodo-2'-deoxyuridine) is an iodinated thymidine analog that inhibits the *in vitro* replication of various DNA viruses, including herpesviruses and poxviruses (Prusoff, 1988). Its structure is

Inhibitory concentrations of idoxuridine for HSV-1 are 2 to 10 $\mu\text{g/ml}$, at least tenfold higher than those of acyclovir. Idoxuridine lacks selectivity, in that low concentrations inhibit the growth of uninfected cells. The triphosphate inhibits viral DNA synthesis and is incorporated into both viral and cellular DNA. Such altered DNA is more susceptible to breakage and also leads to faulty transcription. Resistance to idoxuridine develops readily *in vitro* and occurs in viral isolates recovered from idoxuridine-treated patients with HSV keratitis.

In the United States, idoxuridine is approved only for topical treatment of HSV keratitis, although idoxuridine formulated in *dimethylsulfoxide* is available outside the United States for topical treatment of herpes labialis, genitalis, and zoster. In ocular HSV infections, topical idoxuridine is more effective in epithelial infections, especially initial episodes, than in stromal infections. Adverse reactions include pain, pruritus, inflammation, and edema involving the eye or lids; rarely do allergic reactions occur.

Trifluridine

Trifluridine (5-trifluoromethyl-2'-deoxyuridine) is a fluorinated pyrimidine nucleoside that has *in vitro* inhibitory activity against HSV types 1 and 2, CMV, vaccinia, and to a lesser extent, certain adenoviruses. Its structure is

Concentrations of trifluridine of 0.2 to 10 $\mu\text{g/ml}$ inhibit replication of herpesviruses, including acyclovir-resistant strains. Trifluridine also inhibits cellular DNA synthesis at relatively low concentrations.

Trifluridine Inhibition of Viral DNA Synthesis. Trifluridine monophosphate irreversibly inhibits thymidylate synthase, and trifluridine triphosphate is a competitive inhibitor of thymidine triphosphate incorporation into DNA; trifluridine is incorporated into viral and cellular DNA. Trifluridine-resistant HSV with altered thymidine kinase substrate specificity can be selected *in vitro*, and resistance in clinical isolates has been described.

Trifluridine currently is approved in the United States for treatment of primary keratoconjunctivitis and recurrent epithelial keratitis owing to HSV types 1 and 2. Topical trifluridine is more active than idoxuridine and comparable with vidarabine in HSV ocular infections. Adverse reactions include discomfort on instillation and palpebral edema. Hypersensitivity reactions, irritation, and superficial punctate or epithelial keratopathy are uncommon. Topical trifluridine also appears to be effective in some patients with acyclovir-resistant HSV cutaneous infections.

ANTI-INFLUENZA AGENTS

Amantadine and Rimantadine

Chemistry and Antiviral Activity. *Amantadine* (1-adamantanamine hydrochloride) and its α -methyl derivative *rimantadine* (α -methyl-1-adamantanamine hydrochloride) are uniquely configured tricyclic amines.

Low concentrations of either agent specifically inhibit the replication of influenza A viruses (Hayden and Aoki, 1999). Depending on the assay method and strain, inhibitory concentrations of the drugs range from about 0.03 to 1.0 $\mu\text{g/ml}$ for influenza A viruses. Rimantadine generally is 4 to 10 times more active than amantadine. Concentrations of 10 $\mu\text{g/ml}$ or greater inhibit other enveloped viruses but are not achievable in human beings and may be cytotoxic. Rimantadine is inhibitory *in vitro* for *Trypanosoma brucei*, a cause of African sleeping sickness, at concentrations of 1 to 2.5 $\mu\text{g/ml}$. These agents do not inhibit hepatitis C virus (HCV) enzymes or internal ribosomal entry site-mediated translation but block the ion channel activity of the HCV p7 protein *in vitro* (Griffin *et al.*, 2003).

Mechanisms of Action and Resistance. Amantadine and rimantadine share two mechanisms of antiviral action. They inhibit an early step in viral replication, probably viral uncoating; for some strains, they also have an effect on a late step in viral assembly probably mediated through altering hemagglutinin processing. The primary locus of action is the influenza A virus M2 protein, an integral membrane protein that functions as an ion channel. By interfering with this function of the M2 protein, the drugs inhibit the acid-mediated dissociation of the ribonucleoprotein complex early in replication and potentiate acidic pH-induced conformational changes in the hemagglutinin during its intracellular transport later in replication.

Primary drug resistance is uncommon (<1% to 2.5%) in field isolates but occurs in some avian and swine influenza viruses, including recent H5N1 human isolates.

Resistance is selected readily by virus passage in the presence of drug and is seen commonly (30% or more) in isolates recovered during treatment (Hayden, 1996). Resistance with over one hundredfold increases in inhibitory concentrations has been associated with single-nucleotide changes leading to amino acid substitutions in the transmembrane region of M2 (Hayden, 1996). Amantadine and rimantadine share cross-susceptibility and resistance.

Absorption, Distribution, and Elimination. Amantadine and rimantadine are well absorbed after oral administration (Hayden and Aoki, 1999) (Table 49-3). Peak plasma concentrations of amantadine average 0.5 to 0.8 $\mu\text{g/ml}$ on a 100-mg twice-daily regimen in healthy young adults. Comparable doses of rimantadine give peak and trough plasma concentrations of approximately 0.4 to 0.5 and 0.2 to 0.4 $\mu\text{g/ml}$, respectively. The elderly require only one-half the weight-adjusted dose of amantadine needed for young adults to achieve equivalent trough plasma levels of 0.3 $\mu\text{g/ml}$. Both drugs have very large volumes of distribution. Nasal secretion and salivary levels of amantadine approximate those found in the serum. Amantadine is excreted in breast milk. Rimantadine concentrations in nasal mucus average 50% higher than those in plasma.

Amantadine is excreted largely unmetabolized in the urine through glomerular filtration and probably tubular secretion. The plasma $t_{1/2}$ of elimination is about 12 to 18 hours in young adults. Because amantadine's elimination is highly dependent on renal function, the elimination $t_{1/2}$ increases up to twofold in the elderly and even more in those with renal impairment. Dose adjustments are advisable in those with mild decrements in renal function. In contrast, rimantadine is metabolized extensively by hydroxylation, conjugation, and glucuronidation prior to renal excretion. Following oral administration, the elimination $t_{1/2}$ of rimantadine averages 24 to 36 hours, and 60% to 90% is excreted in the urine as metabolites. Renal clearance of unchanged rimantadine is similar to creatinine clearance.

Table 49-3
Pharmacological Characteristics of Antivirals for Influenza

	AMANTADINE	RIMANTADINE	ZANAMIVIR	OSELTAMIVIR
Spectrum (types of influenza)	A	A	A, B	A, B
Route/formulations	Oral (tablet/capsule/syrup)	Oral (tablet/syrup)	Inhaled (powder) Intravenous*	Oral (capsule/syrup)
Oral bioavailability	> 90%	> 90%	< 5%†	~ 80%‡
Effect of meals on AUC	Negligible	Negligible	Not applicable	Negligible
Plasma $t_{1/2,elim}$, h	12–18	24–36	2.5–5	6–10‡
Protein binding, %	67%	40%	< 10%	3%‡
Metabolism, %	< 10%	~ 75%	Negligible	Negligible‡

Dose adjustments	$Cl_{cr} \leq 50$ Age ≥ 65 yrs	$Cl_{cr} \leq 10$ Age ≥ 65 years	None	$Cl_{cr} \leq 30$

*Investigational at present. †Systemic absorption 4% to 17% after inhalation. ‡For antivirally active oseltamivir carboxylate (GS4071).

Untoward Effects. The most common side effects related to amantadine and rimantadine are minor dose-related gastrointestinal and CNS complaints (Hayden and Aoki, 1999). These include nervousness, light-headedness, difficulty concentrating, insomnia, and loss of appetite or nausea. CNS side effects occur in approximately 5% to 33% of patients treated with amantadine at doses of 200 mg/day but are significantly less frequent with rimantadine. The neurotoxic effects of amantadine appear to be increased by concomitant ingestion of antihistamines and psychotropic or anticholinergic drugs, especially in the elderly. Amantadine dose reductions are required in older adults (100 mg/day) because of decreased renal function, but 20% to 40% of infirm elderly will experience side effects even at this lower dose. At comparable doses of 100 mg/day, rimantadine is significantly better tolerated in nursing home residents than is amantadine (Keyser *et al.*, 2000).

High amantadine plasma concentrations (1.0 to 5.0 $\mu\text{g/ml}$) have been associated with serious neurotoxic reactions, including delirium, hallucinosis, seizures, and coma, and cardiac arrhythmias. Exacerbations of preexisting seizure disorders and psychiatric symptoms may occur with amantadine and possibly with rimantadine. Amantadine is teratogenic in animals. The safety of these drugs has not been established in pregnancy (pregnancy category C).

Therapeutic Uses. Amantadine and rimantadine are effective for the prevention and treatment of influenza A virus infections. Seasonal prophylaxis with either drug (a total of 200 mg/day in one or two divided doses in young adults) is about 70% to 90% protective against influenza A illness (Hayden and Aoki, 1999). Efficacy has been shown during pandemic influenza (Hayden, 2001), in preventing nosocomial influenza, and in curtailing nosocomial outbreaks. Doses of 100 mg/day are better tolerated and still appear to be protective against influenza illness. Postexposure prophylaxis with either drug provides protection of exposed family contacts if ill young children are not concurrently treated (Hayden, 1996).

Seasonal prophylaxis is an alternative in high-risk patients if the influenza vaccine cannot be administered or may be ineffective (*i.e.*, in immunocompromised patients). Prophylaxis should be started as soon as influenza is identified in a community or region and should be continued throughout the period of risk (usually 4 to 8 weeks) because any protective effects are lost several days after cessation of therapy. Alternatively, the drugs can be started in conjunction with immunization and continued for 2 weeks until protective immune responses develop.

In uncomplicated influenza A illness of adults, early amantadine or rimantadine treatment (200 mg/day for 5 days) reduces the duration of fever and systemic complaints by 1 to 2 days, speeds functional recovery, and sometimes decreases the duration of virus shedding (Hayden and Aoki, 1999). In children, rimantadine treatment may be associated with less illness and lower viral titers during the first 2 days of treatment, but rimantadine-treated children have more prolonged shedding of virus. The optimal dose and duration of therapy have not been established in children for either agent. It also is uncertain whether treatment reduces risk of complications in high-risk patients or is useful in patients with established pulmonary complications.

Resistant variants have been recovered from approximately 30% of treated children or outpatient adults by the fifth day of therapy (Hayden, 1996). Resistant variants also arise commonly in immunocompromised patients (Englund *et al.*, 1998). Illnesses owing to apparent transmission of resistant virus associated with failure of drug prophylaxis have been documented in contacts of drug-treated

ill persons in households and in nursing homes (Hayden, 1996). Resistant variants appear to be pathogenic and can cause typical disabling influenza illness.

The discovery that amantadine also is useful in treating parkinsonism was due to serendipity. This application is discussed in Chapter 20. Amantadine and rimantadine have been used alone or in combination with *interferon* and other agents in treating chronic hepatitis C with inconsistent results (Smith *et al.*, 2004).

Oseltamivir

Chemistry and Antiviral Activity. *Oseltamivir carboxylate* [(3*R*, 4*R*, 5*S*)-4-acetylamino-5-amino-3(1-ethylpropoxyl)-1-cyclohexene-1-carboxylic acid] is a transition-state analog of sialic acid that is a potent selective inhibitor of influenza A and B virus neuraminidases. The structure is

OSELTAMIVIR CARBOXYLATE

Oseltamivir phosphate is an ethyl ester prodrug that lacks antiviral activity. Oseltamivir carboxylate has an antiviral spectrum and potency similar to that of *zanamivir* (*see below*). It inhibits amantadine- and rimantadine-resistant influenza A viruses and some zanamivir-resistant variants.

Mechanisms of Action and Resistance. Influenza neuraminidase cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin, which are present on the cell surface, in progeny virions, and in respiratory secretions (Gubareva *et al.*, 2000). This enzymatic action is essential for release of virus from infected cells. Interaction of oseltamivir carboxylate with the neuraminidase causes a conformational change within the enzyme's active site and inhibits its activity. Inhibition of neuraminidase activity leads to viral aggregation at the cell surface and reduced virus spread within the respiratory tract.

Influenza variants selected *in vitro* for resistance to oseltamivir carboxylate contain hemagglutinin and/or neuraminidase mutations. The most commonly recognized variants (mutations at positions 292 in N2 and 274 in N1 neuraminidases) have reduced infectivity and virulence in animal models. Outpatient oseltamivir therapy has been associated with recovery of resistant

variants in about 0.5% of adults and 5.5% of children (Roberts, 2001); a higher frequency (~18%) occurs in hospitalized children.

Absorption, Distribution, and Elimination. Oral oseltamivir phosphate is absorbed rapidly (Table 49–3) and cleaved by esterases in the gastrointestinal tract and liver to the active carboxylate. Low blood levels of the phosphate are detectable, but exposure is only 3% to 5% of that of the metabolite. The bioavailability of the carboxylate is estimated to be approximately 80% (He *et al.*, 1999). The time to maximum plasma concentrations of the carboxylate is about 2.5 to 5 hours. Food does not decrease bioavailability but reduces the risk of gastrointestinal intolerance. After 75-mg doses, peak plasma concentrations average 0.07 $\mu\text{g/ml}$ for oseltamivir phosphate and 0.35 $\mu\text{g/ml}$ for the carboxylate. The carboxylate has a volume of distribution similar to extracellular water. Bronchoalveolar lavage levels in animals and middle ear fluid and sinus concentrations in humans are comparable with plasma levels. Following oral administration, the plasma half-life of oseltamivir phosphate is 1 to 3 hours and that of the carboxylate ranges from 6 to 10 hours. Both the prodrug and active metabolite are eliminated primarily unchanged through the kidney. Probenecid doubles the plasma half-life of the carboxylate, which indicates tubular secretion by the anionic pathway.

Untoward Effects. Oral oseltamivir is associated with nausea, abdominal discomfort, and, less often, emesis, probably owing to local irritation. Gastrointestinal complaints usually are mild-to-moderate in intensity, typically resolve in 1 to 2 days despite continued dosing, and are preventable by administration with food. The frequency of such complaints is about 10% to 15% when oseltamivir is used for the treatment of influenza illness and less than 5% when used for prophylaxis. An increased frequency of headache was reported in one prophylaxis study in elderly adults.

Oseltamivir phosphate and the carboxylate do not interact with the cytochrome P450 enzymes (CYPs) *in vitro*. Their protein binding is low. No clinically significant drug interactions have been recognized to date. Oseltamivir does not appear to impair fertility or to be teratogenic in animal studies, but safety in pregnancy is uncertain (pregnancy category C). Very high doses have been associated with increased mortality, perhaps related to increased brain concentrations, in unweaned rats, and oseltamivir is not approved for use in children younger than 1 year of age.

Therapeutic Uses. Oral oseltamivir is effective in the treatment and prevention of influenza A and B virus infections. Treatment of previously healthy adults (75 mg twice daily for 5 days) or children aged 1 to 12 years (weight-adjusted dosing) with acute influenza reduces illness duration by about 1 to 2 days, speeds functional recovery, and reduces the risk of complications leading to antibiotic use by 40% to 50% (Cooper *et al.*, 2003; Whitley *et al.*, 2001). Treatment is associated with approximate halving of the risk of subsequent hospitalization in adults (Kaiser *et al.*, 2003). When used for prophylaxis during the influenza season, oseltamivir (75 mg once daily) is effective (approximately 70% to 90%) in reducing the likelihood of influenza illness in both unimmunized working adults and in immunized nursing home residents (Cooper *et al.*, 2003); short-term use (7 to 10 days) protects against influenza in household contacts (Hayden *et al.*, 2004).

Zanamivir

Chemistry and Antiviral Activity. Zanamivir (4-guandino-2,4-dideoxy-2,3-dehydro-*N*-acetyl neuraminic acid) is a sialic acid analog that potently and specifically inhibits the neuraminidases of influenza A and B viruses. Depending on the strain, zanamivir competitively inhibits influenza neuraminidase activity at concentrations of approximately 0.2 to 3 ng/ml but affects neuraminidases from other pathogens and mammalian sources only at 10^6 -fold higher concentrations. Zanamivir inhibits *in vitro* replication of influenza A and B viruses, including amantadine- and rimantadine-resistant strains and several oseltamivir-resistant variants. It is active after topical administration in animal models of influenza. Its structure is:

Mechanisms of Action and Resistance. Like oseltamivir, zanamivir inhibits viral neuraminidase and thus causes viral aggregation at the cell surface and reduced spread of virus within the respiratory tract (Gubareva *et al.*, 2000).

In vitro selection of viruses resistant to zanamivir is associated with mutations in the viral hemagglutinin and/or neuraminidase. Hemagglutinin variants generally have mutations in or near the receptor binding site that make them less dependent on neuraminidase action for release from cells *in vitro*, although they typically retain susceptibility *in vivo*. Hemagglutinin variants are cross-resistant to other neuraminidase inhibitors. Neuraminidase variants contain mutations in the enzyme active site that diminish binding of zanamivir, but the altered enzymes show reduced activity or stability. Zanamivir-resistant variants usually have decreased infectivity in animals. Resistance emergence has not been documented with zanamivir in immunocompetent hosts to date but has been seen rarely in highly immunocompromised patients (Gubareva *et al.*, 2000).

Absorption, Distribution, and Elimination. The oral bioavailability of zanamivir is low (<5%) (Table 49–3), and the commercial form is delivered by oral inhalation of dry powder in a lactose carrier. The proprietary inhaler device is breath-actuated and requires a cooperative patient. Following inhalation of the dry powder, approximately 15% is deposited in the lower respiratory tract and

about 80% in the oropharynx (Cass *et al.*, 1999). Overall bioavailability is less than 20%, and plasma levels after 10-mg inhaled doses average about 35 to 100 ng/ml in adults and children (Peng *et al.*, 2000). Median zanamivir concentrations in induced sputum samples are 1336 ng/ml at 6 hours and 47 ng/ml at 24 hours after a single 10-mg dose in healthy volunteers (Peng *et al.*, 2000). The plasma half-life of zanamivir averages 2.5 to 5 hours after oral inhalation but only 1.7 hours following intravenous dosing. Over 90% is eliminated in the urine without recognized metabolism.

Untoward Effects. Topically applied zanamivir generally is well tolerated in ambulatory adults and children with influenza. Wheezing and bronchospasm have been reported in some influenza-infected patients without known airway disease, and acute deteriorations in lung function, including fatal outcomes, have occurred in those with underlying asthma or chronic obstructive airway disease. Tolerability in more serious bronchopulmonary disorders or in intubated patients is uncertain. Zanamivir is not generally recommended for treatment of patients with underlying airway disease (*e.g.*, asthma or chronic obstructive pulmonary disease) because of the risk of serious adverse events.

Preclinical studies of zanamivir revealed no evidence of mutagenic, teratogenic, or oncogenic effects (pregnancy category C). No clinically significant drug interactions have been recognized to date. Zanamivir does not diminish the immune response to injected influenza vaccine.

Therapeutic Uses. Inhaled zanamivir is effective for the prevention and treatment of influenza A and B virus infections. Early zanamivir treatment (10 mg twice daily for 5 days) of febrile influenza in ambulatory adults and children aged 5 years and older shortens the time to illness resolution by 1 to 3 days (Cooper *et al.*, 2003; Hedrick *et al.*, 2000) and in adults reduces by 40% the risk of lower respiratory tract complications leading to antibiotic use (Kaiser *et al.*, 2000). Once-daily inhaled, but not intranasal, zanamivir is highly protective against community-acquired influenza illness (Cooper *et al.*, 2003), and when given for 10 days, it protects against household transmission (Hayden *et al.*, 2004). Intravenous zanamivir is protective against experimental human influenza but has not been studied in treating natural influenza.

ANTIHEPATITIS AGENTS

A number of agents are available for treatment of hepatitis B virus (HBV) and hepatitis C virus (HCV) infections. Several agents (*e.g.*, interferons and *ribavirin*) have other uses as well.

Adefovir

Chemistry and Antiviral Activity. *Adefovir dipivoxil* (9-[2-bis[(pivaloyloxy)methoxy]phosphinyl]methoxyl]ethyl]adenine, bis-POM PMEA) is a diester prodrug of adefovir, an acyclic phosphonate nucleotide analog of adenosine monophosphate. Its structure is:

It is inhibitory *in vitro* against a range of DNA and RNA viruses, but its clinical use is limited to HBV infections (De Clercq, 2003). Inhibitory concentrations for HBV range from 0.2 to 1.2 μM in cell culture, and it is active against lamivudine-resistant HBV strains. Oral adefovir dipivoxil shows dose-dependent inhibition of hepadnavirus replication in animal models. *In vitro* combinations of adefovir and lamivudine or other anti-HBV nucleosides show enhanced antihepadnavirus activity *in vitro* (Delaney *et al.*, 2004), and trials of dual therapy are in progress.

Mechanisms of Action and Resistance. Adefovir dipivoxil enters cells and is deesterified to adefovir. Adefovir is converted by cellular enzymes to the diphosphate, which acts as a competitive inhibitor of viral DNA polymerases and reverse transcriptases with respect to deoxyadenosine triphosphate and also serves as a chain terminator of viral DNA synthesis (Cundy, 1999). Its selectivity relates to a higher affinity for HBV DNA polymerase compared with cellular polymerases. The intracellular $t_{1/2}$ of the diphosphate is prolonged, ranging from 5 to 18 hours, so once-daily dosing is feasible. Adefovir resistance has been detected in a small proportion (~4%) of chronically infected HBV patients during 3 years of treatment. Such variants have unique point mutations in the HBV polymerase but retain susceptibility to lamivudine. The consequences of the emergence of resistance remain to be determined.

Absorption, Distribution, and Elimination. The parent compound has low oral bioavailability (<12%), whereas the dipivoxil prodrug is absorbed rapidly and hydrolyzed by esterases in the intestine and blood to adefovir with liberation of pivalic acid (Cundy *et al.*, 1995). Adefovir bioavailability is approximately 30% to 60%. After 10-mg doses of the prodrug, peak serum concentrations of adefovir average 0.02 $\mu\text{g}/\text{ml}$, and the prodrug is not detectable. Food does not affect bioavailability. Adefovir has low protein binding (<5%) and has a volume of distribution similar to body water (~0.4 L/kg).

Adefovir is eliminated unchanged by renal excretion through a combination of glomerular filtration and tubular secretion. After oral administration of adefovir dipivoxil, about 30% to 45% of the dose is recovered within 24 hours, and the serum $t_{1/2}$ of elimination ranges from 5 to 7.5 hours. Clearance dose reductions are indicated for Cl_{Cr} values of less than 50 ml/min. Adefovir is removed by

hemodialysis, but the effects of peritoneal dialysis or severe hepatic insufficiency on pharmacokinetics are unreported.

Pivalic acid is a product of adefovir dipivoxil metabolism that can cause reduced free carnitine levels. Although L-carnitine has been given in some HIV studies, supplementation generally is not recommended at the doses of adefovir dipivoxil used in chronic HBV infection.

Untoward Effects. Adefovir dipivoxil causes dose-related nephrotoxicity and tubular dysfunction, manifested by azotemia and hypophosphatemia, acidosis, glycosuria, and proteinuria that usually are reversible months after discontinuation. The lower dose (10 mg/day) used in chronic HBV infection patients has been associated with few adverse events (*e.g.*, headache, abdominal discomfort, diarrhea, and asthenia) and negligible renal toxicity compared with a threefold higher dose (Hadziyannis *et al.*, 2003; Marcellin *et al.*, 2003). Adverse events lead to premature discontinuation in about 2% of patients. After 2 years of dosing, the risk of serum creatinine levels rising above 0.5 mg/dl is about 2% but is higher in those with preexisting renal insufficiency. Adefovir is transported efficiently into tubular epithelium by a probenecid-sensitive human organic anion transporter (hOAT1), and the diphosphate's inhibitory effects on renal adenyl cyclase may contribute to nephrotoxicity. Acute, sometimes severe exacerbations of hepatitis can occur in patients stopping adefovir or other anti-HBV therapies. Close monitoring is necessary, and resumption of antiviral therapy may be required in some patients.

No clinically important drug interactions have been recognized to date, although drugs that reduce renal function or compete for active tubular secretion could decrease adefovir clearance. *Ibuprofen* increases adefovir exposure modestly. An increased risk of lactic acidosis and steatosis may exist when adefovir is used in conjunction with nucleoside analogs or other antiretroviral agents.

Adefovir is genotoxic, and high doses cause renal tubular nephropathy, hepatotoxicity, and toxicity to lymphoid tissues in animals. Adefovir dipivoxil is not associated with reproductive toxicity, although high intravenous doses of adefovir cause maternal and embryotoxicity with fetal malformations in rats (pregnancy category C).

Therapeutic Uses. Adefovir dipivoxil is approved for treatment of chronic HBV infections. In patients with HBV e-antigen (HBeAg)-positive chronic hepatitis B, adefovir dipivoxil (10 mg/day) results in over one hundredfold reduced serum HBV DNA levels and, in about one-half of patients, improved hepatic histology and normalization of aminotransferase levels by 48 weeks (Marcellin *et al.*, 2003). Continued therapy is associated with increasing frequencies of aminotransferase normalization and HBeAg seroconversion (De Clercq, 2003). In patients with HBeAg-negative chronic HBV, adefovir is associated with similar biochemical and histologic benefits (Hadziyannis *et al.*, 2003). Regression of cirrhosis may occur in some patients.

In patients with lamivudine-resistant HBV infections, adefovir dipivoxil monotherapy results in sustained reductions in serum HBV DNA levels, but lamivudine alone or added to adefovir is not beneficial (Peters *et al.*, 2004). In patients with dual HIV and lamivudine-resistant HBV infections, adefovir dipivoxil (10 mg/day) causes significant HBV DNA level reductions (Benhamou *et al.*, 2001), and it also has been used successfully in patients with lamivudine-resistant HBV infections both before and following liver transplantation. The optimal duration of treatment in different popu-

lations, possible long-term effects on HBV complications, and combined use with other anti-HBV agents are under study.

Interferons

Classification and Antiviral Activity. Interferons (IFNs) are potent cytokines that possess antiviral, immunomodulating, and antiproliferative activities (Samuel, 2001; Biron, 2001) (*see* Chapter 52). These proteins are synthesized by host cells in response to various inducers and, in turn, cause biochemical changes leading to an antiviral state in cells. Three major classes of human interferons with significant antiviral activity currently are recognized: α (>18 individual species), β , and γ . Clinically used recombinant α IFNs (Table 49–2) are nonglycosylated proteins of approximately 19,500 daltons.

IFN- α and IFN- β may be produced by nearly all cells in response to viral infection and a variety of other stimuli, including double-stranded RNA and certain cytokines (*e.g.*, interleukin 1, interleukin 2, and tumor necrosis factor). IFN- γ production is restricted to T-lymphocytes and natural killer cells responding to antigenic stimuli, mitogens, and specific cytokines. IFN- α and IFN- β exhibit antiviral and antiproliferative actions; stimulate the cytotoxic activity of lymphocytes, natural killer cells, and macrophages; and up-regulate class I major histocompatibility (MHC) antigens and other surface markers. IFN- γ has less antiviral activity but more potent immunoregulatory effects, particularly macrophage activation, expression of class II MHC antigens, and mediation of local inflammatory responses.

Most animal viruses are inhibited by IFNs, although many DNA viruses are relatively insensitive. Considerable differences in sensitivity to the effects of IFNs exist among different viruses and assay systems. The biological activity of IFN usually is measured in terms of antiviral effects in cell culture and generally is expressed as international units (IU) relative to reference standards.

Mechanisms of Action. Following binding to specific cellular receptors, IFNs activate the JAK-STAT signal-transduction pathway and lead to the nuclear translocation of a cellular protein complex that binds to genes containing an IFN-specific response element. This, in turn, leads to synthesis of over two dozen proteins that contribute to viral resistance mediated at different stages of viral penetration (Samuel, 2001; Der *et al.*, 1998) (Figure 49–3). Inhibition of protein synthesis is the major inhibitory effect for many viruses. IFN-induced proteins include 2'-5'-oligoadenylate [2-5(A)] synthetase and a protein kinase, either of which can inhibit protein synthesis in the presence of double-stranded RNA. The 2-5(A) synthetase produces adenylate

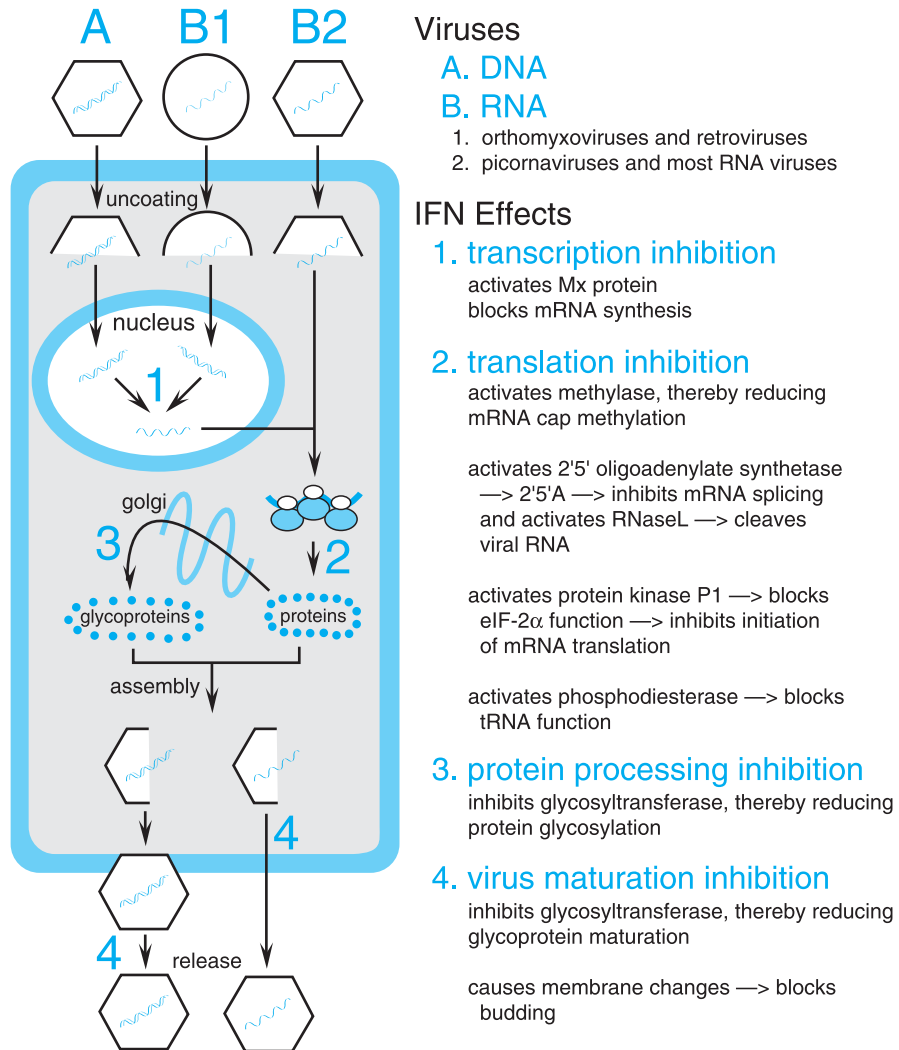

Figure 49–3. Interferon-mediated antiviral activity occurs via multiple mechanisms. The binding of IFN to specific cell surface receptor molecules signals the cell to produce a series of antiviral proteins. The stages of viral replication that are inhibited by various IFN-induced antiviral proteins are shown. Most of these act to inhibit the translation of viral proteins (mechanism 2), but other steps in viral replication also are affected (mechanisms 1, 3, and 4). The roles of these mechanisms in the other actions of IFNs are under study. *Key:* IFN = interferon; mRNA = messenger RNA; Mx = specific cellular protein; tRNA = transfer RNA; RNase L = latent cellular endoribonuclease; 2'5'A = 2'-5'-oligoadenylates; eIF-2α = protein synthesis initiation factor. (Modified from Baron *et al.*, 1992, with permission.)

oligomers that activate a latent cellular endoribonuclease (RNase L) to cleave both cellular and viral single-stranded RNAs. The protein kinase selectively phosphorylates and inactivates a protein involved in protein synthesis, eukaryotic initiation factor 2 (eIF-2). IFN-induced protein kinase also may be an important effector of apoptosis. In addition, IFN induces a phosphodiesterase that cleaves a portion of transfer RNA and thus prevents peptide elongation. A given virus may be inhibited at several steps, and the principal inhibitory effect differs among virus families. Certain

viruses are able to counter IFN effects by blocking production or activity of selected IFN-inducible proteins. For example, IFN resistance in hepatitis C virus is attributable to inhibition of the IFN-induced protein kinase, among other mechanisms.

Complex interactions exist between IFNs and other parts of the immune system, so IFNs may ameliorate viral infections by exerting direct antiviral effects and/or by modifying the immune response to infection (Biron, 2001). For example, IFN-induced expression of MHC antigens may

contribute to the antiviral actions of IFN by enhancing the lytic effects of cytotoxic T-lymphocytes. Conversely, IFNs may mediate some of the systemic symptoms associated with viral infections and contribute to immunologically mediated tissue damage in certain viral diseases.

Absorption, Distribution, and Elimination. Oral administration does not result in detectable IFN levels in serum or increases in 2-5(A) synthetase activity in peripheral blood mononuclear cells (used as a marker of IFN's biologic activity) (Wills, 1990). After intramuscular or subcutaneous injection of IFN- α , absorption exceeds 80%. Plasma levels are dose-related, peaking at 4 to 8 hours and returning to baseline by 18 to 36 hours. Levels of 2-5(A) synthetase in peripheral blood mononuclear cells show increases beginning at 6 hours and lasting through 4 days after a single injection. An antiviral state in peripheral blood mononuclear cells peaks at 24 hours and decreases slowly to baseline by 6 days after injection. Intramuscular or subcutaneous injections of IFN- β result in negligible plasma levels, although increases in 2-5(A) synthetase levels may occur. After systemic administration, low levels of IFN are detected in respiratory secretions, CSF, eye, and brain.

Because IFNs induce long-lasting cellular effects, their activities are not easily predictable from usual pharmacokinetic measures. After intravenous dosing, clearance of IFN from plasma occurs in a complex manner (Bocci, 1992). With subcutaneous or intramuscular dosing, the plasma $t_{1/2}$ of elimination of IFN- α ranges from approximately 3 to 8 hours. Elimination from the blood relates to distribution to the tissues, cellular uptake, and catabolism primarily in the kidney and liver. Negligible amounts are excreted in the urine. Clearance of IFN- $\alpha 2$ is reduced by 64% to 79% in hemodialysis patients.

Attachment of IFN proteins to large, inert polyethylene glycol (PEG) molecules (pegylation) slows absorption, decreases clearance, and provides higher and more prolonged serum concentrations that enable once-weekly dosing (Bruno *et al.*, 2004). Two pegylated IFNs are available commercially: *peginterferon alfa-2a* and *peginterferon alfa-2b*. PegIFN alfa-2b has a straight-chain 12,000-dalton type of PEG that increases the plasma $t_{1/2}$ from approximately 2 to 3 hours to approximately 30 to 54 hours (Glue *et al.*, 2000). PegIFN alfa-2a consists of an ester derivative of a branched-chain 40,000-dalton PEG bonded to IFN- $\alpha 2a$ and has a plasma $t_{1/2}$ averaging about 80 to 90 hours. PegIFN alfa-2a is more stable and dispensed in solution, whereas pegIFN alfa-2b requires reconstitution prior to use. For pegIFN alfa-2a, peak serum concentrations occur up to 120 hours after dosing and remain detectable throughout the weekly dosing interval (Bruno *et al.*, 2004); steady-state levels occur 5 to 8 weeks after initiation of weekly dosing (Keating and Curran, 2003). For pegIFN alfa-2a, dose-related maximum plasma concentrations occur at 15 to 44 hours after dosing and decline by 96 to 168 hours. These differences in pharmacokinetics may be associated with differences in antiviral effects (Bruno *et al.*, 2004). Increasing PEG size is associated with longer $t_{1/2}$ and less renal clearance. About 30% of pegIFN alfa-2b is cleared renally; pegIFN alfa-2a also is cleared primarily by the liver. Dose reductions in both pegylated IFNs are indicated in end-stage renal disease.

Untoward Effects. Injection of IFN doses of 1 to 2 million units (MU) or greater usually is associated with an acute influenzalike syndrome beginning several hours after injection. Symptoms include fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhea (Dusheiko, 1997). Fever usually resolves within

12 hours. Tolerance develops gradually in most patients. Febrile responses can be moderated by pretreatment with various antipyretics. Up to one-half of patients receiving intralesional therapy for genital warts experience the influenzal illness initially, as well as discomfort at the injection site, and leukopenia.

The principal dose-limiting toxicities of systemic IFN are myelosuppression with granulocytopenia and thrombocytopenia; neurotoxicity manifested by somnolence, confusion, behavioral disturbance, and rarely, seizures; debilitating neurasthenia and depression; autoimmune disorders including thyroiditis; and uncommonly, cardiovascular effects with hypotension and tachycardia. The risk of depression appears to be higher in chronically infected HCV than in HBV patients (Marcellin *et al.*, 2004). Elevations in hepatic enzymes and triglycerides, alopecia, proteinuria and azotemia, interstitial nephritis, autoantibody formation, pneumonia, and hepatotoxicity may occur. Alopecia and personality change are common in IFN-treated children (Sokal *et al.*, 1998). The development of serum neutralizing antibodies to exogenous IFNs may be associated infrequently with loss of clinical responsiveness. IFN may impair fertility, and safety during pregnancy is not established.

IFN reduces the metabolism of various drugs by the hepatic CYPs and significantly increases levels of drugs such as theophylline. IFNs can increase the hematologic toxicity of drugs such as zidovudine and ribavirin and may increase the neurotoxicity and cardiotoxic effects of other drugs.

Pegylated IFNs are tolerated about as well as standard IFNs, with discontinuation rates ranging from 2% to 11%, although the frequencies of fever, nausea, injection-site inflammation, and neutropenia may be somewhat higher. Laboratory abnormalities, including severe neutropenia and the need for dose modifications, are higher in HIV-coinfected persons (Torriani, 2004).

Therapeutic Uses. Recombinant, natural, and pegylated IFNs currently are approved in the United States, depending on the specific IFN type, for treatment of condyloma acuminatum, chronic HCV infection, chronic HBV infection, Kaposi's sarcoma in HIV-infected patients, other malignancies, and multiple sclerosis.

Hepatitis B Virus. In patients with chronic HBV infection, parental administration of various IFNs is associated with loss of HBV DNA, loss of HBeAg and development of anti-HBe antibody, and biochemical and histological improvement in about 25% to 50% of the patients. Lasting responses require moderately high IFN doses and prolonged administration (typically 5 MU/day or 10 MU in adults and 6 MU/m² in children three times per week for 4 to 6 months) (Sokal *et al.*, 1998). Plasma HBV DNA and polymerase activity decline promptly in most patients, but complete disappearance is sustained in only about one-third of patients or less. Low pretherapy serum HBV DNA levels and high aminotransferase levels are predictors of response. Sustained responses are infrequent in those with vertically acquired infection, anti-HBe positivity, or concurrent immunosuppression owing to HIV. PegIFN alfa-2a appears superior to conventional IFN alfa-2a in HBeAg-positive patients (Cooksley *et al.*, 2003), and treatment (180 mg once weekly for 24 weeks) is associated with normalization of aminotransferases in about 60% and sustained viral suppression in about 20% of HBeAg-negative patients (Marcellin *et al.*, 2004). Responses with seroconversion to anti-HBe usually are associated with aminotransferase elevations and often a hepatitis-like illness during the second or third month of therapy, likely related to immune clearance of infected hepatocytes. High-dose IFN can cause myelosuppression and clinical deterioration in those with decompensated liver disease.

Remissions in chronic hepatitis B induced by IFN are sustained in over 80% of patients treated and frequently are followed by loss of HBV surface antigen (HbsAg), histological improvement or stabilization, and reduced risk of liver-related complications and mortality (Lau *et al.*, 1997). IFN may benefit some patients with nephrotic syndrome and glomerulonephritis owing to chronic HBV infection. Antiviral effects and improvements occur in about one-half of chronic hepatitis D virus (HDV) infections, but relapse is common unless HbsAg disappears. IFN does not appear to be beneficial in acute HBV or HDV infections.

Hepatitis C Virus. In chronic HCV infection, IFN alfa-2b monotherapy (3 MU three times a week) is associated with an approximate 50% to 70% rate of aminotransferase normalization and loss of plasma viral RNA, but relapse rates are high, and sustained virologic remission (absence of detectable HCV RNA) is observed in only about 10% to 25% of patients. Sustained viral responses are associated with long-term histologic improvement and probably reduced risk of hepatocellular carcinoma and hepatic failure (Coverdale *et al.*, 2004). Viral genotype and pretreatment RNA level influence response to treatment, but early viral clearance is the best predictor of sustained response. Failure to achieve an early viral response (nondetectable HCV RNA or reduction $\geq 2 \log_{10}$ compared with baseline at 12 weeks) predicts lack of sustained viral response with continued treatment (Seeff and Hoofnagle, 2002). Nonresponders generally do not benefit from IFN monotherapy retreatment, but they and patients relapsing after monotherapy often respond to combined pegylated IFN and ribavirin treatment (*see below*). IFN treatment may benefit HCV-associated cryoglobulinemia and glomerulonephritis. IFN administration during acute HCV infection appears to reduce the risk of chronicity (Alberti *et al.*, 2002).

Pegylated IFNs are superior to conventional thrice-weekly IFN monotherapy in inducing sustained remissions in treatment-naïve patients. Monotherapy with pegIFN alfa-2a (180 μg subcutaneously weekly for 48 weeks) or pegIFN alfa-2b (weight-adjusted doses of 1.5 $\mu\text{g}/\text{kg}$ per week) is associated with sustained response in 30% to 39%, including stable cirrhotic patients (Heathcote *et al.*, 2000), and is a treatment option in patients unable to take ribavirin. Studies of prolonged (4 years) maintenance monotherapy with pegylated IFNs are in progress for those not responding to IFN-ribavirin combinations.

The efficacy of conventional and pegylated IFNs is enhanced by the addition of ribavirin to the treatment regimens, particularly for genotype 1 infections. Combined therapy with pegIFN alfa-2a (180 μg once weekly for 48 weeks) and ribavirin (1000 to 1200 mg/day in divided doses) gives higher sustained viral response rates than IFN-ribavirin combinations in previously untreated patients (Fried *et al.*, 2002). A shorter duration of therapy (24 weeks) and lower ribavirin dose (800 mg/day) are effective in genotype 2 and 3 infections, but prolonged therapy and higher ribavirin doses are needed for genotype 1 and 4 infections (Hadziyannis *et al.*, 2004). Approximately 15% to 20% of those failing to respond to combined IFN-ribavirin will have sustained responses to combined pegIFN-ribavirin. Histologic improvement may occur in patients who do not achieve sustained viral responses. In patients with compensated cirrhosis, treatment may reverse cirrhotic changes and possibly reduce the risk of hepatocellular carcinoma (Poynard *et al.*, 2002).

Papillomavirus. In refractory condylomata acuminata (genital warts), intralesional injection of various natural and recombinant IFNs is associated with complete clearance of injected warts in 36% to 62% of patients, but other treatments are preferred (Wiley *et al.*, 2002). Relapse occurs in 20% to 30% of patients. *Verruca vulgaris*

may respond to intralesional IFN- α . Intramuscular or subcutaneous administration is associated with some regression in wart size but greater toxicity. Systemic IFN may provide adjunctive benefit in recurrent juvenile laryngeal papillomatosis and in treating laryngeal disease in older patients.

Other Viruses. IFNs have been shown to have virologic and clinical effects in various herpesvirus infections including genital HSV infections, localized herpes-zoster infection of cancer patients or of older adults, and CMV infections of renal transplant patients. However, IFN generally is associated with more side effects and inferior clinical benefits compared with conventional antiviral therapies. Topically applied IFN and trifluridine combinations appear active in acyclovir-resistant mucocutaneous HSV infections.

In HIV-infected persons, IFNs have been associated with antiretroviral effects. In advanced infection, however, the combination of zidovudine and IFN is associated with only transient benefit and excessive hematological toxicity. IFN- α (3 MU three times weekly) is effective for treatment of HIV-related thrombocytopenia resistant to zidovudine therapy.

Except for adenovirus, IFN has broad-spectrum antiviral activity against respiratory viruses *in vitro*. However, prophylactic intranasal IFN- α is protective only against rhinovirus colds, and chronic use is limited by the occurrence of nasal side effects. Intranasal IFN is therapeutically ineffective in established rhinovirus colds. Systemically administered IFN- α may be beneficial in early treatment of SARS (Loutfy *et al.*, 2003).

Lamivudine

Chemistry and Antiviral Activity. Lamivudine, the (–)-enantiomer of 2',3'-dideoxy-3'-thiacytidine, is a nucleoside analog that inhibits HIV reverse transcriptase and HBV DNA polymerase. Its use as an antiretroviral agent is discussed in Chapter 50. It inhibits HBV replication *in vitro* by 50% at concentrations of 4 to 7 ng/ml with negligible cellular cytotoxicity. Cellular enzymes convert lamivudine to the triphosphate, which competitively inhibits HBV DNA polymerase and causes chain termination. The intracellular $t_{1/2}$ of the triphosphate averages 17 to 19 hours in HBV-infected cells, so infrequent dosing is possible.

Mechanisms of Action and Resistance. Lamivudine triphosphate is a potent inhibitor of the DNA polymerase/reverse transcriptase of HBV, and oral lamivudine is active in animal models of hepadnavirus infection. Lamivudine shows enhanced antiviral activity in combination with adefovir or penciclovir against hepadnaviruses. Point

mutations in the *YMDD* motif of HBV DNA polymerase result in a 40 to 10⁴ times reduction in *in vitro* susceptibility (Ono *et al.*, 2001). Lamivudine resistance confers cross-resistance to related agents such as *emtricitabine* and *clevidine* and is often associated with an additional non-*YMDD* mutation that confers cross-resistance to famciclovir. Lamivudine-resistant HBV retains susceptibility to adefovir and partially to entecavir (Ono *et al.*, 2001). Viruses bearing *YMDD* mutations are less replication competent *in vitro* than wild-type HBV. However, lamivudine resistance is associated with elevated HBV DNA levels, decreased likelihood of HBeAg loss or seroconversion, hepatitis exacerbations, and progressive fibrosis and graft loss in transplant recipients (Dienstag *et al.*, 2003; Lai *et al.*, 2002).

Absorption, Distribution, and Elimination. Following oral administration, lamivudine is absorbed rapidly with a bioavailability of about 80% in adults (Johnson *et al.*, 1999). Peak plasma levels average approximately 1000 ng/ml after 100-mg doses. Lamivudine is distributed widely in a volume comparable with total-body water. The plasma *t*_{1/2} of elimination averages about 9 hours, and approximately 70% of the dose is excreted unchanged in the urine. About 5% is metabolized to an inactive *trans*-sulfoxide metabolite. In HBV-infected children, doses of 3 mg/kg per day provide plasma exposure and trough plasma levels comparable with those in adults receiving 100 mg daily (Sokal *et al.*, 2000). Dose reductions are indicated for moderate renal insufficiency (creatinine clearance < 50 ml/min). *Trimethoprim* decreases the renal clearance of lamivudine.

Untoward Effects. At the doses used for chronic HBV infection, lamivudine generally has been well tolerated. Aminotransferase rises after therapy occur more often in lamivudine recipients, and flares in post-treatment aminotransferase elevations (>500 IU/ml) occur in about 15% of patients after cessation.

Therapeutic Uses. Lamivudine is approved for the treatment of chronic HBV hepatitis in adults and children. In adults, doses of 100 mg/day for 1 year cause suppression of HBV DNA levels, normalization of aminotransferase levels in 41% or more of patients, and reductions in hepatic inflammation in over 50% of patients (Dienstag *et al.*, 1999; Lai *et al.*, 2002). Seroconversion with antibody to HBeAg occurs in fewer than 20% of recipients at 1 year. In children aged 2 to 17 years, lamivudine (3 mg/kg per day to a maximum of 100 mg for 1 year) is associated with normalization of aminotransferase levels in about one-half and seroconversion to anti-Hbe in about one-fifth of cases (Jonas *et al.*, 2002). In those without emergence of resistant variants, prolonged therapy is associated with sustained suppression of HBV DNA, continued histological improvement, and an increased proportion of patients experiencing a virological response (loss of HBeAg and undetectable HBV DNA). Prolonged therapy is associated with an approximate halving of the risk of clinical progression and development of hepatocellular carcinoma in those with advanced fibrosis or cirrhosis (Liaw *et al.*, 2004). However, the frequency of lamivudine-resistant variants increases progressively with continued drug administration, and frequencies of 38%, 53%, and 67% have been found after 2, 3, and 4 years of treatment, respectively (Liaw *et al.*, 2004). The risk of

resistance development is higher after transplantation and in HIV/HBV-coinfected patients.

Combined use of IFN or pegIFN alfa-2a with lamivudine has not improved responses in HBeAg-positive patients consistently. The addition of lamivudine to pegIFN alfa-2a for 1 year of therapy does not improve post-treatment response rates in HBeAg-negative patients (Marcellin *et al.*, 2004). In HIV and HBV coinfections, higher lamivudine doses are associated with antiviral effects and uncommonly anti-HBe seroconversion. Administration of lamivudine before and after liver transplantation may suppress recurrent HBV infection.

Ribavirin

Chemistry and Antiviral Activity. Ribavirin (1-β-D-ribofuranosyl-1*H*-1,2,4-triazole-3-carboxamide) is a purine nucleoside analog with a modified base and D-ribose sugar.

Ribavirin inhibits the replication of a wide range of RNA and DNA viruses, including orthomyxo-, paramyxo-, arena-, bunya-, and flaviviruses *in vitro*. *In vitro* inhibitory concentrations range from 3 to 10 μg/ml for influenza, parainfluenza, and respiratory syncytial (RSV) viruses. Similar concentrations may reversibly inhibit macromolecular synthesis and proliferation of uninfected cells, suppress lymphocyte responses, and alter cytokine profiles *in vitro*.

Mechanisms of Action and Resistance. The antiviral mechanism of ribavirin is incompletely understood but relates to alteration of cellular nucleotide pools and inhibition of viral messenger RNA synthesis (Tam *et al.*, 2002). Intracellular phosphorylation to the mono-, di-, and triphosphate derivatives is mediated by host cell enzymes. In both uninfected and RSV-infected cells, the predominant derivative (>80%) is the triphosphate, which has an intracellular *t*_{1/2} of less than 2 hours.

Ribavirin monophosphate competitively inhibits cellular inosine-5'-phosphate dehydrogenase and interferes with the synthesis of GTP and thus nucleic acid synthesis in general. Ribavirin triphosphate also competitively inhibits the GTP-dependent 5' capping of viral messenger RNA and specifically influenza virus transcriptase

activity. Ribavirin appears to have multiple sites of action, and some of these (*e.g.*, inhibition of GTP synthesis) may potentiate others (*e.g.*, inhibition of GTP-dependent enzymes). Ribavirin also may enhance viral mutagenesis to an extent that some viruses may be inhibited in effective replication, so-called lethal mutagenesis (Hong and Cameron, 2002).

Emergence of viral resistance to ribavirin has not been documented in most viruses but has been reported in Sindbis and HCV (Young *et al.*, 2003); it has been possible to select cells that do not phosphorylate it to its active forms.

Absorption, Distribution, and Elimination. Ribavirin is actively taken up by nucleoside transporters in the proximal small bowel; oral bioavailability averages approximately 50% (Glue, 1999). Extensive accumulation occurs in plasma, and steady state is reached by about 4 weeks. Food increases plasma levels substantially (Glue, 1999). Following single or multiple oral doses of 600 mg, peak plasma concentrations average approximately 0.8 and 3.7 $\mu\text{g/ml}$, respectively. After intravenous doses of 1000 and 500 mg, plasma concentrations average approximately 24 and 17 $\mu\text{g/ml}$, respectively. With aerosol administration, plasma levels increase with the duration of exposure and range from 0.2 to 1.0 $\mu\text{g/ml}$ after 5 days (Englund *et al.*, 1990). Levels in respiratory secretions are much higher but vary up to one thousandfold.

The apparent volume of distribution for ribavirin is large (~10 L/kg) owing to its cellular uptake. Plasma protein binding is negligible. The elimination of ribavirin is complex. The plasma $t_{1/2}$ increases to approximately 200 to 300 hours at steady state. Erythrocytes concentrate ribavirin triphosphate; the drug exits red cells gradually, with a $t_{1/2}$ of approximately 40 days. Hepatic metabolism and renal excretion of ribavirin and its metabolites are the principal routes of elimination. Hepatic metabolism involves deribosylation and hydrolysis to yield a triazole carboxamide. Ribavirin clearance decreases threefold in those with advanced renal insufficiency ($\text{Cl}_{\text{cr}} = 10$ to 30 ml/min); the drug should be used cautiously in patients with creatinine clearances of less than 50 ml/min.

Untoward Effects. Aerosolized ribavirin may cause conjunctival irritation, rash, transient wheezing, and occasional reversible deterioration in pulmonary function. When used in conjunction with mechanical ventilation, equipment modifications and frequent monitoring are required to prevent plugging of ventilator valves and tubing with ribavirin. Techniques to reduce environmental exposure of health care workers are recommended (Shults *et al.*, 1996).

Systemic ribavirin causes dose-related reversible anemia owing to extravascular hemolysis and suppression of bone marrow. Associated increases occur in reticulocyte counts and in serum bilirubin, iron, and uric acid concentrations. High ribavirin triphosphate levels may cause oxidative damage to membranes, leading to erythrophagocytosis by the reticuloendothelial system. Bolus intravenous infusion may cause rigors. About 20% of chronic HCV infection patients receiving combination IFN-ribavirin therapy discontinue treatment early because of side effects. In addition to IFN toxicities, oral ribavirin increases the risk of fatigue, cough, rash, pruritus, nausea, insomnia, dyspnea, depression, and particularly, anemia.

Preclinical studies indicate that ribavirin is teratogenic, embryotoxic, oncogenic, and possibly gonadotoxic. To prevent possible teratogenic effects, up to 6 months is required for washout following cessation of long-term treatment (Glue, 1999).

Pregnant women should not directly care for patients receiving ribavirin aerosol (FDA pregnancy category X).

Ribavirin inhibits the phosphorylation and antiviral activity of pyrimidine nucleoside HIV reverse-transcriptase inhibitors such as zidovudine and stavudine but increases the activity of purine nucleoside reverse-transcriptase inhibitors (*e.g.*, didanosine) *in vitro*. It appears to increase the risk of mitochondrial toxicity from didanosine.

Therapeutic Uses. Oral ribavirin in combination with injected pegIFN alfa-2a or -2b has become standard treatment for chronic HCV infection (Seeff and Hoofnagle, 2002). Ribavirin monotherapy for 6 to 12 months reversibly decreases aminotransferase elevations to normal in about 30% of patients but does not affect HCV RNA levels. Combination therapy with pegIFN alfa-2a and oral ribavirin (500 mg, or 600 mg if weight is greater than 75 kg, twice daily for 24 to 48 weeks) increases the likelihood of sustained biochemical and virologic responses to about 56% depending on genotype (Fried *et al.*, 2002). The combination is superior to IFN or pegIFN monotherapy and combinations of pegIFN alfa-2 and ribavirin in both treatment-naïve patients and those not responding to, or relapsing after, IFN monotherapy. A longer duration of therapy (48 weeks) appears necessary in those with genotype 1 infections, whereas 24 weeks' therapy is adequate in genotype 2 and 3 infections (Hadziyannis *et al.*, 2004). Combined ribavirin and pegIFN alfa-2a or -2b is effective in achieving sustained viral responses in a minority of HCV/HIV-coinfected patients (Torriani, 2004). Combined therapy has been used in the management of recurrent HCV infection after liver transplantation.

Ribavirin aerosol is approved in the United States for treatment of RSV bronchiolitis and pneumonia in hospitalized children. Aerosolized ribavirin (usual dose of 20 mg/ml as the starting solution in the drug reservoir of the small particle aerosol generator unit for 18 hours' exposure per day for 3 to 7 days) may reduce some illness measures, but its use generally is not recommended (Committee on Infectious Diseases American Academy of Pediatrics, 2003). No consistent beneficial effects on duration of hospitalization, ventilatory support, mortality, or long-term pulmonary function have been found. High-dose, reduced-duration therapy (60 mg/ml in the drug reservoir of the small particle aerosol generator unit for 2 hours three times daily) has been used (Englund *et al.*, 1990). Aerosol ribavirin combined with intravenous immunoglobulin appears to reduce mortality of RSV infection in bone marrow transplant and other highly immunocompromised patients (Ghosh *et al.*, 2000).

Intravenous and/or aerosol ribavirin has been used occasionally in treating severe influenza virus infection and in the treatment of immunosuppressed patients with adenovirus, vaccinia, parainfluenza, or measles virus infections. Aerosolized ribavirin is associated with reduced duration of fever but no other clinical or antiviral effects in influenza infections in hospitalized children. Intravenous ribavirin decreases mortality in Lassa fever and has been used in treating other arenavirus-related hemorrhagic fevers. Intravenous ribavirin is beneficial in hemorrhagic fever with renal syndrome owing to hantavirus infection but appears ineffective in hantavirus-associated cardiopulmonary syndrome or SARS. Oral ribavirin has been used for the treatment and prevention of Crimean-Congo hemorrhagic fever and treatment of Nipah virus infections (Mar-

Table 49–4
Examples of Antiviral Agents in Clinical Development

VIRUS	AGENT	CLASSIFICATION/SITE OF ACTION	ROUTE	COMMENT
Hepatitis B virus	Entecavir	Nucleoside RT/DNAp inhibitor	O	Less inhibitory for lamivudine-resistant HBV
	Clevudine	Nucleoside RT/DNAp inhibitor	O	Not inhibitory for lamivudine-resistant HBV
	Emtricitabine	Nucleoside RT/DNAp inhibitor	O	Approved for HIV; not inhibitory for lamivudine-resistant HBV
	Telbivudine	Nucleoside RT/DNAp inhibitor	O	Not inhibitory for lamivudine-resistant HBV
	Tenofovir	Nucleotide RT/DNAp inhibitor	O	Approved for HIV; inhibitory for lamivudine-resistant HBV and active in HBV/HIV coinfections
Hepatitis C virus	Viramidine	Nucleoside analog	O	Ribavirin analog with antiviral and immunomodulatory activities
	BILN 2061 NM283	NS4A protease inhibitor RNA polymerase inhibitor	O O	Valine ester prodrug of ribonucleoside analog
Herpes simplex Cytomegalovirus	Resiquimod	Immune modulator	Topical	
	Maribavir	DNA synthesis inhibitor	O	Novel antiviral action, inhibits UL97 and nuclear egress of virions
Rhinovirus	sICAM-1	Soluble receptor decoy	Intranasal	
	Pleconaril	Capsid binder	Intranasal	
Influenza virus	Peramivir	Neuraminidase inhibitor	O	
	R-118958	Neuraminidase inhibitor	Inhaled	Long acting in murine model

ABBREVIATIONS: RT, reverse transcriptase; DNAp, DNA polymerase; O, oral.

dani *et al.*, 2003). Intravenous ribavirin is investigational in the United States.

OTHER AGENTS

Imiquimod

Imiquimod [1-(2-methylpropyl)-1*H*-imidazo[4,5-*c*]quino-*lin*-4 amine] is a novel immunomodulatory agent that is effective for topical treatment of condylomata acuminata and certain other dermatologic conditions (Skinner, 2003). It lacks direct antiviral or antiproliferative effects *in vitro* but rather induces cytokines and chemokines with antiviral and immunomodulating effects. Imiquimod shows antiviral activity in animal models after systemic or topical administration. When applied topically as a 5% cream to genital warts in humans, it induces local IFN- α , - β , and - γ and TNF- α responses and causes reductions in viral load and wart size. When applied topically

(three times weekly for up to 16 weeks), imiquimod cream is associated with complete clearance of treated genital and perianal warts in about 50% of patients, with response rates being higher in women than in men (Wiley *et al.*, 2002; Skinner, 2003). The median time to clearance is 8 to 10 weeks; relapses are not uncommon. Application is associated with local erythema in about 20% of patients, excoriation/flaking in 18% to 26%, itching in 10% to 20%, burning in 5% to 12%, and less often, erosions or ulcerations.

STRATEGIES UNDER DEVELOPMENT

Table 49–4 summarizes some of the antiviral agents that are in clinical development, excluding those for HIV infection.

More satisfactory antiviral therapies likely will come in part from the identification of agents with improved pharmacokinetic properties, greater potency, and/or improved

toxicity profiles compared with existing ones. New drug-delivery techniques that improve pharmacokinetic properties (e.g., prodrugs to enhance oral bioavailability, carrier molecules to alter absorption and/or degradation) or target particular tissues or cell types are receiving particular attention in drug development. For example, ether lipid esters of cidofovir provide increased cellular uptake and *in vitro* antiviral activity, enhanced oral bioavailability, reduced nephrotoxicity, and activity in animal models of CMV and poxvirus infections (Kern *et al.*, 2004).

As in other areas of antimicrobial chemotherapy, the combined use of antiviral agents has been studied as a means of increasing antiviral activity, reducing drug dosage and the associated risk of toxicity, and preventing or modifying the development of drug resistance. Because viral isolates may be mixtures of sensitive and resistant viruses or viruses with different resistance mutations, treatment with combinations of drugs may provide broader activity than treatment with single agents. Drug combinations may constrain the mutability of the virus, enhance susceptibility to a second agent, or diminish viral replicative capacity.

Future therapeutic breakthroughs probably also will depend on the identification of new molecular targets in viral replication and novel therapeutic modalities. The first antisense oligonucleotide has been approved for a human viral infection (*fomivirsen* for CMV retinitis), but important problems regarding potency, selectivity, and delivery to target cells remain to be solved. An antiviral strategy increasingly used in laboratory studies is RNA interference, a process of gene silencing in which introduced double-stranded RNA (dsRNA) leads to sequence-specific degradation of messenger RNA. Antiviral effects using small interfering RNAs (siRNAs) have been shown in cell culture for a range of viruses, including HCV, influenza, RSV, picornaviruses, and SARS coronavirus in humans and for several in animals, including influenza (Ge *et al.*, 2003). *In vivo* application of this approach is limited by the technical challenges of achieving intracellular delivery of sufficient siRNA, so the clinical potential of RNA interference remains to be determined.

Other approaches that may prove to be useful involve agents to moderate host immunopathological responses, agents to boost host immune responses, and virus-specific immunotherapies (e.g., monoclonal antibodies, therapeutic vaccines) to supplement host responses.

ANTIRETROVIRAL AGENTS AND TREATMENT OF HIV INFECTION

Charles Flexner

I. OVERVIEW OF HIV INFECTION

Combination antiretroviral therapy prolongs life and prevents progression of disease caused by human immunodeficiency virus (HIV). The pharmacotherapy of HIV infection is a rapidly moving field. In 2004, there were 20 antiretroviral drugs available in the United States. Since three-drug combinations are the minimum standard of care for this infection, current agents constitute at least 1140 possible regimens. The long-term management of a patient on antiretroviral therapy can be daunting, even for an experienced healthcare provider. Knowing the essential features of the pathophysiology of this disease and how chemotherapeutic agents affect the virus and the host is critical in developing a rational approach to therapy. *Unique features of this drug class include the need for lifelong administration to control virus replication and the possibility of rapid emergence of permanent drug resistance if these agents are not used properly.*

In 2004, an estimated 42 million people were living with HIV infection worldwide, with the majority in resource-poor countries. Increasingly, the public health impact of this epidemic has shifted to those regions least able to afford treatment. Fewer than 5% of those who would benefit from combination antiretroviral therapy were receiving it, even though such treatment is known to reduce the complications of infection and prolong life (Lee *et al.*, 2001). The causes of maldistribution of effective antiretroviral therapy are complex, including social and economic inequities, patient and provider choice, and shortcomings in the convenience and tolerability of available regimens. Regardless, these drugs have the capacity

to improve the quality of human health substantially and to produce near-normal life expectancies for some patients with a previously lethal disease (Lee *et al.*, 2001).

PATHOGENESIS OF HIV-RELATED DISEASE

Human immunodeficiency viruses (HIV) are lentiviruses, a family of mammalian retroviruses evolved to establish chronic persistent infection with gradual onset of clinical symptoms. Unlike herpesviruses, replication is constant following infection, and although some infected cells may harbor nonreplicating but infectious virus for years, there generally is no true period of viral latency following infection (Greene and Peterlin, 2002). Humans and chimpanzees are the only known hosts for these viruses.

There are two major families of HIV. Most of the epidemic involves HIV-1; HIV-2 is a close relative whose distribution is concentrated in western Africa. HIV-1 is genetically diverse, with at least five distinct subfamilies or clades. HIV-1 and HIV-2 have similar *in vitro* sensitivity to most antiretroviral drugs, although the nonnucleoside reverse transcriptase inhibitors (NNRTIs) are HIV-1-specific and have no activity against HIV-2. Within HIV-1 isolates, clade *per se* does not seem to have a major effect on drug sensitivity.

Virus Structure. HIV is a typical retrovirus with a small RNA genome of 9300 base pairs. Two copies of the genome are contained in a nucleocapsid core surrounded by a lipid bilayer, or envelope, that is derived from the host cell plasma membrane (Figure 50–1). The

Figure 50–1. Replicative cycle of HIV-1 showing the sites of action of available antiretroviral agents. Available antiretroviral agents are shown in blue. Key: RT, reverse transcriptase; cDNA, complementary DNA; mRNA, messenger RNA; RNase H, ribonuclease H; gp120 + gp41, extracellular and intracellular domains, respectively, of envelope glycoprotein. (Adapted from Hirsch and D’Aquila, 1993.)

viral genome encodes three major open reading frames: *gag* encodes a polyprotein that is processed to release the major structural proteins of the virus; *pol* overlaps *gag* and encodes three important enzyme activities—an RNA-dependent DNA polymerase or reverse transcriptase with RNAase activity, protease, and the viral integrase; and *env* encodes the large transmembrane envelope protein responsible for cell binding and entry. Several small genes encode regulatory proteins that enhance virion production or combat host defenses. These include *tat*, *rev*, *nef*, and *vpr* (Greene and Peterlin, 2002).

Virus Life Cycle. HIV tropism is controlled by the envelope protein gp160 (*env*) (Figure 50–1). The major target for *env* binding is the CD4 receptor present on lymphocytes and macrophages, although cell entry also requires binding to a coreceptor, generally the chemokine receptor CCR5 or CXCR4 (Greene and Peterlin, 2002). CCR5 is present on macrophage lineage cells. Most infected individuals harbor predominately the CCR5-tropic virus; it is believed that this virus is responsible for sexual transmission of HIV and that the initial cells infected in sexual transmission express this coreceptor. A shift from CCR5 to CXCR4 utilization is associated with advancing disease, and the affinity of

HIV-1 for CXCR4 allows infection of T-lymphocytes (Berger *et al.*, 1999). A phenotypic switch from CCR5 to CXCR4 heralds accelerated loss of CD4+ helper T cells and increased risk of immunosuppression. Whether coreceptor switch is a cause or a consequence of advancing disease is still unknown.

The gp41 domain of *env* controls the fusion of the virus lipid bilayer with that of the host cell. Following fusion, full-length viral RNA enters the cytoplasm, where it undergoes replication to a short-lived RNA–DNA duplex; the original RNA is degraded by RNase H to allow creation of a full-length double-stranded DNA copy of the virus (Figure 50–1). Because the HIV reverse transcriptase is error-prone and lacks a proofreading function, mutation is quite frequent and estimated to occur at approximately three bases out of every full-length (9300-base-pair) replication (Coffin, 1995). Virus DNA is transported into the nucleus, where it is integrated into a host chromosome by the viral integrase in a random or quasi-random location (Greene and Peterlin, 2002).

Following integration, the virus may remain in a quiescent state, not producing RNA or protein but replicating as the cell divides. When a cell that harbors the virus is activated, viral RNA and proteins are produced. Structural proteins assemble around full-length genomic RNA to form a nucleocapsid (Figure 50–1). The transmem-

brane envelope and other structural proteins assemble at the cell surface, concentrated in cholesterol-rich lipid rafts. The nucleocapsid cores are directed to these sites and bud through the cell membrane, creating a new enveloped HIV particle containing two complete single-stranded RNA genomes. Reverse transcriptase is incorporated into this particle so that replication can begin immediately after the virus enters a new cell (Greene and Peterlin, 2002).

How the Virus Causes Disease. Sexual acquisition of HIV infection is thought to be mediated by one or, at most, a handful of infectious virus particles. Soon after infection, there is a rapid burst of replication peaking at 2 to 4 weeks, with 10^9 or more cells becoming infected. This peak is associated with a transient dip in the number of peripheral CD4+ (helper) T-lymphocytes. As a result of new host immune responses and target cell depletion, the number of infectious virions as reflected by the plasma HIV RNA concentration (also known as *viral load*) declines to a quasi-steady state. This level of virus activity has been termed the *set point* and reflects the interplay between host immunity and the pathogenicity of the infecting virus (Coffin, 1995). Most viruses are derived from CD4+ cells that turn over with a half-life of 2.2 days (Perelson *et al.*, 1996). Thus, in the average infected individual, several billion infectious virus particles are produced every few days.

Eventually, the host CD4+ T-lymphocyte count begins a steady decline, accompanied by a rise in the plasma HIV RNA concentration. Once the peripheral CD4 cell count falls below 200 cells/mm³, there is an increasing risk of opportunistic diseases and ultimately death. Sexual acquisition of CCR5-tropic HIV-1 is associated with a median time to clinical disease (usually an opportunistic infection such as *Pneumocystis carinii* pneumonia) of 8 to 10 years. Some patients, termed *long-term nonprogressors*, can harbor HIV for more than two decades without significant decline in peripheral CD4 cell count or clinical immunosuppression; this may reflect a combination of favorable host immunogenetics and immune responses (Fauci, 1996).

An important question relevant to treatment is whether HIV disease is a consequence purely of CD4+ lymphocyte depletion or other factors. Most natural history data suggest the former, although both the amount of virus measurable in the patient's circulation and the CD4 cell count are independent predictors of disease progression (Mellors *et al.*, 1996, 1997). Regardless, successful therapy is based on inhibition of HIV replication; treatments designed specifically to boost the host immune system

without exerting a direct antiviral effect have had no reliable clinical benefit.

HISTORY OF ANTIRETROVIRAL THERAPY

The rapid discovery and development of combinations of antiretroviral agents capable of long-term control of HIV replication were remarkable achievements. Cooperation between government and academic researchers, the pharmaceutical industry, and regulatory agencies in the United States and Europe quickly converted bench observations into new treatment modalities. The identification of HIV as the causative agent of acquired immune deficiency syndrome (AIDS) in 1985 and the immediate availability of its complete genome (Fisher *et al.*, 1985) paved the way for the development of selective inhibitors.

The first effective antiretroviral agent, *zidovudine*, was synthesized by Horwitz in 1964 as a false nucleoside with disappointing anticancer activity. The drug was shown by Osterag in 1972 to inhibit the *in vitro* replication of a murine type D retrovirus (McLeod and Hammer, 1992). Mitsuya and Broder, working in Bethesda in 1985, reported that this drug had potent *in vitro* anti-HIV activity (Mitsuya *et al.*, 1985). Clinical studies of zidovudine began that same year, and by 1987 this drug was approved and marketed for the control of HIV infection based on the results of a small but definitive randomized clinical trial (Fischl *et al.*, 1987). Large numbers of nucleoside analogs already had been synthesized as potential anticancer and immunomodulatory drugs, and this made it possible for similar compounds to be tested efficiently and approved.

Selective nonnucleoside reverse transcriptase inhibitors (NNRTIs) were identified by iterative screening using purified viral enzyme (Pauwels *et al.*, 1990). The clinical development of these drugs was hindered by the rapid emergence of drug resistance (Wei *et al.*, 1995). However, three drugs in this category were approved by 1998 (Table 50–1). HIV protease inhibitors were the products of rational drug design, relying on technology developed to identify transition-state peptidomimetic antagonists of proteases in the renin–angiotensin cascade (Flexner, 1998). Highly selective antagonists of the HIV protease were reported as early as 1987. Phase I trials of the first of these drugs, *saquinavir*, began in 1989, and this drug was approved for prescription use in 1995. Two additional protease inhibitors, *ritonavir* and *indinavir*, were approved within the next 4 months.

Table 50–1
Antiretroviral Agents Approved for Use in the United States

GENERIC NAME [U.S. TRADE NAME]	ABBREVIATION; CHEMICAL NAMES
<i>Nucleoside reverse transcriptase inhibitors</i>	
Zidovudine [RETROVIR]*	ZDV; azidothymidine (AZT)
Didanosine [VIDEX; VIDEX EC]	ddI; dideoxyinosine
Stavudine [ZERIT; ZERIT XR]	d4T; didehydrodeoxythymidine
Zalcitabine [HIVID]	DDC; dideoxycytidine
Lamivudine [EPIVIR]*	3TC; dideoxythiacytidine
Abacavir [ZIAGEN]*	ABC; cyclopropylaminopurinylicyclopentene
Tenofovir disoproxil [VIREAD]*	TDF; phosphinylmethoxypropyladenine (PMPA)
Emtricitabine [EMTRIVA]*	FTC; fluorooxathiolanyl cytosine
<i>Nonnucleoside reverse transcriptase inhibitors</i>	
Nevirapine [VIRAMUNE]	NVP
Efavirenz [SUSTIVA]	EFV
Delavirdine [RESCRIPTOR]	DLV
<i>Protease inhibitors</i>	
Saquinavir [INVIRASE; FORTOVASE]	SQV
Indinavir [CRIVAN]	IDV
Ritonavir [NORVIR]	RTV
Nelfinavir [VIRACEPT]	NFV
Amprenavir [AGENERASE]	APV
Lopinavir [KALETRA] [†]	LPV/r
Atazanavir [REYATAZ]	ATV
Fosamprenavir [LEXIVA]	FPV
<i>Fusion inhibitor</i>	
Enfuvirtide [FUZEON]	T-20

*A fixed-dose coformulation of zidovudine + lamivudine is available as COMBIVIR; a fixed-dose coformulation of zidovudine + lamivudine + abacavir is available as TRIZIVIR; a fixed-dose coformulation of abacavir with lamivudine is available as EPZICOM; a fixed-dose coformulation of tenofovir with emtricitabine is available as TRUVADA. [†]Lopinavir is only available as part of a fixed-dose coformulation with ritonavir (KALETRA).

Innovation in drug approval and regulation facilitated the availability of multiple agents capable of fighting this infection. In 1989, the U.S. Food and Drug Administration (FDA) agreed to make promising agents available to

patients with advanced disease through an expanded access program. The capacity to assess plasma HIV RNA concentration and CD4 cell count and proof of the relevance of those measures in place of mortality and morbidity (Mellors *et al.*, 1996), made it possible to collapse the time frame for clinical drug development. The most promising drug combinations were identified by their effect on these surrogate endpoints in clinical trials as short as 6 months in duration.

Today, a detailed understanding of the molecular basis of drug resistance guides the search for new agents and informs the selection of combination strategies for existing drugs. The large number of possible drug combinations has given patients more chances at virus control but also complicates the practice of HIV medicine. Current challenges include access to effective long-term treatment in resource-poor countries and identification of new drugs for treatment-experienced patients with resistance to approved drugs. Although many steps in the virus life cycle are potential points for antiviral intervention, only three are targeted by available agents: virus–cell fusion, reverse transcription, and proteolytic processing (Figure 50–1).

PRINCIPLES OF HIV CHEMOTHERAPY

Current treatment assumes that all aspects of disease derive from the direct toxic effects of HIV on host cells, mainly CD4+ T-lymphocytes. This viewpoint is based on studies demonstrating the importance of high plasma HIV RNA concentration (Mellors *et al.*, 1996) and low CD4+ lymphocyte count (Mellors *et al.*, 1997) as predictors of disease progression and mortality. Validation has come from evidence that treatment regimens associated with long-term suppression of HIV replication (as measured by decreased plasma HIV RNA) and repletion of peripheral CD4 cells are clinically beneficial (Lee *et al.*, 2001). The goal of therapy is to suppress virus replication as much as possible for as long as possible.

Deciding when to start antiretroviral therapy has been a shifting target during the epidemic. Zidovudine, the first antiretroviral drug, was approved initially only for patients with advanced, symptomatic disease. In this population, zidovudine monotherapy dramatically reduced HIV-associated mortality after only 6 months of treatment compared with placebo (Fischl *et al.*, 1987). The clinical benefit of this drug in patients with less advanced disease or no symptoms was more difficult to demonstrate, and two large comparative trials showed no benefit of early

versus delayed initiation of therapy (Hamilton *et al.*, 1992; Concorde Coordinating Committee, 1994).

The more substantial antiretroviral effects of the HIV protease inhibitors and NNRTIs (Ho *et al.*, 1995; Wei *et al.*, 1995) prompted a new look at early and widespread treatment of infected persons. Because these agents caused a rapid 99% to 99.9% decline in plasma HIV RNA concentration (as opposed to the 70% drop caused by zidovudine), it was thought erroneously that combining these drugs with nucleoside analogs might eradicate the virus from infected individuals after only a few years of treatment (Perelson *et al.*, 1996). Because newer agents increased CD4 cell counts to normal or near-normal levels, some felt that earlier institution of therapy might preserve the immune system before it could be further ravaged by the virus. The concept of “hit early, hit hard” led many patients to seek combination therapy regardless of disease stage or symptoms.

Several findings reversed this enthusiasm for universal treatment (Harrington and Carpenter, 2000). First, a number of studies indicated the low likelihood that HIV could be eradicated with drug therapy. A reservoir of long-lived quiescent T cells harboring infectious HIV DNA integrated into the host chromosome was identified independently by several groups of investigators (Chun *et al.*, 1998; Finzi *et al.*, 1997). Infectious HIV could be produced by these quiescent cells after chemical activation *ex vivo* (and presumably if the cells were activated by immune stimuli *in vivo*), but the nonreplicating form of the viral genome was not susceptible to drugs. Recent estimates suggest that at least some of these cells will survive for decades and probably for the life of the patient (Siliciano *et al.*, 2003) regardless of treatment.

More recent natural history studies point to the low risk of short-term disease progression when the CD4 cell count is greater than 350 cells/mm³ or plasma HIV RNA concentrations are less than 50,000 copies/ml (Phair *et al.*, 2002). The toxic risks of long-term combination chemotherapy, the need for nearly perfect adherence to prescribed regimens, the inconvenience of some regimens, and the high cost of lifelong treatment point to a risk-benefit ratio that favors treating only patients with low CD4 counts and/or very high viral load (Table 50–2). As simpler, less toxic, and better-tolerated drug regimens become available, there may be renewed interest in earlier initiation of treatment.

Drug resistance is also a more extensive and serious problem than imagined originally. There is a high likelihood that any infected individual will harbor viruses with single-amino-acid mutations conferring some degree of resistance to any known antiretroviral drug because of the

high mutation rate of HIV and the tremendous number of infectious virions (Coffin, 1995). As a consequence, treatment with only a single antiretroviral drug inevitably provokes the emergence of drug-resistant virus, in some cases within a few weeks (Wei *et al.*, 1995). Drug therapy does not cause mutation but provides the necessary selective pressure to promote growth of drug-resistant viruses that arise naturally (Coffin, 1995). A combination of active agents therefore is required to prevent drug resistance, analogous to strategies employed in the treatment of tuberculosis (*see* Chapter 47). Intentional drug holidays, also known as *structured treatment interruptions*, allow the virus to replicate anew and increase the risk of drug resistance and disease progression (Lawrence *et al.*, 2003) and therefore are not recommended. This reflects the ability of the virus to persist indefinitely in the face of effective therapy (Kieffer *et al.*, 2004). As more clinical safety data accumulate, there may be further exploration of treatment interruptions as a strategy for lowering drug costs and toxicity in selected patients. At present, all antiretroviral therapy outside the research setting is combination therapy. The current standard of care is to use at least three drugs simultaneously for the entire duration of treatment (Table 50–2). The expected outcome of initial therapy in a previously untreated patient is an undetectable viral load (plasma HIV RNA of less than 50 copies/ml) within 24 weeks of starting treatment (Department of Health and Human Services, 2004). In prospective comparative trials, two-drug regimens were more effective than single-drug regimens (Fischl *et al.*, 1995; Hammer *et al.*, 1996; Saag *et al.*, 1998), and three-drug regimens are more effective still (Collier *et al.*, 1996; Gulick *et al.*, 1997; Hammer *et al.*, 1997). Mathematical models of HIV replication suggest that three is the minimum number of agents required to guarantee effective long-term suppression of HIV replication without resistance (Muller and Bonhoeffer, 2003). In treatment-naïve patients, a regimen containing a nonnucleoside plus two nucleoside reverse transcriptase inhibitors was as effective as a regimen containing an additional nucleoside (Shafer *et al.*, 2003), indicating the equivalence of these three-drug and four-drug regimens. Four or more drugs often are used simultaneously in pretreated patients harboring drug-resistant virus (Piketty *et al.*, 1999), but the number of agents a patient can take is limited by toxicity and inconvenience.

Pharmacodynamic synergy is probably not an important consideration in regimen selection, although most prescribers prefer to use drugs that attack at least two different molecular sites. This could include nucleoside reverse transcriptase inhibitors that target the active site of the enzyme combined with a nonnucleoside inhibitor that binds to a different site on the same enzyme or an inhibitor of a

Table 50–2

U.S. Department of Health and Human Services Guidelines for Initiating Therapy in Treatment-Naive HIV-Infected Patients, 2004

A. Patient Characteristics			
CLINICAL CATEGORY	CD4 COUNT	PLASMA HIV RNA	RECOMMENDATION
AIDS-defining illness* or severe symptoms	Any value	Any value	Treat.
Asymptomatic	<200 cells/mm ³	Any value	Treat.
Asymptomatic	>200 cells/mm ³ , but <350 cells/mm ³	Any value	Offer treatment, following full discussion of pros and cons with each patient.
Asymptomatic	>350 cells/mm ³	>100,000 copies/ml	Most physicians recommend deferring therapy, but some will treat.
Asymptomatic	>350 cells/mm ³	<100,000 copies/ml	Defer therapy.
B. Preferred and Alternative Regimens			
PREFERRED REGIMENS			NUMBER OF PILLS PER DAY
NNRTI-based	EFV + (3TC or FTC) + (AZT or TDF) (not for use in first trimester of pregnancy or in women with high pregnancy potential)		2–3
PI-based	LPV/r + (3TC or FTC) + AZT		8–9
ALTERNATIVE REGIMENS			NUMBER OF PILLS PER DAY
NNRTI-based	EFV + (3TC or FTC) + (ABC or ddI or d4T)		2–4
	NVP + (3TC or FTC) + (AZT or d4T or ddI or ABC or TDF)		3–6
PI-based	ATV + (3TC or FTC) + (AZT or d4T or ABC or ddI) or (TDF + RTV 100 mg/d)		3–6
	FosAPV + (3TC or FTC) + (AZT or d4T or ABC or TDF or ddI)		5–8
	FosAPV/RTV [†] + (3TC or FTC) + (AZT or d4T or ABC or TDF or ddI)		5–8
	IDV/RTV [†] + (3TC or FTC) + (AZT or d4T or ABC or TDF or ddI)		7–12
	LPV/r + (3TC or FTC) + (d4T or ABC or TDF or ddI)		7–10
	NFV + (3TC or FTC) + (AZT or d4T or ABC or TDF or ddI)		5–8
	SQV/RTV [†] + (3TC or FTC) + (AZT or d4T or ABC or TDF or ddI)		13–16
	3 NRTI-based [‡]	ABC + AZT + 3TC, only when a preferred or an alternative NNRTI- or a PI-based regimen cannot or should not be used	

(Continued)

Table 50–2

U.S. Department of Health and Human Services Guidelines for Initiating Therapy in Treatment-Naive HIV-Infected Patients, 2004 (Continued)

REGIMENS THAT SHOULD NOT BE USED	RATIONALE
AZT + d4T	Pharmacologic antagonism between AZT and d4T
ABC + TDF + 3TC once daily as a triple-NRTI regimen	High rate of early virological nonresponse seen in treatment-naive patients
TDF + ddI + 3TC combination once daily as a triple-NRTI regimen	High rate of early virological nonresponse seen in treatment-naive patients
ATV + IDV	Potential additive hyperbilirubinemia
ddI + DDC	Additive peripheral neuropathy
FTC + 3TC	Similar resistance profile with no potential benefit
3TC + DDC	<i>In vitro</i> antagonism
SQV hard-gel capsule as single protease inhibitor	Poor oral bioavailability and inferior antiretroviral activity when compared with other protease inhibitors
d4T + DDC	Additive peripheral neuropathy

ABBREVIATIONS: EFV, efavirenz; 3TC, lamivudine; AZT, zidovudine; TDF, tenofovir disoproxil fumarate; d4T, stavudine; LPV/r, lopinavir/ritonavir coformulation; FTC, emtricitabine; NVP, nevirapine; ddI, didanosine; ATV, atazanavir; fosAPV, fosamprenavir; RTV, ritonavir; IDV, indinavir; NFV, nelfinavir; SQV, saquinavir *Higher incidence of lipotrophy, hyperlipidemia, and mitochondrial toxicities reported with d4T than with other NRTIs. *AIDS-defining illness per Centers for Disease Control, 1993. Severe symptoms include unexplained fever or diarrhea > 2–4 weeks, oral candidiasis, or >10% unexplained weight loss. †Low-dose (100–400 mg) ritonavir per day. ‡The triple-NRTI regimen had reduced efficacy compared with NNRTI-based regimens in one large controlled clinical trial and should be used only when an NNRTI- or PI-based regimen cannot or should not be used as first-line therapy. SOURCE: Adapted from Panel on Clinical Practices for Treatment of HIV Infection, 2004.

different enzyme, the HIV protease (Table 50–2). The preceding regimens have similar long-term efficacy. However, a three-drug regimen containing a single drug class is not as effective as a two-class regimen in treatment-naive patients. In one large randomized, controlled trial, 89% of patients taking two nucleoside analogs plus an NNRTI had undetectable plasma HIV RNA at 32 weeks as compared with 79% of those taking three nucleosides (Gulick *et al.*, 2004). Whether this reflects the inferiority of attacking only a single viral target or the inferiority of the specific drugs involved has yet to be determined. Nonetheless, enthusiasm for single-class therapy is limited at present. Regimens containing three or four different drug classes are reserved for treatment-experienced patients who have failed multiple previous regimens. This acknowledges the benefit of reserving at least one drug class for future treatment in case of failure (Department of Health and Human Services, 2004).

Failure of an antiretroviral regimen involves a persistent increase in plasma HIV RNA concentrations in a previously undetectable patient despite continued treatment or failure to reduce plasma HIV RNA significantly in a patient who has taken a prescribed regimen for more than 12 weeks (Department of Health and Human Services, 2004). This indicates resistance to one or more drugs in the regimen and necessitates a change in treatment. Once resistance occurs, resistant strains remain in tissues indefinitely, even though the resistant virus may not be detectable in the plasma. The selection of new agents is informed by the patient's treatment history, as well as viral resistance testing, preferably obtained while the patient is still taking a failing regimen to facilitate proper recovery and characterization of the patient's virus (Kuritzkes, 2004). Treatment failure generally requires the implementation of a completely new combination

of drugs. Adding a single agent to a three-drug regimen sometimes is employed as a form of treatment intensification for patients whose viral load has fallen but is not undetectable. However, adding a single effective agent to a failing regimen is functional monotherapy if the patient is resistant to all drugs in the regimen.

The risk of failing a regimen depends on the percent of prescribed doses taken in any given period of treatment. After a median of 6 months of treatment, virologic failure occurred in 22% of those taking 95% or more of their antiretroviral doses but in more than half of those taking less than 95% of prescribed doses (Paterson *et al.*, 2000). This places an important educational burden on the health care provider and requires exceptional patient responsibility. Resistance owing to poor adherence probably is inescapable for a virus that is persistent, prolific, and error-prone in its replication because these three qualities nearly guarantee drug resistance if drugs are not taken as recommended. Despite the availability of highly effective and well-tolerated drugs, long-term success, as defined by the percent of patients with an undetectable plasma HIV RNA after 1 year, is only 30% to 50% in patients treated outside clinical trials in the United States (Lucas *et al.*, 1999). This relatively low effectiveness reflects in part the type of patient seen in urban clinical care settings but also indicates the extreme degree of adherence to prescribed medications needed to maintain suppression of HIV.

One recent concern of long-term therapy is the development of a metabolic syndrome characterized by insulin resistance, fat redistribution, and hyperlipidemia and known as the *HIV lipodystrophy syndrome*. Lipodystrophy occurs in 10% to 40% of treated patients and has been seen with most drug combinations used in clinical tri-

als. The pathogenesis is somewhat mysterious but involves phenotypic and metabolic changes similar to those seen with other human lipodystrophy syndromes (Garg, 2004). Clinical features include peripheral fat wasting (lipoatrophy), central fat accumulation including enlarged breasts and buffalo hump, insulin resistance and hyperglycemia, and elevations in serum cholesterol and triglycerides. Switching from one drug regimen to another may not reverse the symptoms, emphasizing its ubiquitous nature and possible role of HIV infection *per se*. Treatment is symptom-directed and should include management of hyperlipidemias as recommended by the American Heart Association (see Chapter 35). Lipodystrophy has been associated with an increased risk of myocardial infarction in virologically controlled patients, emphasizing the importance of cardiovascular risk factor reduction (Sekhar *et al.*, 2004).

II. DRUGS USED TO TREAT HIV INFECTION

NUCLEOSIDE AND NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS

The HIV-encoded, RNA-dependent DNA polymerase, also called *reverse transcriptase*, converts viral RNA into proviral DNA that is then incorporated into a host cell chromosome. Available inhibitors of this enzyme are either nucleoside/nucleotide analogs or nonnucleoside inhibitors (Figure 50–2 and Table 50–3).

Like all available antiretroviral drugs, nucleoside and nucleotide reverse transcriptase inhibitors prevent infection of susceptible cells but have no impact on cells that already harbor HIV. Nucleoside and nucleotide analogs must enter cells and undergo phosphorylation to generate synthetic substrates for the enzyme (Table 50–3). The fully phosphorylated analogs block replication of the viral genome both by competitively inhibiting incorporation of native nucleotides and by terminating elongation of nascent proviral DNA because they lack a 3-hydroxyl group.

All but one of the drugs in this class are nucleosides that must be triphosphorylated at the 5'-hydroxyl to exert activity. The sole exception, *tenofovir*, is a nucleotide monophosphate analog that requires two additional phosphates to acquire full activity. These compounds inhibit both HIV-1 and HIV-2, and several have broad-spectrum activity against other human and animal retroviruses; *emtricitabine*, *lamivudine*, *zalcitabine*, and *tenofovir* are active against hepatitis B virus (HBV) *in vitro*, and *tenofovir* also has activity against herpesviruses (De Clercq, 2003).

The selective toxicity of these drugs depends on their ability to inhibit the HIV reverse transcriptase without inhibiting host cell DNA polymerases. Although the intracellular triphosphates for all these drugs have low affinity for human DNA polymerase- α and - β , some are capable of inhibiting human DNA polymerase- γ which is

the mitochondrial enzyme. As a result, the important toxicities common to this class of drugs result in part from the inhibition of mitochondrial DNA synthesis (Chen *et al.*, 1991; Lee *et al.*, 2003). These toxicities include anemia, granulocytopenia, myopathy, peripheral neuropathy, and pancreatitis. Lactic acidosis with or without hepatomegaly and hepatic steatosis is a rare but potentially fatal complication seen with *stavudine*, *zidovudine*, *didanosine*, and *zalcitabine*; it is probably not associated independently with the other drugs (Tripuraneni *et al.*, 2004). Phosphorylated *emtricitabine*, *lamivudine*, and *tenofovir* have low affinity for DNA polymerase- γ and are largely devoid of mitochondrial toxicity.

The chemical structures of the eight currently approved nucleoside and nucleotide reverse transcriptase inhibitors are shown in Figure 50–2; their pharmacokinetic properties are summarized in Table 50–3. Phosphorylation pathways for these eight drugs are summarized in Figure 50–3. Most nucleoside and nucleotide reverse transcriptase inhibitors are eliminated from the body primarily by renal excretion. *Zidovudine* and *abacavir*, however, are cleared mainly by hepatic glucuronidation. Most of the parent compounds are eliminated rapidly from the plasma, with elimination half-lives of 1 to 10 hours (Table 50–3). *Tenofovir*, however, has a plasma half-life of 14 to 17 hours. Despite rapid clearance from the plasma, the critical pharmacological pathway for these agents is production and elimination of the intracellular nucleoside triphosphate or nucleotide diphosphate, which is the active anabolite. In general, the phosphorylated anabolites are eliminated from cells much more gradually than the parent drug is eliminated from the plasma. Estimated elimination half-lives for intracellular triphosphates range from 2 to 50 hours (Table 50–3). This allows for less frequent dosing than would be predicted from plasma half-lives of the parent compounds. All approved nucleoside and nucleotide reverse transcriptase inhibitors are dosed once or twice daily, with the exception of *zalcitabine*, which is dosed every 8 hours.

These drugs generally are not involved in clinically significant pharmacokinetic drug interactions because they are not substrates for hepatic cytochrome P450 enzymes (CYPs). However, *tenofovir* increases concentrations of concurrent *didanosine* by 25% to 40% perhaps through inhibition of purine nucleoside phosphorylase, and a reduction of the *didanosine* dose is recommended when these agents are given together (Chapman *et al.*, 2003). *Tenofovir* also may reduce the concentrations of some concurrently administered HIV protease inhibitors by 25% or more, although the pharmacological mechanisms responsible for these drug interactions are unknown.

High-level resistance to nucleoside reverse transcriptase inhibitors, especially thymidine analogs, occurs slowly as compared with NNRTIs and protease inhibitors. *Zidovudine* resistance was noted in only one-third of treated subjects after 1 year of monotherapy (Fischl *et al.*, 1995). High-level resistance can occur rapidly with *lamivudine* and *emtricitabine*. In most cases, high-level resistance requires accumulation of a minimum of three to four codon substitutions, although a recently described two-amino-acid insertion is associated with resistance to all drugs in this class (Gallant *et al.*, 2003). Cross-resistance is common but often confined to drugs having similar chemical structures; for example, *zidovudine* is a thymidine analog, and a *zidovudine*-resistant isolate is much more likely to be cross-resistant to the thymidine analog *stavudine* than to the cytosine analog *lamivudine*.

When used investigational as monotherapy, most of these drugs induce only a 30% to 90% mean peak decrease in plasma concentrations of HIV RNA; *abacavir*, however, can cause up to a 99% decrease (Hervey and Perry, 2000). CD4 lymphocyte count increas-

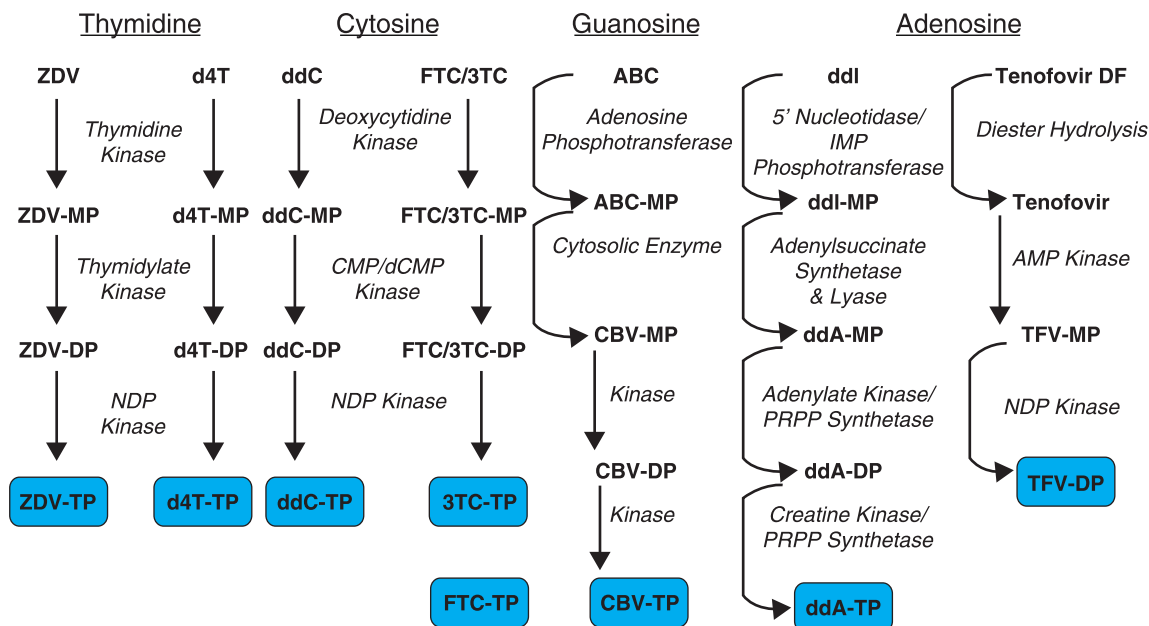

Figure 50–3. Intracellular activation of nucleoside analog reverse transcriptase inhibitors. Drugs and phosphorylated analogs are abbreviated; the enzymes responsible for each conversion are spelled out. The active antiretroviral analog for each drug is shown in the blue box. Key: ZDV, zidovudine; d4T, stavudine; ddC, dideoxycytidine; FTC, emtricitabine; 3TC, lamivudine; ABC, abacavir; ddl, didanosine; DF, disoproxil fumarate; MP, monophosphate; DP, diphosphate; TP, triphosphate; AMP, adenosine monophosphate; CMP, cytosine monophosphate; dCMP, deoxycytosine monophosphate; IMP, inosine 5'-monophosphate; PRPP, phosphoribosyl pyrophosphate; NDP, nucleoside diphosphate. (Adapted from Khoo *et al.*, 2002.)

es are also modest with nucleoside monotherapy (mean increases of 50 to 100 cells/mm³, depending on disease stage). Nonetheless, these drugs remain a critical component of therapy, and nearly all patients taking antiretroviral therapy are currently taking at least one agent from this class. Although modest in their own antiviral potency, several nucleoside analogs have favorable safety and tolerability profiles and are useful in suppressing the emergence of HIV isolates resistant to the more potent drugs in combination regimens.

Zidovudine

Chemistry and Antiviral Activity. Zidovudine (3'-azido-3'-deoxythymidine) is a synthetic thymidine analog with potent *in vitro* activity against a broad spectrum of retroviruses including HIV-1, HIV-2, and human T-cell lymphotropic viruses (HTLV) I and II (McLeod and Hammer, 1992). Its IC₅₀ against laboratory and clinical isolates of HIV-1 ranges from 10 to 48 nM. Zidovudine is active in lymphoblastic and monocytic cell lines but is substantially less active in chronically infected cells (Geleziunas *et al.*, 1993) probably because it has no impact on cells already infected with HIV. Zidovudine appears to be more active in lymphocytes than in monocyte-macrophage cells because of enhanced phosphorylation in the former. For the same reason, the drug is more potent in activated than in resting lymphocytes because the phos-

phorylating enzyme, thymidine kinase, is S-phase-specific (Gao *et al.*, 1994).

Mechanism of Action and Resistance. Intracellular zidovudine is phosphorylated by thymidine kinase to zidovudine 5'-monophosphate, which is then phosphorylated by thymidylate kinase to the diphosphate and by nucleoside diphosphate kinase to zidovudine 5'-triphosphate (Furman *et al.*, 1986) (Figure 50–3). Because the conversion of zidovudine 5'-monophosphate to diphosphate is very inefficient, high concentrations of the monophosphate accumulate inside the cell (Slusher *et al.*, 1992) and may serve as a precursor depot for formation of triphosphate. As a consequence, there is little correlation between extracellular concentrations of parent drug and intracellular concentrations of triphosphate (Dudley, 1995), and higher plasma concentrations of zidovudine do not increase intracellular triphosphate concentrations proportionately. Zidovudine 5'-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3'-hydroxyl group. The monophosphate competitively inhibits cellular thymidylate kinase, and this may reduce the amount of intracellular thymidine triphosphate (Furman *et al.*, 1986). Although this latter effect could increase antiviral activity, it also may contribute to toxicity. Zidovudine 5'-triphosphate only weakly inhibits cellular DNA polymerase- α but is a more potent inhibitor of mitochondrial polymerase- γ .

Resistance to zidovudine is associated with mutations at reverse transcriptase codons 41, 44, 67, 70, 118, 210, 215, and 219 (Gallant *et al.*, 2003). These mutations are referred to as *thymidine analog mutations* (TAMs) because of their ability to confer cross-resistance

to other thymidine analogs such as stavudine. Two clusters of resistance mutations occur commonly. Using the single-letter amino-acid symbols: the pattern of 41L, 210W, and 215Y is associated with high-level resistance to zidovudine, as well as cross-resistance to other drugs in this class, including tenofovir and abacavir. The pattern 67N, 70R, 215F, and 219Q pattern is less common and is also associated with lower levels of resistance and cross-resistance. TAMs associated with resistance to zidovudine and stavudine promote excision of the incorporated triphosphate analogs through pyrophosphorolysis (Naeger *et al.*, 2002). Mutations accumulated gradually when zidovudine was used as the sole antiretroviral agent, and clinical resistance developed in only 31% of patients after 1 year of zidovudine monotherapy (Fischl *et al.*, 1995). Cross-resistance to multiple nucleoside analogs has been reported following prolonged therapy and has been associated with a mutation cluster involving codons 62, 75, 77, 116, and 151. In addition, a recently described mutation at codon 69 (typically T69S) followed by a two-amino-acid insertion produces cross-resistance to all current nucleoside and nucleotide analogs (Gallant *et al.*, 2003).

Absorption, Distribution, and Elimination. Zidovudine is absorbed rapidly and reaches peak plasma concentrations within 1 hour (Dudley, 1995). Like other nucleoside analogs, the elimination half-life of the parent compound (about 1 hour) is considerably shorter than that of the intracellular triphosphate, which is 3 to 4 hours (Table 50–3). Failure to recognize this led to serious overdosing of the drug when it was first approved; the recommended dose was 250 mg every 4 hours in 1987, compared with 300 mg twice a day presently.

Zidovudine undergoes rapid first-pass hepatic metabolism by conversion to 5-glucuronyl zidovudine. This limits systemic bioavailability to about 64%. Food may slow absorption but does not alter the *AUC* (area under the plasma concentration–time curve) (Table 50–3), and the drug can be administered regardless of food intake (Dudley, 1995). Total urinary recoveries of zidovudine and its glucuronide metabolite are 14% and 74%, respectively. The pharmacokinetic profile of zidovudine is not altered significantly during pregnancy, and drug concentrations in the newborn approach those of the mother (Watts *et al.*, 1991). Zidovudine is not bound to plasma proteins to a significant degree. Parent drug crosses the blood–brain barrier relatively well and achieves a cerebrospinal fluid (CSF)–plasma ratio of approximately 0.6. Zidovudine also is detectable in breast milk, semen, and fetal tissue (Gillet *et al.*, 1989; Watts *et al.*, 1991). Zidovudine concentrations are higher in the male genital tract than in the peripheral circulation, suggesting active transport or trapping.

Untoward Effects. Patients initiating zidovudine treatment often complain of fatigue, malaise, myalgia, nausea, anorexia, headache, and insomnia. These symptoms usually resolve within the first few weeks of treatment. Bone marrow suppression, mainly anemia and granulocytopenia, occurs most often in individuals with advanced HIV disease and very low CD4 counts and also was more common with the higher doses used when the drug was first approved. In such patients, anemia may develop within 4 weeks of starting therapy and probably reflects toxic effects on erythroid stem cells. Anemia can be managed by administering recombinant human erythropoietin. Erythrocytic macrocytosis is seen in approximately 90% of all patients but usually is not associated with anemia. Neutropenia is uncommon but can be managed with recombinant granulocyte or granulocyte–macrophage colony-stimulating factors (*see* Chapter 53).

Chronic zidovudine administration has been associated with nail hyperpigmentation. Skeletal muscle myopathy can occur and is associated with depletion of mitochondrial DNA, most likely as a consequence of inhibition of DNA polymerase- γ (Arnaudo *et al.*, 1991). Serious hepatic toxicity, with or without steatosis and lactic acidosis, is rare but can be fatal. Risk factors for the lactic acidosis–steatosis syndrome include female sex, obesity, and prolonged exposure to the drug (Tripuraneni *et al.*, 2004).

Drug Interactions and Precautions. Zidovudine is not a substrate or inhibitor of CYPs. However, *probenecid*, *fluconazole*, *atovaquone*, and *valproic acid* may increase plasma concentrations of zidovudine probably through inhibition of glucuronosyl transferase (Dudley, 1995). The clinical significance of these interactions is unknown because intracellular triphosphate levels may be unchanged despite higher plasma concentrations. Zidovudine can cause bone marrow suppression and should be used cautiously in patients with preexisting anemia or granulocytopenia and in those taking other marrow-suppressive drugs. Stavudine and zidovudine compete for intracellular phosphorylation and should not be used concomitantly. Three clinical trials found a significantly worse virologic outcome in patients taking these two drugs together as compared with either agent used alone (Havlir *et al.*, 2000).

Therapeutic Uses. Zidovudine is FDA approved for the treatment of adults and children with HIV infection and for preventing mother-to-child transmission of HIV infection; it is also recommended for postexposure prophylaxis in HIV-exposed healthcare workers, also in combination with other antiretroviral agents.

Zidovudine is more effective when combined with other antiretroviral drugs. Zidovudine combined with lamivudine, didanosine, or zalcitabine is more effective than zidovudine alone (Hammer *et al.*, 1996). Greater benefit is achieved when zidovudine is combined with two nucleoside analogs (Saag *et al.*, 1998). The current standard of care for treatment-naïve patients (Table 50–2B) is to combine zidovudine with a potent protease inhibitor and another nucleoside analog (Hammer *et al.*, 1997) or with an NNRTI and another nucleoside analog (Staszewski *et al.*, 1999).

The M184V substitution in the reverse transcriptase gene associated with the use of lamivudine or emtricitabine greatly restores sensitivity to zidovudine (Gallant *et al.*, 2003). The combination of zidovudine and lamivudine produces greater long-term suppression of plasma HIV RNA than does zidovudine alone (Eron *et al.*, 1995). As a result, this agent is often combined with lamivudine in clinical practice.

Zidovudine monotherapy reduced the risk of perinatal transmission of HIV by 67% (Connor *et al.*, 1994), and combining zidovudine with other antiretroviral drugs is even more efficacious in this setting. Zidovudine is also recommended as a component of combination therapy administered to healthcare workers soon after exposure to contami-

nated blood or body fluids to prevent HIV transmission (Cardo *et al.*, 1997). Despite being the oldest antiretroviral drug, zidovudine remains a popular component of combination regimens. This is a consequence of broad experience with the drug and its well-known tolerability, toxicity, and efficacy profiles. Zidovudine is available in coformulated tablets with lamivudine or with lamivudine and abacavir.

Didanosine

Chemistry and Antiviral Activity. Didanosine (2',3'-dideoxyinosine) is a purine nucleoside analog active against HIV-1, HIV-2, and other retroviruses including HTLV-1 (Perry and Noble, 1999). Its IC_{50} against HIV-1 ranges from 10 nM in monocytes-macrophage cells, to 10 μ M in lymphoblast cell lines.

Mechanism of Action and Resistance. Didanosine is transported into cells by a nucleobase carrier and undergoes initial phosphorylation by 5'-nucleotidase and inosine 5'-monophosphate phosphotransferase (Dudley, 1995; Khoo *et al.*, 2002). Didanosine 5'-monophosphate is then converted to dideoxyadenosine 5'-monophosphate by adenylosuccinate synthetase and adenylosuccinate lyase (Figure 50-3). Adenylate kinase and phosphoribosyl pyrophosphate synthetase produce dideoxyadenosine 5'-diphosphate, which is converted to the triphosphate by creatine kinase and phosphoribosyl pyrophosphate synthetase. Dideoxyadenosine 5'-triphosphate is the active anabolite of didanosine, which therefore functions as an antiviral adenosine analog. Dideoxyadenosine 5'-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent HIV DNA but lacks a 3'-hydroxyl group.

Resistance to didanosine is associated with mutations at reverse transcriptase codons 65 and 74. The L74V substitution, which reduces susceptibility 5 to 26 times *in vitro*, is seen most commonly in patients failing to respond to didanosine. Other nucleoside analog mutations, including thymidine analog mutations, can contribute to didanosine resistance even though the drug does not appear to select for these mutations *de novo*. The reverse transcriptase insertion mutations at codon 69 produce cross-resistance to all current nucleoside analogs, including didanosine (Gallant *et al.*, 2003). The M184V mutation seen in response to emtricitabine and lamivudine reduces didanosine susceptibility *in vitro* but probably plays no role in clinical resistance to this drug.

Absorption, Distribution, and Elimination. Didanosine is acid labile and is degraded at low gastric pH (Dudley, 1995). An antacid buffer is used in most formulations to improve bioavailability. Chewable tablets contain calcium carbonate and magnesium hydroxide, whereas the powder form contains citrate-phosphate buffer. The pediatric powder formulation lacks buffer and is reconstituted with purified water and mixed with a liquid antacid preparation. Food decreases didanosine bioavailability (*AUC*) by approximately 55%, so all formulations of didanosine must be administered at least 30 minutes before or 2 hours after eating (Perry and Noble, 1999). This complicates dosing of didanosine in combination with antiretroviral drugs that must be given with food, as is the case for most HIV protease inhibitors. The enzyme purine nucleoside phosphorylase

(PNP) probably contributes to the presystemic clearance of didanosine because tenofovir, which inhibits PNP, greatly increases concentrations of orally administered didanosine (Robbins *et al.*, 2003). PNP converts didanosine to hypoxanthine, which is ultimately converted to uric acid.

Peak plasma concentrations of didanosine are seen approximately 1 hour after oral administration of the chewable tablets or powder formulations and 2 hours after delayed-release capsules. The plasma elimination half-life of parent drug is approximately 1.5 hours, but the estimated intracellular half-life of dideoxyadenosine 5'-triphosphate is substantially longer, 25 to 40 hours (Perry and Noble, 1999). As a result, didanosine can be administered once daily. Didanosine is excreted both by glomerular filtration and by tubular secretion and does not undergo metabolism to a significant degree. Drug doses therefore must be adjusted in patients with renal insufficiency or renal failure (Jayasekara *et al.*, 1999).

Didanosine is not protein bound to a significant degree. The cerebrospinal penetration of didanosine is less than that of zidovudine, with a CSF-plasma ratio of 0.2, but the clinical significance of this is unclear. Didanosine has been detected in placental and fetal circulation at a small fraction of concentrations in maternal circulation (Dancis *et al.*, 1993).

Untoward Effects. The most serious toxicities associated with didanosine include peripheral neuropathy and pancreatitis, both of which are thought to be a consequence of mitochondrial toxicity. Up to 20% of patients reported peripheral neuropathy in early clinical trials (Perry and Noble, 1999). As with other dideoxynucleosides, peripheral neuropathy is more common with higher doses or concentrations of didanosine and is more prevalent in patients with underlying HIV-related neuropathy or in those receiving other neurotoxic drugs. Typically, this is a symmetrical distal sensory neuropathy that begins in the feet and lower extremities but may involve the hands as it progresses (stocking/glove distribution). Patients complain of pain, numbness, and tingling in the affected extremities. If the drug is stopped as soon as symptoms appear, the neuropathy will stabilize and should improve or resolve. Retinal changes and optic neuritis also have been reported with didanosine, and patients should undergo periodic retinal examinations.

Acute pancreatitis is a rare but potentially fatal complication of didanosine. Acute pancreatitis is associated with higher doses and concentrations of didanosine but has occurred in up to 7% of patients using the recommended dose of 200 mg twice daily (Perry and Noble, 1996). Pancreatitis is more common with advanced HIV disease, and other risk factors include a previous history of pancreatitis, alcohol or illicit drug use, and hypertriglyceridemia. Combining didanosine with stavudine, which is also associated with peripheral neuropathy and pancreatitis, increases the risk and severity of both toxicities (Havlir *et al.*, 2001; Moore *et al.*, 2000).

As with other dideoxynucleosides and zidovudine, serious hepatic toxicity—with or without steatosis, hepatomegaly, and lactic acidosis—occurs very rarely but can be fatal. Risk factors for the lactic acidosis-steatosis syndrome include female sex, obesity, and prolonged exposure to the drug (Tripuraneni *et al.*, 2004).

Other reported adverse effects include elevated hepatic transaminases, headache, and asymptomatic hyperuricemia. Diarrhea is reported more frequently with didanosine than with other nucleoside analogs and has been attributed to the antacid in the buffered oral preparations (Perry and Noble, 1999). Didanosine chewable tablets contain 36.5 mg phenylalanine and should be avoided in those with phenylketonuria. Buffered powder for oral solution contains 1.4 g

sodium per packet and should be used cautiously in those on sodium-restricted diets.

Drug Interactions and Precautions. Buffering agents included in didanosine formulations can interfere with the bioavailability of some coadministered drugs because of altered pH or chelation with cations in the buffer. For example, the *ciprofloxacin* AUC is decreased by up to 98% when given with didanosine, and concentrations of *ketocazole* and *itraconazole*, whose absorption is pH-dependent, also are diminished (Piscitelli and Gallicano, 2001). A 200-mg dose of buffered didanosine reduced the indinavir AUC by 84%. These interactions generally can be avoided by separating administration of didanosine from that of other agents by at least 2 hours. The enteric-coated formulation of didanosine does not alter ciprofloxacin or indinavir absorption.

Didanosine is excreted renally, and shared renal excretory mechanisms provide a basis for drug interactions with didanosine. Oral *ganciclovir* can increase plasma didanosine concentrations approximately twofold and may be associated with an increase in didanosine toxicity. *Allopurinol* can increase the didanosine AUC more than fourfold and should be avoided. Tenofovir increases the didanosine AUC by 44% to 60% and also may increase the risk of didanosine toxicity. If these two drugs must be given together, it is recommended to decrease the didanosine dose from 400 to 250 mg once daily (Chapman *et al.*, 2003). *Methadone* decreases the didanosine AUC by 57% to 63% (Rainey *et al.*, 2000) possibly as a consequence of altered gastrointestinal motility and delayed absorption, although this has not been associated with a higher risk of failing didanosine treatment.

Didanosine should be avoided in patients with a history of pancreatitis or neuropathy because the risk and severity of both complications increase. Coadministration of other drugs that cause pancreatitis or neuropathy also will increase the risk and severity of these symptoms. For this reason, stavudine and zalcitabine should be avoided or used only with great caution. *Ethambutol*, *isoniazid*, *vincristine*, *cisplatin*, and *pentamidine* also should be avoided.

The combination of didanosine and *hydroxyurea* was used to exploit a beneficial interaction that creates a favorable intracellular ratio of concentrations of dideoxyadenosine 5'-triphosphate to deoxythymidine 5'-triphosphate (Frank *et al.*, 2004). Although this combination may boost didanosine antiviral activity modestly, it increases toxicity substantially, producing peripheral neuropathy and fatal pancreatitis, and should be avoided (Havlir *et al.*, 2001; Moore *et al.*, 2000).

Therapeutic Use. Didanosine is FDA approved for adults and children with HIV infection in combination with other antiretroviral agents. Didanosine reduced disease progression and death in early monotherapy studies, although HIV plasma RNA concentrations generally fell at most by 90% when the drug was used as a sole agent (Dolin *et al.*, 1995). Didanosine combined with another nucleoside analog reduced clinical disease progression and afforded greater viral suppression compared with zidovudine monotherapy (Hammer *et al.*, 1996; Saravolatz *et al.*, 1996). Didanosine has long-term efficacy when combined with other nucleoside analogs and HIV protease inhibitors or NNRTIs (Table 50–2). Didanosine as a component of combination therapy

also has beneficial effects in infants and children (Luzuriaga *et al.*, 1997).

Stavudine

Chemistry and Antiviral Activity. Stavudine (2',3'-dideohydro-2',3'-dideoxythymidine, d4T) is a synthetic thymidine analog reverse transcriptase inhibitor that is active *in vitro* against HIV-1 and HIV-2. Its IC₅₀ in lymphoblastoid and monocytic cell lines and in primary mononuclear cells ranges from 0.009 to 4 μM (Hurst and Noble, 1999).

Mechanism of Action and Resistance. Intracellular stavudine is phosphorylated by thymidine kinase to stavudine 5'-monophosphate, which is then phosphorylated by thymidylate kinase to the diphosphate and by nucleoside diphosphate kinase to stavudine 5'-triphosphate (Hurst and Noble, 1999) (Figure 50–3). Unlike zidovudine monophosphate, stavudine monophosphate does not accumulate in the cell, and the rate-limiting step in activation appears to be generation of the monophosphate. Stavudine 5'-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3'-hydroxyl group. Like zidovudine, stavudine is most potent in activated cells probably because thymidine kinase is an S-phase-specific enzyme (Gao *et al.*, 1994). Stavudine and zidovudine are antagonistic *in vitro*, and thymidine kinase has a higher affinity for zidovudine than for stavudine (Merrill *et al.*, 1996).

Stavudine resistance is seen most frequently with mutations at reverse transcriptase codons 41, 44, 67, 70, 118, 210, 215, and 219 (Gallant *et al.*, 2003), which are the same mutations associated with zidovudine resistance. Clusters of resistance mutations that include M41L, K70R, and T215Y are associated with a lower level of *in vitro* resistance than seen with zidovudine but are found in up to 38% of patients who fail to respond to stavudine. TAMs associated with resistance to zidovudine and stavudine promote excision of the incorporated triphosphate anabolites through pyrophosphorolysis (Naeger *et al.*, 2002). As with zidovudine, resistance mutations for stavudine appear to accumulate slowly. Cross-resistance to multiple nucleoside analogs has been reported following prolonged therapy and has been associated with a mutation cluster involving codons 62, 75, 77, 116, and 151. In addition, a recently described mutation at codon 69 (typically T69S) followed by a 2-amino-acid insertion produces cross-resistance to all current nucleoside and nucleotide analogs (Gallant *et al.*, 2003).

Absorption, Distribution, and Elimination. Stavudine is well absorbed and reaches peak plasma concentrations within 1 hour (Hurst and Noble, 1999). Bioavailability is not affected by food. The drug undergoes active tubular secretion, and renal elimination accounts for about 40% of parent drug. Stavudine concentrations are higher in patients with low body weight, and the dose should be decreased from 40 to 30 mg twice daily in patients weighing less than 60 kg. Dose also should be adjusted in patients with renal insufficiency (Jayasekara *et al.*, 1999). A sustained-release formulation that can be given once daily was approved recently by the FDA.

Plasma protein binding is less than 5%. The drug penetrates well into the CSF, achieving concentrations that are about 40% of those in plasma. Stavudine also readily crosses the human placenta and

reaches concentrations in the circulation of fetal macaques that are about 80% of those in the mother (Odinec *et al.*, 1996). Placental concentrations of stavudine are about half those of zidovudine, possibly reflecting stavudine's lower lipid solubility.

Untoward Effects. The most common serious toxicity of stavudine is peripheral neuropathy. Neuropathy occurred in up to 71% of patients in initial monotherapy trials with a dose of 4 mg/kg per day. With the current recommended dose of 40 mg twice daily, the neuropathy incidence is about 12% (Hurst and Noble, 1999). Although this is thought to reflect mitochondrial toxicity, stavudine is a less potent inhibitor of DNA polymerase- γ than either didanosine or zalcitabine, suggesting that other mechanisms may be involved (Cui *et al.*, 1997). As with other dideoxynucleosides, peripheral neuropathy is more common with higher doses or concentrations of stavudine and is more prevalent in patients with underlying HIV-related neuropathy or in those receiving other neurotoxic drugs. Stavudine is also associated with a progressive motor neuropathy characterized by weakness and in some cases respiratory failure, similar to Guillain-Barré syndrome (HIV Neuromuscular Syndrome Study Group, 2004).

Lactic acidosis and hepatic steatosis have been associated with stavudine use. This may be more common when stavudine and didanosine are combined. Elevated serum lactate is more common with stavudine than with zidovudine or abacavir (Tripuraneni *et al.*, 2004), although the relationship to relative risk of hepatic steatosis is unknown. Acute pancreatitis is not highly associated with stavudine but is more common when stavudine is combined with didanosine than when didanosine is given alone (Havlr *et al.*, 2001; Moore *et al.*, 2000).

Stavudine recently has been implicated in the etiology of HIV lipodystrophy syndrome, especially lipoatrophy. Of all nucleoside analogs, stavudine use is associated most strongly with fat wasting (Mallal *et al.*, 2000; Heath *et al.*, 2001). Whether this is a consequence of the extensive use of this agent combined with its mitochondrial toxicity or reflects a pathogenetic mechanism that has yet to be discovered remains to be determined. Other reported adverse effects include elevated hepatic transaminases, headache, nausea, and rash, although these side effects are almost never severe enough to cause discontinuation of the drug.

Drug Interactions and Precautions. Stavudine is largely renally cleared and is not subject to metabolic drug interactions. The incidence and severity of peripheral neuropathy may be increased when stavudine is combined with other neuropathic medications, and therefore drugs such as ethambutol, isoniazid, *phenytoin*, and vincristine should be avoided. Combining stavudine with didanosine leads to increased risk and severity of peripheral neuropathy and potentially fatal pancreatitis; therefore, *these two drugs should not be used together under most circumstances* (Havlr *et al.*, 2001; Moore *et al.*, 2000). Stavudine and zidovudine compete for intracellular phosphorylation and should not be used concomitantly. Three clinical trials found a significantly worse virologic outcome in patients taking these two drugs together as compared with either agent used alone (Havlr *et al.*, 2000).

Therapeutic Use. In early monotherapy trials, stavudine reduced plasma HIV RNA by 70% to 90% and delayed disease progression compared with continued zidovudine therapy (Spruance *et al.*, 1997). Lamivudine improves the long-term virologic response to stavudine, possibly reflecting the benefits of the M184V mutation (Kuritzkes *et al.*, 1999).

Many large prospective clinical trials have demonstrated potent and durable suppression of viremia and sustained increases in CD4+ cell counts when stavudine is combined with other nucleoside analogs plus NNRTIs or protease inhibitors (Hurst and Noble, 1999). The drug therefore remains a common component of antiretroviral regimens.

Zalcitabine

Chemistry and Antiviral Activity. Zalcitabine (2',3'-dideoxycytidine, ddC) is a synthetic cytosine analog reverse transcriptase inhibitor. It is active against HIV-1, HIV-2, and hepatitis B virus (HBV). The *in vitro* IC₅₀ of zalcitabine against HIV-1 ranges from 2 nM in monocytes-macrophage cell lines to 0.5 μ M in human peripheral blood mononuclear cells. Zalcitabine has considerably more antiretroviral activity in monocytes-macrophage cell lines than other nucleoside analogs, but the potential clinical utility of this observation is uncertain.

Mechanisms of Action and Resistance. Zalcitabine enters cells by both carrier-mediated transport and passive diffusion (Adkins *et al.*, 1997). It is converted to the monophosphate by deoxycytidine kinase and undergoes further phosphorylation by deoxycytidine monophosphate kinase and nucleoside diphosphate kinase to yield dideoxycytidine 5'-triphosphate, which is the active anabolite (Adkins *et al.*, 1997) (Figure 50-3). Zalcitabine is more efficiently phosphorylated in resting cells and therefore is more potent in resting cells than other nucleoside analogs (Gao *et al.*, 1993), although the clinical relevance of this is unknown. As with other dideoxynucleoside analogs, dideoxycytidine 5'-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent HIV DNA but lacks a 3'-hydroxyl group. Zalcitabine inhibits human DNA polymerases- β and - γ and also decreases intracellular deoxycytidine triphosphate pools, factors that may contribute to its cellular and host toxicity (Chen *et al.*, 1991).

High-level resistance has not been reported in patients receiving zalcitabine as a sole nucleoside analog or in combination with zidovudine (Adkins *et al.*, 1997). However, low-to-moderate *in vitro* resistance is seen with four mutations associated with zalcitabine use that occur at reverse transcriptase codons 65, 69, 74, and 184 (Gallant *et al.*, 2003). The K65R substitution is associated with cross-resistance to didanosine, abacavir, and tenofovir, as well as the cytosine analogs lamivudine and emtricitabine. The M184V substitution is also associated with the use of lamivudine or emtricitabine and enhances HIV-1 sensitivity to zidovudine *in vitro*; the presence of this mutation is associated with improved long-term suppression of viremia when zidovudine is combined with lamivudine or emtricitabine, although a similar effect has not been demonstrated for the combination of zalcitabine and zidovudine. The T69D substitution is unique to zalcitabine but overlaps a recently described mutation at codon 69 (typically T69S) followed by a 2-amino-acid insertion that produces cross-resistance to all current nucleoside and nucleotide analogs (Gallant *et al.*, 2003).

Absorption, Distribution, and Elimination. The oral bioavailability of zalcitabine is greater than 80%, and 60% to 80% of the parent

compound is recovered unchanged in the urine (Adkins *et al.*, 1997). Food has a negligible effect on oral bioavailability. Clearance is greatly diminished in patients with compromised renal function, and daily doses should be reduced in this population (Jayasekara *et al.*, 1999). The half-life of intracellular dideoxycytidine 5'-triphosphate is estimated to be 2 to 3 hours. It is therefore recommended that zalcitabine be administered every 8 hours in patients with normal renal function. The CSF-plasma concentration ratio ranges from 0.09 to 0.37, although the clinical significance of CSF penetration is not known.

Untoward Effects. Zalcitabine toxicities are similar to those of the other dideoxynucleoside analogs didanosine and stavudine. Severe peripheral neuropathy has been reported in up to 15% of patients. Peripheral neuropathy is dose-related and more common with pre-existing HIV-associated neuropathy and advanced HIV disease. This is a symmetrical distal sensory neuropathy that begins in the feet but may progress to a stocking/glove distribution. Other specific risk factors for neuropathy include alcohol consumption, diabetes, and low vitamin B₁₂ concentrations (Fichtenbaum *et al.*, 1995). If the drug is stopped as soon as symptoms appear, the neuropathy usually stabilizes and should improve or resolve. Pancreatitis occurs rarely with zalcitabine therapy and appears to be less frequent than with didanosine (Saravolatz *et al.*, 1996).

One toxicity unique to zalcitabine is oral ulceration and stomatitis, suggesting that this drug may have toxicity in rapidly dividing mucosal cells. Ulcerations of the buccal mucosa, soft palate, tongue, or pharynx occur in up to 4% of patients (Adkins *et al.*, 1997) but may resolve with continued therapy. An erythematous maculopapular rash is reported commonly during the first 14 days of therapy but generally is self-limited and mild. Other reported toxicities include cardiomyopathy, arthralgias, myalgias, and elevated hepatic transaminases.

Drug Interactions and Precautions. Lamivudine inhibits the intracellular phosphorylation of zalcitabine (Veal *et al.*, 1996) and antagonizes zalcitabine's antiretroviral activity *in vitro* (Merrill *et al.*, 1996), although the clinical significance of this interaction is unknown. Probenecid increases the zalcitabine AUC by about 50% probably through inhibition of tubular secretion; *cimetidine* increases the AUC by 36% via an unknown mechanism (Adkins *et al.*, 1997). Zalcitabine should be avoided in patients with a history of pancreatitis or neuropathy because the risk and severity of both complications increase. Coadministration of other drugs that cause pancreatitis or neuropathy also will increase the risk and severity of these symptoms. Ethambutol, isoniazid, vincristine, cisplatin, and pentamidine, as well as the antiretroviral drugs didanosine and stavudine, therefore should be avoided.

Therapeutic Use. Zalcitabine has long-term efficacy in three-drug combination regimens. For example, the combination of zalcitabine, zidovudine, and saquinavir was superior to two-drug regimens in a prospective, randomized clinical trial (Collier *et al.*, 1996). Zalcitabine is used infrequently in the United States because it is the only nucleoside analog that still must be administered every 8 hours, carries significant toxicity risks, and has inferior antiviral activity compared with more convenient agents.

Lamivudine

Chemistry and Antiviral Activity. Lamivudine [(−)2', 3'-dideoxy, 3'-thiacytidine, 3TC] is a cytosine analog reverse transcriptase inhibitor that is active against HIV-1, HIV-2, and HBV. The molecule has two chiral centers and is manufactured as the pure 2*R*, *cis*(−)-enantiomer (Figure 50–2). The racemic mixture from which lamivudine originates has antiretroviral activity but is less potent and substantially more toxic than the pure (−)-enantiomer. Compared with the (+)-enantiomer, the phosphorylated (−)-enantiomer is more resistant to cleavage from nascent RNA/DNA duplexes by cellular 3'-5' exonucleases, which may contribute to its greater potency (Skalski *et al.*, 1993). The IC₅₀ of lamivudine against laboratory strains of HIV-1 ranges from 2 to 670 nM, although the IC₅₀ in primary human peripheral blood mononuclear cells is as high as 15 μM (Perry and Faulds, 1997).

Mechanism of Action and Resistance. Lamivudine enters cells by passive diffusion, where it is converted to the monophosphate by deoxycytidine kinase, and undergoes further phosphorylation by deoxycytidine monophosphate kinase and nucleoside diphosphate kinase to yield lamivudine 5'-triphosphate, which is the active anabolite (Perry and Faulds, 1997) (Figure 50–3). The intracellular triphosphate acts as a competitive inhibitor of reverse transcriptase and is incorporated into HIV DNA to cause chain termination. Lamivudine is phosphorylated more efficiently in resting cells, which may explain its reduced potency in primary peripheral blood mononuclear cells as compared with cell lines (Gao *et al.*, 1994). Lamivudine has low affinity for human DNA polymerases, explaining its low toxicity to the host.

High-level resistance to lamivudine occurs with single-amino-acid substitutions, M184V or M184I. These mutations can reduce *in vitro* sensitivity to lamivudine by up to one thousandfold (Perry and Faulds, 1997). The same mutations confer high-level cross-resistance to emtricitabine and a lesser degree of resistance to zalcitabine and abacavir (Gallant *et al.*, 2003). The M184V mutation restores zidovudine susceptibility in zidovudine-resistant HIV (Larder *et al.*, 1995) and also partially restores tenofovir susceptibility in tenofovir-resistant HIV harboring the K65R mutation (Wainberg *et al.*, 1999). The same K65R mutation confers resistance to lamivudine and the other cytosine analogs emtricitabine and zalcitabine, as well as didanosine, stavudine, and abacavir.

HIV-1 isolates harboring the M184V mutation have increased transcriptional fidelity *in vitro* (Wainberg *et al.*, 1996) and decreased replication capacity (Miller *et al.*, 1999). Variants with the M184I mutation are even more impaired with regard to *in vitro* replication (Larder *et al.*, 1995) and usually are replaced in lamivudine-treated patients by the M184V mutation. The reduced fitness of lamivudine-resistant viruses harboring these mutations and their ability to prevent or partially reverse the effect of thymidine analog mutations may contribute to the sustained virologic benefits of zidovudine and lamivudine combination therapy (Eron *et al.*, 1995).

Although the use of lamivudine to treat HBV infection is discussed in Chapter 49, some parallels in drug resistance are worth noting. High-level resistance to lamivudine occurs with a single mutation in the HBV DNA polymerase gene; as with HIV, this con-

sists of a methionine-to-valine substitution (M204I/V) in the enzyme active site. Resistance to lamivudine occurs in up to 90% of HIV/ HBV coinfecting patients after 4 years of treatment. However, virologic benefits persist in some treated patients harboring lamivudine-resistant HBV possibly because the mutated virus has substantially reduced replicative capacity (Leung *et al.*, 2001).

Absorption, Distribution, and Elimination. The oral bioavailability of lamivudine is greater than 80% and is not affected by food. Although lamivudine was marketed originally with a recommended dose of 150 mg twice daily based on the short plasma half-life of the parent compound, the intracellular half-life of lamivudine 5'-triphosphate is 12 to 18 hours, and the drug is now approved for use once daily at 300 mg (Moore *et al.*, 1999). Lamivudine is excreted primarily unchanged in the urine, and dose adjustment is recommended for patients with a creatinine clearance of less than 50 ml/min (Jayasekara *et al.*, 1999). Lamivudine does not bind significantly to plasma proteins and freely crosses the placenta into the fetal circulation. Like zidovudine, lamivudine concentrations are higher in the male genital tract than in the peripheral circulation, suggesting active transport or trapping. Central nervous system (CNS) penetration appears to be poor, with a CSF-plasma concentration ratio of 0.15 or less (Perry and Faulds, 1997). The clinical significance of the low CSF penetration is unknown.

Untoward Effects. Lamivudine is one of the least toxic antiretroviral drugs and has few significant adverse effects. Neutropenia, headache, and nausea have been reported at higher than recommended doses. Pancreatitis has been reported in pediatric patients, but this has not been confirmed in controlled trials of adults or children. Because lamivudine also has activity against HBV and substantially lowers plasma HBV DNA concentrations, caution is warranted in using this drug in patients coinfecting with HBV; discontinuation of lamivudine may be associated with a rebound of HBV replication and exacerbation of hepatitis.

Drug Interactions and Precautions. Lamivudine inhibits the intracellular phosphorylation of the cytosine analog zalcitabine (Veal *et al.*, 1996) and antagonizes zalcitabine's antiretroviral activity *in vitro* (Merrill *et al.*, 1996), although the clinical significance of this interaction is unknown. Since lamivudine and emtricitabine have nearly identical resistance and activity patterns, there is no rationale for their combined use. Lamivudine is synergistic with most other nucleoside analogs *in vitro* (Merrill *et al.*, 1996; Veal *et al.*, 1996). *Trimethoprim-sulfamethoxazole* increases the lamivudine plasma AUC by 43% presumably through inhibition of renal tubular secretion (Moore *et al.*, 1996). However, the effect on intracellular triphosphate concentrations is unknown, and dose adjustment is not recommended.

Therapeutic Use. In early monotherapy studies, initial declines in plasma HIV-1 RNA concentrations of up to 90% occurred within 14 days but rebounded rapidly with emergence of lamivudine-resistant HIV (Perry and Faulds, 1997). Patients randomized to the combination of lamivudine plus zidovudine had substantially better mean decreases in plasma HIV-1 RNA at 52 weeks (97% versus 70% decrease in copies/ml) and increases in CD4+ lymphocyte counts (+61 versus -53 cells/mm³) compared with those receiving zidovudine alone (Eron *et al.*, 1995). In a large

randomized, double-blind trial, combining lamivudine with zidovudine or stavudine caused about a twelvefold further decline in viral load at 24 weeks compared with zidovudine or stavudine monotherapy (Kuritzkes *et al.*, 1999); in the same trial, combining lamivudine with didanosine conferred no additional benefits. Many trials have confirmed the value of using lamivudine in three-drug regimens with other nucleoside analogs, protease inhibitors, and/or NRTIs. Lamivudine has been effective in combination with other antiretroviral drugs in both treatment-naïve and experienced patients (Perry and Faulds, 1997) and is a common component of therapy (Table 50-2B), given its safety, convenience, and efficacy.

Abacavir

Chemistry and Antiviral Activity. Abacavir is a synthetic carbocyclic purine analog [(1*S*, *cis*)-4-[2-amino-6-(cyclopropylamino)-9H-purin-9-yl]-2-cyclopentene-1-methanol] (Figure 50-2). Abacavir is converted inside cells to an active metabolite, carbovir 5'-triphosphate (Figure 50-3), which is a potent inhibitor of the HIV-1 reverse transcriptase. [*Carbovir*, a related guanine analog, was withdrawn from clinical development owing to poor oral bioavailability (Hervey and Perry, 2000)]. The IC₅₀ of abacavir for primary clinical HIV-1 isolates is 0.26 μM, and its IC₅₀ for laboratory strains ranges from 0.07 to 5.8 μM.

Mechanisms of Action and Resistance. Abacavir is the only approved antiretroviral that is active as a guanosine analog. It is initially monophosphorylated by adenosine phosphotransferase. The monophosphate is then converted to (-)-carbovir 3'-monophosphate, which is then phosphorylated to the di- and triphosphates by cellular kinases (Figure 50-3). Carbovir 5'-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3'-hydroxyl group.

Clinical resistance to abacavir is associated with four specific codon substitutions: K65R, L74V, Y115F, and M184V (Gallant *et al.*, 2003). Individually, these substitutions produce only modest (two- to fourfold) resistance to abacavir compared to virus *in vitro* but in combination can reduce susceptibility by up to tenfold. The Y115F mutation is seen uniquely with abacavir. The L74V mutation is associated with cross-resistance to the purine analog didanosine and the cytosine analog zalcitabine. K65R confers cross-resistance to all nucleosides except zidovudine. An alternate pathway for abacavir resistance involves mutations at codons 41, 210, and 215, which have been associated with a reduced likelihood of virologic response. Abacavir sensitivity is greatly reduced by the multinucleoside resistance clusters, including that associated with the Q151M substitution, as well as the two-amino-acid insertion following codon 69 (Gallant *et al.*, 2003).

Absorption, Distribution, and Elimination. Abacavir's oral bioavailability is greater than 80% regardless of food intake (Table 50-3). Abacavir is eliminated by metabolism to the 5'-carboxylic acid

derivative catalyzed by alcohol dehydrogenase and by glucuronidation to the 5'-glucuronide. These metabolites account for 30% and 36% of elimination, respectively (Hervey and Perry, 2000). Abacavir is not a substrate or inhibitor of CYPs. Abacavir is 50% bound to plasma proteins, and the CSF-plasma *AUC* is approximately 0.3. Although the introduced dose of abacavir was 300 mg twice daily, carbovir triphosphate accumulates inside the cell and has a reported elimination half-life of up to 21 hours (Hervey and Perry, 2000) (Table 50-2); thus a regimen of 600 mg once daily is approved.

Untoward Effects. The most important adverse effect of abacavir is a unique and potentially fatal hypersensitivity syndrome. This syndrome is characterized by fever, abdominal pain, and other gastrointestinal complaints; a mild maculopapular rash; and malaise or fatigue. Respiratory complaints (cough, pharyngitis, dyspnea), musculoskeletal complaints, headache, and paresthesias are reported less commonly. Median time to onset of symptoms is 11 days, and 93% of cases occur within 6 weeks of initiating therapy (Hetherington *et al.*, 2002). The presence of concurrent fever, abdominal pain, and rash within 6 weeks of starting abacavir is diagnostic and necessitates immediate discontinuation of the drug. Patients having only one of these symptoms may be observed to see if additional symptoms appear. Unlike many hypersensitivity syndromes, this condition worsens with continued treatment. *Abacavir can never be restarted once discontinued for hypersensitivity because reintroduction of the drug leads to rapid recurrence of severe symptoms, accompanied by hypotension, a shocklike state, and possibly death.* The reported mortality rate of restarting abacavir in sensitive individuals is 4% (Hervey and Perry, 2000).

Abacavir hypersensitivity occurs in 2% to 9% of patients depending on the population studied. The cause is a genetically mediated immune response linked to both the *HLA-B*5701* locus and the M493T allele in the heat-shock locus *Hsp70-Hom* (Martin *et al.*, 2004). One of the strongest pharmacogenetic associations ever described, the latter gene is implicated in antigen presentation, and this haplotype is associated with aberrant tumor necrosis factor- α release after exposure of human lymphocytes to abacavir *ex vivo*. In one Caucasian population, the combination of these two markers occurred in 94.4% of cases and less than 0.5% of controls for a positive predictive value of 93.8% and a negative predictive value of 99.5% (Martin *et al.*, 2004). Other genes may be involved because the syndrome is much less common in populations with a low prevalence of *HLA-B*5701* (e.g., African-Americans), but it can occur in patients lacking this HLA type (Hetherington *et al.*, 2002).

In those without true hypersensitivity, abacavir is a well-tolerated drug. Carbovir 5'-triphosphate is a weak inhibitor of human DNA polymerases, including DNA polymerase- γ (Hervey and Perry, 2000). Abacavir therefore has not been associated with adverse events thought to be due to mitochondrial toxicity, such as myelosuppression, peripheral neuropathy, and pancreatitis.

Drug Interactions and Precautions. Abacavir is not associated with any clinically significant pharmacokinetic drug interactions. However, a large dose of *ethanol* (0.7 g/kg) increased the abacavir plasma *AUC* by 41% and prolonged the elimination half-life by 26% (McDowell *et al.*, 2000) possibly owing to competition for alcohol dehydrogenase. Patients starting abacavir must be warned about the symptoms of abacavir hypersensitivity and instructed to seek medical help immediately if symptoms occur.

Therapeutic Use. In initial monotherapy studies, abacavir reduced HIV plasma RNA concentrations up to 300 times more than that seen with other antiretroviral nucleosides, and increased CD4+ lymphocyte counts by 80 to 200 cells/mm³ (Hervey and Perry, 2000). Abacavir is not a more potent inhibitor of HIV replication than other nucleosides *in vitro*, and the mechanism for its more potent *in vivo* activity is unexplained.

Abacavir is effective in combination with other nucleoside analogs, NNRTIs, and protease inhibitors. Adding abacavir to zidovudine and lamivudine results in a substantially greater decrease in plasma HIV-1 RNA than seen with the two-drug regimen of zidovudine plus lamivudine in adults (Hervey and Perry, 2000) and children (Saez-Llorens *et al.*, 2001). Adding abacavir to stable antiretroviral therapy can result in additional antiviral effect, but treatment-experienced patients are much less likely to benefit from this drug if there are multiple preexisting nucleoside resistance mutations.

Abacavir is available in a coformulation with zidovudine and lamivudine for twice-daily dosing. However, the combination of abacavir, zidovudine, and lamivudine was somewhat less effective in a randomized, double-blind, placebo-controlled trial in 1147 treatment-naive patients than was the combination of zidovudine, lamivudine, and *efavirenz* or the four-drug regimen of zidovudine, lamivudine, abacavir, and *efavirenz*; 79% of patients in the abacavir, zidovudine, lamivudine group had undetectable plasma HIV RNA at 32 weeks as compared with 89% with the other regimens (Gulick *et al.*, 2004). Abacavir is also available in a coformulation with lamivudine for once-daily dosing.

Tenofovir

Chemistry and Antiviral Activity. Tenofovir is a derivative of adenosine 5'-monophosphate lacking a complete ribose ring and is the only nucleotide analog currently marketed for the treatment of HIV infection. Because the parent compound had very poor oral bioavailability, tenofovir is available only as the disoproxil fumarate prodrug, which has improved oral absorption and cellular penetration substantially. Like lamivudine and emtricitabine, tenofovir is active against HIV-1, HIV-2, and HBV. The IC₅₀ of tenofovir disoproxil fumarate against laboratory strains of HIV-1 ranges from 2 to 7 nM, making the prodrug about one hundredfold more active *in vitro* than the parent compound (Chapman *et al.*, 2003).

Mechanism of Action and Resistance. Tenofovir disoproxil fumarate is hydrolyzed rapidly to tenofovir and then is phosphorylated by cellular kinases to its active metabolite, tenofovir diphosphate (Fig-

ure 50–3); the active moiety is, in fact, a triphosphate compound because the parent drug starts out as the monophosphate. The intracellular diphosphate is a competitive inhibitor of viral reverse transcriptases and is incorporated into HIV DNA to cause chain termination because it has an incomplete ribose ring. Although tenofovir diphosphate has broad-spectrum activity against viral DNA polymerases, it has low affinity for human DNA polymerases- α , - β , and - γ , which is the basis for its selective toxicity.

Virus replication in the presence of suboptimal concentrations of drug can select for mutations conferring resistance to tenofovir. Specific resistance occurs with a single substitution at codon 65 of reverse transcriptase (K65R). This mutation reduces *in vitro* sensitivity by only three- to fourfold but has been associated with clinical failure of tenofovir-containing regimens (Chapman *et al.*, 2003). Tenofovir sensitivity and virologic efficacy also are reduced in patients harboring HIV isolates with high-level resistance to zidovudine or stavudine, specifically those having three or more TAMs, including M41L or L120W. However, HIV variants that are resistant to zidovudine show only partial resistance to tenofovir, possibly a reflection of the much less efficient excision of tenofovir diphosphate by pyrophosphorolysis (Naeger *et al.*, 2002). The M184V mutation associated with lamivudine or emtricitabine resistance partially restores susceptibility in tenofovir-resistant HIV harboring the K65R mutation (Wainberg *et al.*, 1999).

The K65R mutation was reported in only 2% to 3% of tenofovir-treated patients in initial clinical studies, and this mutation usually was not associated with treatment failure. Patients failing most tenofovir-containing regimens are more likely to harbor genotypic resistance to the other drugs in the regimen. Notable exceptions are once-daily combination regimens of three nucleosides, specifically tenofovir plus didanosine and lamivudine and tenofovir plus abacavir and lamivudine. Both these regimens were associated with very high early rates of virologic failure or nonresponse, and at the time of failure, the K65R mutation was present in 36% to 64% of virus isolated from patients participating in these trials (Department of Health and Human Services, 2004).

Absorption, Distribution, and Elimination. Tenofovir disoproxil fumarate has an oral bioavailability of 25%. A high-fat meal increases the oral bioavailability to 39%, but the drug can be taken without regard to food (Chapman *et al.*, 2003). Tenofovir is not bound significantly to plasma proteins. The plasma elimination half-life ranges from 14 to 17 hours (Bang and Scott, 2003). The reported half-life of intracellular tenofovir diphosphate is 11 hours in activated peripheral blood mononuclear cells and 49 hours or longer in resting cells (Chapman *et al.*, 2003). The drug therefore can be dosed once daily. Tenofovir undergoes both glomerular filtration and active tubular secretion. Between 70% and 80% of an intravenous dose of tenofovir is recovered unchanged in the urine. Doses should be decreased in those with renal insufficiency (Chapman *et al.*, 2003).

Untoward Effects. Tenofovir generally is well tolerated, with few significant adverse effects reported except for flatulence. In placebo-controlled, double-blinded trials, the drug had no other adverse effects reported more frequently than with placebo after treatment for up to 24 weeks; tenofovir was significantly less toxic than stavudine. Unlike the antiviral nucleotides *adefovir* and *cidofovir* (see Chapter 49), tenofovir is not toxic to human renal tubular cells *in vitro* (Chapman *et al.*, 2003). However, rare episodes of acute renal failure and Fanconi syndrome have been reported with tenofovir, and this drug should be used

with caution in patients with preexisting renal disease. Because tenofovir also has activity against HBV and may lower plasma HBV DNA concentrations, caution is warranted in using this drug in patients coinfecting with HBV; discontinuation of tenofovir may be associated with a rebound of HBV replication and exacerbation of hepatitis.

Drug Interactions and Precautions. Tenofovir is not metabolized to a significant extent by CYPs and is not known to inhibit or induce these enzymes. However, tenofovir has been associated with a few potentially important pharmacokinetic drug interactions. A 300-mg dose of tenofovir increased the didanosine *AUC* by 44% to 60% probably as a consequence of inhibition of the enzyme purine nucleoside phosphorylase by both tenofovir and tenofovir monophosphate (Robbins *et al.*, 2003). These two drugs probably should not be used together, or if this is essential, the dose of didanosine should be reduced from 400 to 250 mg/day (Chapman *et al.*, 2003). Although tenofovir is not known to induce CYPs, it has been reported to reduce the *atazanavir* *AUC* by approximately 26%. In addition, low-dose ritonavir (100 mg twice daily) increases the tenofovir *AUC* by 34%, and atazanavir increases the tenofovir *AUC* by 25%. The mechanism of these interactions is unknown.

Therapeutic Use. Tenofovir is FDA approved for treating HIV infection in adults in combination with other antiretroviral agents. The use of tenofovir in antiretroviral-experienced patients resulted in a further sustained decrease in HIV plasma RNA concentrations of 4.5 to 7.4 times relative to placebo after 48 weeks of treatment (Chapman *et al.*, 2003). Several large trials have confirmed the antiretroviral activity of tenofovir in three-drug regimens with other agents, including other nucleoside analogs, protease inhibitors, and/or NNRTIs. In a randomized, double-blind comparison trial in which treatment-naïve patients also received lamivudine and efavirenz, tenofovir 300 mg once daily was as effective and less toxic than stavudine 40 mg twice daily (Gallant *et al.*, 2004).

Emtricitabine

Chemistry and Antiviral Activity. Emtricitabine is a cytosine analog that is chemically related to lamivudine and shares many of that drug's pharmacodynamic properties. Like lamivudine, it has two chiral centers and is manufactured as the enantiomerically pure (2*R*,5*S*)-5-fluoro-1-[2-(hydroxymethyl)-1,3-oxathiolan-5-yl]cytosine (FTC) (Figure 50–2). Emtricitabine is active against HIV-1, HIV-2, and HBV. The IC_{50} of emtricitabine against laboratory strains of HIV-1 ranges from 2 to 530 nM, although, on average, the drug is about 10 times more active *in vitro* than lamivudine (Bang and Scott, 2003).

Mechanism of Action and Resistance. Emtricitabine enters cells by passive diffusion and is phosphorylated by deoxycytidine kinase and cellular kinases to its active metabolite, emtricitabine 5'-triphos-

phate (Figure 50–3). The intracellular triphosphate acts as a competitive inhibitor of reverse transcriptase and is incorporated into HIV DNA to cause chain termination. Like lamivudine, emtricitabine has low affinity for human DNA polymerases, explaining its low toxicity to the host.

High-level resistance to emtricitabine occurs with the same mutation (methionine-to-valine substitution at codon 184) affecting lamivudine, although this appears to occur less frequently with emtricitabine. In three studies, M184V occurred about half as frequently with emtricitabine-containing regimens as with lamivudine, and patients presenting with virologic failure were two to three times as likely to have wild-type virus at the time of failure as compared with lamivudine (Bang and Scott, 2003). The M184V mutation restores zidovudine susceptibility to zidovudine-resistant HIV and also partially restores tenofovir susceptibility to tenofovir-resistant HIV harboring the K65R mutation (Wainberg *et al.*, 1999). The same K65R mutation confers resistance to emtricitabine and the other cytosine analogs lamivudine and zalcitabine, as well as didanosine, stavudine, and abacavir.

Absorption, Distribution, and Elimination. Emtricitabine is absorbed rapidly and has an oral bioavailability of 93%. Food reduces the C_{max} but does not affect the AUC , and the drug can be taken without regard to meals. Emtricitabine is not bound significantly to plasma proteins. Compared with other nucleoside analogs, the drug has a slow systemic clearance and long elimination half-life of 8 to 10 hours (Bang and Scott, 2003). In addition, the estimated half-life of the intracellular triphosphate is very long, up to 39 hours in one report. This provides the pharmacokinetic rationale for once-daily dosing of this drug. Emtricitabine is excreted primarily unchanged in the urine, undergoing glomerular filtration and active tubular secretion.

Untoward Effects. Emtricitabine is one of the least toxic antiretroviral drugs and, like its chemical relative lamivudine, has few significant adverse effects and no effect on mitochondrial DNA *in vitro* (Bang and Scott, 2003). Prolonged exposure has been associated with hyperpigmentation of the skin, especially in sun-exposed areas. Elevated hepatic transaminases, hepatitis, and pancreatitis have been reported, but these have occurred in association with other drugs known to cause these toxicities. Since emtricitabine also has *in vitro* activity against HBV, caution is warranted in using this drug in patients coinfecting with HBV; discontinuation of lamivudine, which is closely related to emtricitabine, has been associated with a rebound of HBV replication and exacerbation of hepatitis.

Drug Interactions and Precautions. Emtricitabine is not metabolized to a significant extent by CYPs, and it is not susceptible to any known metabolic drug interactions. The possibility of a pharmacokinetic interaction involving renal tubular secretion, such as that between trimethoprim and lamivudine, has not been investigated for emtricitabine, although the drug does not alter the pharmacokinetics of tenofovir.

Therapeutic Use. Emtricitabine is FDA approved for treating HIV infection in adults in combination with other antiretroviral agents. Two small monotherapy trials showed that the maximal antiviral effect of emtricitabine (mean 1.9 log unit decrease in plasma HIV RNA concentration) was achieved with a dose of 200 mg/day. Several

large trials have confirmed the antiretroviral activity of emtricitabine in three-drug regimens with other agents, including nucleoside or nucleotide analogs, protease inhibitors, and/or NNRTIs. In two randomized comparison studies, emtricitabine- and lamivudine-based triple-combination regimens had similar efficacy (Bang and Scott, 2003).

NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

Nonnucleoside reverse transcriptase inhibitors (NNRTIs) include a variety of chemical substrates that bind to a hydrophobic pocket in the p66 subunit of the HIV-1 reverse transcriptase. The NNRTI-binding pocket is not essential for the function of the enzyme and is distant from the active site. These compounds induce a conformational change in the three-dimensional structure of the enzyme that greatly reduces its activity, and thus they act as noncompetitive inhibitors (Spence *et al.*, 1995). Unlike nucleoside and nucleotide reverse transcriptase inhibitors, these compounds do not require intracellular phosphorylation to attain activity. Because the binding site for NNRTIs is virus-strain-specific, the approved agents are active against HIV-1 but not HIV-2 or other retroviruses and should not be used to treat HIV-2 infection (Harris and Montaner, 2000). These compounds also have no activity against host cell DNA polymerases. The two most commonly used agents in this category, efavirenz and *nevirapine*, are quite potent and transiently decrease plasma HIV RNA concentrations by two orders of magnitude or more when used as sole agents (Havlir *et al.*, 1995; Wei *et al.*, 1995). The chemical structures of the three approved NNRTIs are shown in Figure 50–4, and their pharmacokinetic properties are summarized in Table 50–4.

All three approved NNRTIs are eliminated from the body by hepatic metabolism. Nevirapine and *delavirdine* are primarily substrates for the CYP3A4 isoform, whereas efavirenz is a substrate for CYP2B6 (Smith *et al.*, 2001) and CYP3A4. The steady-state elimination half-lives of efavirenz and nevirapine range from 24 to 72 hours, allowing daily dosing. Efavirenz and nevirapine are moderately potent inducers of hepatic drug-metabolizing enzymes including CYP3A4, whereas delavirdine is a CYP3A4 inhibitor. Pharmacokinetic drug interactions are thus an important consideration with this class of compounds and represent a potential toxicity.

The NNRTIs are more susceptible to high-level drug resistance than other classes of antiretroviral drugs because a single-amino-acid change in the NNRTI-binding pocket (usually in codons 103 or 181) renders the virus resistant to all available drugs in the class. Unlike nucleoside analogs or protease inhibitors, NNRTIs can induce resistance and virologic relapse within a few days or weeks

Figure 50–4. Structures and mechanism of nonnucleoside reverse transcriptase inhibitors.

ABBREVIATIONS: *AUC*, area under plasma concentration–time curve; *t*_{1/2,elim}, half-life of elimination; ↑, increase; ↓, decrease; ↔, no effect. *Reported mean values in adults with normal renal and hepatic function. [†]Values at steady state after multiple oral doses.

if given as monotherapy (Wei *et al.*, 1995). Exposure to even a single dose of nevirapine in the absence of other antiretroviral drugs is associated with resistance mutations in up to one-third of patients (Eshleman *et al.*, 2004). *These agents are potent and highly effective but must be combined with at least two other active agents to avoid resistance* (Table 50–2B).

The use of efavirenz or nevirapine in combination with other antiretroviral drugs is associated with favorable long-term suppression of viremia and elevation of CD4+ lymphocyte counts (Harris and Montaner, 2000). Efavirenz in particular is a common component of first regimens for treatment-naïve patients in recognition of its convenience, tolerability, and potency. Rashes occur frequently with all NNRTIs, usually during the first 4 weeks of therapy. These generally are mild and self-limited, although rare cases of potentially fatal Stevens-Johnson syndrome have been reported with nevirapine and efavirenz. Fat accumulation can be seen after long-term use of NNRTIs (Mallal *et al.*, 2000; Heath *et al.*, 2001), and fatal hepatitis has been associated with nevirapine use.

Nevirapine

Chemistry and Antiviral Activity. Nevirapine is a dipyridodiazepinone NNRTI with potent activity against HIV-1. The *in vitro* IC₅₀ of this drug ranges from 10 to 100 nM. Like other compounds in this class, nevirapine does not have significant activity against HIV-2 or other retroviruses (Harris and Montaner, 2000).

Mechanism of Action and Resistance. Nevirapine is a noncompetitive inhibitor that binds to a site on the HIV-1 reverse transcriptase that is distant from the active site, inducing a conformational change that disrupts catalytic activity. Since the target site is HIV-1-specific and is not essential for the enzyme, resistance can develop rapidly. A single mutation at either codon 103 or codon 181 of reverse transcriptase decreases susceptibility more than one hundredfold (Kuritzkes, 2004). Nevirapine resistance is also associated with mutations at codons 100, 106, 108, 188, and 190, but either the K103N or the Y181C mutation is sufficient to produce clinical treatment failure (Eshleman *et al.*, 2004). *Cross-resistance extends to all FDA-approved NNRTIs with the most common mutations. Therefore, any patient who fails treatment with one NNRTI because of a specific resistance mutation should be considered to have failed the entire class.*

Absorption, Distribution, and Elimination. Nevirapine is well absorbed, and its bioavailability is not altered by food or antacids (Smith *et al.*, 2001). The drug readily crosses the placenta and has been found in breast milk, a feature that has encouraged use of nevirapine for prevention of mother-to-child transmission of HIV (Mirochnick *et al.*, 1998).

Nevirapine is eliminated mainly by oxidative metabolism involving CYP3A4 and CYP2B6. Less than 3% of the parent drug is eliminated unchanged in the urine (Smith *et al.*, 2001). Nevirapine has a long elimination half-life of 25 to 30 hours at steady state. The drug is a moderate inducer of CYPs, including CYP3A4; thus the drug induces its own metabolism, which decreases the half-life from 45 hours following the first dose to 25 to 30 hours after 2 weeks. To compensate for this, it is recommended that the drug be initiated at a dose of 200 mg once daily for 14 days, with the dose then increased to 200 mg twice daily if no adverse reactions have

occurred. Because of its long half-life, current clinical studies are investigating once-daily dosing of nevirapine.

Untoward Effects. The most frequent adverse event associated with nevirapine is rash, which occurs in approximately 16% of patients. Mild macular or papular eruptions commonly involve the trunk, face, and extremities and generally occur within the first 6 weeks of therapy. Pruritus is also common. In the majority of patients, the rash resolves with continued administration of drug. Up to 7% of patients discontinue therapy owing to rash, and administration of glucocorticoids may cause a more severe rash. Life-threatening Stevens-Johnson syndrome is rare but occurs in up to 0.3% of recipients (Harris and Montaner, 2000).

Elevated hepatic transaminases occur in up to 14% of patients. Clinical hepatitis occurs in up to 1% of patients. Severe and fatal hepatitis has been associated with nevirapine use, and this may be more common in women, especially during pregnancy (Dieterich *et al.*, 2004). Other reported side effects include fever, fatigue, headache, somnolence, and nausea.

Drug Interactions and Precautions. Because nevirapine induces CYP3A4, this drug may lower plasma concentrations of coadministered CYP3A4 substrates. Methadone withdrawal has been reported in patients receiving nevirapine (Altice *et al.*, 1999), presumably as a consequence of enhanced methadone clearance. Plasma *ethinyl estradiol* and *norethindrone* concentrations decrease by 20% with nevirapine, and alternative methods of birth control are advised (Smith *et al.*, 2001). Nevirapine also can reduce concentrations of some coadministered HIV protease inhibitors (Table 50–5).

Therapeutic Use. Nevirapine is FDA approved for the treatment of HIV-1 infection in adults and children in combination with other antiretroviral agents. In original monotherapy studies, a rapid fall in plasma HIV RNA concentrations of 99% or greater was followed by a return toward baseline within 8 weeks because of rapid emergence of resistance (Havlir *et al.*, 1995; Wei *et al.*, 1995). Nevirapine therefore never should be used as a single agent or as the sole addition to a failing regimen. The three-drug regimen of nevirapine, zidovudine, and didanosine reduced the plasma HIV RNA concentration to undetectable levels (<400 copies/ml) in 52% of antiretroviral-naïve adults (Montaner *et al.*, 1998).

Single-dose nevirapine has been used commonly in pregnant HIV-infected women to prevent mother-to-child transmission. A single oral intrapartum dose of 200 mg nevirapine followed by a single dose given to the newborn reduced neonatal HIV infection to 13% compared with 21.5% infection with a more complicated zidovudine regimen (Guay *et al.*, 1999). Although this regimen is very inexpensive and generally well tolerated, the high prevalence of nevirapine resistance following the single oral dose (Eshleman *et al.*, 2004), coupled with the recent recognition of fatal nevirapine hepatitis, has prompted a reexamination of the role this regimen should play in the prevention of vertical transmission.

Table 50–5

Drug Interactions Between Nonnucleoside Reverse Transcriptase Inhibitors and HIV Protease Inhibitors*

ABBREVIATIONS: NNRTI, nonnucleoside reverse transcriptase inhibitor; PI, HIV protease inhibitor; AUC, area under the plasma concentration–time curve; ↑, increase, ↓, decrease; ↔, no change; NR, not reported. *Reported mean change in the AUC of the standard dose of the affected drug by the standard dose of the affecting drug; studies using modified dosing regimens were dose-normalized. [†]Parameters reported for the saquinavir soft-gel capsule formulation. [‡]Lopinavir is only available in a coformulation with ritonavir.

Delavirdine

Chemistry and Antiviral Activity. Delavirdine is a bis-heteroarylpiperazine NNRTI that selectively inhibits HIV-1. The *in vitro* IC₅₀ ranges from 6 to 30 nM for laboratory HIV-1 isolates to 1 to 700 nM for clinical isolates (Scott and Perry, 2000). Delavirdine does not have significant activity against HIV-2 or other retroviruses.

Mechanism of Action and Resistance. Delavirdine is a noncompetitive inhibitor that binds to a peripheral site on the HIV-1 reverse transcriptase and induces a conformational change that disrupts catalytic activity. The delavirdine–reverse transcriptase complex is stabilized by hydrogen bonding to the lysine at codon 103 and strong hydrophobic interactions with the proline at position 236 (Spence *et al.*, 1995). Since the target site is HIV-1-specific and is not essential for the enzyme, resistance can develop rapidly. A single mutation at either codon 103 or codon 181 of reverse transcriptase decreases susceptibility more than one hundredfold (Kuritzkes, 2004). Delavirdine resistance also is associated with mutations at codons 106, 188, and 236, but either the K103N or the Y181C mutation is sufficient to produce clinical treatment failure. Cross-resistance extends to all FDA-approved NNRTIs with the most common mutations. Therefore, any patient who fails treatment with one NNRTI because of a specific resistance mutation should be considered to have failed the entire class.

Absorption, Distribution, and Elimination. Delavirdine is well absorbed, especially at pH less than 2. Antacids, histamine H₂-receptor antagonists, proton pump inhibitors, and achlorhydria may decrease its absorption. Standard meals do not alter the delavirdine AUC, and the drug can be administered irrespective of food (Smith *et al.*, 2001). The drug may have nonlinear pharmacokinetics because the plasma half-life increases with increasing doses (Scott and Perry, 2000).

Delavirdine clearance is primarily through oxidative metabolism by CYP3A4, with less than 5% of a dose recovered unchanged in the urine. At the recommended dose of 400 mg three times daily, the mean elimination half-life is 5.8 hours, but it ranges from 2 to 11 hours because of the considerable interpatient variability in clearance (Smith *et al.*, 2001). Delavirdine is 98% bound to plasma proteins, mainly albumin. The penetration of delavirdine into CSF and semen is poor, possibly reflecting extensive plasma protein binding.

Untoward Effects. As with all drugs in this class, the most common side effect of delavirdine is rash, which occurs in 18% to 36% of subjects. Rash usually is seen in the first few weeks of treatment and often resolves despite continued therapy. The rash may be macular, papular, erythematous, or pruritic and usually involves the trunk and extremities. Fewer than 5% of patients discontinue delavirdine because of rash. Severe dermatitis, including *erythema multiforme* and Stevens-Johnson syndrome, has been reported but is rare. Elevated hepatic transaminases also have been reported, but delavirdine use is not associated with fatal hepatitis. Neutropenia also may occur rarely (Para *et al.*, 1999).

Drug Interactions and Precautions. Delavirdine is both a substrate for and an inhibitor of CYP3A4 and can alter the metabolism of other CYP3A4 substrates. Delavirdine therefore should be avoided with certain CYP3A4 substrates with a low therapeutic index, including *amiodarone*, *propafenone*, *ergot derivatives*, *pimozide*, *triazolam*, and *midazolam*. Delavirdine is a weak inhibitor of CYP2C9, CYP2D6, and CYP2C19 *in vitro*. Potent inducers of CYP3A4, such as *carbamazepine*, *phenobarbital*, *phenytoin*, *rifabutin*, and *rifampin*, may decrease delavirdine concentrations and should be avoided. Delavirdine increases the plasma concentrations of most HIV protease inhibitors (Table 50–5) and could be used to modestly enhance the pharmacokinetic profile or reduce the dose of these agents (Scott and Perry, 2000).

Therapeutic Use. Initial monotherapy studies with delavirdine produced only transient decreases in plasma HIV RNA concentrations owing to rapid emergence of resistance. Later studies of delavirdine in combination with nucleoside analogs showed sustained decreases in HIV-1 RNA (Friedland *et al.*, 1999; Para *et al.*, 1999). Delavirdine is not used as widely as other NNRTIs in large measure because of its short half-life and requirement for thrice-daily dosing.

Efavirenz

Chemistry and Antiviral Activity. Efavirenz is a 1,4-dihydro-2H-3,1-benzoxazin-2-one NNRTI (Figure 50-4) with potent activity against HIV-1. The *in vitro* IC₅₀ of this drug ranges from 3 to 9 nM (Young *et al.*, 1995). Like other compounds in this class, efavirenz does not have significant activity against HIV-2 or other retroviruses.

Mechanism of Action and Resistance. Efavirenz is a noncompetitive inhibitor that binds to a site on the HIV-1 reverse transcriptase that is distant from the active site, thus inducing a conformational change that disrupts catalytic activity. Because the target site is HIV-1-specific and is not essential for the enzyme, resistance can develop rapidly. The most common resistance mutation seen clinically is at codon 103 of reverse transcriptase (K103N), and this decreases susceptibility up to one hundredfold or greater (Kuritzkes, 2004). Additional resistance mutations have been seen at codons 100, 106, 108, 181, 188, 190, and 225, but either the K103N or Y181C mutation is sufficient to produce clinical treatment failure. Cross-resistance extends to all FDA-approved NNRTIs.

Absorption, Distribution, and Elimination. Efavirenz is well absorbed from the gastrointestinal tract and reaches peak plasma concentrations within 5 hours. There is diminished absorption of the drug with increasing doses. Bioavailability (*AUC*) is increased by 22% with a high-fat meal. Efavirenz is more than 99% bound to plasma proteins and, as a consequence, has a low CSF-plasma ratio of 0.01 (Smith *et al.*, 2001). The clinical significance of this low CNS penetration is unclear, especially since the major toxicities of efavirenz involve the CNS. It is recommended that the drug be taken initially on an empty stomach at bedtime to reduce side effects.

Efavirenz is cleared *via* oxidative metabolism, mainly by CYP2B6 and to a lesser extent by CYP3A4. The parent drug is not excreted renally to a significant degree (Smith *et al.*, 2001). Efavirenz is cleared slowly, with an elimination half-life of 40 to 55 hours at steady state. This safely allows once-daily dosing.

Untoward Effects. Rash occurs frequently with efavirenz, in up to 27% of adult patients (Adkins and Noble, 1998). Rash usually occurs within the first few weeks of treatment and rarely requires drug discontinuation. Life-threatening skin eruptions such as Stevens-Johnson syndrome have been reported during postmarketing experience with efavirenz but are rare.

The most important adverse effects of efavirenz involve the CNS. Up to 53% of patients report some CNS or psychiatric side effects, but fewer than 5% discontinue the drug for this reason. CNS symptoms may occur with the first dose and may last for hours. More severe symptoms may require weeks to resolve. Patients commonly report dizziness, impaired concentration, dysphoria, vivid or disturbing dreams, and insomnia. Episodes of frank psychosis

(depression, hallucinations, and/or mania) have been associated with initiating efavirenz. Fortunately, CNS side effects generally become more tolerable and resolve within the first 4 weeks of therapy.

Other side effects reported with efavirenz include headache, increased hepatic transaminases, and elevated serum cholesterol. False-positive urine screening tests for marijuana metabolites also can occur depending on the assay used (Adkins and Noble, 1998).

Efavirenz is the only antiretroviral drug that is unequivocally teratogenic in primates. When efavirenz was administered to pregnant cynomolgus monkeys, 25% of fetuses developed malformations. In six cases where women were exposed to efavirenz during the first trimester of pregnancy, fetuses or infants had significant malformations, mainly of the brain and spinal cord. *Women of child-bearing potential therefore should use two methods of birth control and avoid pregnancy while taking efavirenz.*

Drug Interactions and Precautions. Efavirenz is a moderate inducer of hepatic enzymes, especially CYP3A4. It undergoes limited auto-induction, but because of its long half-life, there is no need to alter drug dose during the first few weeks of treatment. Efavirenz decreases concentrations of phenobarbital, phenytoin, and carbamazepine; the methadone *AUC* is reduced by 33% to 66% at steady state (Adkins and Noble, 1998). Rifampin concentrations are unchanged by concurrent efavirenz, but rifampin may reduce efavirenz concentrations. Efavirenz reduces the rifabutin *AUC* by 38% on average. Efavirenz has a variable effect on HIV protease inhibitors (Table 50-5). Indinavir, saquinavir, and *amprenavir* concentrations are reduced, but ritonavir and *nelfinavir* concentrations are increased (Adkins and Noble, 1998). Drugs that induce CYP2B6 or CYP3A4 (*e.g.*, phenobarbital, phenytoin, and carbamazepine) would be expected to increase the clearance of efavirenz and should be avoided.

Therapeutic Use. Efavirenz was the first antiretroviral agent approved by the FDA for once-daily administration. Initial short-term monotherapy studies showed substantial decreases in plasma HIV RNA, but the drug should only be used in combination with other effective agents and should not be added as the sole new agent to a failing regimen. In antiretroviral-naïve patients receiving efavirenz, zidovudine, and lamivudine, 70% achieved undetectable plasma HIV-1 RNA compared with 48% of those receiving indinavir plus zidovudine and lamivudine (Staszewski *et al.*, 1999). Much of this difference appeared to be the consequence of improved patient adherence to the efavirenz regimen. Efavirenz also has been used effectively in patients who have failed previous antiretroviral therapy in combination with other active drugs (Falloon *et al.*, 2000; Piketty *et al.*, 1999). In pediatric HIV infection, 60% of children failing prior therapy with a nucleoside reverse transcriptase inhibitor had sustained virologic benefit after 48 weeks of treatment with efavirenz, nelfinavir, and a nucleoside analog (Starr *et al.*, 1999).

Efavirenz is used widely in the developed world because of its convenience, effectiveness, and long-term tolerability. To date, no antiretroviral regimen has produced better long-

term treatment responses than any efavirenz-containing regimen in randomized, prospective clinical trials. As a result, efavirenz plus two nucleoside reverse transcriptase inhibitors was one of two regimens preferred in 2004 for treatment-naïve patients (Table 50–2).

HIV PROTEASE INHIBITORS

HIV protease inhibitors are peptidlike chemicals that competitively inhibit the action of the virus aspartyl protease (Figure 50–5). This protease is a homodimer consisting of two 99-amino-acid monomers; each monomer contributes an aspartic acid residue that is essential for catalysis (Pearl and Taylor, 1987). The preferred cleavage site for this enzyme is the N-terminal side of proline residues, especially between phenylalanine and proline. Human aspartyl proteases (*i.e.*, renin, pepsin, gastricsin, and cathepsins D and E) contain only one polypeptide chain and are not significantly inhibited by HIV protease inhibitors. These drugs prevent proteolytic cleavage of HIV gag and pol polyproteins that include essential structural (p17, p24, p9, and p7) and enzymatic (reverse transcriptase, protease, and integrase) components of the virus. This prevents the metamorphosis of HIV virus particles into their mature infectious form (Flexner, 1998). Infected patients treated with HIV protease inhibitors as sole agents experienced a one hundred- to one thousand-fold mean decrease in plasma HIV RNA concentrations within 12 weeks, an effect similar in magnitude to that produced by NNRTIs (Ho *et al.*, 1995).

The clearance of all approved HIV protease inhibitors is mainly through hepatic oxidative metabolism. All but one of these drugs are substrates predominately for CYP3A4. Nelfinavir's major metabolite, M8, is formed by CYP2C19, and M8 is then cleared by CYP3A4. Elimination half-lives of the HIV protease inhibitors range from 1.8 to 10 hours (Table 50–6), and most of these drugs can be dosed once or twice daily. Pharmacokinetic properties are characterized by high interindividual variability, which may reflect differential activity of intestinal and hepatic CYP450 isoforms (Back *et al.*, 2002; Rendic and Di Carlo, 1997).

Most HIV protease inhibitors are substrates for the P-glycoprotein drug transporter (P-gp), which is an efflux pump encoded by the *mdr1* gene. P-gp in capillary endothelial cells of the blood–brain barrier limits the penetration of HIV protease inhibitors into the brain (Kim *et al.*, 1998), although the low CSF–plasma drug concentration ratio characteristic of these drugs also may reflect exten-

sive binding to plasma proteins. Most HIV protease inhibitors penetrate less well into semen than do nucleoside reverse transcriptase inhibitors and NNRTIs. Virologic responses in plasma, CSF, and semen usually are concordant (Taylor *et al.*, 1999), and the clinical significance of P-gp and protein-binding effects is unclear.

An important toxicity common to all approved HIV protease inhibitors is the potential for metabolic drug interactions (Tables 50–5 and 50–7). Most of these drugs inhibit CYP3A4 at clinically achieved concentrations, although the magnitude of inhibition varies greatly, with ritonavir being by far the most potent (Piscitelli and Gallicano, 2001). Ritonavir, nelfinavir, and amprenavir are also moderate inducers of hepatic enzymes including CYP3A4 and glucuronosyl *S*-transferase. Concentrations of all approved HIV protease inhibitors may be reduced in the presence of other CYP inducers. Patients and care providers must be vigilant about the possibility of clinically significant pharmacokinetic drug interactions in patients receiving these drugs. Nausea, vomiting, and diarrhea are also common, although symptoms generally resolve within 4 weeks of starting treatment.

It is a common practice to combine HIV protease inhibitors with a low dose of ritonavir to take advantage of that drug's remarkable capacity to inhibit CYP3A4 metabolism (Flexner, 2000). Although the approved dose of ritonavir for antiretroviral treatment is 600 mg twice daily, doses of 100 or 200 mg twice daily are sufficient to inhibit CYP3A4 and increase the concentrations of concurrently administered CYP3A4 substrates. Furthermore, lower doses of ritonavir are much better tolerated. The enhanced pharmacokinetic profile of HIV protease inhibitors administered with ritonavir reflects inhibition of both first-pass and systemic clearance, resulting in improved oral bioavailability and a longer elimination half-life of the coadministered drug. This allows a reduction in both drug dose and dosing frequency while increasing systemic concentrations (Flexner, 2000). Combinations of amprenavir, *fosamprenavir*, or atazanavir with ritonavir are approved for once-daily administration, and other once-daily dual protease inhibitor combinations are under investigation. *Lopinavir* is available only in a coformulation with ritonavir that is designed to take advantage of this beneficial pharmacokinetic drug interaction.

The speed with which HIV develops resistance to protease inhibitors is intermediate between that of nucleoside analogs and NNRTIs. In initial monotherapy studies, the median time to rebound in HIV plasma RNA concentrations of one log or greater was 3 to 4 months (Flexner, 1998). In contrast to NNRTIs, high-level resistance to these drugs generally requires accumulation of a minimum of four to five codon substitutions, which may take

Figure 50–5. Mechanism of action of an HIV protease inhibitor.

many months. Initial (primary) resistance mutations in the enzymatic active site confer only a three- to fivefold drop in sensitivity to most drugs, although primary mutations have a more pronounced effect on atazanavir and nelfinavir. However, these are followed by secondary mutations often distant from the active site that compensate for

the reduction in proteolytic efficiency. Resistance to one HIV protease inhibitor occurs often, with the patient retaining sensitivity to other drugs in the class, although accumulation of secondary resistance mutations decreases the likelihood of long-term response to the next agent used (Flexner, 1998; Kuritzkes, 2004).

ABBREVIATIONS: AUC, area under the plasma concentration–time curve; ↑, increase, ↓, decrease; ↔, no change; NR, not reported. *Reported mean change in the AUC of the standard dose of the affected drug by the standard dose of the affecting drug; studies using modified dosing regimens were dose-normalized. [†]Parameters reported for the saquinavir soft-gel capsule formulation. [‡]Lopinavir is only available in a coformulation with ritonavir. [§]This represents the impact of additional ritonavir (100 mg bid) on the AUC of lopinavir in the coformulation of 400 mg lopinavir with 100 mg ritonavir bid.

HIV protease inhibitors produce favorable long-term suppression of viremia, elevation of CD4+ lymphocyte counts, reduced disease progression, and improved survival when combined with other active antiretroviral drugs (Flexner, 1998). With potent activity and favorable resistance profiles, these drugs are a common component of regimens for treatment-experienced patients. However, the virologic benefits of these drugs must be balanced against short- and long-term toxicities, including the risk of insulin resistance and lipodystrophy (Garg, 2004). In addition, dosing of some agents in this class may require as many as 18 capsules per day (Table 50–2), which makes adherence problematic.

Saquinavir

Chemistry and Antiviral Activity. Saquinavir is a peptidomimetic hydroxyethylamine HIV protease inhibitor. It is a transition-state analog of a phenylalanine–proline cleavage site in one of the native substrate sequences for the HIV aspartyl protease and was the product of a rational drug-design program (Roberts *et al.*, 1990). Saquinavir inhibits both HIV-1 and HIV-2 replication and has an *in vitro* IC₅₀ in peripheral blood lymphocytes that ranges from 3.5 to 10 nM (Noble and Faulds, 1996).

Mechanisms of Action and Resistance. Saquinavir is selectively toxic by potently inhibiting the HIV-encoded protease but not host-encoded aspartyl proteases. Saquinavir reversibly binds to the active site of HIV protease, preventing polypeptide processing and subsequent virus maturation. Virus particles are produced in the presence of saquinavir but are noninfectious.

Virus replication in the presence of saquinavir selects for drug-resistant virus. The primary saquinavir resistance mutation occurs at HIV protease codon 90 (a leucine-to-methionine substitution), although primary resistance also has been reported with a glycine-to-valine substitution at codon 48. Secondary resistance mutations occur at codons 36, 46, 82, 84, and others, and these are associated with clinical saquinavir resistance as well as cross-resistance to other HIV protease inhibitors (Ives *et al.*, 1997). As is typical of HIV protease inhibitors, high-level resistance requires accumulation of multiple resistance mutations.

Absorption, Distribution, and Elimination. Saquinavir is marketed in two formulations, a hard-gelatin (INVIRASE) and a soft-gelatin (FORTOVASE) capsule. Fractional oral bioavailability of the original hard-gelatin capsule was only about 4% owing mainly to extensive first-pass metabolism (Flexner, 1998). The soft-gelatin capsule formulation has threefold greater oral bioavailability, although the hard-gel capsule is used when this drug is combined with ritonavir (Perry and Noble, 1998) (*see below*). The bioavailability of saquinavir is increased up to sixfold with a high-calorie, high-fat meal. Saquinavir has nonlinear pharmacokinetics with increasing dose; for example, tripling the oral dose of saquinavir is associated with an eightfold increase in *AUC*. Substances that inhibit intestinal but not hepatic CYP3A4, such as grapefruit juice, increase the saquinavir *AUC* by threefold at most (Flexner, 2000).

Saquinavir is metabolized primarily by intestinal and hepatic CYP3A4 (Fitzsimmons and Collins, 1997). Its metabolites are not known to be active against HIV-1. Saquinavir and its metabolites are eliminated through the biliary system and feces (>95% of drug), with minimal urinary excretion (<3%). Saquinavir's short half-life requires administration every 8 hours. However, saquinavir metabolism is exquisitely sensitive to inhibition by ritonavir (Table 50–7); thus saquinavir is usefully combined with low doses of ritonavir to allow once- or twice-daily administration. Low doses of ritonavir increase the saquinavir steady-state *AUC* by twenty- to thirtyfold (Flexner, 2000).

Untoward Effects. The most frequent side effects of saquinavir are gastrointestinal and include nausea, vomiting, diarrhea, and abdominal discomfort. Diarrhea and other gastrointestinal side effects may be more prevalent with the soft-gelatin formulation. Most side effects of saquinavir are mild and short-lived, although long-term use is associated with lipodystrophy.

Precautions and Interactions. Of all the HIV protease inhibitors, saquinavir is the least potent inhibitor of CYP3A4. Nonetheless, it is recommended that the drug not be coadministered with ergot derivatives, triazolam, midazolam, or other CYP3A4 substrates with a low therapeutic index. Saquinavir clearance is increased with CYP3A4 induction; thus coadministration of rifampin, nevirapine, or efavirenz lowers saquinavir concentrations and should be avoided (Flexner, 1998). The effect of nevirapine or efavirenz on saquinavir may be partially or completely reversed with ritonavir.

Therapeutic Use. In initial clinical trials, hard-gelatin capsules of saquinavir mesylate at the approved dose (600 mg three times daily) produced only modest virologic effect most likely because of poor oral bioavailability. Greater activity was achieved by increasing the dose fourfold, to 1200 mg six times daily (Schapiro *et al.*, 1996). When combined with ritonavir and nucleoside analogs, saquinavir produces viral load reductions comparable with those of other HIV protease inhibitor regimens (Flexner, 2000).

Ritonavir

Chemistry and Antiviral Activity. Ritonavir is a peptidomimetic HIV protease inhibitor designed to complement the C₂-symmetry of the enzyme active site (Flexner, 1998) (Figure 50–5). Ritonavir is active against both HIV-1 and HIV-2, although it may be slightly less active against the latter. Its IC₅₀ for wild-type HIV-1 variants in the absence of human serum ranges from 4 to 150 nM.

Mechanisms of Action and Resistance. Ritonavir reversibly binds to the active site of the HIV protease, preventing polypeptide processing and subsequent virus maturation. Virus particles are produced in the presence of ritonavir but are noninfectious.

In patients treated with ritonavir as the sole protease inhibitor, virus replication in the presence of drug selects for drug-resistance

mutations (Molla *et al.*, 1996). The primary ritonavir resistance mutation is usually at protease codon 82 (several possible substitutions for valine) or codon 84 (isoleucine-to-valine substitution). Additional mutations associated with increasing resistance occur at codons 20, 32, 46, 54, 63, 71, 84, and 90. High-level resistance requires accumulation of multiple mutations.

Absorption, Distribution, and Elimination. Absorption of ritonavir is rapid and is only slightly affected by food, depending on the formulation. The overall absorption of ritonavir from the capsule formulation increases by 13% when the capsule is taken with meals, but the bioavailability of the oral solution decreases by 7% (Flexner, 1998). Interindividual variability in pharmacokinetics is high, with a greater than sixfold variability in trough concentrations among patients given 600 mg ritonavir every 12 hours (Hsu *et al.*, 1998).

Ritonavir is metabolized primarily by CYP3A4 and to a lesser extent by CYP2D6. Ritonavir and its metabolites are mainly eliminated in feces (86% of parent drug and metabolites), with only 3% of drug eliminated unchanged in the urine. Ritonavir is 98% to 99% bound to plasma proteins, mainly to α_1 -acid glycoprotein. Physiological concentrations of α_1 -acid glycoprotein increase the *in vitro* IC₅₀ by a factor of 10, whereas albumin increases the IC₅₀ by a factor of four (Molla *et al.*, 1998).

Untoward Effects. The major side effects of ritonavir are gastrointestinal and include nausea, vomiting, diarrhea, anorexia, abdominal pain, and taste perversion. These side effects are dose-dependent and are less common with lower doses. Gastrointestinal toxicity may be reduced if the drug is taken with meals. Peripheral and perioral paresthesias also are common. These side effects generally abate within a few weeks of starting therapy.

Ritonavir induces its own metabolism, and gradual dose escalation over the first 2 weeks may minimize early intolerance. When ritonavir is used as the sole protease inhibitor, it should be initiated at 300 mg every 12 hours and escalated gradually to 600 mg every 12 hours by day 14 of therapy. Ritonavir causes dose-dependent elevations in serum total cholesterol and triglycerides, as well as other signs of lipodystrophy, and could increase the long-term risk of atherosclerosis in some patients.

Precautions and Interactions. Ritonavir is one of the most potent known inhibitors of CYP3A4, markedly increasing the plasma concentration and prolonging the elimination of many drugs including amiodarone, propafenone, ergot derivatives, pimozide, triazolam, and midazolam. This drug should be avoided or used with caution in combination with any CYP3A4 substrate, especially those with a narrow therapeutic index (Flexner, 1998). Ritonavir is also a weak inhibitor of CYP2D6. Potent inducers of CYP3A4 activity such as rifampin may lower ritonavir concentrations and should be avoided or dosage adjustments considered. The capsule and solution formulations of ritonavir contain alcohol and should not be administered with *disulfiram* or *metronidazole* (see Chapter 22).

Ritonavir is a moderate inducer of CYP3A4, glucuronosyl *S*-transferase, and possibly other hepatic enzymes. The concentrations of some drugs therefore will be decreased in the presence of ritonavir. Ritonavir reduces the ethinyl estradiol *AUC* by 40%, and alternative forms of contraception should be used (Piscitelli and Gallicano, 2001).

Therapeutic Use. Among patients with susceptible strains of HIV-1, ritonavir as a sole agent lowers plasma HIV-1

RNA concentrations by one hundred- to one thousandfold (Ho *et al.*, 1995). In a double-blind, randomized, placebo-controlled trial in 1090 patients with advanced HIV disease, the addition of ritonavir to current therapy reduced HIV-related mortality and disease progression by about 50% over a median of 6 months of follow-up (Cameron *et al.*, 1998). Ritonavir is used infrequently as the sole protease inhibitor in combination regimens because of gastrointestinal toxicity. However, numerous clinical trials have shown efficacy for ritonavir in various dual protease inhibitor combinations (Flexner, 2000).

Use of Ritonavir as a CYP3A4 Inhibitor. Ritonavir inhibits the metabolism of all current HIV protease inhibitors (Table 50–7) and is frequently combined with most of these drugs, with the exception of nelfinavir, to enhance their pharmacokinetic profile and allow a reduction in dose and dosing frequency of the coadministered drug (Flexner, 2000). Ritonavir also overcomes the deleterious effect of food on indinavir bioavailability. Under most circumstances, low doses of ritonavir (100 or 200 mg twice daily) are just as effective at inhibiting CYP3A4 and are much better tolerated than the 600-mg twice-daily treatment dose. The positive impact of low-dose ritonavir on the pharmacokinetics of lopinavir made possible the development and eventual approval of that drug, which is a component of one of two preferred starting regimens recommended by the U.S. Department of Health and Human Services in 2004 (Table 50–2).

Indinavir

Chemistry and Antiviral Activity. Indinavir is a peptidomimetic hydroxyethylene HIV protease inhibitor (Plosker and Noble, 1999). It is formulated as the sulfate salt to yield better solubility and more consistent plasma concentrations as compared with the free base. The molecule was based on a renin inhibitor with some similarity to a phenylalanine-proline cleavage site in the HIV gag polyprotein (Vacca *et al.*, 1994), although indinavir is not itself a renin inhibitor. Indinavir is tenfold more potent against the HIV-1 protease than that of HIV-2, and its 95% inhibitory concentration (IC₉₅) for wild-type HIV-1 ranges from 25 to 100 nM.

Mechanisms of Action and Resistance. Indinavir is selectively toxic by potently inhibiting the HIV-encoded protease but not host-encoded aspartyl proteases. Indinavir reversibly binds to the active site of HIV protease, preventing polypeptide processing and subsequent virus maturation. Virus particles are produced in the presence of indinavir but are noninfectious.

Viral replication in the presence of indinavir selects for drug-resistant virus. The primary indinavir resistance mutations occur at HIV protease codons 46 (a methionine-to-isoleucine or leucine), 82,

and 84. However, secondary resistance mutations can accumulate at codons 10, 20, 24, 46, 54, 63, 71, 82, 84, and 90, and these are associated with clinical indinavir resistance as well as cross-resistance to other HIV protease inhibitors (Condra *et al.*, 1995).

Absorption, Distribution, and Elimination. Indinavir is absorbed rapidly after oral administration, with peak concentrations achieved in approximately 1 hour. Unlike other drugs in this class, food can adversely affect indinavir bioavailability; a high-calorie, high-fat meal reduces plasma concentrations by 75% (Plosker and Noble, 1999). Absorption is unaffected by light low-fat meals. Therefore, indinavir must be taken while fasting or with a low-fat meal. Indinavir has the lowest protein binding of the HIV protease inhibitors, with only 60% of drug bound to plasma proteins (Plosker and Noble, 1999). As a consequence, indinavir has higher fractional CSF penetration than other drugs in this class, although the clinical significance of this is unknown.

Indinavir undergoes extensive hepatic metabolism by CYP3A4. Indinavir and its metabolites are eliminated primarily in feces (81% of parent drug and metabolites). Plasma indinavir concentrations may increase with moderate liver disease, and dose reduction may be required. The short half-life of indinavir makes thrice-daily (every 8 hours) dosing necessary. However, indinavir clearance is greatly reduced by low doses of ritonavir, which also overcomes the deleterious effect of food on bioavailability (Flexner, 2000). This allows indinavir to be dosed twice daily regardless of meals.

Untoward Effects. A unique and common adverse effect of indinavir is crystalluria and nephrolithiasis. This stems from the poor solubility of the drug, which is lower at pH 7.4 than at pH 3.5 (Plosker and Noble, 1999). Precipitation of indinavir and its metabolites in urine can cause renal colic, and nephrolithiasis occurs in approximately 3% of patients. Patients must drink sufficient fluids to maintain dilute urine and prevent renal complications. Risk of nephrolithiasis is related to higher plasma drug concentrations, which presumably produce higher urine concentrations, regardless of whether or not the drug is combined with ritonavir (Dieleman *et al.*, 1999).

Indinavir frequently causes unconjugated hyperbilirubinemia, and 10% of patients develop an indirect serum bilirubin concentration of greater than 2.5 mg/dl (Plosker and Noble, 1999). This is generally asymptomatic and is not associated with serious long-term sequelae. As with other HIV protease inhibitors, prolonged administration of indinavir is associated with the HIV lipodystrophy syndrome, especially fat accumulation. Indinavir has been associated with hyperglycemia and can induce a relative state of insulin resistance in healthy HIV-seronegative volunteers following a single 800-mg dose (Noor *et al.*, 2002). Dermatologic complications have been reported, including hair loss, dry skin, dry and cracked lips, and ingrown toenails (Plosker and Noble, 1999). Gastrointestinal side effects are less common with indinavir than with other HIV protease inhibitors.

Precautions and Interactions. Patients taking indinavir should drink at least 2 L of water daily to prevent renal complications. Since indinavir solubility decreases at higher pH, antacids or other buffering agents *should not* be taken at the same time. Didanosine formulations containing an antacid buffer should not be taken within 2 hours before or 1 hour after indinavir. Like most other HIV protease inhibitors, indinavir is metabolized by CYP3A4 and is a moderately potent CYP3A4 inhibitor. Indinavir should not be coadministered with other CYP3A4 substrates that have a narrow therapeutic index.

Indinavir raises rifabutin concentrations and increases rifabutin toxicity; the rifabutin daily dose, therefore, should be reduced by 50% (Hamzeh *et al.*, 2003). Drugs that induce CYP3A4 may lower indinavir concentrations and should be avoided. Rifampin lowers the indinavir *AUC* by 90% and is contraindicated (Flexner, 1998); efavirenz, nevirapine, and rifabutin lower indinavir levels less substantially (by 25% to 35%) and may necessitate an increased indinavir dose (Hamzeh *et al.*, 2003).

Therapeutic Use. Large clinical trials have demonstrated both virologic and survival benefit of indinavir three times daily in combination with zidovudine and lamivudine (Gulick *et al.*, 1997; Hammer *et al.*, 1997). Twice-daily administration of the same total daily dose of indinavir (without ritonavir) was less efficacious (Haas *et al.*, 2000), possibly reflecting inadequate trough concentrations with less frequent dosing. However, when combined with ritonavir and nucleoside analogs, twice-daily indinavir produces viral load reductions comparable with those of other HIV protease inhibitor regimens (Flexner, 2000).

Nelfinavir

Chemistry and Antiviral Activity. Nelfinavir is a non-peptidic protease inhibitor that is active against both HIV-1 and HIV-2 and is formulated as the mesylate salt of a basic amine (Bardsley-Elliott and Plosker, 2000) (Figure 50–6). The mean IC_{95} for HIV-1 in various *in vitro* assays is 59 nM. Like most drugs in this class, nelfinavir was a product of rational drug design (Roberts *et al.*, 1990).

Mechanisms of Action and Resistance. Nelfinavir reversibly binds to the active site of the HIV protease, preventing polypeptide processing and subsequent virus maturation.

Viral replication in the presence of nelfinavir selects for drug resistance. The primary nelfinavir resistance mutation is unique to this drug and occurs at HIV protease codon 30 (aspartic acid-to-asparagine substitution); this mutation results in a sevenfold decrease in susceptibility. Isolates with only this mutation retain full sensitivity to other HIV protease inhibitors (Bardsley-Elliott and Plosker, 2000). Less commonly, a primary resistance mutation occurs at position 90, which can confer cross-resistance. In addition, secondary resistance mutations can accumulate at codons 35, 36, 46, 71, 77, 88, and 90, and these are associated with further resistance to nelfinavir, as well as cross-resistance to other HIV protease inhibitors.

Absorption, Distribution, and Elimination. Nelfinavir is absorbed more slowly than other HIV-1 protease inhibitors, with peak concentrations achieved in 2 to 4 hours. As a result, drug concentrations continue to fall for 2 to 3 hours after taking the next dose of drug. Nelfinavir absorption is very sensitive to food effects; a moderate-fat meal increases the *AUC* two- to threefold, and higher concentrations are achieved with high-fat meals (Bardsley-Elliott and Plosker, 2000). Intraindividual and interindividual variabilities in plasma nelfinavir concentrations are considerable largely as a consequence of variable absorption. Originally approved at a dose of 750 mg

Figure 50–6. Structure of HIV protease inhibitors.

three times daily, nelfinavir is now administered at a dose of 1250 mg twice daily using a reduced-volume 625-mg tablet.

Nelfinavir undergoes oxidative metabolism in the liver primarily by CYP2C19 but also by CYP3A4 and CYP2D6. Its major hydroxy-*t*-butylamide metabolite, M8, is formed by CYP2C19 and has *in vitro*

antiretroviral activity similar to that of the parent drug. This is the only known active metabolite of an HIV protease inhibitor. M8 concentrations are 30% to 40% those of parent drug. Nelfinavir and its metabolites are eliminated primarily in feces, with less than 2% of drug excreted unchanged in the urine. Moderate or severe liver dis-

ease may prolong the half-life and increase plasma concentrations of the parent drug while lowering plasma concentrations of M8. Nelfinavir induces its own metabolism, and average trough concentrations after 1 week of therapy are approximately one-half those at day 2 of therapy (Bardsley-Elliot and Plosker, 2000).

Nelfinavir is greater than 98% bound to plasma proteins, mostly to albumin and α_1 -acid glycoprotein. It is present in CSF at less than 1% of plasma concentrations at least in part owing to its extensive binding to plasma proteins and possibly to export by P-gp at the blood-brain barrier (Aweeka *et al.*, 1999).

Untoward Effects. The most important side effect of nelfinavir is diarrhea or loose stools, which resolve in most patients within the first 4 weeks of therapy. Up to 20% of patients report chronic occasional diarrhea lasting more than 3 months, although fewer than 2% of patients discontinue the drug because of diarrhea. Nelfinavir augments intestinal calcium-dependent chloride channel secretory responses *in vitro*, and electrolyte analysis of stool is most consistent with a secretory diarrhea (Rufo *et al.*, 2004). Otherwise, nelfinavir is generally well tolerated but has been associated with glucose intolerance, elevated cholesterol levels, and elevated triglycerides.

Precautions and Interactions. Because nelfinavir is metabolized by CYP2C19 and CYP3A4, concomitant administration of agents that induce these enzymes may be contraindicated (as with rifampin) or may necessitate an increased nelfinavir dose (as with rifabutin). Nelfinavir is a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. Nelfinavir inhibits CYP3A4 less than does ritonavir and does not appear to inhibit other CYP isoforms. Nelfinavir is also an inducer of hepatic drug-metabolizing enzymes, reducing the *AUC* of ethinyl estradiol by 47% and norethindrone by 18% (Flexner, 1998). Combination oral contraceptives therefore should not be used as the sole form of contraception in patients taking nelfinavir. Nelfinavir reduces the zidovudine *AUC* by 35%, suggesting induction of glucuronosyl *S*-transferase.

Therapeutic Use. Nelfinavir is indicated for the treatment of HIV infection in adults and children in combination with other antiretroviral drugs. Large clinical trials have demonstrated both virologic and clinical benefit when patients naive to HIV protease inhibitors and lamivudine received nelfinavir in combination with zidovudine and lamivudine (Bardsley-Elliot and Plosker, 2000). Recent large randomized, comparative trials have found that long-term virologic suppression with nelfinavir-based combination regimens is statistically significantly inferior to those using lopinavir-ritonavir (Cvetkovic and Goa, 2003), atazanavir, or efavirenz. This could reflect the unpredictable nature of nelfinavir absorption. Nelfinavir is well tolerated in pregnant HIV-infected women and shows no evidence of teratogenesis. The drug also has been used in HIV-infected patients with significant hepatic dysfunction without evidence of untoward toxicity despite higher drug concentrations (Khaliq *et al.*, 2000).

Amprenavir and Fosamprenavir

Chemistry and Antiviral Activity. Amprenavir is an *N,N*-disubstituted (hydroxyethyl) amino sulfonamide nonpeptide HIV protease inhibitor (Adkins and Faulds, 1998). Although developed using a sophisticated structure-based drug-design program, the same compound was identified previously using a more traditional high-throughput screen of an available chemical library (Werth, 1994). Amprenavir is the only available HIV protease inhibitor that contains a sulfonamide moiety, which may play a role in its dermatological side effects. The drug is active against both HIV-1 and HIV-2, with an IC_{90} for wild-type HIV-1 of approximately 80 nM.

Fosamprenavir is a phosphonoxy prodrug of amprenavir that has the advantage of greatly increased water solubility and improved oral bioavailability (Ellis *et al.*, 2004). This allows reduction in the pill burden from 16 capsules to 4 tablets per day. The original amprenavir formulation contained *D*- α -tocopheryl polyethylene glycol, which delivered a high daily dose of vitamin E; this excipient is not required with fosamprenavir. Fosamprenavir is as effective, more convenient, and generally better tolerated than amprenavir, and as a result, amprenavir 150-mg capsules were removed from the market at the end of 2004.

Mechanisms of Action and Resistance. Amprenavir is an active-site inhibitor of HIV protease. Virus replication in the presence of amprenavir selects for drug-resistant virus. Amprenavir's primary resistance mutation occurs at HIV protease codon 50; this isoleucine-to-valine substitution confers only twofold decreased susceptibility *in vitro*. Primary resistance occurs less frequently at codon 84. Secondary resistance mutations occur at codons 10, 32, 46, 47, 54, 73, and 90, which greatly increase resistance and cross-resistance. The same resistance patterns occur with fosamprenavir treatment (Ellis *et al.*, 2004).

Absorption, Distribution, and Elimination. Amprenavir is absorbed rapidly after oral administration. Taking amprenavir with a standard meal reduces the plasma *AUC* by only 13%, and the drug therefore can be administered without regard to food. Fosamprenavir is dephosphorylated rapidly to amprenavir in the intestinal mucosa. The phosphorylated prodrug is approximately 2000 times more water-soluble than amprenavir, allowing a more compact formulation. Meals have no significant effect on fosamprenavir pharmacokinetics (Ellis *et al.*, 2004). Amprenavir is 90% bound to plasma proteins, mostly α_1 -acid glycoprotein. This binding is relatively weak, and physiological concentrations of α_1 -acid glycoprotein increase the *in vitro* IC_{50} only three- to fivefold.

Amprenavir clearance is mainly by hepatic CYP3A4, and excretion is *via* the biliary route. Amprenavir is a moderate inhibitor and inducer of CYP3A4. Ritonavir increases amprenavir concentrations by inhibiting CYP3A4, allowing lower amprenavir doses. The daily amprenavir dose may be reduced from 1200 to 600 mg twice daily when 100-mg twice-daily ritonavir also is given or to 1200 mg once

daily when 200 mg ritonavir also is given once daily (Flexner, 2000). Similar dose reductions are achieved by combining fosamprenavir with ritonavir.

Untoward Effects. The most common adverse effects associated with amprenavir are gastrointestinal and include nausea, vomiting, diarrhea, or loose stools. Hyperglycemia, fatigue, paresthesias, and headache also have been reported. Amprenavir is the HIV protease inhibitor that is most likely to produce skin eruptions; in one study of amprenavir monotherapy, rash occurred in 5 of 35 patients over 24 weeks and began within 7 to 12 days of starting therapy (Adkins and Faulds, 1998). Amprenavir is reported to have fewer effects on plasma lipid profiles compared with ritonavir-based protease inhibitor regimens. Fosamprenavir has a similar toxicity profile, but gastrointestinal side effects are much less frequent than with amprenavir, and rash also may be less frequent (19% versus 27%) (Ellis *et al.*, 2004).

Precautions and Interactions. Inducers of hepatic CYP3A4 activity (*e.g.*, rifampin and efavirenz) may lower plasma amprenavir concentrations. Because amprenavir is both a CYP3A4 inhibitor and inducer, metabolic drug interactions can occur and may be unpredictable. For example, atorvastatin, ketoconazole, and rifabutin concentrations increase significantly with amprenavir, whereas delavirdine and methadone concentrations decrease. Fosamprenavir is expected to have a drug-interaction potential similar to that of amprenavir.

Therapeutic Use. Clinical trials have demonstrated long-term virologic benefit in treatment-naïve patients receiving amprenavir (1200 mg every 12 hours) in combination with zidovudine and lamivudine (Adkins and Faulds, 1998). Similar results are seen when amprenavir is combined with ritonavir.

One comparative trial found that an amprenavir-based regimen was less effective than an indinavir-based regimen, with HIV RNA values of less than 400 copies/ml in only 30% of the amprenavir-treated patients compared with 49% of the indinavir-treated patients after 48 weeks (Ellis *et al.*, 2004). This may reflect poor adherence to amprenavir owing to high pill burden and side effects. Several large randomized trials have established a better track record for fosamprenavir, showing equivalent or superior long-term viral RNA effects as nelfinavir in treatment-naïve patients. However, in one comparative trial in treatment-experienced patients, fosamprenavir combined with ritonavir was marginally inferior to the lopinavir–ritonavir coformulation (Ellis *et al.*, 2004).

Lopinavir

Chemistry and Antiviral Activity. Lopinavir is a peptidomimetic HIV protease inhibitor that is structurally similar to ritonavir (Figure 50–6) but is three- to tenfold more potent against HIV-1 *in vitro*. Lopinavir is active against both HIV-1 and HIV-2; its IC_{50} for wild-type HIV variants

in the presence of 50% human serum ranges from 65 to 290 nM. Lopinavir is available only in coformulation with low doses of ritonavir, which is used to inhibit CYP3A4 metabolism and increase concentrations of lopinavir.

Mechanisms of Action and Resistance. Lopinavir is selectively toxic by potently inhibiting the HIV-encoded protease but not host-encoded aspartyl proteases. Protease-specific resistance mutations are identified with less frequency in patients taking lopinavir than with other HIV protease inhibitors. Treatment-naïve patients who fail a first regimen containing lopinavir generally do not have HIV protease mutations but may have genetic resistance to the other drugs in the regimen (Cvetkovic *et al.*, 2003). For treatment-experienced patients, accumulation of four or more HIV protease inhibitor resistance mutations is associated with a reduced likelihood of virus suppression after starting lopinavir (Kuritzkes, 2004). Mutations associated with lopinavir failure in treatment-experienced patients include those at HIV protease codons 10, 20, 24, 32, 33, 36, 46, 47, 50, 53, 54, 63, 71, 73, 82, 84, and 90 (Cvetkovic *et al.*, 2003). There is no evidence that exposure to the low doses of ritonavir in the lopinavir–ritonavir coformulation selects for ritonavir-specific resistance mutations.

Absorption, Distribution, and Elimination. Lopinavir is only available as a coformulation with low doses of ritonavir. When administered orally without ritonavir, lopinavir plasma concentrations were exceedingly low mainly owing to first-pass metabolism. Both the first-pass metabolism and systemic clearance of lopinavir are very sensitive to inhibition by ritonavir. A single 50-mg dose of ritonavir increased the lopinavir *AUC* by 77 times compared with that produced with 400 mg lopinavir alone; 100 mg ritonavir increased the lopinavir *AUC* by 155-fold. Lopinavir trough concentrations were increased fifty to one hundredfold by coadministration of low doses of ritonavir (Cvetkovic *et al.*, 2003). Multiple-dose pharmacokinetic studies have not been conducted with lopinavir in the absence of ritonavir. Adding 100 mg ritonavir twice daily to the lopinavir–ritonavir coformulation (a total of 200 mg twice daily of ritonavir) has only a modest further effect on lopinavir concentrations, increasing the mean steady-state *AUC* by 46%.

Lopinavir is absorbed rapidly after oral administration. A moderate- to high-fat meal increases oral bioavailability by up to 50%, and it is therefore recommended that the drug be taken with food. Although the capsules contain lopinavir–ritonavir in a fixed 4:1 ratio, the observed plasma concentration ratio for these two drugs following oral administration is nearly 20:1, reflecting the sensitivity of lopinavir to the inhibitory effect of ritonavir on CYP3A4. Lopinavir undergoes extensive hepatic oxidative metabolism by CYP3A4. Approximately 90% of total drug in plasma is the parent compound, and less than 3% of a dose is eliminated unchanged in the urine. Both lopinavir and ritonavir are highly bound to plasma proteins, mainly to α_1 -acid glycoprotein, and therefore have a low fractional penetration into CSF and semen. Unlike ritonavir, the *in vitro* IC_{50} of lopinavir is not affected by physiological concentrations of albumin (Molla *et al.*, 1998).

Untoward Effects. The most common adverse events reported with the lopinavir–ritonavir coformulation have been gastrointestinal, including loose stools, diarrhea, nausea, and vomiting. These are less frequent and less severe than those reported with the 600-mg twice-daily standard dose of ritonavir. The most common laboratory

abnormalities include elevated total cholesterol and triglycerides. Because the same adverse effects occur with ritonavir, it is unclear whether the side effects are due to ritonavir, lopinavir, or both.

Precautions and Interactions. Because lopinavir metabolism is highly dependent on CYP3A4, concomitant administration of agents that induce CYP3A4, such as rifampin, may lower plasma lopinavir concentrations considerably. St. John's wort is a known inducer of CYP3A4, leading to lower concentrations of lopinavir and possible loss of antiviral effectiveness. Coadministration of other antiretrovirals that can induce CYP3A4, including amprenavir, nevirapine or efavirenz, may require increasing the dose of lopinavir (Cvetkovic *et al.*, 2003).

Although lopinavir is a weak inhibitor of CYP3A4 *in vitro*, the ritonavir in the coformulated capsule strongly inhibits CYP3A4 activity and probably dwarfs any lopinavir effect. Ritonavir increases concentrations of a number of drugs with narrow therapeutic indices (*e.g.*, midazolam, triazolam, propafenone, and ergot derivatives), and coadministration of these agents should be avoided. The liquid (but not capsule) formulation of lopinavir contains 42% ethanol and should not be administered with disulfiram or metronidazole (*see* Chapter 22). Ritonavir is also a moderate CYP inducer at the dose employed in the coformulation and can adversely decrease concentrations of some coadministered drugs, *e.g.*, oral contraceptives. There is no direct proof that lopinavir is a CYP inducer *in vivo*; however, concentrations of some coadministered drugs, *e.g.*, amprenavir and phenytoin, are lower with the lopinavir–ritonavir coformulation than would have been expected with low-dose ritonavir alone (Cvetkovic *et al.*, 2003).

Therapeutic Use. In comparative clinical trials, lopinavir has antiretroviral activity at least comparable with that of other potent HIV protease inhibitors and better than that of nelfinavir. A lopinavir-based regimen was one of the two preferred regimens for treatment-naïve HIV-infected adults in 2004 (Table 50–2). Lopinavir also has considerable and sustained antiretroviral activity in patients who failed previous HIV protease inhibitor–containing regimens. In one study, 70 subjects who had failed therapy with one previous HIV protease inhibitor were treated for 2 weeks with lopinavir, followed by the addition of nevirapine. At 48 weeks, 60% of subjects had plasma HIV-1 RNA levels of less than 50 copies/ml despite substantial phenotypic resistance to other HIV protease inhibitors (Cvetkovic *et al.*, 2003). Because plasma concentrations of lopinavir generally are much higher than those required to suppress HIV replication *in vitro*, the drug may be capable of suppressing HIV isolates with low-level protease inhibitor resistance.

Atazanavir

Chemistry and Antiviral Activity. Atazanavir is an azapeptide protease inhibitor with a C₂-symmetric chemical structure that is active against both HIV-1 and HIV-2 (Goldsmith and Perry, 2003) (Figure 50–6). The IC₅₀ for

HIV-1 in various *in vitro* assays ranges from 2 to 15 nM. In the presence of 40% human serum, the *in vitro* IC₅₀ is increased three- to fourfold (Goldsmith and Perry, 2003). Like most drugs in this class, atazanavir was a product of rational drug design based on the X-ray crystal structure of a peptide–enzyme complex (Roberts *et al.*, 1990).

Mechanisms of Action and Resistance. Atazanavir reversibly binds to the active site of HIV protease, preventing polypeptide processing and subsequent virus maturation. Viral replication in the presence of atazanavir selects for drug resistance. The primary atazanavir resistance mutation occurs at HIV protease codon 50 and confers approximately ninefold decreased susceptibility. This is an isoleucine-to-leucine substitution (I50L) that is distinct from the isoleucine-to-valine substitution selected by amprenavir. This mutation was present in 100% of viruses isolated from patients failing therapy in one clinical trial (Goldsmith and Perry, 2003). Isolates with only this mutation are still susceptible to inhibition by other protease inhibitors. Sensitivity to atazanavir is affected by various primary and secondary mutations that accumulate in patients who have failed other HIV protease inhibitors, with high-level resistance more likely if five or more additional mutations are present (Colonna *et al.*, 2003).

Absorption, Distribution, and Elimination. Atazanavir is absorbed rapidly after oral administration, with peak concentrations occurring about 2 hours after dosing. Atazanavir absorption is sensitive to food: A light meal increases the AUC by 70%, whereas a high-fat meal increases the AUC by 35% (Goldsmith and Perry, 2003). It is therefore recommended that the drug be administered with food, which also decreases the interindividual variability in pharmacokinetics. Absorption may be pH-dependent because proton pump inhibitors substantially reduce atazanavir concentrations after oral dosing.

Atazanavir undergoes oxidative metabolism in the liver primarily by CYP3A4, which accounts for most of the elimination of this drug. Only 7% of the parent drug is excreted unchanged in the urine. The mean elimination half-life of atazanavir at the standard 400-mg once-daily dose is approximately 7 hours; however, the drug has nonlinear pharmacokinetics, and the half-life increases to nearly 10 hours at a dose of 600 mg (Goldsmith and Perry, 2003). Atazanavir is 86% bound to plasma proteins, both to albumin and α_1 -acid glycoprotein. It is present in CSF at less than 3% of plasma concentrations but has excellent penetration into seminal fluid (Goldsmith and Perry, 2003).

Untoward Effects. Like indinavir, atazanavir frequently causes unconjugated hyperbilirubinemia, although this is mainly a cosmetic side effect and is not associated with other hepatotoxicity. Approximately 40% of subjects receiving 400 mg atazanavir once daily in initial clinical trials developed a significant increase in total bilirubin (Goldsmith and Perry, 2003), although only 5% developed jaundice. Other side effects reported with atazanavir include diarrhea and nausea, mainly during the first few weeks of therapy. Overall, 6% of patients discontinued atazanavir because of side effects during 48 weeks of treatment. Patients treated with atazanavir in randomized clinical trials had significantly lower fasting triglyceride and cholesterol concentrations than patients treated with nelfinavir or efavirenz (Goldsmith and Perry, 2003), suggesting a reduced propensity to cause these side effects. In addition, atazanavir is not known to cause glucose intolerance or changes in insulin sensitivity.

Precautions and Interactions. Because atazanavir is metabolized by CYP3A4, concomitant administration of agents that induce this enzyme (e.g., rifampin) is contraindicated. Efavirenz 600 mg once daily reduced the atazanavir *AUC* by 74%. Atazanavir is a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. Atazanavir inhibits CYP3A4 less than does ritonavir and does not appear to inhibit other CYP isoforms. Atazanavir is not known to induce hepatic drug-metabolizing enzymes.

Ritonavir significantly increases the atazanavir *AUC* and reduces atazanavir systemic clearance. Ritonavir 100 mg once daily increases the atazanavir 300-mg once-daily steady-state *AUC* by 2.5 times and increases the C_{\min} 6.5 times (Goldsmith and Perry, 2003). Low-dose ritonavir also counters the effect of efavirenz on the atazanavir *AUC*; the *AUC* of atazanavir 300 mg with ritonavir 100 mg and efavirenz 600 mg is 30% higher than the *AUC* of atazanavir 400 mg alone.

Proton pump inhibitors reduce atazanavir concentrations substantially with concomitant administration. These drugs and H_2 blockers should be avoided in patients receiving atazanavir.

Therapeutic Use. In randomized clinical trials in treatment-naïve patients, virologic and CD4 effects of atazanavir were similar to those of nelfinavir (Goldsmith and Perry, 2003) and, in one study, similar to those of efavirenz plus nucleoside analogs (Squires *et al.*, 2004). However, in treatment-experienced patients, atazanavir 400 mg once daily without ritonavir was inferior to the lopinavir–ritonavir coformulation given twice daily; 81% of lopinavir–ritonavir–treated patients had plasma HIV RNA concentrations less than 400 copies/ml at week 24 compared with 61% of atazanavir-treated patients. The combination of atazanavir and low-dose ritonavir had a similar viral-load effect as the lopinavir–ritonavir coformulation in one study (Goldsmith and Perry, 2003), suggesting that this drug should be combined with ritonavir in treatment-experienced patients—and perhaps in treatment-naïve patients with high baseline viral load—in order to take advantage of the enhanced pharmacokinetic profile.

ENTRY INHIBITORS

Enfuvirtide is the only available HIV entry inhibitor, although there are a number of investigational drugs in this class. *Enfuvirtide* is a large, synthetic HIV-derived peptide that was investigated originally as a possible vaccine component in part because of a high degree of sequence conservation among HIV-1 strains. This peptide turned out to have potent anti-HIV activity *in vitro*, a property eventually attributed to selective inhibition of HIV-mediated membrane fusion (Jiang *et al.*, 1993; Wild *et al.*, 1994). *Enfuvirtide* is expensive to manufacture and must be administered by subcutaneous injection twice daily. Thus cost and route of administration may limit its

use. In contrast, most investigational entry inhibitors are orally available small molecules.

Enfuvirtide

Chemistry and Antiviral Activity. *Enfuvirtide* is a 36-amino-acid synthetic peptide whose sequence is derived from a part of the transmembrane gp41 region of HIV-1 that is involved in fusion of the virus membrane lipid bilayer with that of the host cell. *Enfuvirtide* is not active against HIV-2 but has a broad range of potencies against HIV-1 laboratory and clinical isolates. The reported *in vitro* IC_{50} ranges from 0.1 nM to 1.7 μ M depending on the HIV-1 strain and testing method employed (Dando and Perry, 2003).

Mechanisms of Action and Resistance. *Enfuvirtide* has a unique mechanism of antiretroviral action. The peptide blocks the interaction between the N36 and C34 sequences of the gp41 glycoprotein by binding to a hydrophobic groove in the N36 coil (Sodroski, 1999). This prevents formation of a six-helix bundle critical for membrane fusion and viral entry into the host cell. *Enfuvirtide* inhibits infection of CD4+ cells by free virus particles, as well as cell-to-cell transmission of HIV *in vitro*. *Enfuvirtide* retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.

HIV can develop resistance to this drug through specific mutations in the *enfuvirtide*-binding domain of gp41 (Rimsky *et al.*, 1998). Of the patients experiencing virologic failure during *enfuvirtide* treatment, 94% had mutations in the gp41 region associated with *enfuvirtide* resistance *in vitro*. The most common mutations involve a V38A or N43D substitution. Single-amino-acid substitutions can confer up to 450 times resistance *in vitro*, although high-level clinical resistance is usually associated with two or more amino acid changes (Dando and Perry, 2003).

Absorption, Distribution, and Elimination. *Enfuvirtide* is the only approved antiretroviral drug that must be administered parenterally. The bioavailability of subcutaneous *enfuvirtide* is 84% compared with an intravenous dose (Dando and Perry, 2003). Peak concentrations after subcutaneous administration occur on average 4 hours after dosing, with an average apparent volume of distribution of 5.5 L. Pharmacokinetics of the subcutaneous drug are not affected by site of injection.

A deamidated metabolite at the C-terminal phenylalanine is present in humans with an *AUC* that is 2% to 15% that of the parent drug (Dando and Perry, 2003), and no other significant metabolites are detected. The major route of elimination for *enfuvirtide* has not been determined. The mean elimination half-life of parenteral drug is 3.8 hours, necessitating twice-daily administration. *Enfuvirtide* is 98% bound to plasma proteins, mainly albumin.

Untoward Effects. The most prominent adverse effects of *enfuvirtide* are injection-site reactions. In 98% of patients, one or more local side effects including pain, erythema, and induration at the site of injection are seen; 80% of patients develop nodules or cysts (Dando and Perry, 2003). Between 4% and 5% of patients discontinue treatment because of local reactions. Use of *enfuvirtide* has been associated with a higher incidence of lymphadenopathy and

pneumonia in at least one study. Whether these are direct drug effects, a secondary consequence of drug-related immune dysfunction, or effects from another mechanism is currently the subject of investigation. Enfuvirtide suppresses interleukin 12 production *in vitro* by more than 90% at concentrations equal to or less than those required to inhibit HIV replication (Braun *et al.*, 2001), although the role this might play in clinical immunosuppression is unclear.

Precautions and Interactions. Enfuvirtide is not metabolized to a significant extent (*see above*) and is not known to alter the concentrations of any coadministered drugs. Ritonavir, rifampin, or ritonavir plus saquinavir did not alter enfuvirtide concentrations (Dando and Perry, 2003).

Therapeutic Use. Enfuvirtide is approved by the FDA for use only in treatment-experienced adults who have evidence of HIV replication despite ongoing antiretroviral therapy. In phase III clinical trials involving heavily pretreated patients with documented multidrug-resistant HIV-1, the administration of enfuvirtide (90 mg subcutaneously twice daily) in combination with an optimized background regimen was associated with undetectable (<50 copies/ml) plasma HIV-1 RNA concentrations after 24 weeks of treatment in twice as many patients as those who used the optimized background regimen alone (12.2% to 19.6% *versus* 5.3% to 7.3%) (Lalezari *et al.*, 2003; Lazzarin *et al.*, 2003). Treatment response appears to be much more likely in patients with at least two other active drugs in the regimen, based on history and HIV genotype. Given the cost, inconvenience, and cutaneous toxicity of this drug, enfuvirtide generally is reserved for patients who have failed all other feasible antiretroviral regimens.

CURRENT TREATMENT GUIDELINES; CLINICAL SUMMARY

Several expert panels issue periodic recommendations for best combinations of antiretroviral drugs for treatment-naïve and treatment-experienced patients. In the United States, the Panel on Clinical Practices for Treatment of HIV Infection convened by the Department of Health and Human Services (DHHS) issues updated guidelines approximately every 6 months. The October 2004 DHHS guidelines for initiating therapy in treatment-naïve HIV-infected patients are summarized in Table 50–2. These recommendations are based on a consensus assessment of the results of published clinical trials regarding when to initiate treatment, when to change treatment regimens, and which regimens perform best in terms of antiviral efficacy, safety, and tolerability.

Practitioners need to be aware that guidelines are intended to provide general guidance rather than absolute recommendations for an average uncomplicated patient and may

Table 50–8
New Classes of Antiretroviral Agents
in Clinical Development

DRUG CLASS	EXAMPLES
Entry inhibitors	
Attachment inhibitors	BMS-488043, PRO-542, TNX-355
Chemokine receptor antagonists	
CCR5 antagonists	AK-602, AMD-887, GSK-873140, PRO-140, SCH-417690, TAK-220, UK-427,857
CXCR4 antagonists	AMD-3100, AMD-070, KRH-2731
Integrase inhibitors	L-870810
Inhibitors of gag processing	PA-457
Regulatory protein antagonists	
Vif inhibitors	Mifepristone
Immune modifiers	
Therapeutic HIV vaccines	MRK Ad5 gag (replication-deficient adenovirus vector)

need to be modified based on intercurrent disease, concurrent medications, and other circumstances. U.S. guidelines sometimes are contradicted by guidelines designed for use in other countries or specific patient populations; these differences may reflect the different priorities given to drug costs and the importance of long-term toxicities.

Current treatment guidelines center around two important questions: when to start therapy in treatment-naïve individuals and when to change therapy in individuals who are failing their current regimen. In each of these settings, there is a complex algorithm of possible drug choices depending on patient and virus demographics. The specific drugs recommended may change from year to year as new choices become available (Table 50–8) and clinical research data accumulate. However, *it is likely that future treatment guidelines will continue to be driven by the important principles mentioned earlier: (1) combination therapy in order to prevent the emergence of resistant virus; (2) emphasis on regimen convenience, tolerability, and adherence in order to chronically suppress HIV replication; and (3) the need for life-long treatment under most circumstances.*

Treatment guidelines are not sufficient to dictate all aspects of patient management. It is therefore imperative that prescribers of antiretroviral therapy maintain a comprehensive and current fund of knowledge regarding this disease and its pharmacotherapy. Because the treatment of HIV infection is a long-lived and complex affair, and because mistakes can have dire and irreversible consequences for the patient, the use of these drugs should be limited to those with specialized training.

SECTION IX

Chemotherapy of Neoplastic Diseases

CHAPTER 51

ANTINEOPLASTIC AGENTS

Bruce A. Chabner, Philip C. Amrein, Brian J. Druker, M. Dror Michaelson, Constantine S. Mitsiades, Paul E. Goss, David P. Ryan, Sumant Ramachandra, Paul G. Richardson, Jeffrey G. Supko, Wyndham H. Wilson

The practice of cancer medicine has changed dramatically in the past four decades, as curative treatments have been identified for a number of previously fatal malignancies such as testicular cancer, lymphomas, and leukemia. New drugs have entered clinical use for disease presentations that were previously either untreatable or amenable only to local therapies such as surgery and irradiation. At present, adjuvant chemotherapy routinely follows local treatment of breast, colorectal, and lung cancer, and chemotherapy is employed as part of a multimodal approach to the initial treatment of many other tumors, including locally advanced stages of head and neck, lung, and esophageal cancer, soft tissue sarcomas, and pediatric solid tumors. Genetic therapies, vaccines, and other manipulations of the immune system are under active investigation, and drugs now are in common use for restoring bone marrow function after chemotherapy, induction of differentiation in tumor tissues, and inhibition of angiogenesis. At the same time, chemotherapeutic drugs have found expanded utility in noncancerous diseases. The same drugs used for cytotoxic antitumor therapy have become important components of immunosuppressive regimens for rheumatoid arthritis (*methotrexate* and *cyclophosphamide*), organ transplantation (*methotrexate* and *azathioprine*), sickle cell anemia (*5-azacytadine* and *hydroxyurea*), anti-infective chemotherapy (*trimetrexate* and *leucovorin*), and psoriasis (*methotrexate*).

While their range of uses has grown, few categories of medication have a narrower therapeutic index and a greater potential for causing harmful side effects than do the antineoplastic drugs. A thorough understanding of their pharmacology, drug interactions, and clinical pharmacokinetics is essential for safe and effective use in humans. The diversity of agents useful in treatment of neoplastic disease is summarized in Table 51–1.

Traditionally, cancer drugs were discovered through large-scale testing of synthetic chemicals and natural products against rapidly proliferating animal tumor systems, primarily murine leukemias (Chabner and Roberts, 2005). Most of the agents discovered in the first two decades of cancer chemotherapy (1950 to 1970) interacted with DNA or its precursors, inhibiting the synthesis of new genetic material or causing irreparable damage to DNA itself. In recent years, the discovery of new agents has extended from the more conventional natural products such as *paclitaxel* and semisynthetic agents such as *etoposide*, both of which target the proliferative process, to entirely new fields of investigation. These new fields represent the harvest of new knowledge about cancer biology, leading to the discovery of drugs that inhibit novel molecular targets. One such agent, *all-trans-retinoic acid*, elicits differentiation and can be used to promote remission in acute promyelocytic leukemia (APL) through its interaction with the unique fusion protein produced by the (15:17) RAR-PML translation, even after failure of standard chemotherapy. Initial success in characterizing unique tumor antigens and oncogenes has introduced new therapeutic opportunities. Thus, the *bcr-abl* translocation in chronic myelocytic leukemia

Table 51-1**Chemotherapeutic Agents Useful in Neoplastic Disease**

CLASS	TYPE OF AGENT	NONPROPRIETARY NAMES (OTHER NAMES)	DISEASE*
<i>Alkylating agents</i>	Nitrogen mustards	Mechlorethamine	Hodgkin's disease; non-Hodgkin's lymphoma
		Cyclophosphamide Ifosfamide	Acute and chronic lymphocytic leukemia; Hodgkin's disease; non-Hodgkin's lymphoma; multiple myeloma; neuroblastoma; breast, ovary, lung cancer; Wilms' tumor; cervix, testis cancer; soft-tissue sarcoma
		Melphalan (L-sarcolysin) Chlorambucil	Multiple myeloma; breast, ovarian cancer Chronic lymphocytic leukemia; primary macroglobulinemia; Hodgkin's disease; non-Hodgkin's lymphoma
	Ethyleneimines and methylmelamines	Altretamine	Ovarian cancer
		Thiotepa	Bladder, breast, ovarian cancer
	Methylhydrazine derivative	Procarbazine (<i>N</i> -methylhydrazine, MIH)	Hodgkin's disease
	Alkyl sulfonate	Busulfan	Chronic myelogenous leukemia
	Nitrosoureas	Carmustine (BCNU)	Hodgkin's disease; non-Hodgkin's lymphoma; primary brain tumor; melanoma
			Streptozocin (streptozotocin)
		Triazenes	Dacarbazine (DTIC; dimethyl-triazenoimidazole carboxamide), temozolomide
Platinum coordination complexes		Cisplatin, carboplatin, oxaliplatin	Testicular, ovarian, bladder, esophageal, lung, colon cancer
<i>Antimetabolites</i>	Folic acid analogs	Methotrexate (amethopterin)	Acute lymphocytic leukemia; choriocarcinoma; breast, head, neck, and lung cancer; osteogenic sarcoma; bladder cancer
		Pyrimidine analogs	Pemetrexed
	Fluorouracil (5-fluorouracil; 5-FU), capecitabine		Breast, colon, esophageal, stomach, pancreas, head and neck; premalignant skin lesion (topical)
	Cytarabine (cytosine arabinoside)		Acute myelogenous and acute lymphocytic leukemia; non-Hodgkin's lymphoma
	Purine analogs and related inhibitors	Gemcitabine	Pancreatic, ovarian, lung cancer
		Mercaptopurine (6-mercaptopurine; 6-MP)	Acute lymphocytic and myelogenous leukemia
		Pentostatin (2'-deoxycoformycin), cladribine, fludarabine	Hairy cell leukemia; chronic lymphocytic leukemia; small cell non-Hodgkin's lymphoma

(Continued)

Table 51-1

Chemotherapeutic Agents Useful in Neoplastic Disease (Continued)

CLASS	TYPE OF AGENT	NONPROPRIETARY NAMES (OTHER NAMES)	DISEASE*
<i>Natural products</i>	Vinca alkaloids	Vinblastine, vinorelbine	Hodgkin's disease; non-Hodgkin's lymphoma; breast, lung, and testis cancer
		Vincristine	Acute lymphocytic leukemia; neuroblastoma; Wilms' tumor; rhabdomyosarcoma; Hodgkin's disease; non-Hodgkin's lymphoma
	Taxanes	Paclitaxel, docetaxel	Ovarian, breast, lung, bladder, head and neck cancer
	Epipodophyllotoxins	Etoposide	Testis, small-cell lung, and other lung cancer; breast cancer; Hodgkin's disease; non-Hodgkin's lymphomas; acute myelogenous leukemia; Kaposi's sarcoma
		Teniposide	Same as etoposide; also acute lymphoblastic leukemia in children
	Camptothecins	Topotecan, irinotecan	Ovarian cancer; small-cell lung cancer; colon and lung cancer
	Antibiotics	Dactinomycin (actinomycin D)	Choriocarcinoma; Wilms' tumor; rhabdomyosarcoma; testis; Kaposi's sarcoma
		Daunorubicin (daunomycin, rubidomycin)	Acute myelogenous and acute lymphocytic leukemia
		Doxorubicin	Soft-tissue, osteogenic, and other sarcoma; Hodgkin's disease; non-Hodgkin's lymphoma; acute leukemia; breast, genitourinary, thyroid, lung, stomach cancer; neuroblastoma and other childhood sarcoma
	Anthracenedione	Mitoxantrone	Acute myelogenous leukemia; breast and prostate cancer
Bleomycin		Testis, and cervical cancer; Hodgkin's disease; non-Hodgkin's lymphoma	
Mitomycin (mitomycin C)		Stomach, anal, and lung cancer	
<i>Miscellaneous agents</i>	Enzymes	L-Asparaginase	Acute lymphocytic leukemia
	Substituted urea	Hydroxyurea	Chronic myelogenous leukemia; polycythemia vera; essential thrombocytosis
	Differentiating agents	Tretinoin, arsenic trioxide	Acute promyelocytic leukemia
	Protein tyrosine kinase inhibitor	Imatinib	Chronic myelocytic leukemia; gastrointestinal stromal tumors; hyper-eosinophilia syndrome
	Proteasome inhibitor	Gefitinib Bortezomib	Non-small-cell lung cancer Multiple myeloma

(Continued)

Table 51-1

Chemotherapeutic Agents Useful in Neoplastic Disease (Continued)

CLASS	TYPE OF AGENT	NONPROPRIETARY NAMES (OTHER NAMES)	DISEASE*
<i>Hormones and antagonists</i>	Biological response modifiers	Interferon-alfa, interleukin 2	Hairy cell leukemia; Kaposi's sarcoma; melanoma; carcinoid; renal cell; ovary; bladder; non-Hodgkin's lymphoma; mycosis fungoides; multiple myeloma; chronic myelogenous leukemia; malignant melanoma
	Antibodies (<i>see</i> Tables 51-3 and 51-4)		
	Adrenocortical suppressants	Mitotane (<i>o,p'</i> -DDD) Aminoglutethimide	Adrenal cortex cancer Breast cancer
	Adrenocorticosteroids	Prednisone (several other equivalent preparations available; <i>see</i> Chapter 59)	Acute and chronic lymphocytic leukemia; non-Hodgkin's lymphoma; Hodgkin's disease; breast cancer
	Progestins	Hydroxyprogesterone caproate, medroxyprogesterone acetate, megestrol acetate	Endometrial, breast cancer
	Estrogens	Diethylstilbestrol, ethinyl estradiol (other preparations available; <i>see</i> Chapter 57)	Breast, prostate cancer
	Anti-estrogens	Tamoxifen, toremifene	Breast cancer
	Aromatase inhibitors	Anastrozole, letrozole, exemestane	Breast cancer
	Androgens	Testosterone propionate, fluoxymesterone (other preparations available; <i>see</i> Chapter 58)	Breast cancer
	Anti-androgen	Flutamide	Prostate cancer
Gonadotropin-releasing hormone analog	Leuprolide	Prostate cancer	

*Neoplasms are carcinomas unless otherwise indicated.

(CML) encodes a tyrosine kinase essential to cell proliferation and survival. Inhibition of the kinase by *imatinib* (STI-571), a new molecularly targeted drug, has become the standard treatment for CML, producing hematologic and cytogenic remission in the majority of patients. Similarly targeted immunological approaches use monoclonal antibodies against tumor-associated antigens such as the her-2/neu receptor in breast cancer cells, often in conjunction with cytotoxic drugs (Slamon *et al.*, 2001). These examples emphasize that both the strategy for drug evaluation and the routine care of cancer patients are likely to undergo revolutionary changes as entirely new treatment approaches arise from new knowledge of cancer biology. Figure 51-1 outlines some of the common targets for chemotherapeutic agents currently used for neoplastic disease. New clinical trial designs, aimed at determining effects of new drugs at the molecular level, increasingly will employ urinary and blood markers of tumor proliferation, angiogenesis, and other bio-

logical endpoints. Imaging of molecular, metabolic, or physiologic effects of drugs will become increasingly important in establishing that drugs effectively engage their targets (Fox *et al.*, 2002).

While molecularly targeted drugs have had outstanding success in CML and APL, it is unlikely that new therapies will replace cytotoxics in the near future. When used in combination and in early stages of disease, the cytotoxics have become increasingly effective. At the same time, their toxicities have become more manageable with the development of better anti-nausea drugs and with granulocyte colony-stimulating factor (G-CSF) and erythropoietin to restore marrow function (*see* Chapter 53). Finally, a greater insight into the mechanisms of tumor cell resistance to chemotherapy has led to the more rational construction of drug regimens and the earlier use of intensive therapies. Drug-resistant cells may be selected from the larger tumor population by exposure to low-dose, single-agent chemotherapy. The resistance that arises

Figure 51-1. Summary of the mechanisms and sites of action of some chemotherapeutic agents useful in neoplastic disease. PALA = N-phosphonoacetyl-L-aspartate; TMP = thymidine monophosphate.

may be specific for the selecting agent, such as the loss of a necessary activating enzyme (deoxycytidine kinase for cytosine arabinoside), or may affect broader categories of disease, such as the overexpression of a general drug-efflux pump, the P-glycoprotein, a product of the *MDR* gene. This membrane protein is one of several ATP-dependent transporters that confer resistance to a broad range of natural products used in cancer treatment (Borst and Oude Elfrink, 2002; see also Chapter 2). More recently, it has become appreciated that mutations that raise the threshold for programmed cell death (apoptosis), such as the loss of the p53 tumor suppressor oncogene, enhanced activity of a mutated EGF receptor, or increased expression of the anti-apoptotic bcl-2, may lead to drug resistance (Ibrado *et al.*, 1996). Drug discovery efforts now are directed toward lowering the threshold for apoptosis in tumor cells, and restoring tumor cell sensitivity to drugs.

In designing specific regimens for clinical use, a number of factors must be taken into account. Drugs are most effective in combination, and may be synergistic because of their biochemical interactions. It is more effective to combine drugs that do not share common mechanisms of

resistance and that do not overlap in their major toxicities. Cytotoxic drugs should be used as close as possible to their maximum individual doses and should be given as frequently as possible to discourage tumor regrowth and to maximize dose intensity, the dose given per unit time, a key parameter in the success of chemotherapy (Citron *et al.*, 2003). Since the tumor cell population in patients with clinically detectable disease exceeds 1 g, or 10^9 cells, and since each cycle of therapy kills less than 99% of the cells, it is necessary to repeat treatments in multiple cycles to eradicate the tumor cells.

The Cell Cycle. An understanding of cell-cycle kinetics is essential for the proper use of antineoplastic agents (Figure 51-2). Many of the most effective cytotoxic agents act by damaging DNA. Their toxicity is greater during the S, or DNA synthetic, phase of the cell cycle, while others, such as the vinca alkaloids and taxanes, block the formation of a

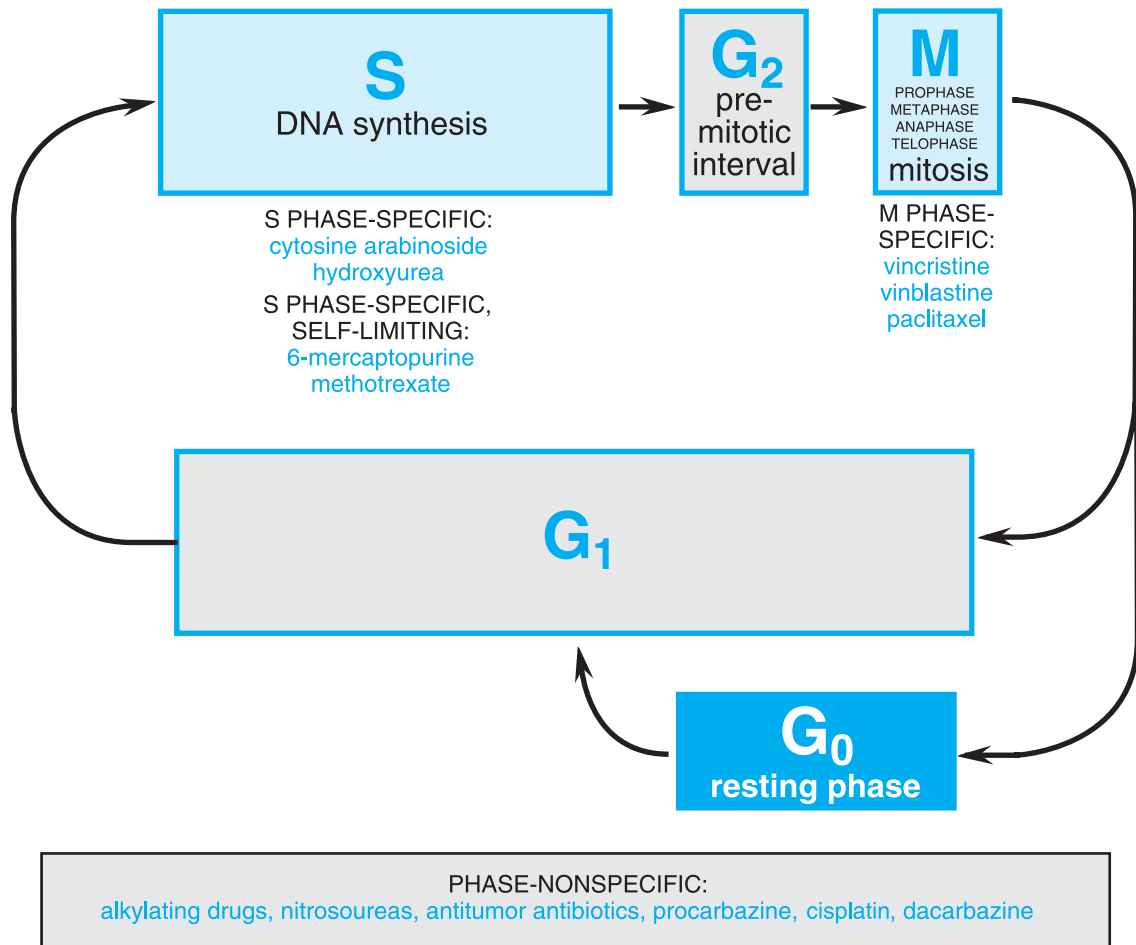

Figure 51-2. The cell cycle and the relationship of anticancer drug action to the cycle. G₁ is the gap period between mitosis and the beginning of DNA synthesis. Resting cells (cells that are not preparing for cell division) are said to be in a subphase of G₁, G₀. S is the period of DNA synthesis, G₂ the premitotic interval, and M the period of mitosis. Examples of cell cycle-dependent anticancer drugs are listed in blue below the phase in which they act. Drugs that are cytotoxic for cells at any point in the cycle are called cycle-phase-nonspecific drugs. (Modified from Pratt *et al.*, 1994 with permission.)

functional mitotic spindle in M phase. These agents have activity against cells that pass through the most vulnerable phase of the cell cycle. Accordingly, human neoplasms that currently are most susceptible to chemotherapeutic measures are those with a high percentage of cells undergoing division. Similarly, normal tissues that proliferate rapidly (bone marrow, hair follicles, and intestinal epithelium) are subject to damage by most cytotoxic drugs, which often limits their usefulness. Conversely, slowly growing tumors with a small growth fraction (for example, carcinomas of the colon or non-small cell lung cancer) often are less responsive to cycle-specific drugs.

Although differences in the duration of the cell cycle occur between cells of various types, all cells display a similar pattern during the division process: (1) a phase

that precedes DNA synthesis (G₁); (2) a DNA synthesis phase (S); (3) an interval following the termination of DNA synthesis (G₂); and (4) the mitotic phase (M) in which the cell, containing a double complement of DNA, divides into two daughter G₁ cells. Each of these daughter cells may immediately re-enter the cell cycle or pass into a nonproliferative stage, referred to as G₀. The G₀ cells of certain specialized tissues may differentiate into functional cells that no longer are capable of division. On the other hand, many cells, especially those in slow-growing tumors, may remain in the G₀ state for prolonged periods, only to re-enter the division cycle at a later time. Each transition in the cell cycle is controlled by the activity of specific cyclin-dependent kinases (CDKs), which are activated by their corre-

sponding small regulatory proteins called cyclins, and inhibited by proteins such as p16. Mutations or loss of p16 or other components of the so-called retinoblastoma pathway such as retinoblastoma protein itself, or enhanced cyclin or CDK activity, will lead to relentless proliferation in tumor cells. Consequently, CDKs and their effector proteins have become attractive molecular targets for new antineoplastic agents.

Because of the central importance of DNA to the identity and functionality of a cell, elaborate mechanisms have evolved to monitor DNA integrity. If a cell expresses normal p53 protein, DNA damage activates a normal checkpoint function and damaged cells undergo apoptosis, or programmed cell death, when they reach the G₁/S boundary. If the p53 gene product is mutated or absent and the checkpoint function fails, damaged cells will not be diverted to the apoptotic pathway but will proceed through S phase. At the G₂-M interface, other checkpoint proteins monitor DNA integrity and may delay progression into M phase. Absence or mutation of these checkpoints allows cells to pass through mitosis and survive DNA damage (Lane and Fischer, 2004). These cells can proceed through S phase and some will emerge as a mutated and potentially drug-resistant population. *Thus, an understanding of cell-cycle kinetics and the controls of normal and malignant cell growth is crucial to the design of current therapeutic regimens and the search for new drugs.*

Achieving Therapeutic Balance and Efficacy. The treatment of most cancer patients requires a skillful interdigitation of multiple modalities of treatment, including surgery and irradiation, with drugs. Each of these forms of treatment carries its own risks and benefits. It is obvious that not all drug regimens are appropriate for all patients. Numerous factors must be considered, such as renal and hepatic function, bone marrow reserve, general performance status, and concurrent medical problems. Beyond those considerations, however, are less quantifiable factors such as the likely natural history of the tumor being treated, the patient's willingness to undergo difficult and potentially dangerous treatments, the patient's physical and emotional tolerance for side effects, and the likely long-term gains and risks involved.

One of the greatest challenges of therapeutics is to adjust dose to achieve a therapeutic, but nontoxic, outcome. While it is customary to base dose on body surface area for individual patients, this practice is not based on solid data (Sawyer and Ratain, 2001). Dose adjustment based on renal function or on pharmacokinetic monitoring does help meet specific targets such as desired drug concentration in plasma or area under the

concentration–time curve (AUC), a measure of tissue exposure to the agent in question.

Two important examples of improved therapy based on pharmacokinetic targeting are the following:

1. Calvert and Egorin showed that the thrombocytopenia caused by *carboplatin* was a direct function of AUC, which in turn was determined by renal clearance of the parent drug. They devised a formula for targeting a desired AUC based on creatinine clearance (Calvert *et al.*, 1995; Calvert and Egorin, 2002).
2. Relling and colleagues determined that therapeutic success was related to achieving targeted methotrexate concentrations in plasma during high-dose therapy for pediatric acute lymphoblastic leukemia (ALL). Monitoring of steady-state levels of methotrexate allowed dose adjustment and improvement in outcome (Relling *et al.*, 1999).

Molecular tests increasingly are being employed to identify patients likely to benefit from treatment and those at highest risk of toxicity (Chabner and Roberts, 2005). Pretreatment testing to select patients for response to treatment has become standard practice for hormonal therapy of breast cancer and for treatment with antibodies such as *trastuzumab* (her-2/neu receptor) and *rituximab* (CD20). However, in the use of traditional cytotoxic therapy, molecular testing has not been routinely employed. Inherited differences in protein sequence or expression levels (polymorphisms) occur commonly in the population, and affect either toxicity or response. In *fluorouracil* therapy, polymorphisms of drug target genes affect both response rates and toxicity. Tandem repeats in the promoter region of the gene encoding thymidylate synthase, the target of 5-fluorouracil, determine the level of expression of the enzyme. Increased numbers of repeats are associated with increased gene expression, a lower incidence of toxicity, and a decreased rate of response in patients with colorectal cancer (Pullarkat *et al.*, 2001). Polymorphisms of the dihydropyrimidine dehydrogenase gene, which is responsible for degradation of 5-fluorouracil, are associated with decreased enzyme activity and a significant risk of overwhelming drug toxicity, particularly in the rare individual homozygous for the polymorphic genes (Van Kuilenburg *et al.*, 2002). Other polymorphisms appear to affect the clearance and therapeutic activity of cancer drugs, including methotrexate, *irinotecan*, and *6-mercaptopurine* (*see below*) (Watters and McLeod, 2002).

Other aspects of molecular biology are entering into clinical decision-making in oncology. Gene expression profiling, in which the level of messenger RNA from thousands of genes are randomly surveyed for associations with tumor progression, response, or treatment outcome, have revealed tumor profiles that are highly associated with metastasis (Ramaswamy *et al.*, 2003) or with drug response. Perhaps the best example is the high correlation of HOX B13, a transcription factor, with disease recurrence in patients receiving adjuvant hormonal therapy in breast cancer (Ma *et al.*, 2004). An alternative approach, detailed sequencing of the drug target, has revealed that activating mutations in the epidermal growth factor receptor (EGFR) gene are associated with a high rate of response to *gefitinib* (IRESSA), an EGFR inhibitor, in patients with adenocarci-

Figure 51-4. Nitrogen mustards employed in therapy.

the cross-linking of two nucleic acid chains or the linking of a nucleic acid to a protein, alterations that would cause a major disruption in nucleic acid function. Any of these effects could adequately explain both the mutagenic and the cytotoxic effects of alkylating agents. However, cytotoxicity of bifunctional alkylators correlates very closely with interstrand cross-linkage of DNA (Garcia *et al.*, 1988).

The ultimate cause of cell death related to DNA damage is not known. Specific cellular responses include cell-cycle arrest and attempts to repair DNA. Alternatively, recognition of extensively damaged DNA by p53 can trigger apoptosis. Mutations of p53 lead to alkylating-agent resistance (Kastan, 1999).

Structure-Activity Relationship. The alkylating agents used in chemotherapy share the capacity to contribute alkyl groups to biologically vital macromolecules such as DNA. Modification of the basic chloroethylamine structure changes reactivity, lipophilicity, active transport across biological membranes, sites of macromolecular attack, and mechanisms of DNA repair, all of which properties determine drug activity *in vivo*. With several of the most valuable agents (*e.g.*, cyclophosphamide and ifosfamide), the active alkylating moieties are generated *in vivo* after metabolism.

Figure 51-5. Metabolism of cyclophosphamide.

The biological activity of nitrogen mustards is based upon the presence of the *bis*-(2-chloroethyl) grouping. While mechlorethamine has been widely used in the past, linkage of the *bis*-(2-chloroethyl) group to electron-rich substitutions such as unsaturated ring systems has yielded more stable drugs with greater selective killing of tumor cells. *Bis*-(2-chloroethyl) groups have been linked to amino acids (phenylalanine) and substituted phenyl groups (aminophenol butyric acid, as in *chlorambucil*) in an effort to make a more stable and orally available form. The rationale for the synthesis of cyclophosphamide can be found in previous editions of this textbook. The structures of important nitrogen mustards are shown in Figure 51-4.

A classical example of the role of host metabolism in the activation of an alkylating agent is seen with cyclophosphamide, now the most widely used agent of this class. The drug undergoes metabolic activation (hydroxylation) by cytochrome P450 isoenzyme 2B (CYP2B) (Figure 51-5), with subsequent transport of the activated intermediate to sites of action, as discussed below. The selectivity of cyclophosphamide against certain malignant tissues may result in part from the capacity of normal tissues, such as liver, to protect themselves against cytotoxicity by enzymatic degradation of the activated intermediates *via* aldehyde dehydrogenase, glutathione transferase, and other pathways.

Ifosfamide is an oxazaphosphorine, similar to cyclophosphamide. Cyclophosphamide has two chloroethyl groups on the exocyclic nitrogen atom, whereas one of the two-chloroethyl groups of ifosfamide is on the cyclic phosphoamide nitrogen of the oxazaphosphorine ring. Ifosfamide is activated in the liver by CYP3A4. The activation of ifosfamide proceeds more slowly, with greater production of dechlorinated metabolites and chloroacetaldehyde. These differences in metabolism likely account for the higher doses of ifosfamide required for equitoxic effects, the greater neurotoxicity of ifosfamide, and the possible differences in antitumor spectrum of the two agents (Furlanot and Franceschi, 2003).

Although initially considered an antimetabolite, the triazene derivative 5-(3,3-dimethyl-1-triazeno)-imidazole-4-carboxamide, usually referred to as *dacarbazine* or DTIC, functions through alkylation. Its structural formula is:

Dacarbazine requires initial activation by the CYP system of the liver through an *N*-demethylation reaction. In the target cell, sponta-

neous cleavage of the metabolite, methyltriazenoimidazolecarboxamide (MTIC) yields an alkylating moiety, a methyl diazonium ion. A related triazene, *temozolomide*, undergoes spontaneous, nonenzymatic activation to MTIC, and has significant activity against gliomas. Its structure is:

The nitrosoureas, which include compounds such as 1,3-bis-(2-chloroethyl)-1-nitrosourea (*carmustine*; BCNU), 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (*lomustine*; CCNU), and its methyl derivative (*semustine*; methyl-CCNU), as well as the antibiotic *streptozocin* (streptozotocin), exert their cytotoxicity through the spontaneous breakdown to an alkylating intermediate, the 2-chloroethyl diazonium ion. The structural formula of *carmustine* is:

The 2-chloroethyl diazonium ion, a strong electrophile, can alkylate a variety of substances; guanine, cytidine, and adenine adducts have been identified (Ludlum, 1990). Displacement of the halogen atom can then lead to interstrand or intrastrand cross-linking of the DNA. The formation of the cross-links after the initial alkylation reaction is relatively slow and can be interrupted by the DNA repair enzyme *O*⁶-alkyl, alkyl guanine transferase (AGT) (Dolan *et al.*, 1990), which displaces the chloroethyl adduct from its binding to guanine in a suicide reaction. The same enzyme, when expressed in human gliomas, produces resistance to nitrosoureas (Middleton and Margison, 2003) and various methylating agents, including DTIC, temozolomide, and *procarbazine*. As with the nitrogen mustards, interstrand cross-linking appears to be the primary lesion responsible for the cytotoxicity of nitrosoureas (Ludlum, 1990). The reactions of the nitrosoureas with macromolecules are shown in Figure 51–6.

Since the formation of the ethyleniminium ion constitutes the initial reaction of the nitrogen mustards, it is not surprising that stable ethyleneimine derivatives have antitumor activity. Several compounds of this type, including *triethylenemelamine* (TEM) and *triethylene thiophosphoramide* (thiotepa), have been used clinically. In standard doses, thiotepa produces little toxicity other than myelosuppression; it also is used for high-dose chemotherapy regimens, in which it causes both mucosal and central nervous system toxicity. *Altretamine* (hexamethylmelamine; HMM) is mentioned here because of its chemical similarity to TEM. The methylmelamines are *N*-demethylated by hepatic microsomes (Friedman, 2001) with the release of formaldehyde, and there is a direct relationship between the degree of the demethylation and their activity against murine tumors.

Esters of alkanesulfonic acids alkylate DNA through the release of methyl radicals. *Busulfan* is of value in the treatment of CML and in high-dose chemotherapy; its structural formula is:

Figure 51–6. Degradation of *carmustine* (BCNU) with generation of alkylating and carbamoylating intermediates.

Pharmacological Actions

Cytotoxic Actions. The most important pharmacological actions of the alkylating agents are those that disturb DNA synthesis and cell division. The capacity of these drugs to interfere with DNA integrity and function and to induce cell death in rapidly proliferating tissues provides the basis for their therapeutic and toxic properties. Whereas certain alkylating agents may have damaging effects on tissues with normally low mitotic indices—for example, liver, kidney, and mature lymphocytes—these tissues usually are affected in a delayed time frame. Acute effects are manifest primarily against rapidly proliferating tissues. Lethality of DNA alkylation depends on the recognition of the adduct, the creation of DNA strand breaks by repair enzymes, and an intact apoptotic response. The actual mechanism(s) of cell death related to DNA alkylation are not yet well characterized.

In nondividing cells, DNA damage activates a checkpoint that depends on the presence of a normal p53 gene. Cells thus blocked in the G₁/S interface either repair DNA alkylation or undergo apoptosis. Malignant cells with mutant or absent p53 fail to suspend cell-cycle progres-

sion, do not undergo apoptosis (Fisher, 1994), and exhibit resistance to these drugs.

While DNA is the ultimate target of all alkylating agents, a crucial distinction must be made between the bifunctional agents, in which cytotoxic effects predominate, and the monofunctional methylating agents (procarbazine, temozolomide), which have greater capacity for mutagenesis and carcinogenesis. This suggests that the cross-linking of DNA strands represents a much greater threat to cellular survival than do other effects, such as single-base alkylation and the resulting depurination and chain scission. On the other hand, the more frequent methylation may be bypassed by DNA polymerases, leading to mispairing reactions that permanently modify DNA sequence. These new sequences are transmitted to subsequent generations, and may result in mutagenesis or carcinogenesis. Some methylating agents, such as procarbazine, are highly carcinogenic.

The DNA repair systems play an important role in removing adducts, and thereby determine the selectivity of action against particular cell types, and acquired resistance to alkylating agents. Alkylation of a single strand of DNA (mono adducts) is repaired by the nucleotide excision repair pathway, while the less frequent cross-links require participation of nonhomologous end joining, an error-prone pathway, or the error-free homologous recombination pathway. After drug infusion in humans, mono adducts appear rapidly and peak within 2 hours of drug exposure, while cross-links peak at 8 hours. The half-lives for repair of adducts varies among normal tissues and tumors; in peripheral blood mononuclear cells, both mono adducts and cross-links disappear with a half-life of 12 to 16 hours (Souliotis *et al.*, 2003).

The homologous end-joining pathway has multiple components: sensors of DNA integrity (such as p53); activation signals such as the ataxia-telangiectasia-mutated (ATM) and ataxia-telangiectasia and rad-related (ATR) proteins; the activated repair complex composed of Fanconi anemia proteins and BRCA2, which localize at the site of DNA damage and initiate removal of the cross-linked segment of DNA; and homologous recombination, which allows resynthesis of the damaged DNA sequence followed by religation of the repaired sequences (Wang *et al.*, 2001). The process depends on the presence and accurate functioning of multiple proteins. Their absence or mutation, as in Fanconi anemia or ataxia telangiectasia, leads to extreme sensitivity to DNA cross-linking agents such as *mitomycin*, *cisplatin*, or classical alkylators (Venkitaraman, 2004).

Other repair enzymes specific for removing methyl and ethyl adducts from the O6 of guanine (AGT) and from the N3 of adenine and N7 of guanine (3-methyladenine-DNA glycosylase) have been identified (Matijasevic *et al.*, 1993). High expression of AGT protects cells from cytotoxic effects of nitrosoureas and methylating agents and confers drug resistance, while methylation and silencing of the gene in brain tumors is associated with high response rates to BCNU and improved survival (Esteller and Herman, 2004).

Detailed information is lacking on mechanisms of cellular uptake of alkylating agents. Mechlorethamine enters murine tumor cells by an active transport system, the natural substrate of which is choline. *Melphalan*, an analog of phenylalanine, is taken up by at

least two active transport systems that carry leucine and other neutral amino acids. The highly lipophilic drugs, including nitrosoureas, carmustine, and lomustine, diffuse into cells passively.

Mechanisms of Resistance to Alkylating Agents. Resistance to an alkylating agent develops rapidly when it is used as a single agent. Specific biochemical changes implicated in the development of resistance include:

1. Decreased permeation of actively transported drugs (mechlorethamine and melphalan);
2. Increased intracellular concentrations of nucleophilic substances, principally thiols such as glutathione, which can conjugate with and detoxify electrophilic intermediates;
3. Increased activity of DNA repair pathways, which may differ for the various alkylating agents. Thus, increased activity of the complex nucleotide excision repair (NER) pathway seems to correlate with resistance to most chloroethyl and platinum adducts (Taniguchi *et al.*, 2003). AGT activity determines response to BCNU and to methylating drugs such as the triazenes, procarbazine and busulfan (Middleton and Margison, 2003); and
4. Increased rates of metabolism of the activated forms of cyclophosphamide and ifosfamide to their inactive keto and carboxy metabolites by aldehyde dehydrogenase (Figure 51–5).

To reverse cellular changes that lead to resistance, strategies have been devised that are effective in selected experimental tumors. These include the use of compounds that deplete glutathione, such as *L-buthionine-sulfoximine*; sulfhydryl compounds such as amifostine (WR-2721) that selectively detoxify alkylating species in normal cells and thereby prevent toxicity; *O*⁶-*benzylguanine*, which inactivates the guanine *O*⁶-alkyl transferase DNA repair enzyme; and compounds such as *ethacrynic acid* that inhibit the enzymes (glutathione transferases) that conjugate thiols with alkylating agents. While each of these modalities has experimental evidence to support its use, they all have the potential of increasing toxicity, and their clinical efficacy has not yet been proven. *O*⁶-*benzylguanine* has advanced to phase II trials used in conjunction with carmustine or procarbazine against malignant gliomas (Middleton and Margison, 2003).

TOXICITIES OF ALKYLATING AGENTS

Bone Marrow Toxicity

The alkylating agents differ in their patterns of antitumor activity and in the sites and severity of their side effects. Most cause dose-limiting toxicity to bone marrow elements, and to a lesser extent, intestinal mucosa. Most alkylating agents, including nitrogen mustard, melphalan, chlorambucil, cyclophosphamide, and ifosfamide, cause acute myelosuppression, with a nadir of the peripheral blood granulocyte count at 6 to 10 days and recovery in 14 to 21 days. Cyclophosphamide has lesser effects on peripheral blood platelet counts than do the other agents. Busulfan suppresses all blood elements, particularly stem cells, and

Table 51–2
Dose-Limiting Extramedullary Toxicities of Single Alkylating Agents

DRUG	MTD,* mg/m ²	FOLD INCREASE OVER STANDARD DOSE	MAJOR ORGAN TOXICITIES
Cyclophosphamide	7000	7	Cardiac, hepatic VOD
Ifosfamide	16,000	2.7	Renal, CNS, hepatic VOD
Thiotepa	1000	18	GI, CNS, hepatic VOD
Melphalan	180	5.6	GI, hepatic VOD
Busulfan	640	9	GI, hepatic VOD
Carmustine (BCNU)	1050	5.3	Lung, hepatic VOD
Cisplatin	200	2	PN, renal
Carboplatin	2000	5	Renal, PN, hepatic VOD

*Maximum tolerated dose (MTD; cumulative) in treatment protocols. Abbreviations: GI, gastrointestinal; CNS, central nervous system; PN, peripheral neuropathy; VOD, veno-occlusive disease.

may produce a prolonged and cumulative myelosuppression lasting months or even years. For this reason, it is used as a preparative regimen in allogenic bone marrow transplantation. Carmustine and other chloroethylnitrosoureas cause delayed and prolonged suppression of both platelets and granulocytes, reaching a nadir 4 to 6 weeks after drug administration and reversing slowly thereafter.

Both cellular and humoral immunity are suppressed by alkylating agents, which have been used to treat various autoimmune diseases. Immunosuppression is reversible at doses used in most anticancer protocols.

Mucosal Toxicity

In addition to effects on the hematopoietic system, alkylating agents are highly toxic to dividing mucosal cells, leading to oral mucosal ulceration and intestinal denudation. The mucosal effects are particularly significant in high-dose chemotherapy protocols associated with bone marrow reconstitution, as they predispose to bacterial sepsis arising from the gastrointestinal tract. In these protocols, cyclophosphamide, melphalan, and thiotepa have the advantage of causing less mucosal damage than the other agents. In high-dose protocols, however, a number of additional toxicities become limiting. They are listed in Table 51–2.

Neurotoxicity

CNS toxicity is manifest in the form of nausea and vomiting, particularly after intravenous administration of nitrogen mustard or BCNU. Ifosfamide is the most neurotoxic of this class of agents, producing altered mental status, coma, generalized seizures, and cerebellar ataxia. These

side effects have been linked to the release of chloroacetaldehyde from the phosphate-linked chloroethyl side chain of ifosfamide. High-dose busulfan may cause seizures; in addition, it accelerates the clearance of *phenytoin*, an antiseizure medication (*see* Chapter 19).

Other Organ Toxicities

While mucosal and bone marrow toxicities occur predictably and acutely with conventional doses of these drugs, other organ toxicities may occur after prolonged or high-dose use; these effects can appear after months or years, and may be irreversible and even lethal. All alkylating agents have caused pulmonary fibrosis, usually several months after treatment. In high-dose regimens, particularly those employing busulfan or BCNU, vascular endothelial damage may precipitate veno-occlusive disease (VOD) of the liver, an often fatal side effect that is successfully reversed by the investigational drug *defibrotide* (Richardson, 2003). The nitrosoureas and ifosfamide, after multiple cycles of therapy, may lead to renal failure. Cyclophosphamide and ifosfamide release a nephrotoxic and urotoxic metabolite, acrolein, which causes a severe hemorrhagic cystitis, a side effect that in high-dose regimens can be prevented by coadministration of *2-mercaptoethanesulfonate* (mesna or MESNEX), which conjugates acrolein in urine. Ifosfamide in high doses for transplant causes a chronic, and often irreversible, renal toxicity. Proximal, and less commonly distal, tubules may be affected, with difficulties in Ca²⁺ and Mg²⁺ reabsorption, glycosuria, and renal tubular acidosis. Nephrotoxicity is correlated with the total dose of drug received and increases in frequency in children less than 5 years of age. The syndrome has been attributed to chloroacetaldehyde and/or acrolein excreted in the urine (Skinner, 2003).

The more unstable alkylating agents (particularly mechlorethamine and the nitrosoureas) have strong vesicant properties, damage veins with repeated use, and if extravasated, produce ulceration. Most alkylating agents cause alopecia.

Finally, all alkylating agents have toxic effects on the male and female reproductive systems, causing an often permanent amenorrhea, particularly in perimenopausal women, and an irreversible azoospermia in men.

Leukemogenesis

As a class of drugs, the alkylating agents are highly leukemogenic. Acute nonlymphocytic leukemia, often associated with partial or total deletions of chromosome 5 or 7, peaks in incidence about 4 years after therapy and may affect up to 5% of patients treated on regimens containing alkylating drugs (Levine and Bloomfield, 1992). It often is preceded by a period of neutropenia or anemia, and bone marrow morphology consistent with myelodysplasia. Melphalan, the nitrosoureas, and the methylating agent procarbazine have the greatest propensity to cause leukemia, while it is less common with cyclophosphamide.

CLINICAL PHARMACOLOGY

Nitrogen Mustards

The chemistry and the pharmacological actions of the alkylating agents as a group, and of the nitrogen mustards, have been presented above. Only the unique pharmacological characteristics of the individual agents are considered below.

Mechlorethamine. Mechlorethamine was the first clinically used nitrogen mustard and is the most reactive of the drugs in this class.

Absorption and Fate. Severe local reactions of exposed tissues necessitate rapid intravenous injection of mechlorethamine for most clinical uses. In either water or body fluids, at rates affected markedly by pH, mechlorethamine rapidly undergoes chemical degradation as it combines with either water or cellular nucleophiles, and the parent compound disappears within minutes from the bloodstream.

Therapeutic Uses. Mechlorethamine HCl (MUSTARGEN) was formerly used primarily in the combination chemotherapy regimen MOPP (mechlorethamine, vincristine [ONCOVIN], procarbazine, and prednisone) in patients with Hodgkin's disease. It is given by intravenous bolus administration in doses of 6 mg/m² on days 1 and 8 of the 28-day cycles of each course of treatment. It has been largely replaced by cyclophosphamide, melphalan, and other more stable alkylating agents.

It also is used topically for treatment of cutaneous T-cell lymphoma as a solution that is rapidly mixed and applied to affected areas of skin.

Clinical Toxicity. The major acute toxic manifestations of mechlorethamine are nausea and vomiting, lacrimation, and myelosuppression. Leukopenia and thrombocytopenia limit the amount of drug that can be given in a single course.

Like other alkylating agents, nitrogen mustard blocks reproductive function and may produce menstrual irregularities or premature ovarian failure in women and oligospermia in men. Since fetal abnormali-

ties can be induced, this drug as well as other alkylating agents should not be used in the first trimester of pregnancy and should only be used with caution in later stages of pregnancy. Breast-feeding must be terminated before therapy with mechlorethamine is initiated.

Local reactions to extravasation of mechlorethamine into the subcutaneous tissue result in a severe, brawny, tender induration that may persist for a long time. If the local reaction is unusually severe, a slough may result. If it is obvious that extravasation has occurred, the involved area should be promptly infiltrated with a sterile isotonic solution of sodium thiosulfate (167 mM); an ice compress then should be applied intermittently for 6 to 12 hours. Thiosulfate reacts avidly with nitrogen mustard and thereby protects tissue constituents.

Cyclophosphamide. Pharmacological and Cytotoxic Actions. The general cytotoxic action of this drug is similar to that of other alkylating agents. The drug is not a vesicant, and produces no local irritation.

Absorption, Fate, and Excretion. Cyclophosphamide is well absorbed orally. The drug is activated by CYP2B (Xie *et al.*, 2003) to 4-hydroxycyclophosphamide (Figure 51–5), which is in a steady state with the acyclic tautomer aldophosphamide. A closely related oxazaphosphorine, ifosfamide, is hydroxylated by CYP3A4. This difference may account for the somewhat slower activation of ifosfamide *in vivo*, and the interpatient variability in toxicity of both molecules. The rate of metabolic activation of cyclophosphamide exhibits significant interpatient variability and increases with successive doses in high-dose regimens, but appears to be saturable above infusion rates of 4 g/90 minutes and concentrations of parent compound above 150 μM (Chen *et al.*, 1995). 4-Hydroxycyclophosphamide may be oxidized further by aldehyde oxidase, either in liver or in tumor tissue, and perhaps by other enzymes, yielding the inactive metabolites carboxyphosphamide and 4-ketocyclophosphamide, and ifosfamide is inactivated in an analogous reaction. The active cyclophosphamide metabolites such as 4-hydroxycyclophosphamide and its tautomer, aldophosphamide, are carried in the circulation to tumor cells where aldophosphamide cleaves spontaneously, generating stoichiometric amounts of phosphoramidate mustard and acrolein. Phosphoramidate mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with cyclophosphamide. As mentioned above, cystitis can be reduced in intensity or prevented by the parenteral coadministration of mesna. Mesna does not negate the systemic antitumor activity of the drug.

For routine clinical use, ample fluid intake is recommended and vigorous intravenous hydration is required during high-dose treatment. Brisk hematuria in a patient receiving daily oral therapy should lead to immediate drug discontinuation. Refractory bladder hemorrhage may require cystectomy for control of bleeding.

The syndrome of inappropriate secretion of antidiuretic hormone has been observed in patients receiving cyclophosphamide, usually at doses higher than 50 mg/kg (DeFronzo *et al.*, 1973) (see Chapter 29). It is important to be aware of the possibility of water intoxication, since these patients usually are vigorously hydrated to prevent bladder toxicity.

Pretreatment with CYP inducers such as phenobarbital enhances the rate of activation of the azoxyphosphorines but does not alter total exposure to active metabolites over time and does not affect toxicity or therapeutic activity in humans (Jao *et al.*, 1972). Cyclophosphamide can be used in full doses in patients with renal dysfunction, as it is eliminated by hepatic metabolism.

Urinary and fecal recovery of unchanged cyclophosphamide is minimal after intravenous administration. Maximal concentrations in plasma are achieved 1 hour after oral administration, and the half-life of parent drug in plasma is about 7 hours.

Therapeutic Uses. Cyclophosphamide (CYTOXAN, NEO-SAR, others) is administered orally or intravenously. Recommended doses vary widely, and published protocols for the dosage of cyclophosphamide and other chemotherapeutic agents and for the method and sequence of administration should be consulted.

As a single agent, a daily oral dose of 100 mg/m² for 14 days has been recommended as adjuvant therapy for breast cancer, and for patients with lymphomas and chronic lymphocytic leukemia. A higher dosage of 500 mg/m² intravenously every 2 to 4 weeks in combination with other drugs often is employed in the treatment of breast cancer and lymphomas. The neutrophil nadir of 500 to 1000 cells per mm³ generally serves as a guide to dosage adjustments in prolonged therapy. In regimens associated with bone marrow or peripheral stem cell rescue, cyclophosphamide may be given in total doses of 5 to 7 g/m² over a 3- to 5-day period. Gastrointestinal ulceration, cystitis (counteracted by mesna and diuresis), and less commonly pulmonary, renal, hepatic, and cardiac toxicities (a hemorrhagic myocardial necrosis) may occur after high-dose therapy with total doses above 200 mg/kg.

The clinical spectrum of activity for cyclophosphamide is very broad. It is an essential component of many effective drug combinations for non-Hodgkin's lymphomas, ovarian cancers, and solid tumors in children. Complete remissions and presumed cures have been reported when cyclophosphamide was given as a single agent for Burkitt's lymphoma. It frequently is used in combination with methotrexate (or *doxorubicin*) and fluorouracil as adjuvant therapy after surgery for carcinoma of the breast.

Because of its potent immunosuppressive properties, cyclophosphamide has been used to prevent organ rejection after transplantation. It has activity in nonneoplastic disorders associated with altered immune reactivity, including Wegener's granulomatosis, rheumatoid arthritis, and the nephrotic syndrome. Caution is advised when the drug is considered for use in these conditions, not only because of its acute toxic effects but also because of its potential for inducing sterility, teratogenic effects, and leukemia.

Ifosfamide. Ifosfamide (IFEX), an analog of cyclophosphamide, also is activated by ring hydroxylation in the liver. Severe urinary tract and CNS toxicity limited the use of ifosfamide when it first was introduced in the early 1970s. However, adequate hydration and coadministration of mesna have reduced its bladder toxicity.

Therapeutic Uses. Ifosfamide is approved for use in combination for germ cell testicular cancer and is widely used to treat pediatric and adult sarcomas. It is a common component of high-dose chemotherapy regimens with bone marrow or stem cell rescue; in these regimens, in total doses of 12 to 14 g/m², it may cause severe neurological toxicity, including hallucinations, coma, and death, with symptoms appearing 12 hours to 7 days after beginning the ifosfamide infusion. This toxicity is thought to result from a metabolite, chloroacetaldehyde.

Although the clinical experience is limited, administration of methylene blue, 50 mg, the day before ifosfamide and three times per day during drug infusion, lowers the incidence of neurotoxicity from a high of 30% to near zero (Nicolao and Giometto, 2003). In addition, ifosfamide causes nausea, vomiting, anorexia, leukopenia, nephrotoxicity, and veno-occlusive disease of the liver.

In nonmyeloablative regimens, ifosfamide is infused intravenously over at least 30 minutes at a dose of up to 1.2 g/m² per day for 5 days. Intravenous mesna is given as bolus injections in a dosage equal to 20% of the ifosfamide dosage concomitantly and again 4 and 8 hours later, for a total mesna dose of 60% of the ifosfamide dose. Alternatively, mesna may be given concomitantly in a single dose equal to the ifosfamide dose. Patients also should receive at least 2 L of oral or intravenous fluid daily. Treatment cycles usually are repeated every 3 to 4 weeks.

Pharmacokinetics. The parent compound, ifosfamide, has an elimination half-life in plasma of approximately 15 hours after doses of 3.8 to 5 g/m² and a somewhat shorter half-life at lower doses, although its pharmacokinetics are highly variable from patient to patient due to variable rates of hepatic metabolism.

Toxicity. Ifosfamide has virtually the same toxicity profile as cyclophosphamide, although it causes greater platelet suppression, neurotoxicity, nephrotoxicity, and in the absence of mesna, urothelial damage.

Melphalan. Pharmacological and Cytotoxic Actions. The general pharmacological and cytotoxic actions of melphalan, the phenylalanine derivative of nitrogen mustard, are similar to those of other mechlorethamine. The drug is not a vesicant.

Absorption, Fate, and Excretion. When given orally, melphalan is absorbed in an incomplete and variable manner, and 20% to 50% of the drug is recovered in the stool. The drug has a half-life in plasma of approximately 45 to 90 minutes, and 10% to 15% of an administered dose is excreted unchanged in the urine (Alberts *et al.*, 1979). Patients with decreased renal failure may develop unexpectedly severe myelosuppression (Cornwell *et al.*, 1982).

Therapeutic Uses. Oral *melphalan* (ALKERAN) for multiple myeloma is used in doses of 6 to 8 mg daily for a period of 4 days, in combination with other agents. A rest period of up to 4 weeks should then intervene. The usual intravenous dose is 15 mg/m² infused over 15 to 20 minutes. Doses are repeated at 2-week intervals for four doses and then at 4-week intervals based on response and tolerance. Dosage adjustments should be considered based on blood cell counts and in patients with renal impairment.

Melphalan also may be used in myeloablative regimens followed by bone marrow or peripheral blood stem cell reconstitution. For this use, the dose is 180 to 200 mg/m².

Clinical Toxicity. The clinical toxicity of melphalan is mostly hematological and is similar to that of other alkylating agents. Nausea and vomiting are less frequent. Alopecia does not occur at standard doses, and changes in renal or hepatic function have not been observed.

Chlorambucil. Pharmacological and Cytotoxic Actions. The cytotoxic effects of chlorambucil on the bone marrow, lymphoid organs, and epithelial tissues are similar to those observed with the nitrogen mustards. As an orally

administered agent, chlorambucil is well tolerated in small daily doses, and provides flexible titration of blood counts. Nausea and vomiting may result from single oral doses of 20 mg or more.

Absorption, Fate, and Excretion. Oral absorption of chlorambucil is adequate and reliable. The drug has a half-life in plasma of approximately 1.5 hours, and it is almost completely metabolized (Alberts *et al.*, 1979) to phenyl acetic acid mustard and to decomposition products.

Therapeutic Uses. In treating chronic lymphocytic leukemia (CLL), the standard initial daily dosage of chlorambucil (LEUKERAN) is 0.1 to 0.2 mg/kg, given once daily and continued for 3 to 6 weeks. With a fall in the peripheral total leukocyte count or clinical improvement, the dosage is titrated to maintain neutrophils and platelets at acceptable levels. Maintenance therapy (usually 2 mg daily) often is required to maintain clinical remission.

It is a standard agent for patients with chronic lymphocytic leukemia and primary (Waldenström's) macroglobulinemia, and may be used for follicular lymphoma.

Clinical Toxicity. In CLL, chlorambucil may be given orally for months or years, achieving its effects gradually and often without significant toxicity to a compromised bone marrow.

Although it is possible to induce marked hypoplasia of the bone marrow with excessive doses of chlorambucil administered over long periods, its myelosuppressive action usually is moderate, gradual, and rapidly reversible. GI discomfort, azoospermia, amenorrhea, pulmonary fibrosis, seizures, dermatitis, and hepatotoxicity may rarely be encountered. A marked increase in the incidence of acute myelocytic leukemia (AML) and other tumors was noted in a large controlled study of its use for the treatment of polycythemia vera by the National Polycythemia Vera Study Group and in patients with breast cancer receiving chlorambucil as adjuvant chemotherapy (Lerner, 1978).

MISCELLANEOUS ALKYLATING DRUGS

While nitrogen mustards containing chlorethyl groups constitute the most widely used class of alkylating agents, alternative structures with greater chemical stability and defined activity in specific types of cancer continue to have value in clinical practice.

Ethylenimines and Methylmelamines

Altretamine. Pharmacology and Cytotoxic Effects. Altretamine (HEXALEN), formerly known as hexamethylmelamine, is structurally similar to the alkylating agent triethylenemelamine (*tretamine*). However, *in vitro* tests for alkylating activity of altretamine and its metabolites have been negative, and the precise mechanism of the cytotoxic action of altretamine is unknown. It is used as a palliative treatment for persistent or recurrent ovarian cancer following treatment failure with a cisplatin- or alkylating agent-

based combination. A review of the pharmacodynamic and pharmacokinetic properties and clinical use has been published by Lee and Faulds (1995). The usual dose of altretamine as a single agent in ovarian cancer is 260 mg/m² daily in four divided doses, for 14 or 21 consecutive days out of a 28-day cycle, for up to 12 cycles.

Absorption, Fate and Excretion. Following oral administration, altretamine is well absorbed from the GI tract and undergoes rapid demethylation in the liver. Peak plasma levels, which vary widely, are reached between 0.5 and 3 hours. The principal metabolites are pentamethylmelamine and tetramethylmelamine, which are highly bound to plasma proteins (75% and 50%, respectively) and excreted *via* the urine. The elimination half-life is reported to be 4 to 10 hours (Damia and D'Incalci, 1995).

Clinical Toxicities. The main toxicities of altretamine are myelosuppression and neurotoxicity. Altretamine causes both peripheral and central neurotoxicity. CNS symptoms include ataxia, depression, confusion, drowsiness, hallucinations, dizziness, and vertigo. Neurologic toxicity appears to be reversible upon discontinuation of therapy and may be prevented or decreased by concomitant administration of *pyridoxine*, although this remains unproven. Peripheral blood counts and a neurologic examination should be performed prior to the initiation of each course of therapy. Therapy should be interrupted for at least 14 days, and subsequently restarted at a lower dose of 200 mg/m² daily, if the white cell count falls below 2000 cells/mm³ or the platelet count below 75,000 cells/mm³ or if neurotoxic or intolerable gastrointestinal symptoms occur. If neurologic symptoms fail to stabilize on the reduced dose schedule, altretamine should be discontinued. Nausea and vomiting also are common side effects and may be dose-limiting. Renal toxicity also may be dose-limiting. Other rare adverse effects include rashes, alopecia, and hepatic toxicity. Severe, life-threatening orthostatic hypotension developed in patients who received amitriptyline, imipramine, or phenelzine concurrently with altretamine (Bruckner and Schleifer, 1983).

Thiotepa. Pharmacological and Cytotoxic Effects. Thiotepa (THIOPLEX) is composed of three ethyleneimine groups stabilized by attachment to the nucleophilic thiophosphoryl base. Its current use is primarily for high-dose chemotherapy regimens.

Both thiotepa and its desulfurated primary metabolite, triethylenephosphoramidate (TEPA), to which it is rapidly converted by hepatic CYPs (Ng and Waxman, 1991), form DNA cross-links. The aziridine rings open after protonation of the ring-nitrogen, leading to a reactive molecule.

Absorption, Fate, and Excretion. TEPA becomes the predominant form of the drug present in plasma within hours of thiotepa administration. The parent compound has a plasma half-life of 1.2 to 2 hours, as compared to a longer half-life of 3 to 24 hours for TEPA. Thiotepa pharmacokinetics are essentially the same in children as in adults at conventional doses (up to 80 mg/m²), and drug and metabolite half-lives are unchanged in children receiving high-dose therapy of 300 mg/m² per day for 3 days. Less than 10% of the administered drug appears in urine as the parent drug or the primary

metabolite. Multiple secondary metabolites and chemical degradation products account for the remainder of parent.

Clinical Toxicities. The toxicities of thiotepea are essentially the same as those of the other alkylating agents, namely myelosuppression, and to a lesser extent mucositis. Myelosuppression tends to develop somewhat later than with cyclophosphamide, with leukopenic nadirs at 2 weeks and platelet nadirs at 3 weeks. In high-dose regimens thiotepea produces neurotoxic symptoms, including coma and seizures.

Alkyl Sulfonates

Busulfan. Pharmacological and Cytotoxic Actions. Busulfan exerts few pharmacological actions other than myelosuppression at conventional doses, and prior to the advent of imatinib mesylate (GLEEVEC), often was used in the chronic phase of CML to suppress granulocyte counts. In some patients a severe and prolonged pancytopenia resulted. In high-dose regimens, pulmonary fibrosis, gastrointestinal mucosal damage, and veno-occlusive disease of the liver become important.

Absorption, Fate, and Excretion. Busulfan is well absorbed after oral administration in doses of 2 to 6 mg/day, and has a plasma half-life of 2 to 3 hours. The drug is conjugated to glutathione by glutathione S-transferase A1A and further degraded by CYP-dependent pathways, and its major urinary metabolite is methane sulfonic acid. In high doses, children under 18 years of age clear the drug two to four times faster than adults, and tolerate higher doses (Vassal *et al.*, 1993). A dose of 40 mg/m² given every 6 hours for 4 days has been suggested for children weighing less than 20 kg.

An intravenous preparation is available for high-dose regimens. With doses of 1 mg/kg every 6 hours for 4 days, peak drug concentrations reach up to 10 μM in adults, but are 1 to 5 μM in children 1 to 3 years of age, because of faster clearance. There is significant variability in busulfan clearance among patients. Veno-occlusive disease is associated with high AUC and peak drug levels (AUC >1500 μM x min) and slow clearance, leading to recommendations for dose adjustment based on drug level monitoring (Grochow, 1993). A target of C_{ss} = 600 to 900 ng/ml in adults or AUC <1000 μM x min in children appears to achieve an appropriate balance between toxicity and therapeutic benefit (Witherspoon *et al.*, 2001; Tran *et al.*, 2000).

Therapeutic Uses. In treating CML, the initial oral dose of busulfan (MYLERAN, BUSULFEX) varies with the total leukocyte count and the severity of the disease; daily doses from 2 to 8 mg for adults (~60 μg/kg or 1.8 mg/m² for children) are used to initiate therapy and are adjusted appropriately to subsequent hematological and clinical responses, with the aim of reduction of the total leukocyte count to ≤10,000 cells/mm³. A decrease in the leukocyte count is not usually seen during the first 10 to 15 days of treatment and the leukocyte count may actually increase; during this period an increase in leukocyte count should not be interpreted as drug resistance nor should the dose be increased. Because the leukocyte count may fall for more than a month after discontinuing the drug, it is recommended that busulfan be withdrawn when the total leukocyte count has declined to ~15,000 cells/mm³. A normal leukocyte count usually is achieved within 12 to 20 weeks. During remission, daily treatment resumes when the total leukocyte count reaches ~50,000

cells/mm³. Daily maintenance doses are 1 to 3 mg. In high-dose therapy, doses of 1 mg/kg are given every 6 hours for 4 days, with adjustment based on pharmacokinetics.

High doses of busulfan also have been used effectively in combination with high doses of cyclophosphamide to prepare leukemia patients for bone marrow transplantation. In high-dose regimens, as a component of conditioning before bone marrow or peripheral blood progenitor cell replacement support, busulfan is given at 0.8 mg/kg every 6 hours for 4 days. Anticonvulsants must be used concomitantly to protect against acute CNS toxicities, including tonic-clonic seizures, which may occur several hours after each dose. Busulfan induces the metabolism of phenytoin. In patients requiring antiseizure medication, non-enzyme inducing drugs such as *lorazepam* are recommended as an alternative to phenytoin. When phenytoin is used concurrently, plasma busulfan levels should be monitored and the busulfan dose adjusted accordingly.

Clinical Toxicity. The major toxic effects of busulfan are related to its myelosuppressive properties, and prolonged thrombocytopenia may be a hazard. Occasional patients experience nausea, vomiting, and diarrhea. Long-term use leads to impotence, sterility, amenorrhea, and fetal malformation. Rarely, patients develop asthenia and hypotension, a syndrome resembling Addison's disease, but without abnormalities of corticosteroid production.

High-dose busulfan causes veno-occlusive disease of the liver in up to 10% of patients, as well as seizures, hemorrhagic cystitis, permanent alopecia, and cataracts. The coincidence of veno-occlusive disease and hepatotoxicity is increased by its coadministration with drugs that inhibit CYPs, including imidazoles and *metronidazole*, possibly through inhibition of the clearance of busulfan and/or its toxic metabolites (Nilsson *et al.*, 2003).

Nitrosoureas

The nitrosoureas have an important role in the treatment of brain tumors and find occasional use in treating lymphomas and in high-dose regimens with bone marrow reconstitution. They function as bifunctional alkylating agents but differ in both pharmacological and toxicological properties from conventional nitrogen mustards. Carmustine (BCNU) and lomustine (CCNU) are highly lipophilic, and thus readily cross the blood-brain barrier, an important property in the treatment of brain tumors. Unfortunately, with the exception of streptozocin, nitrosoureas cause profound and delayed myelosuppression with recovery 4 to 6 weeks after a single dose. Long-term treatment with the nitrosoureas, especially semustine (methyl-CCNU), has resulted in renal failure. As with other alkylating agents, the nitrosoureas are highly carcinogenic and mutagenic. They generate both alkylating and carbamoylating moieties as illustrated in Figure 51-6.

Carmustine (BCNU). Pharmacological and Cytotoxic Actions. Carmustine's major action is its alkylation of DNA at the O⁶-guanine position, an adduct repaired by AGT. Methylation of the AGT promoter region inhibits its expression in about 30% of primary gliomas, and is associated with sensitivity to nitrosoureas. In high doses with bone marrow rescue,

it produces hepatic veno-occlusive disease, pulmonary fibrosis, renal failure, and secondary leukemia (Tew *et al.*, 2001).

Absorption, Fate, and Excretion. Carmustine is unstable in aqueous solution and in body fluids. After intravenous infusion, it disappears from the plasma with a highly variable half-life of 15 to 90 minutes or longer (Levin *et al.*, 1978). Approximately 30% to 80% of the drug appears in the urine within 24 hours as degradation products. The entry of alkylating metabolites into the cerebrospinal fluid (CSF) is rapid, and their concentrations in the CSF are 15% to 30% of the concurrent plasma values.

Therapeutic Uses. When used alone, carmustine (BICNU) usually is administered intravenously at doses of 150 to 200 mg/m², given by infusion over 1 to 2 hours and repeated at 6 weeks.

Because of its ability to cross the blood–brain barrier, carmustine is used with procarbazine in the treatment of malignant gliomas. An implantable carmustine wafer (GLIADEL) is available for use as an adjunct to surgery and radiation in newly diagnosed high-grade malignant glioma patients and as an adjunct to surgery for recurrent glioblastoma multiforme.

Streptozocin. This antibiotic has a methylnitrosourea (MNU) moiety attached to the 2 carbon of glucose. It has a high affinity for cells of the islets of Langerhans and causes diabetes in experimental animals.

Absorption, Fate, and Excretion. After intravenous infusions of 200 to 1600 mg/m², peak concentrations of streptozocin in the plasma are 30 to 40 μg/ml; the half-life of the drug is approximately 15 minutes. Only 10% to 20% of a dose is recovered intact in the urine.

Therapeutic Uses. Streptozocin (ZANOSAR) is useful in the treatment of human pancreatic islet cell carcinoma and malignant carcinoid tumors. It is administered intravenously, 500 mg/m² once daily for 5 days; this course is repeated every 6 weeks. Alternatively, 1000 mg/m² can be given weekly for 2 weeks, and the weekly dose then can be increased to a maximum of 1500 mg/m², depending on tolerance.

Clinical Toxicity. Nausea is frequent. Mild, reversible renal or hepatic toxicity occurs in approximately two-thirds of cases; in less than 10% of patients, renal toxicity may be cumulative with each dose and may be fatal. A serial determination of urinary protein excretion is an early sign of tubular damage and impending renal failure. Streptozocin should not be given with other nephrotoxic drugs. Hematological toxicity—*anemia, leukopenia, or thrombocytopenia*—occurs in 20% of patients.

Triazines

Dacarbazine (DTIC). Dacarbazine functions as a methylating agent after metabolic activation in the liver. Its active metabolite is a monomethyl triazeno metabolite, MTIC, and it kills cells in all phases of the cell cycle. Resistance has been ascribed to the removal of methyl groups from the O⁶-guanine bases in DNA by AGT.

Absorption, Fate, and Excretion. Dacarbazine is administered intravenously. After an initial rapid phase of disappearance (half-life of about 20 minutes), dacarbazine is removed from plasma with a terminal half-life of about 5 hours (Loo *et al.*, 1976). The half-life is

prolonged in the presence of hepatic or renal disease. Almost 50% of the compound is excreted intact in the urine by tubular secretion. Elevated urinary concentrations of 5-aminoimidazole-4-carboxamide are derived from the catabolism of dacarbazine, rather than by inhibition of *de novo* purine biosynthesis.

Therapeutic Uses. Dacarbazine (DTIC-DOME, others) for malignant melanoma is given in doses of 3.5 mg/kg per day, intravenously, for a 10-day period, repeated every 28 days. Alternatively, 250 mg/m² can be given daily for 5 days and repeated every 3 weeks. Extravasation of the drug may cause tissue damage and severe pain.

At present, dacarbazine is employed in combination regimens for the treatment of Hodgkin's disease. It is less effective against malignant melanoma and adult sarcomas.

Clinical Toxicity. The toxicity of DTIC includes nausea and vomiting in more than 90% of patients; vomiting usually develops 1 to 3 hours after treatment and may last up to 12 hours. Myelosuppression, with both leukopenia and thrombocytopenia, usually is mild to moderate. A flulike syndrome consisting of chills, fever, malaise, and myalgias, may occur during treatment with DTIC. Hepatotoxicity, alopecia, facial flushing, neurotoxicity, and dermatologic reactions also have been reported.

Temozolomide. Temozolomide (TEMODAR) is a recently introduced triazene that has significant activity in patients with malignant gliomas, where it is the standard agent in combination with radiation therapy. Temozolomide, like dacarbazine, forms the methylating metabolite MTIC and kills cells in all phases of the cell cycle.

Absorption, Fate, and Excretion. Temozolomide is administered orally and its bioavailability approaches 100%. Maximum drug concentration reaches 5 μg/ml, or about 10 μM in plasma, approximately 1 hour after administration of a dose of 200 mg, and declines with an elimination half-life of 1.2 hours. The primary active metabolite MTIC reaches a maximum plasma concentration of 150 ng/ml 90 minutes after a dose, and declines with a half-life of 2 hours. Little intact drug is recovered in the urine, the primary urinary metabolite being the inactive imidazole carboxamide (Baker *et al.*, 1999). The pharmacokinetics of temozolomide are linear over the dose range of 100 to 260 mg/m².

Clinical Toxicity. The toxicities of temozolomide mirror those of DTIC.

Methylhydrazines

Procarbazine. The methylhydrazine derivatives were synthesized in a search for inhibitors of monoamine neurotransmitters (Bollag, 1963). Several compounds in this series were discovered to have anticancer activity, but only procarbazine (*N*-isopropyl- α -(2-methylhydrazino)-*p*-toluamide), an agent useful in Hodgkin's disease and malignant brain tumors, has won a place in clinical chemotherapy. The structural formula for procarbazine is:

Cytotoxic Action. The antineoplastic activity of procarbazine results from its conversion to highly reactive alkylating species, which methylate DNA by CYP-mediated hepatic oxidative metabolism (Erikson *et al.*, 1989; Swaffar *et al.*, 1989). The activation pathways are complex and not fully understood. The first step involves oxidation of the hydrazine function, yielding the azo metabolite, which exists in equilibrium with its hydrazone tautomer. *N*-oxidation of azoprocarbazine generates the isomeric benzylazoxy and methylazoxy metabolites, the latter of which liberates an entity resembling diazomethane, a potent methylating reagent (Swaffar *et al.*, 1989). Free-radical intermediates also may be involved in cytotoxicity. Activated procarbazine can produce chromosomal damage, including chromatid breaks and translocations, consistent with its mutagenic and carcinogenic actions. Exposure to procarbazine leads to inhibition of DNA, RNA, and protein synthesis *in vivo*. Resistance to procarbazine develops rapidly when it is used as a single agent. One mechanism results from the increased ability to repair methylation of guanine *via* guanine-*O*⁶-alkyl transferase (Soultis *et al.*, 1990).

Absorption, Fate, and Excretion. The pharmacokinetic behavior of procarbazine has not yet been thoroughly defined. Early studies using radiotracer techniques and other indirect methods demonstrated that procarbazine is efficiently absorbed from the gastrointestinal tract and that it rapidly distributes into the CNS (Oliverio *et al.*, 1964). The drug and its metabolites are predominantly eliminated in the urine, with *N*-isopropyl-terephthalamide acid being the major metabolite, accounting for about 25% of doses given either orally or intravenously to humans (Oliverio *et al.*, 1964). Mass spectrometric methods have identified the azo, methylazoxy, and benzylazoxy metabolites of the drug in the plasma of a cancer patient treated with oral procarbazine (Shiba and Weinkam, 1982). A marked decrease in the apparent clearance of the drug upon repeated daily oral administration has been observed (Shiba and Weinkam, 1982). In brain cancer patients, the concurrent use of antiepileptic drugs that induce hepatic CYPs did not significantly alter the pharmacokinetics of the parent drug (He *et al.*, 2004). This is somewhat surprising, because of the established role of CYPs in the bioactivation of procarbazine and the observation that its activity against tumors growing in mice is significantly enhanced by pretreatment with enzyme-inducing drugs, including *phenobarbital* and *phenytoin* (Shiba and Weinkam, 1983).

Therapeutic Uses. The recommended dose of procarbazine (MATULANE) for adults is 100 mg/m² daily for 10 to 14 days in combination regimens. The drug rarely is used alone. Procarbazine is used in combination with mechlorethamine, vincristine, and prednisone (the MOPP regimen) for the treatment of Hodgkin's disease (DeVita, 1981). Alternative regimens with less leukemogenic potential have largely replaced MOPP. Of primary importance, procarbazine lacks cross-resistance with other mustard-type alkylating agents. Procarbazine has been used in combination with lomustine and vincristine (the PCV regimen) since the 1970s for treating patients with newly diagnosed or recurrent primary brain tumors (Grossman, 1997).

Clinical Toxicity. The most common toxic effects include leukopenia and thrombocytopenia, which begin during the second week of therapy and reverse within 2 weeks off treatment. GI symptoms such as mild nausea and vomiting occur in most patients; gastrointestinal symptoms and neurological and dermatological manifestations have been noted in 5% to 10% of cases.

Behavioral disturbances also have been reported. Because of augmentation of sedative effects, the concomitant use of CNS depressants should be avoided. Since procarbazine is a weak monoamine oxidase inhibitor, hypertensive reactions may result from its use concurrently with sympathomimetic agents, tricyclic antidepressants, or ingestion of foods with high tyramine content. Procarbazine has disulfiram-like actions (*see* Chapter 22), and therefore the ingestion of alcohol should be avoided. Procarbazine is highly carcinogenic, mutagenic, and teratogenic, and its use in MOPP therapy is associated with a 5% to 10% risk of acute leukemia; the greatest risk is for patients who also receive radiation therapy (Tucker *et al.*, 1988). Procarbazine also is a potent immunosuppressive agent and it causes infertility, particularly in males.

PLATINUM COORDINATION COMPLEXES

The platinum coordination complexes were first identified as potential antiproliferative agents in 1965 by Rosenberg and coworkers. They observed that a current delivered between platinum electrodes produced inhibition of *E. coli* proliferation. The inhibitory effects on bacterial replication later were ascribed to the formation of inorganic platinum-containing compounds in the presence of ammonium and chloride ions. *Cis*-diamminedichloro-platinum (II) (cisplatin) was the most active of these substances in experimental tumor systems and has proven to be of great clinical value. Since that discovery, many platinum-containing compounds have been synthesized and tested. Carboplatin was approved for treatment of ovarian cancers in 1989, and *oxaliplatin* was approved by the FDA for colon cancer in 2003 (Ibrahim *et al.*, 2004). As a group, these agents have broad antineoplastic activity, and have become the foundation for treatment of testicular cancer, ovarian cancer, and cancers of the head and neck, bladder, esophagus, lung, and colon. Although cisplatin and other platinum complexes do not form carbonium ion intermediates like other alkylating agents and/or formally alkylate DNA, they covalently bind to nucleophilic sites on DNA and share many pharmacological attributes, justifying their inclusion in the alkylating agent class.

Chemistry. Cisplatin and carboplatin are divalent inorganic, water-soluble, platinum-containing complexes, while oxaliplatin, which does not display cross-resistance in some experimental tumors, is tetravalent. In each case, the coordination of di- or tetravalent platinum with various organic adducts reduces its renal toxicity and stabilizes the metal ion, as compared to the inorganic divalent platinum ion. The structural formulas of cisplatin, carboplatin, and oxaliplatin are:

Mechanism of Action. Cisplatin, carboplatin, and oxaliplatin enter cells by diffusion, and by an active Cu²⁺ transporter (Kruh, 2003). Inside the cell, the chloride atoms of cisplatin may be displaced and the compound may be inactivated directly by reaction with nucleophiles such as thiols. Chloride is replaced by water, yielding a positively charged molecule. In the primary cytotoxic reaction, the aquated species of the drug then reacts with nucleophilic sites on DNA and proteins. Aquation is favored at the low concentrations of chloride inside the cell and in the urine. High concentrations of chloride stabilize the drug, explaining the effectiveness of chloride diuresis in preventing nephrotoxicity (*see below*). Hydrolysis of carboplatin removes the bidentate cyclobutanedicarboxylate group; this activation reaction occurs slowly.

The platinum complexes can react with DNA, forming both intrastrand and interstrand cross-links. The N7 of guanine is a particularly reactive site, leading to platinum cross-links between adjacent guanines on the same DNA strand; guanine–adenine cross-links also readily form and may be critical to cytotoxicity (Parker *et al.*, 1991). The formation of interstrand cross-links is less favored. DNA adducts formed by cisplatin inhibit DNA replication and transcription and lead to breaks and miscoding, and if recognized by p53 and other checkpoint proteins, induction of apoptosis. Although no conclusive association between platinum–DNA adduct formation and efficacy has been documented, the ability of patients to form and sustain platinum adducts appears to be an important predictor of clinical response (Reed *et al.*, 1986). Preclinical data suggest that the formation of the platinum–adenosine-to-guanosine adduct may be the most critical adduct in terms of cytotoxicity.

The specificity of cisplatin with regard to phase of the cell cycle appears to differ among cell types, although the effects of cross-linking are most pronounced during the S phase. Cisplatin is mutagenic, teratogenic, and carcinogenic. The use of cisplatin- or carboplatin-based chemotherapy for women with ovarian cancer is associated with a fourfold increased risk of developing secondary leukemia (Travis *et al.*, 1999).

Resistance to Platinum Analogs

The causes of tumor cell resistance to cisplatin and its analogs are incompletely understood. The various analogs differ in their degree of cross-resistance with cisplatin in experimental tumor systems. Carboplatin shares cross-resistance with cisplatin in most experimental tumors, while oxaliplatin and other tetravalent analogs do not. A number of factors influence cisplatin sensitivity in experimental cells, including intracellular drug accumulation and intracellular levels of glutathione and other sulfhydryls such as metallothionein that bind to and inactivate the drug (Meijer *et al.*, 1990), and

rates of repair of DNA adducts (Parker *et al.*, 1991). Repair of cisplatin–DNA adducts occurs through the nucleotide excision repair (NER) pathway (Reed, 1998). Inhibition or loss of NER increases sensitivity to cisplatin in ovarian cancer patients (Taniguchi *et al.*, 2003), while overexpression of NER components is associated with poor response to cisplatin-based therapy in lung cancer (Rosell *et al.*, 2003).

Resistance to cisplatin, but not oxaliplatin, appears to be partly mediated through loss of function in the mismatch repair (MMR) proteins (Vaisman *et al.*, 1998). MMR proteins, particularly hMLH1, hMLH2, or hMSH6, recognize platinum–DNA adducts and initiate apoptosis. Loss of MMR has been associated in some studies with resistance to cisplatin *in vitro* (Mello, 1996). Through an hMLH1-dependent event, cisplatin induces overexpression of p73, a member of the p53 family, as well as c-ABL tyrosine kinase, and consequently activates apoptosis (Gong *et al.*, 1999). In response to cisplatin exposure, apoptosis is not induced in cells deficient in MMR or in cells unable to upregulate c-ABL tyrosine kinase. By contrast, MMR repair proficiency is not required for oxaliplatin cytotoxicity (Fink *et al.*, 1996).

In the absence of effective repair of DNA–platinum adducts, sensitive cells cannot replicate or transcribe affected portions of the DNA strand. However, it is clear that some DNA polymerases are able to bypass adducts. It remains unproven whether these polymerases contribute to resistance. Cisplatin resistance related to loss of active uptake has been demonstrated in yeast; overexpression of copper efflux transporters, ATP7A and ATP7B, has been described in human tumors, and correlates with poor survival after cisplatin-based therapy for ovarian cancer (Kruh, 2003).

Cisplatin

Absorption, Fate, and Excretion. After intravenous administration, cisplatin has an initial plasma elimination half-life of 25 to 50 minutes; concentrations of total (bound and unbound) drug fall thereafter, with a half-life of 24 hours or longer. More than 90% of the platinum in the blood is covalently bound to plasma proteins. The unbound fraction, composed predominantly of parent drug, is cleared within minutes. High concentrations of cisplatin are found in the tissues of the kidney, liver, intestine, and testes, but there is poor penetration into the CNS. Only a small portion of the drug is excreted by the kidney during the first 6 hours; by 24 hours up to 25% is excreted, and by 5 days up to 43% of the administered dose is recovered in the urine, mostly covalently bound to protein and peptides. Biliary or intestinal excretion of cisplatin is minimal.

Therapeutic Uses. Cisplatin (PLATINOL-AQ, others) is given only by the intravenous route. The usual dose is 20 mg/m² per day for 5 days, 20 to 30 mg weekly for 3 to 4 weeks, or 100 mg/m², given once every 4 weeks. *To prevent renal toxicity, it is important to establish a chloride diuresis by the infusion of 1 to 2 liters of normal saline prior to treatment.* The appropriate amount of cisplatin then is diluted in a solution of dextrose and saline and administered intravenously over a period of 4 to 6 hours. Since aluminum reacts with and inactivates cisplatin, it is important not to use needles or other infusion equipment that contain aluminum when preparing or administering the drug.

Cisplatin, in combination with *bleomycin*, etoposide, ifosfamide, or *vinblastine* cures 90% of patients with testicular cancer. Used with paclitaxel, cisplatin induces complete response in the majority of patients with carcinoma of the ovary. Cisplatin produces responses in cancers of the bladder, head and neck, cervix, and endometrium; all forms of carcinoma of the lung; anal and rectal carcinomas; and neoplasms of childhood. Interestingly, the drug also sensitizes cells to radiation therapy and enhances control of locally advanced lung, esophageal, and head and neck tumors when given with irradiation.

Clinical Toxicities. Cisplatin-induced nephrotoxicity has been largely abrogated by adequate pretreatment hydration and diuresis. *Amifostine* (ETHYOL) is a thiophosphate cytoprotective agent that is labeled for the reduction of renal toxicity associated with repeated administration of cisplatin. Amifostine is dephosphorylated by alkaline phosphatase to a pharmacologically active free thiol metabolite. Faster dephosphorylation and preferential uptake by normal tissues results in a higher concentration of the thiol metabolite available to scavenge reactive cisplatin metabolites in normal tissues. Amifostine also is used to reduce xerostomia in patients undergoing irradiation for head and neck cancer, where the radiation port includes a substantial portion of the parotid glands. A review of the clinical status of amifostine as a cytoprotectant has been published.

Ototoxicity caused by cisplatin is unaffected by diuresis and is manifested by tinnitus and high-frequency hearing loss. The ototoxicity can be unilateral or bilateral, tends to be more frequent and severe with repeated doses, and may be more pronounced in children. Marked nausea and vomiting occur in almost all patients and usually can be controlled with 5-hydroxytryptamine (5-HT₃) antagonists, neurokinin-1 (NK1) receptor antagonists, and high-dose corticosteroids (*see* Chapter 37). At higher doses or after multiple cycles of treatment, cisplatin causes a progressive peripheral motor and sensory neuropathy, which may worsen after discontinuation of the drug and may be aggravated by subsequent or simultaneous treatment with taxanes or other neurotoxic drugs. Cisplatin causes mild-to-moderate myelosuppression, with transient leukopenia and thrombocytopenia. Anemia may become prominent after multiple cycles of treatment. Electrolyte disturbances, including hypomagnesemia, hypocalcemia, hypokalemia, and hypophosphatemia, are common. Hypocalcemia and hypomagnesemia secondary to renal electrolyte wasting may produce tetany if untreated. Routine measurement of Mg²⁺ concentrations in plasma is recommended. Hyperuricemia, hemolytic anemia, and cardiac abnormalities are rare side effects. Anaphylactic-like reactions, characterized by facial edema, bronchoconstriction, tachycardia, and hypotension, may occur within minutes after administration and should be treated by intravenous injection of epinephrine and with corticosteroids or antihistamines. Cisplatin has been associated with the development of AML, usually 4 years or more after treatment.

Carboplatin

The mechanisms of action and resistance and the spectrum of clinical activity of carboplatin (CBDCA, JM-8) are similar to those of

cisplatin (*see* above). However, the two drugs differ significantly in their chemical, pharmacokinetic, and toxicological properties.

Because carboplatin is much less reactive than cisplatin, the majority of drug in plasma remains in its parent form, unbound to proteins. Most drug is eliminated *via* renal excretion, with a half-life in plasma of about 2 hours. A small fraction of platinum does become irreversibly bound to plasma proteins, and disappears slowly, with a half-life of 5 days or more.

Carboplatin is relatively well tolerated clinically, with less nausea, neurotoxicity, ototoxicity, and nephrotoxicity than that associated with cisplatin. Instead, the dose-limiting toxicity is myelosuppression, primarily evident as thrombocytopenia.

Carboplatin and cisplatin appear to be equally effective in the treatment of suboptimally debulked ovarian cancer, non-small cell lung cancer, and extensive stage small cell lung cancer; however, carboplatin may be less effective than cisplatin in germ cell, head and neck, and esophageal cancers (Go and Adjei, 1999). Carboplatin is an effective alternative for responsive tumors in patients unable to tolerate cisplatin because of impaired renal function, refractory nausea, significant hearing impairment, or neuropathy, but doses must be adjusted for renal function. In addition, it may be used in high-dose therapy with bone marrow or peripheral stem cell rescue. The dose of carboplatin should be adjusted in proportion to the reduction in creatinine clearance for patients with a creatinine clearance below 60 ml/min (Van Echo *et al.*, 1989; Calvert *et al.*, 1989; Calvert and Egarin, 2002). The following formula has been proposed for calculation of dose:

$$\text{Dose (mg)} = \text{AUC} \times (\text{GFR} + 25) \quad (51-1)$$

where the target AUC (area under the plasma concentration–time curve) is in the range of 5 to 7 mg/ml per minute for acceptable toxicity in patients receiving single-agent carboplatin (GFR = glomerular filtration rate).

Carboplatin (PARAPLATIN) is administered as an intravenous infusion over at least 15 minutes, using the above-mentioned formula, and is given once every 28 days. Carboplatin currently has FDA approval for use in combination with paclitaxel or cyclophosphamide in patients with advanced ovarian cancer and lung cancer.

Oxaliplatin

Absorption, Fate and Excretion. Oxaliplatin, like cisplatin, has a very brief half-life in plasma, probably as a result of its rapid uptake by tissues and its reactivity. Maximum concentrations in plasma range from 1 to 1.5 μg platinum/ml for patients receiving 80 to 130 mg/m² intravenously, and decline thereafter with an initial half-life of 0.28 hours. While the ultrafiltrable component has a slow terminal clearance from plasma (half-life of 273 hours), most of the low-molecular-weight platinum species represent inactive degradation products. These metabolites undergo renal excretion at a rate dependent on the creatinine clearance. However, no dose adjustment is required for patients with creatinine clearances of greater than 20 ml/min, as decreased renal function does not affect the rapid chemical inactivation of the drug and its toxicity at doses of 65 to 130 mg/m² (Takimoto *et al.*, 2003).

Therapeutic Uses. Oxaliplatin exhibits a wide range of antitumor activity that differs from other platinum agents, and includes gastric and colorectal cancer. Oxaliplatin's effectiveness in colorectal can-

cer is perhaps due to its MMR-independent effects. It also suppresses expression of thymidylate synthase (TS), the target enzyme of 5-fluorouracil (5-FU) action, which may promote synergy of these two drugs. In combination with 5-fluorouracil, it is approved for treatment of patients with advanced colorectal cancer.

Clinical Toxicity. The dose-limiting toxicity of oxaliplatin is a peripheral neuropathy. An acute form often is triggered by exposure to cold, and manifests as paresthesias and/or dysesthesias in the upper and lower extremities, mouth, and throat. A second type of peripheral neuropathy is more closely related to cumulative dose and similar to that seen with cisplatin; 75% of patients receiving a cumulative dose of 1560 mg/m² experience some neurotoxicity. Hematologic toxicity is mild to moderate, and nausea is well controlled with 5-HT₃ receptor antagonists (*see* Chapter 37). Oxaliplatin is unstable in the presence of chloride or alkaline solutions.

II. ANTIMETABOLITES

FOLIC ACID ANALOGS

Antifolate chemotherapy occupies a special place in the history of cancer treatment, as this class of drugs produced the first striking, although temporary, remissions in leukemia (Farber *et al.*, 1948), and the first cure of a solid tumor, choriocarcinoma (Berlin *et al.*, 1963). These advances provided great impetus to the development of chemotherapy for cancer. Interest in folate antagonists further increased with the development of curative combination therapy for childhood acute lymphocytic leukemia; in this therapy, methotrexate played a critical role in both systemic treatment and intrathecal therapy. Introduction of high-dose regimens with “rescue” of host toxicity by the reduced folate, leucovorin (folinic acid, citrovorum factor, 5-formyl tetrahydrofolate, N⁵-formyl FH₄), further extended the effectiveness of this drug to both systemic and CNS lymphomas, osteogenic sarcoma, and leukemias. Most recently, *pemetrexed*, an analogue that differs from methotrexate in its transport properties and sites of action, has proven useful in treating mesothelioma and lung cancer.

Recognition that methotrexate, an inhibitor of dihydrofolate reductase, also directly inhibits the folate-dependent enzymes of *de novo* purine and thymidylate synthesis focused attention on the development of antifolate analogs that specifically target these other folate-dependent enzymes (Figure 51–7). Replacement of the N5 and/or N8 nitrogens of the pteridine ring and the N10 nitrogen of the bridge between the pteridine and benzoate rings of folate, as well as various side-chain substitutions, have generated a series of new inhibitors.

Figure 51–7. Sites of action of methotrexate and its polyglutamates. AICAR, aminoimidazole carboxamide; TMP, thymidine monophosphate; dUMP, deoxyuridine monophosphate; FH_2Glu_n , dihydrofolate polyglutamate; FH_4Glu_n , tetrahydrofolate polyglutamate; GAR, glycylamide ribonucleotide; IMP, inosine monophosphate; PRPP, 5-phosphoribosyl-1-pyrophosphate.

These new agents have greater capacity for transport into tumor cells, and exert their primary inhibitory effect on thymidylate synthase (*raltitrexed*, TOMUDEX), early steps in purine biosynthesis (*lometrexol*) or both (the multitargeted antifolate, *pemetrexed*) (Vogelzang *et al.*, 2003).

Aside from its antineoplastic activity, methotrexate also has been used with benefit in the therapy of psoriasis (*see* Chapter 62). Additionally, methotrexate inhibits cell-mediated immune reactions and is employed as an immunosuppressive agent to suppress graft-versus-host disease in allogeneic bone marrow and organ transplantation and for the treatment of dermatomyositis, rheumatoid arthritis, Wegener’s granulomatosis, and Crohn’s disease (*see* Chapters 38 and 52).

Structure–Activity Relationship. Folic acid is an essential dietary factor. It is converted by enzymatic reduction to a series of tetrahydrofolate cofactors that provide carbon groups for the synthesis of precursors of DNA (thymidylate and purines) and RNA (purines). The biological functions and therapeutic applications of folic acid are further described in Chapter 53.

The primary target of methotrexate is the enzyme dihydrofolate reductase (DHFR) (Figure 51–7). Inhibition of DHFR leads to partial

depletion of the tetrahydrofolate cofactors (5-10 methylene tetrahydrofolic acid and N-10 formyl tetrahydrofolic acid) required for the respective synthesis of thymidylate and purines. In addition, methotrexate, like its physiologic counterparts (the folates), undergoes conversion to a series of polyglutamates (MTX-PGs) in both normal and tumor cells. These MTX-PGs constitute an intracellular storage form of folates and folate analogs, and dramatically increase inhibitory potency of the analog for additional sites, including thymidylate synthase (TS) and two early enzymes in the purine biosynthetic pathway (Figure 51–7). Finally, the dihydrofolic acid polyglutamates that accumulate in cells behind the blocked DHFR reaction also act as inhibitors of TS and other enzymes (Figure 51–7) (Allegra *et al.*, 1987b). Inhibitors of DHFR differ in their relative potency for blocking enzymes from different species. Agents have been identified that have little effect on the human enzyme, but have strong activity against bacterial and parasitic infections (*see* discussions of *trimethoprim*, Chapter 43; *pyrimethamine*, Chapter 39). By contrast, methotrexate is an effective inhibitor of DHFR in all species investigated. Crystallographic studies have revealed the structural basis for the high affinity of methotrexate for DHFR (Blakley and Sorrentino, 1998) and the species specificity of the various DHFR inhibitors (Matthews *et al.*, 1985).

Because folic acid and many of its analogs are polar, they cross the blood–brain barrier poorly and require specific transport mechanisms to enter mammalian cells (Elwood, 1989). Three inward folate transport systems are found on mammalian cells: (1) a folate receptor, which has high affinity for folic acid but much reduced ability to transport methotrexate and other analogs (Elwood, 1989); (2) the reduced folate transporter, the major transit protein for methotrexate, raltitrexed, pemetrexed, and most analogs (Westerhof *et al.*, 1995); and (3) a poorly characterized transporter that is active at low pH. The importance of transport in determining drug sensitivity is illustrated by the finding that the reduced folate transporter is highly expressed in the hyperdiploid subtype of acute lymphoblastic leukemia, due to the presence of multiple copies of chromosome 21, on which its gene resides; these cells have extreme sensitivity to methotrexate (Pui *et al.*, 2004). Once in the cell, additional glutamyl residues are added to the molecule by the enzyme folylpolyglutamate synthetase. Intracellular methotrexate polyglutamates have been identified with up to six glutamyl residues. Since these higher polyglutamates are strongly charged and cross cellular membranes poorly, if at all, polyglutamation serves as a mechanism of entrapment and may account for the prolonged retention of methotrexate in chorionic epithelium (where it is a potent abortifacient), in tumors derived from this tissue, such as choriocarcinoma cells, and in normal tissues subject to cumulative drug toxicity, such as liver. Polyglutamylated folates and analogs have substantially greater affinity than the monoglutamate form for folate-dependent enzymes that are required for purine and thymidylate synthesis, and have at least equal affinity for DHFR.

New folate antagonists have been identified that are better substrates for the reduced folate carrier. Pemetrexed appears to have significant advantages in clinical chemotherapy (*see* below). In efforts to bypass the obligatory membrane transport system and to facilitate penetration of the blood–brain barrier, lipid-soluble folate antagonists also have been synthesized. Trimetrexate (NEUTREXIN) (Figure 51–8) was one of the first to be tested for clinical activity. The analog has modest antitumor activity, primarily in combination with leucovorin rescue. However, it is beneficial in the treatment of *Pneumocystis jirovecii* (*Pneumocystis carinii*) pneumonia (Allegra *et al.*, 1987a), where leucovorin provides differential rescue of the host but not the parasite.

The most important new folate analog, MTA or pemetrexed (ALIMTA) (Figure 51–8), is a pyrrole-pyrimidine folate analog (Tay-

lor *et al.*, 1992). It is avidly transported into cells *via* the reduced folate carrier, but also may gain entry by a unique folate transport activity found in mesothelioma cell lines (Wang *et al.*, 2002). It readily is converted to polyglutamates that inhibit TS and glycine amide ribonucleotide transformylase, as well as dihydrofolate reductase. It has shown activity against colon cancer, mesothelioma, and non–small cell lung cancer, and has been approved for treatment of mesothelioma (Vogelzang *et al.*, 2003).

Mechanism of Action. To function as a cofactor in one-carbon transfer reactions, folate must first be reduced by DHFR to tetrahydrofolate (FH₄). Single-carbon fragments are added enzymatically to FH₄ in various configurations and then may be transferred in specific synthetic reactions. In a key metabolic event catalyzed by TS (Figure 51–7), deoxyuridine monophosphate (dUMP) is converted to thymidine monophosphate (TMP), an essential component of DNA. In this reaction, a one-carbon group is transferred to dUMP from 5,10-methylene FH₄, and the reduced folate cofactor is oxidized to dihydrofolate (FH₂). To function again as a cofactor, FH₂ must be reduced to FH₄ by DHFR. Inhibitors such as methotrexate, with a high affinity for DHFR ($K_i \sim 0.01$ to 0.2 nM), prevent the formation of FH₄ and allow a vast accumulation of the toxic inhibitory substrate, FH₂ polyglutamate, behind the blocked reaction. The one-carbon transfer reactions crucial for the *de novo* synthesis of purine nucleotides and thymidylate cease, with the subsequent interruption of the synthesis of DNA and RNA. The toxic effects of methotrexate may be terminated by administering leucovorin, a fully reduced folate coenzyme, which replenishes the intracellular pool of tetrahydrofolate cofactors.

As with most antimetabolites, methotrexate is only partially selective for tumor cells and is toxic to all rapidly dividing normal cells, such as those of the intestinal epithelium and bone marrow. Folate antagonists kill cells during the S phase of the cell cycle and are most effective when cells are proliferating rapidly.

Pemetrexed and its polyglutamates have a somewhat different spectrum of biochemical actions. Like methotrexate, it inhibits DHFR, but as a polyglutamate, even more potently glycylamide ribonucleotide formyltransferase (GART) and TS. Unlike methotrexate, it produces little change in the pool of reduced folates, indicating that the distal sites of inhibition (TS and GART) predominate. Its pattern of deoxynucleotide depletion, as studied in cell lines, also differs, with little effect on deoxyadenosine triphosphate (dATP), a profile more characteristic of primary TS inhibition (Chen *et al.*, 1998). Like methotrexate, it induces p53 and cell-cycle arrest, but this effect does not seem to depend on downstream induction of p21.

Mechanisms of Resistance to Antifolates. In experimental systems, different biochemical mechanisms of acquired resistance to methotrexate affect each known step in methotrexate action, including: (1) impaired transport of methotrexate into cells (Assaraf *et al.*, 2003; Trippett *et al.*, 1992); (2) production of altered forms of DHFR that have decreased affinity for the inhibitor (Srimatkandada *et al.*, 1989); (3) increased concentrations of intracellular DHFR through gene amplification or altered gene regulation (Matherly *et al.*, 1997); (4) decreased ability to synthesize methotrexate polyglutamates (Li *et al.*, 1992); and (5) increased expression of a drug efflux transporter, of the MRP (multidrug resistance protein) class (Stashenko *et al.*, 1980).

DHFR levels in leukemic cells increase within 24 hours after treatment of patients with methotrexate; this likely reflects induction of new enzyme synthesis. The unbound DHFR protein may bind to its own message and inhibit translational efficiency of its own synthesis,

Figure 51–8. The structure–activity bases for antifolate action.

while the DHFR-MTX complex is ineffective in blocking the DHFR translation. With longer periods of drug exposure, tumor cell populations emerge that contain markedly increased levels of DHFR. These cells contain multiple gene copies of DHFR either in mitotically unstable double-minute chromosomes (extrachromosomal elements formed by amplification of DHFR genes in response to methotrexate treatment) or in stably integrated, homogeneously staining chromosomal regions or amplicons. First identified as an explanation for resistance to methotrexate (Schimke *et al.*, 1978), gene amplification of a target protein has since been implicated in the resistance to many antitumor agents, including 5-fluorouracil and *pentostatin* (2'-deoxycoformycin) (Stark and Wahl, 1984), and has been observed in patients with lung cancer (Curt *et al.*, 1985) and leukemia (Goker *et al.*, 1995).

To overcome resistance, high doses of methotrexate may permit entry of drug into transport-defective cells and may permit the intracellular accumulation of methotrexate in concentrations that inactivate high levels of DHFR.

The understanding of resistance to pemetrexed is incomplete. In various cell lines, resistance to this agent seems to arise either from TS amplification, changes in purine biosynthetic pathways, or both (Schultz *et al.*, 1999).

General Toxicity and Cytotoxic Action. The primary toxic effects of methotrexate and other folate antagonists used in cancer chemotherapy are exerted against rapidly dividing cells of the bone marrow

and GI epithelium. Mucositis, myelosuppression, and thrombocytopenia reach their maximum in 5 to 10 days after drug administration, and except in instances of altered drug excretion, reverse rapidly thereafter.

In addition to its acute toxicities, methotrexate can cause pneumonitis, characterized by patchy inflammatory infiltrates that regress upon discontinuation of the drug. In some cases, patients can be rechallenged with drug without toxicity. The etiology is not clearly allergic.

A second toxicity of particular significance in chronic administration to patients with psoriasis or rheumatoid arthritis is hepatic fibrosis and cirrhosis. Increased hepatic portal fibrosis is detected with higher frequency than in control patients after 6 months or longer of continuous oral methotrexate treatment of psoriasis. Its presence mandates discontinuation of methotrexate. Acute, reversible elevation of hepatic enzymes is detected in serum after high-dose administration but rarely is associated with permanent changes.

Folic acid antagonists are toxic to developing embryos. Methotrexate is highly effective when used with the prostaglandin analog *misoprostol* in inducing abortion in first-trimester pregnancy (Hausknecht, 1995).

Absorption, Fate, and Excretion. Methotrexate is readily absorbed from the gastrointestinal tract at doses of less than 25 mg/m², but larger doses are absorbed incompletely and are routinely administered intravenously. Peak concentrations in the plasma of 1 to 10

μM are obtained after doses of 25 to 100 mg/m^2 , and concentrations of 0.1 to 1 mM are achieved after high-dose infusions of 1.5 to 20 g/m^2 . After intravenous administration, the drug disappears from plasma in a triphasic fashion (Sonneveld *et al.*, 1986). The rapid distribution phase is followed by a second phase, which reflects renal clearance (half-life of about 2 to 3 hours). A third phase has a half-life of approximately 8 to 10 hours. This terminal phase of disappearance, if unduly prolonged by renal failure, may be responsible for major toxic effects of the drug on the marrow, GI epithelium, and skin. Distribution of methotrexate into body spaces, such as the pleural or peritoneal cavity, occurs slowly. However, if such spaces are expanded (*e.g.*, by ascites or pleural effusion), they may act as a site of storage and slow release of drug, with resultant prolonged elevation of plasma concentrations and more severe toxicity.

Approximately 50% of methotrexate is bound to plasma proteins and may be displaced from plasma albumin by a number of drugs, including sulfonamides, salicylates, tetracycline, chloramphenicol, and phenytoin; caution should be used if these are given concomitantly. Up to 90% of a given dose is excreted unchanged in the urine within 48 hours, mostly within the first 8 to 12 hours. A small amount of methotrexate also is excreted in the stool. Metabolism of methotrexate in humans is usually minimal. After high doses, however, metabolites are readily detectable; these include 7-hydroxy-methotrexate, which is potentially nephrotoxic. Renal excretion of methotrexate occurs through a combination of glomerular filtration and active tubular secretion. Therefore, the concurrent use of drugs that reduce renal blood flow (*e.g.*, nonsteroidal antiinflammatory agents), that are nephrotoxic (*e.g.*, cisplatin), or that are weak organic acids (*e.g.*, aspirin or piperacillin) can delay drug excretion and lead to severe myelosuppression (Thyss *et al.*, 1986). Particular caution must be exercised in treating patients with renal insufficiency. In such patients, the dose should be adjusted in proportion to decreases in renal function, and high-dose regimens should be avoided if possible.

Methotrexate is retained in the form of polyglutamates for long periods—for example, for weeks in the kidneys and for several months in the liver.

It is important to emphasize that concentrations of methotrexate in CSF are only 3% of those in the systemic circulation at steady state; hence, neoplastic cells in the CNS probably are not killed by standard dosage regimens. When high doses of methotrexate are given ($>1.5 \text{ g}/\text{m}^2$; *see below*), cytotoxic concentrations of methotrexate may be attained in the CNS.

Pharmacogenetics may influence the response to antifolates and their toxicity. The C677T substitution in methylenetetrahydrofolate reductase reduces the activity of the enzyme that generates methylenetetrahydrofolate, the cofactor for TS, and thereby increases methotrexate toxicity (Pullarkat *et al.*, 2001). The presence of this polymorphism in leukemic cells confers increased sensitivity to methotrexate, and might also modulate the toxicity and therapeutic effect of pemetrexed, a predominant TS inhibitor. Likewise, polymorphisms in the promoter region of TS govern the translation efficiency of this message, and by governing the intracellular levels of TS, modulate the response and toxicity of both antifolates (Pui *et al.*, 2004) and fluoropyrimidines (Pullarkat *et al.*, 2001).

Therapeutic Uses. Methotrexate (*amethopterin*; RHEUMATREX, TREXALL, others) has been used in the treatment of severe, disabling psoriasis in doses of 2.5 mg orally for 5 days, followed by a rest period of at least 2 days, or 10 to 25 mg intravenously weekly. It also is used intermittently at

low dosage to induce remission in refractory rheumatoid arthritis (Hoffmeister, 1983). Complete awareness of the pharmacology and toxic potential of methotrexate is a prerequisite for its use in these non-neoplastic disorders.

Methotrexate is a critical drug in the management of acute lymphoblastic leukemia (ALL) in children. It is of great value in remission induction and consolidation, used in high doses, and in the maintenance of remissions in this highly curable disease. For maintenance therapy, it is administered intermittently at doses of 30 mg/m^2 intramuscularly weekly in two divided doses or in 2-day “pulses” of 175 to 525 mg/m^2 at monthly intervals. Outcome of treatment in children correlates inversely with the rate of drug clearance. During methotrexate infusion, high steady-state levels are associated with a lower leukemia relapse rate (Pui *et al.*, 2004). Methotrexate is of limited value in the types of leukemia seen in adults, except for treatment and prevention of leukemic meningitis. The intrathecal administration of methotrexate has been employed for treatment or prophylaxis of meningeal leukemia or lymphoma and for treatment of meningeal carcinomatosis. This route of administration achieves high concentrations of methotrexate in the CSF and is also effective in patients whose systemic disease has become resistant to methotrexate. The recommended intrathecal dose in all patients over 3 years of age is 12 mg (Bleyer, 1978). The dose is repeated every 4 days until malignant cells no longer are evident in the CSF. Leucovorin may be administered to counteract the toxicity of methotrexate that escapes into the systemic circulation, although this generally is not necessary. Since methotrexate administered into the lumbar space distributes poorly over the cerebral convexities, the drug may be more effective when given *via* an intraventricular Ommaya reservoir. Methotrexate is of established value in choriocarcinoma and related trophoblastic tumors of women; cure is achieved in approximately 75% of advanced cases treated sequentially with methotrexate and *dactinomycin*, and in more than 90% when early diagnosis is made. In the treatment of choriocarcinoma, 1 mg/kg of methotrexate is administered intramuscularly every other day for four doses, alternating with leucovorin (0.1 mg/kg every other day). Courses are repeated at 3-week intervals, toxicity permitting, and urinary β -human chorionic gonadotropin titers are used as a guide for persistence of disease.

Beneficial effects also are observed in the combination therapy of Burkitt's and other non-Hodgkin's lymphomas, and methotrexate is a component of regimens for carcinomas of the breast, head and neck, ovary, and bladder. High-dose methotrexate with leucovorin rescue (HDM-L) is a component of the standard regimen for adjuvant therapy of osteosarcoma, produces a high complete response

rate in CNS lymphomas, and is a part of standard curative therapy for childhood ALL. A 6- to 72-hour infusion of relatively large doses of methotrexate may be employed every 2 to 4 weeks (from 1 to 7.5 g/m² or more), but only when leucovorin rescue is used. Such regimens produce cytotoxic concentrations of drug in the CSF and protect against leukemic meningitis. A typical regimen includes the infusion of 7.5 g/m² methotrexate for 6 hours followed by leucovorin at a dose of 15 mg/m² every 6 hours for seven doses, with the goal of rescuing normal cells to prevent toxicity. Other dosage regimens also are used.

The administration of HDM-L has the potential for renal toxicity, probably related to the precipitation of the drug, a weak acid, in the acidic tubular fluid. Thus, vigorous hydration and alkalinization of urine pH are required prior to drug administration. HDM-L should be performed only by experienced clinicians who are familiar with hydration regimens and who have access to laboratories that monitor concentrations of methotrexate in plasma. If methotrexate values measured 48 hours after drug administration are 1 μM or higher, higher doses (100 mg/m²) of leucovorin must be given until the plasma concentration of methotrexate falls below a level of 50 nM (Stoller *et al.*, 1977). With appropriate hydration and urine alkalinization, and in patients with normal renal function, the incidence of nephrotoxicity following HDM-L approaches 2% (Widemann *et al.*, 2004). In patients who become oliguric, intermittent hemodialysis is ineffective in reducing methotrexate levels. Continuous-flow hemodialysis can eliminate methotrexate at a rate approximating 50% of the clearance rate in patients with intact renal function (Wall *et al.*, 1996). Alternatively, a methotrexate-cleaving enzyme, carboxypeptidase G2, can be obtained from the Cancer Therapy Evaluation Program at the National Cancer Institute. When administered intravenously, it rapidly clears the drug (DeAngelis *et al.*, 1996). Methotrexate concentrations in plasma fall by 99% or greater within 5 to 15 minutes following enzyme administration, with insignificant rebound. Carboxypeptidase G2 also has received limited evaluation as the sole rescue for high-dose methotrexate, without leucovorin, and was effective. Systemically administered carboxypeptidase G2 has little effect on methotrexate levels in the CSF.

At present, the only FDA-approved indication for pemetrexed is for second-line therapy in mesothelioma; it also is used, however, for refractory non-small cell lung cancer. Promising results have been published in its first-line use with cisplatin in both tumors (Scagliotti *et al.*, 2003; Manegold, 2004).

Clinical Toxicities. As previously stated, the primary toxicities of antifolates affect the bone marrow and the intestinal epithelium. Such patients may be at risk for spontaneous hemorrhage or life-threatening infection, and they may require prophylactic transfusion of platelets and broad-spectrum antibiotics if febrile. Side effects usually reverse completely within 2 weeks, but prolonged myelosuppression may occur in patients with compromised renal function who have delayed excretion of the drug. The dosage of methotrexate (and likely pemetrexed) must be reduced in proportion to any reduction in creatinine clearance.

Additional toxicities of methotrexate include alopecia, dermatitis, interstitial pneumonitis, nephrotoxicity, defective oogenesis or spermatogenesis, abortion, and teratogenesis. Elevation of hepatic enzymes is a consistent finding with high-dose methotrexate, but usually is reversible. On the other hand, low-dose methotrexate may lead to cirrhosis after long-term continuous treatment, as in patients with psoriasis. Intrathecal administration of methotrexate often causes meningismus and an inflammatory response in the CSF. Seizures, coma, and death may occur rarely. Leucovorin does not reverse neurotoxicity.

Pemetrexed toxicity mirrors that of methotrexate, with the additional feature of a prominent erythematous and pruritic rash in 40% of patients. *Dexamethasone*, 4 mg twice-daily on days -1, 0, and +1, markedly diminishes this toxicity. Unpredictably severe myelosuppression with pemetrexed, seen especially in patients with preexisting homocystinemia and possibly reflecting folate deficiency, is largely eliminated by concurrent administration of low doses of *folic acid*, 350 to 1000 mg per day, beginning 1 to 2 weeks prior to pemetrexed and continuing while the drug is administered. Intramuscular vitamin B₁₂ (1 mg) is given with the first dose of pemetrexed to correct possible B₁₂ deficiency. There is no evidence that these small doses of folate and B₁₂ compromise the therapeutic effect (Scagliotti *et al.*, 2003).

PYRIMIDINE ANALOGS

The antimetabolites as a class encompass a diverse group of drugs that inhibit RNA and DNA function in a variety of ways. Some, such as the fluoropyrimidines and the purine base analogs (6-mercaptopurine and 6-thioguanine) inhibit the synthesis of essential precursors of DNA. Others, particularly the cytidine and adenosine nucleoside analogs, become incorporated into DNA and block its further elongation and its function. Other metabolic effects of these analogs may contribute to their cytotoxicity and even their ability to induce differentiation.

To understand the role of these drugs, it is useful to review the nomenclature of the DNA bases and their metabolic intermediates. Four bases, shown in Figure 51-9, form DNA; these include two pyrimidines, thymine and cytosine; and two purines, guanine and adenine. The base composition of RNA differs in that it incorporates uracil instead of thymine. Uracil may serve as a precursor of deoxythymidine monophosphate; in the final step of this conversion, TS adds a methyl group to the 5 position of deoxyuridine monophosphate. Cells can make these bases *de novo* and convert them to their active deoxynucleoside triphosphates (dNTPs). The dNTPs then act as substrates for DNA polymerase and become linked in 3'-5' phosphate ester bonds to form DNA strands; their base sequence provides the code for subsequent RNA and protein sequences.

As an alternative to synthesis of new precursor molecules, cells can salvage either free bases or their deoxynucleosides (Figure 51-9), which are found in the systemic circulation, presumably the products of degradation of DNA. Certain bases, such as uracil, guanine, and their analogs, can be taken up by cells and converted intracellularly to (deoxy) nucleotides by the addition of deoxyribose and phosphate groups. Other bases, including cytosine, thymine, and adenine, cannot be activated by mammalian cells, which lack the ability to add the necessary ribose or deoxy ribose groups to these particular bases; however, preformed deoxy-

Pyrimidines

Figure 51–9. Chemical structures of the four bases incorporated into DNA and their analogs. Shown here are the chemical structures of the four bases that become incorporated into DNA, as well as the various modifications found in analogs that function as cytotoxic chemotherapeutic drugs. These modifications involve not only substitutions on the bases but changes in the deoxyribose ring to which the bases are attached (indicated by the asterisk). Some compounds, such as capecitabine and fludarabine, contain multiple substitutions. Others, such as 5-azacytidine, have ribose, rather than deoxyribose, at R₂. The rationale for these substitutions and their effect on DNA synthesis and function are discussed in the text.

nucleosides containing a deoxyribose linked to cytosine or adenine are readily transported into cells and activated by conversion to deoxynucleotides by intracellular kinases.

The limitations of cell uptake and conversion to active triphosphates determine the form in which specific analogs have been synthesized, varying from base analogs such as

5-FU to nucleosides such as cytosine arabinoside, and even to nucleotides such as fludarabine phosphate. Uracil and guanine analogs, containing substitutions on the base itself, are efficiently taken up into cells and converted to dNTPs. Some are useful drugs, such as 5-FU or 6-thioguanine. Because of the inability to activate cytosine or adenine

FLUOROPYRIMIDINE ANALOGS

CYTIDINE ANALOGS

Figure 51-10. Structures of available pyrimidine analogs.

bases, analogs of cytosine and adenine are synthesized as nucleosides, in which form (*cytosine arabinoside* [*cytarabine*; Ara-C] and *gemcitabine*, for example) they are readily transported into cells and converted by kinases to the active dNTPs (Figure 51-10). *Fludarabine phosphate*, a nucleotide, is dephosphorylated rapidly in plasma, releasing the nucleoside that is readily taken up by cells. Analogs may differ from the physiologic bases by alterations in purine or pyrimidine ring or by altering the sugar attached to the base, as in the arabinoside Ara-C, or by altering both the base and sugar, as in fludarabine phosphate.

General Mechanism of Action of Pyrimidine Antimetabolites. The best-characterized agents in this class are the halogenated pyrimidines, a group that includes fluorouracil (5-fluorouracil, or 5-FU), *floxuridine* (5-fluoro-2'-deoxyuridine, or 5-FUdR), and *idoxuridine* (5-iododeoxyuridine) (see Chapter 49). If one compares the van der Waals radii of the various 5-position substituents, the dimension of the fluorine atom resembles that of hydrogen, whereas the bromine and iodine atoms are larger and close in size to the methyl group. Thus, iododeoxyuridine behaves as an analog of thymidine, and its primary biological action results from its phosphorylation and ultimate incorporation into DNA in place of thymidylate. In 5-FU, the

smaller fluorine at position 5 allows the molecule to mimic uracil biochemically. However, the fluorine-carbon bond is much tighter than that of C—H and prevents the methylation of the 5 position of 5-FU by thymidylate synthase. Instead, in the presence of the physiological cofactor 5,10-methylene tetrahydrofolate, the fluoropyrimidine locks the enzyme in an inhibited state and prevents the synthesis of thymidylate, a required DNA precursor.

A number of 5-FU analogs have reached the clinic. The most important of these is *capecitabine* (N4-pentoxycarbonyl-5'-deoxy-5-fluorocytidine) (Figure 51-10), a drug active against colon and breast cancers. This orally administered agent is converted to 5'-deoxy-5-fluorocytidine by carboxylesterase activity in liver and other normal and malignant tissues. From that point, it is converted to 5'-deoxy-fluorodeoxyuridine by the ubiquitous cytosine deaminase. The final step in its activation occurs when thymidine phosphorylase cleaves off the 5'-deoxy sugar, leaving intracellular 5-FU. Tumors with elevated thymidine phosphorylase activity seem particularly susceptible to this drug (Ishikawa *et al.*, 1998).

Analogs of cytidine also are potent antitumor agents. Nucleotides in RNA and DNA contain ribose and 2'-deoxyribose, respectively. The replacement of the ribose of cytidine with arabinose has yielded a useful chemotherapeutic agent, cytarabine (Ara-C). As may be seen in Figure 51-10, the hydroxyl group in Ara-C is attached to the 2'-carbon in the β , or upward, configuration, as compared with the α , or downward, position of the 2'-hydroxyl in

Figure 51–11. Activation pathways for 5-fluorouracil (5-FU) and 5-floxuridine (FUR). ribose. The arabinose analog is recognized enzymatically as a 2'-deoxyriboside; it is phosphorylated to a nucleoside triphosphate that competes with deoxycytidine triphosphate (dCTP) for incorporation into DNA (Chabner, 2001). When incorporated into DNA, it blocks elongation of the DNA strand and its template function.

Other cytidine analogs have received extensive clinical evaluation. *Azacitidine* (5-azacytidine) and its deoxyanalogue, *decitabine*, inhibit DNA methyltransferase. They have antileukemic as well as differentiating actions. A newer analog, 2',2'-difluorodeoxycytidine (gemcitabine) (Figure 51–10), becomes incorporated into DNA and inhibits the elongation of nascent DNA strands. It has useful activity in various human solid tumors, including pancreatic, lung, and ovarian cancer.

Fluorouracil and Floxuridine (Fluorodeoxyuridine)

Mechanism of Action. Fluorouracil (5-FU) requires enzymatic conversion to the nucleotide (ribosylation and phosphorylation) in order to exert its cytotoxic activity (Figure 51–11). Several routes are available for the formation of floxuridine monophosphate (FUMP). 5-FU may be converted to fluorouridine by uridine phosphorylase and then to FUMP by uridine kinase, or it may react directly with 5-phosphoribosyl-1-pyrophosphate (PRPP), in a reaction catalyzed by orotate phosphoribosyl transferase, to form FUMP. Many metabolic pathways are available to FUMP. As the triphosphate FUTP it may be incorporated into RNA. An alternative reaction sequence crucial for antineoplastic activity involves reduction of FUDP by ribonucleotide reductase to the deoxynucleotide level and formation of fluorodeoxyuridine monophosphate (FdUMP). 5-FU also may be converted by thymidine phosphorylase to the deoxyriboside fluorodeoxyuridine (FdUR), and then by thymidine kinase to fluorodeoxyuridine monophosphate (FdUMP), a potent inhibitor of thymidylate synthase. This complex metabolic pathway for the generation of FdUMP may be bypassed through administration of floxuridine (fluorodeoxyuridine; FdUR), which is converted directly to FdUMP by thymidine kinase. FdUR is rarely used in clinical practice.

The interaction between FdUMP and TS blocks the synthesis of thymidine triphosphate (TTP), a necessary constituent of DNA (Figure 51–12). The folate cofactor, 5,10-methylenetetrahydrofolate, and FdUMP form a covalently bound ternary complex with TS. This inhibited complex resembles the transition state formed during the normal enzymatic reaction when dUMP is converted to thymidylate.

While the physiological complex of TS-folate-dUMP progresses to the synthesis of thymidylate by transfer of the methylene group and two hydrogen atoms from folate to dUMP, this reaction is blocked in the inhibited complex of TS-FdUMP-folate by the stability of the fluorine carbon bond on FdUMP; sustained inhibition of the enzyme results (Santi *et al.*, 1974).

5-FU also is incorporated into both RNA and DNA. In 5-FU-treated cells, both fluorodeoxyuridine triphosphate (FdUTP) and deoxyuridine triphosphate (dUTP) (the substrate that accumulates behind the blocked thymidylate synthase reaction) incorporate into DNA in place of the depleted physiological TTP. The significance of the incorporation of FdUTP and dUTP into DNA is unclear (Canman *et al.*, 1993). Presumably, the incorporation of deoxyuridylylate and/or fluorodeoxyuridylylate into DNA would call into action the excision–repair process. This process may result in DNA strand breakage because DNA repair requires TTP, but this substrate is

Other actions of 5-FU nucleotides:

- Inhibition of RNA processing
- Incorporation into DNA

Figure 51–12. lacking as a result of thymidylate synthase inhibition. 5-FU incorporation into RNA also causes toxicity as the result of major effects on both the processing and functions of RNA (Danenberg *et al.*, 1990).

A number of biochemical mechanisms have been identified that are associated with resistance to the cytotoxic effects of 5-FU or FdUR. These mechanisms include loss or decreased activity of the enzymes necessary for activation of 5-FU, amplification of TS (Washtein, 1982), and mutation of TS to a form that is not inhibited by FdUMP (Barbour *et al.*, 1990).

Both experimental studies and clinical trials support the position that the response to 5-FU correlates significantly with low levels of the degradative enzymes dihydrouracil dehydrogenase and thymidine phosphorylase, and a low level of expression of TS (Van Triest *et al.*, 2000). TS levels are finely controlled by an autoregulatory feedback mechanism wherein the unbound enzyme interacts with and inhibits the translational efficiency of its own mRNA, which provides for the rapid TS modulation needed for cellular division. When TS is bound to FdUMP, inhibition of translation is relieved, and levels of free TS rise, restoring thymidylate synthesis. Thus, TS autoregulation may be an important mechanism by which malignant cells become insensitive to the effects of 5-FU (Chu *et al.*, 1991).

Some malignant cells appear to have insufficient concentrations of 5,10-methylene tetrahydrofolate, and thus cannot form maximal levels of the inhibited ternary complex with TS. Addition of exogenous folate in the form of 5-formyl-tetrahydrofolate (leucovorin) increases formation of the complex and has enhanced responses to 5-FU in clinical trials (Grogan *et al.*, 1993). It is unclear the degree to which these mechanisms contribute to clinical resistance to 5-FU and its derivatives.

In addition to leucovorin, a number of other agents have been combined with 5-FU in attempts to enhance the cytotoxic activity through biochemical modulation. Methotrexate, by inhibiting purine synthesis and increasing cellular pools of PRPP, enhances the activation of 5-FU and increases antitumor activity of 5-FU when given prior to but not following 5-FU. In clinical trials, the combination of cisplatin and 5-FU has yielded impressive responses in tumors of the upper aerodigestive tract, but the molecular basis of their interaction is not well understood (Grem, 2001). Oxaliplatin is commonly used with 5-FU and leucovorin for treating metastatic colorectal cancer. The mechanism responsible for the synergistic clinical effect of adding oxaliplatin to 5-FU has not been fully elucidated. Experimental studies indicate that oxaliplatin may inhibit catabolism of 5-FU, perhaps by inhibiting dihydropyrimidine dehydrogenase (Fischel *et al.*, 2002). In addition, oxaliplatin also may inhibit expression of TS. Perhaps the most important interaction is the enhancement of irradiation by fluoropyrimidines, the basis for which is unclear. 5-FU with simultaneous irradiation is curative therapy for anal cancer and enhances local tumor control in head and neck, cervical, rectal, gastroesophageal, and pancreatic cancer.

Absorption, Fate, and Excretion. 5-FU is administered parenterally, since absorption after ingestion of the drug is unpredictable and incomplete. Metabolic degradation occurs in many tissues, particularly the liver. 5-FU is inactivated by reduction of the pyrimidine ring; this reaction is carried out by dihydropyrimidine dehydrogenase (DPD), which is found in liver, intestinal mucosa, tumor cells, and other tissues. Inherited deficiency of this enzyme leads to greatly increased sensitivity to the drug (Milano *et al.*, 1999). The rare individual who totally lacks this enzyme may experience profound drug toxicity following conventional doses of the drug. DPD deficiency can be detected either by enzymatic or molecular assays

using peripheral white blood cells, or by determining the plasma ratio of 5-FU to its metabolite, 5-fluoro-5,6-dihydrouracil, which is ultimately degraded to β -fluoro-alanine.

Rapid intravenous administration of 5-FU produces plasma concentrations of 0.1 to 1 mM; plasma clearance is rapid (half-life of 10 to 20 minutes). Urinary excretion of a single dose of 5-FU given intravenously amounts to only 5% to 10% in 24 hours. Although the liver contains high concentrations of DPD, dosage does not have to be modified in patients with hepatic dysfunction, presumably because of degradation of the drug at extrahepatic sites or by vast excess of this enzyme in the liver. Given by continuous intravenous infusion for 24 to 120 hours, 5-FU achieves plasma concentrations in the range of 0.5 to 8 μ M. 5-FU enters the CSF in minimal amounts. Concentrations greater than 0.01 μ M are sustained for up to 12 hours following conventional doses (Grem, 2001).

Capecitabine is well absorbed orally. It is rapidly de-esterified and deaminated, yielding high plasma concentrations of 5'-deoxy-fluorodeoxyuridine (5'-dFdU), which disappears with a half-life of about 1 hour. 5-FU levels are less than 10% of those of 5'-dFdU, reaching a maximum of 0.3 mg/L or 1 μ M at 2 hours. The conversion of 5'-dFdU to 5-FU by thymidine phosphorylase occurs in liver, peripheral tissues, and tumors. Liver dysfunction delays the conversion of the parent compound to 5'-dFdU and 5-FU, but there is no consistent effect on toxicity (Twelves *et al.*, 1999).

Therapeutic Uses. 5-Fluorouracil. 5-Fluorouracil produces partial responses in 10% to 20% of patients with metastatic colon carcinomas, upper gastrointestinal tract carcinomas, and breast carcinomas. The administration of 5-FU in combination with leucovorin in the adjuvant setting is associated with a survival advantage for patients with colorectal cancers and gastric cancers.

For average-risk patients in good nutritional status with adequate hematopoietic function, the weekly dosage regimen employs 500 to 600 mg/m² with leucovorin once each week for 6 of 8 weeks. Other regimens use daily doses of 500 mg/m² for 5 days, repeated in monthly cycles. When used with leucovorin, doses of daily 5-FU for 5 days must be reduced to 375 to 425 mg/m² because of mucositis and diarrhea. 5-FU is increasingly used as a biweekly loading dose followed by a 48-hour continuous infusion, a schedule that has less overall toxicity as well as superior response rates and progression-free survival for patients with metastatic colon cancer (De Gramont *et al.*, 1998).

Floxuridine (FUdR). FUdR (fluorodeoxyuridine; FUDR) is used primarily by continuous infusion into the hepatic artery for treatment of metastatic carcinoma of the colon or following resection of hepatic metastases (Kemeny *et al.*, 1999); the response rate to such infusion is 40% to 50%, or double that observed with intravenous administration. Intrahepatic arterial infusion for 14 to 21 days may be used with minimal systemic toxicity. However, there is a significant risk of biliary sclerosis if this route is used for multiple cycles of therapy. Treatment should be discontinued at the earliest manifestation of toxicity (usually stomatitis or diarrhea) because the maximal effects of bone marrow suppression and gut toxicity will not be evident until days 7 to 14.

Capecitabine (XELODA). Capecitabine is approved by the FDA for the treatment of (1) metastatic breast cancer in patients who have not responded to a regimen of paclitaxel and an anthracycline anti-

biotic; (2) metastatic breast cancer when used in combination with *docetaxel* in patients who have had a prior anthracycline-containing regimen; and (3) metastatic colorectal cancer for patients in whom fluoropyrimidine monotherapy is preferred. The recommended dose is 2500 mg/m² daily, given orally in two divided doses with food, for 2 weeks followed by a rest period of 1 week. This cycle is then repeated two more times.

Combination Therapy. Higher response rates are seen when 5-FU is used in combination with other agents, such as cyclophosphamide and methotrexate (breast cancer), cisplatin (head and neck cancer), and with oxaliplatin or irinotecan in colon cancer. The combination of 5-FU and oxaliplatin or irinotecan has become the standard first-line treatment for patients with metastatic colorectal cancer (Goldberg, 2004). The use of 5-FU in combination regimens has improved survival in the adjuvant treatment for breast cancer (Early Breast Cancer Trialists' Collaborative Group, 1988), and with oxaliplatin and leucovorin, for colorectal cancer (Andre, 2004). 5-FU also is a potent radiation sensitizer. Beneficial effects also have been reported when combined with irradiation for cancers of the esophagus, stomach, pancreas, cervix, anus, and head and neck. 5-FU is used widely with very favorable results for the topical treatment of premalignant keratoses of the skin and multiple superficial basal cell carcinomas.

Clinical Toxicities. The clinical manifestations of toxicity caused by 5-FU and floxuridine are similar and may be difficult to anticipate because of their delayed appearance. The earliest untoward symptoms during a course of therapy are anorexia and nausea; these are followed by stomatitis and diarrhea, which constitute reliable warning signs that a sufficient dose has been administered. Mucosal ulcerations occur throughout the gastrointestinal tract and may lead to fulminant diarrhea, shock, and death, particularly in patients who are DPD deficient. The major toxic effects of bolus-dose regimens result from the myelosuppressive action of 5-FU. The nadir of leukopenia usually is between days 9 and 14 after the first injection of drug. Thrombocytopenia and anemia also may occur. Loss of hair, occasionally progressing to total alopecia, nail changes, dermatitis, and increased pigmentation and atrophy of the skin may be encountered. Hand-foot syndrome consisting of erythema, desquamation, pain, and sensitivity to touch of the palms and soles also can occur. Neurological manifestations, including an acute cerebellar syndrome, have been reported, and myelopathy has been observed after the intrathecal administration of 5-FU. Cardiac toxicity, particularly acute chest pain with evidence of ischemia in the electrocardiogram, also may occur. In general, myelosuppression, mucositis, and diarrhea occur less often with infusional regimens than bolus regimens, while hand-foot syndrome occurs more often with infusional regimens than bolus regimens. The low therapeutic indices of these agents emphasize the need for very skillful supervision by physicians familiar with the action of the fluorinated pyrimidines and the possible hazards of chemotherapy.

Capecitabine causes much the same spectrum of toxicities as 5-FU (diarrhea, myelosuppression), but the hand-foot syndrome

occurs more frequently and may require dose reduction or cessation of therapy.

CYTIDINE ANALOGS

Cytarabine (Cytosine Arabinoside; Ara-C)

Cytarabine (1- β -D-arabinofuranosylcytosine; Ara-C) is the most important antimetabolite used in the therapy of acute myelocytic leukemia (AML). It is the single most effective agent for induction of remission in this disease.

Mechanism of Action. This compound is an analog of 2'-deoxycytidine with the 2'-hydroxyl in a position *trans* to the 3'-hydroxyl of the sugar, as shown in Figure 51-9. The 2'-hydroxyl hinders rotation of the pyrimidine base around the nucleosidic bond and interferes with base stacking.

Ara-C penetrates cells by a carrier-mediated process shared by physiological nucleosides. Several candidate carriers bring nucleosides into cells. In infants and adults with ALL and the t(4;11) MLL translocation, high-dose Ara-C is particularly effective; in these patients, the nucleoside transporter, hENT1, is highly expressed (Pui *et al.*, 2004), and its expression correlates with sensitivity to Ara-C. hENT1 inhibition by nitrobenzylmercaptapurine riboside (NBMPR) prevents Ara-C toxicity to both ALL and AML cells. At extracellular drug concentrations above 10 μ M (levels achievable with high-dose Ara-C), the nucleoside transporter no longer limits drug accumulation, and intracellular metabolism to a triphosphate becomes rate limiting.

As with most purine and pyrimidine antimetabolites, Ara-C must be "activated" by conversion to the 5'-monophosphate nucleotide (Ara-CMP), a reaction catalyzed by deoxycytidine kinase. Ara-CMP can then react with appropriate deoxynucleotide kinases to form the diphosphate and triphosphates (Ara-CDP and Ara-CTP). Ara-CTP competes with the physiological substrate deoxycytidine 5'-triphosphate (dCTP) for incorporation into DNA by DNA polymerases. The incorporated Ara-CMP residue is a potent inhibitor of DNA polymerase, both in replication and repair. Inhibition of DNA synthesis correlates with the total Ara-C incorporated into DNA. Thus, incorporation of about five molecules of Ara-C per 10⁴ bases of DNA decreases cellular clonogenicity by about 50% (Kufe *et al.*, 1984).

Ara-C induces terminal differentiation of leukemic cells in tissue culture, an effect that is accompanied by decreased *c-myc* oncogene expression (Bianchi Scarra *et al.*, 1986). These changes in morphology, differentiation, and oncogene expression occur at concentrations above the threshold for cytotoxicity and may simply represent terminal injury of cells. However, molecular analysis of bone marrow specimens from some leukemic patients in remission after Ara-C therapy has revealed persistence of leukemic markers, suggesting that differentiation may have occurred.

The contribution of each of the above actions to cellular death caused by Ara-C is not fully understood. Fragmentation of DNA is observed in Ara-C-treated cells, and there is cytological and biochemical evidence for apoptosis in both tumor and normal tissues (Smets, 1994).

Ara-C exposure activates a complex system of secondary intracellular signals that determine whether a cell survives or undergoes

apoptosis. It activates the transcription factor AP-1 and stimulates the formation of ceramide, a potent inducer of apoptosis. On the other hand, it promotes an increase in PKC and the cell damage response factor NF- κ B in leukemic cells. Finally, the level of expression of BCL-2 and BCL-X_L proteins correlates with relative sensitivity to Ara-C (Ibrado *et al.*, 1996). Thus, the lethal actions may depend on its relative effects on pro-apoptotic and damage response pathways.

In addition to transport and biochemical factors that determine response, cell kinetic properties exert an important influence on the results of Ara-C treatment. It is likely that continued inhibition of DNA synthesis for a duration equivalent to at least one cell cycle is necessary to expose cells during the S, or DNA-synthetic, phase of the cycle. The mean cycle time of acute myelocytic leukemia cells is 1 to 2 days. The optimal interval between bolus doses of Ara-C is about 8 to 12 hours, a schedule that maintains intracellular concentrations of Ara-CTP at inhibitory levels for at least one cell cycle. Typical schedules for administration of Ara-C employ bolus doses every 12 hours for 5 to 7 days or a continuous infusion for 7 days.

Particular subtypes of AML derive benefit from high-dose Ara-C treatment; these include t(8;21), inv(16), t(9;16), and del(16), all of which involve core-binding factors that regulate hematopoiesis (Widemann, 1997).

Mechanisms of Resistance to Cytarabine. Response to Ara-C is strongly influenced by the relative activities of anabolic and catabolic enzymes that determine the proportion of drug converted to Ara-CTP. The rate-limiting enzyme is deoxycytidine kinase, which produces Ara-CMP. An important degradative enzyme is cytidine deaminase, which deaminates Ara-C to a nontoxic metabolite, arauridine. Cytidine deaminase is found in high activity in many tissues, including some human tumors. A second degradative enzyme, dCMP deaminase, converts Ara-CMP to the inactive metabolite, Ara-UMP. Increased synthesis and retention of Ara-CTP in leukemic cells is associated with a longer duration of complete remission in patients with AML (Preisler *et al.*, 1985). As discussed above, the ability of cells to transport Ara-C also affects the clinical response.

Because drug concentration in plasma rapidly falls below the level needed to saturate transport and activation processes, clinicians have employed high-dose regimens (2 to 3 g/m² every 12 hours for 6 doses) to achieve 20- to 50 times higher serum levels with improved results in remission induction and consolidation (Mayer *et al.*, 1994) for AML.

Absorption, Fate, and Excretion. Due to the presence of high concentrations of cytidine deaminase in the gastrointestinal mucosa and liver, only about 20% of the drug reaches the circulation after oral Ara-C administration; thus, the drug must be given intravenously. Peak concentrations of 2 to 50 μ M are measurable in plasma after intravenous injection of 30 to 300 mg/m² but disappear rapidly (half-life of 10 minutes) from plasma. Less than 10% of the injected dose is excreted unchanged in the urine within 12 to 24 hours, while most appears as the inactive deaminated product, arabinosyl uracil. Higher concentrations of Ara-C are found in CSF after continuous infusion than after rapid intravenous injection. After intrathecal administration of the drug at a dose of 50 mg/m², relatively little deamination occurs, even after 7 hours, and peak concentrations of 1 to 2 μ M are achieved that decline slowly with a half-life of approximately 3.4 hours. Concentrations above the threshold for cytotoxicity (0.4 μ M) are maintained in the CSF for 24 hours or longer. More recently, a formulation of Ara-C (DEPOCYT) has been

developed for sustained release into the cerebrospinal fluid. After a standard 50-mg dose, cytarabine concentration is maintained at cytotoxic levels for an average of 12 days, thus avoiding the need for repeated lumbar punctures. A possible benefit in terms of time to neurologic progression was suggested in a preliminary study comparing the administration of the sustained-release formulation, 50 mg every 2 weeks, with the standard intrathecal formulation in patients with lymphomatous meningitis (Glantz *et al.*, 1999). It also appears to give equivalent results to standard intrathecal methotrexate in patients with carcinomatous meningitis (Cole *et al.*, 2003).

Therapeutic Uses. Two standard dosage schedules are recommended for administration of cytarabine (CYTOSAR-U, TARABINE PFS, others): (1) rapid intravenous infusion of 100 mg/m² every 12 hours for 5 to 7 days; or (2) continuous intravenous infusion of 100 to 200 mg/m² daily for 5 to 7 days. In general, children tolerate higher doses than do adults. Intrathecal doses of 30 mg/m² every 4 days have been used to treat meningeal leukemia. The intrathecal administration of 50 to 70 mg of the liposomal formulation of cytarabine (DEPOCYT) every 2 weeks seems to be equally effective as the every-four-day regimen.

Conventional cytarabine is indicated for induction and maintenance of remission in acute nonlymphocytic leukemia and is useful in the treatment of other leukemias, such as ALL, AML, and CML in the blast phase. Intrathecal cytarabine is indicated for meningeal leukemia. A depot formulation of cytarabine is indicated for the intrathecal treatment of lymphomatous meningitis and may be useful for carcinomatous meningitis.

Clinical Toxicities. Cytarabine is a potent myelosuppressive agent capable of producing acute, severe leukopenia, thrombocytopenia, and anemia with striking megaloblastic changes. Other toxic manifestations include gastrointestinal disturbances, stomatitis, conjunctivitis, reversible hepatic enzyme elevations, noncardiogenic pulmonary edema, and dermatitis. Cerebellar toxicity, manifest as ataxia and slurred speech, and cerebral toxicity, including seizures, dementia, and coma, may follow intrathecal administration or high-dose systemic administration to patients older than 50 years of age and/or patients with poor renal function.

Azacitidine (5-Azacitidine)

5-Azacitidine and the closely related investigational drug decitabine (2'-deoxy-5-azacitidine), have antileukemic activity and induce differentiation. 5-Azacitidine is approved for treatment of myelodysplasia, for which it induces normalization of bone marrow in 15% to 20% of patients and a reduction in transfusion requirement in one-third of patients. It becomes incorporated into RNA and DNA and inhibits methylation of DNA, inducing the expression of silenced genes. Thus, it also is used for inducing fetal hemoglobin synthesis in sickle cell anemia, although it has been largely replaced for this indication by hydroxyurea. It undergoes very rapid deamination by cytidine deaminase, the product hydrolyzing to inactive metabolites. Its major toxicities include myelosuppression, and rather severe nausea and vomiting when given

intravenously in large doses (150 to 200 mg/m² per day for 5 days). In low-dose daily subcutaneous regimens for myelodysplasia, 30 mg/m² per day, it is well tolerated.

Gemcitabine

Gemcitabine (2',2' difluorodeoxycytidine; dFdC), a difluoro analog of deoxycytidine, has become an important drug for patients with metastatic pancreatic cancer, non-small cell lung cancer, ovarian, bladder, esophageal, and head and neck cancer (Hertel *et al.*, 1990).

Mechanism of Action. Gemcitabine enters cells *via* active nucleoside transporters (Mackey *et al.*, 1998). Intracellularly, deoxycytidine kinase phosphorylates gemcitabine to produce difluorodeoxycytidine monophosphate (dFdCMP), from which point it is converted to difluorodeoxycytidine di- and triphosphate (dFdCDP and dFdCTP). While its anabolism and effects on DNA in general mimic those of cytarabine, there are differences in kinetics of inhibition, additional sites of action, effects of incorporation into DNA, and spectrum of clinical activity (Iwasaki *et al.*, 1997). Unlike cytarabine, the cytotoxicity of gemcitabine is not confined to the S phase of the cell cycle, and the drug is equally effective against confluent cells and cells in logarithmic growth phase. The cytotoxic activity may be a result of several actions on DNA synthesis: dFdCTP competes with dCTP as a weak inhibitor of DNA polymerase; dFdCDP is a potent inhibitor of ribonucleotide reductase, resulting in depletion of deoxyribonucleotide pools necessary for DNA synthesis; and dFdCTP is incorporated into DNA and after the incorporation of one more additional nucleotide leads to DNA strand termination (Heinemann *et al.*, 1988). This “extra” nucleotide may be important in hiding the dFdCTP from DNA repair enzymes, as the incorporated dFdCMP appears to be resistant to repair. The ability of cells to incorporate dFdCTP into DNA is critical for gemcitabine-induced apoptosis (Huang and Plunkett, 1995).

Absorption, Fate, and Elimination. Gemcitabine is administered as an intravenous infusion. The pharmacokinetics of the parent compound are largely determined by deamination, and the predominant urinary elimination product is the inactive metabolite difluorodeoxyuridine (dFdU). Gemcitabine has a short plasma half-life of approximately 15 minutes, with women and elderly subjects having slower clearance (Abbruzzese *et al.*, 1991). Clearance is dose-independent but can vary widely among individuals.

Similar to that of cytarabine, conversion of gemcitabine to dFdCMP by deoxycytidine kinase is saturated at infusion rates of approximately 10 mg/m² per minute, which produce plasma drug concentrations in the range of 15 to 20 μM (Grunewald *et al.*, 1991; Grunewald *et al.*, 1992). In an attempt to increase dFdCTP formation, the duration of infusion at this maximum concentration has been extended to 150 minutes. In contrast to a fixed infusion duration of 30 minutes, the 150-minute infusion produces a higher level of dFdCTP within peripheral blood mononuclear cells, increases the degree of myelosuppression, but has uncertain effects on antitumor activity (Tempero *et al.*, 2003).

The activity of dFdCTP on DNA repair mechanisms may allow for increased cytotoxicity of other chemotherapeutic agents, particularly platinum compounds. Preclinical studies of tumor cell lines

show that cisplatin-DNA adducts are enhanced in the presence of gemcitabine, presumably through suppression of nuclear excision repair (Van Moorsel *et al.*, 1999).

Therapeutic Uses. The standard dosing schedule for gemcitabine (GEMZAR) is a 30-minute intravenous infusion of 1 to 1.2 g/m² on days 1, 8, and 15 of each 28-day cycle.

Clinical Toxicities. The principal toxicity of gemcitabine is myelosuppression. In general, the longer-duration infusions lead to greater myelosuppression. Nonhematologic toxicities including a flu-like syndrome, asthenia, and mild elevation in liver transaminases may occur in 40% or more of patients. Although severe nonhematologic toxicities are rare, interstitial pneumonitis may occur and is responsive to steroids. Rarely, patients on gemcitabine treatment for many months may develop a slowly progressive hemolytic uremic syndrome, necessitating drug discontinuation. (Humphreys *et al.*, 2004). Gemcitabine is a very potent radiosensitizer and should not be used with radiotherapy except in closely monitored clinical trials (Lawrence *et al.*, 1999).

PURINE ANALOGS

The pioneering studies of Hitchings and Elion begun in 1942 identified analogues of naturally occurring purine bases with antileukemic and immunosuppressant properties. Their work led to the development of drugs used not only in the treatment of malignant diseases (mercaptopurine, thioguanine), but also for immunosuppression (azathioprine) and antiviral chemotherapy (*acyclovir*, *ganciclovir*, *vidarabine*, and *zidovudine*) (Figure 51–13). The hypoxanthine analog *allopurinol*, a potent inhibitor of xanthine oxidase, is an important by-product of this effort (*see* Chapter 26). Other purine analogs have found important use in cancer therapy. These include pentostatin (2'-deoxycoformycin), the first effective agent against hairy cell leukemia. Pentostatin has largely been replaced by another adenosine analog, *cladribine*, while the closely related fludarabine phosphate has become a standard treatment for chronic lymphocytic leukemia (CLL) and follicular lymphomas (Beutler, 1992).

6-Thiopurine Analogs

Structure–Activity Relationship. 6-Mercaptopurine (6-MP) and 6-thioguanine (6-TG) are approved agents for human leukemias, and function as analogs of the natural purines, hypoxanthine and guanine. The substitution of sulfur for oxygen on C6 of the purine ring creates compounds that are readily converted to nucleotides in normal and malignant cells. Nucleotides formed from 6-MP and 6-TG inhibit *de novo* purine synthesis and also become incorporated into nucleic acids. The structural formula of 6-MP and other purine analogs is shown in Figure 51–13.

Figure 51-13. Structural formulas of adenosine and various purine analogs.

Mechanism of Action. Both 6-TG and 6-MP are excellent substrates for hypoxanthine guanine phosphoribosyl transferase (HGPRT) and are converted in a single step to the ribonucleotides 6-thioguanosine-5'-monophosphate (6-thioGMP) and 6-thioinosine-5'-monophosphate (T-IMP), respectively. Because T-IMP is a poor substrate for guanylyl kinase, the enzyme that converts guanosine monophosphate (GMP) to guanosine diphosphate (GDP), T-IMP accumulates intracellularly. Small amounts of 6-MP, however, also can be incorporated into cellular DNA in the form of thio guanine deoxyribonucleotide. T-IMP inhibits the first step in the *de novo* synthesis of the purine base. The formation of ribosyl-5-phosphate, as well as conversion of inosine-5'-monophosphate (IMP) to adenine and guanine nucleotides, also are inhibited. Of these, the most important point of attack seems to be the reaction of glutamine and 5-phosphoribosyl-1-pyrophosphate (PRPP) to form ribosyl-5-phosphate, the first committed step in the *de novo* pathway.

Despite extensive investigations, the role of incorporation of thiopurines into cellular DNA in the production of either the therapeutic or toxic effects remains unknown (Bo *et al.*, 1999). The incidence of pregnancy-related complications, however, was significantly increased when fathers used mercaptopurine within 3 months of conception (Rajapakse *et al.*, 2000). These compounds can cause marked inhibition of the coordinated induction of various enzymes required for DNA synthesis, as well as potentially critical alterations in the synthesis of polyadenylate-containing RNA (Giverhaug *et al.*, 1999).

Mechanisms of Resistance to the Thiopurine Antimetabolites. As with other tumor-inhibiting antimetabolites, acquired resistance is a major obstacle with the purine analogs. The most commonly encountered mechanism of 6-MP resistance observed *in vitro* is deficiency or complete lack of the activating enzyme, HGPRT.

Another mechanism of 6-MP resistance identified in cells from leukemic patients is an increase in particulate alkaline phosphatase activity. Other potential mechanisms for resistance to 6-MP include (1) decreased drug transport; (2) alteration in allosteric inhibition of ribosylamine 5-phosphate synthase; (3) altered recognition of DNA breaks and mismatches induced by 6-MP; and (4) increased activity of multidrug resistance protein 5, which exports nucleoside analogs (Wijnholds *et al.*, 2000).

Mercaptopurine Pharmacokinetics and Toxicity.

Absorption of mercaptopurine is incomplete after oral ingestion and bioavailability is reduced by first-pass metabolism by xanthine oxidase in the liver. Oral bioavailability is only 10% to 50%, with great interpatient variability and decreased absorption in the presence of food or oral antibiotics. Thus, when used in combination with other drugs, doses should be titrated according to the white blood cell and platelet counts. Bioavailability is increased when mercaptopurine is combined with high-dose methotrexate (Innocenti *et al.*, 1996).

After an intravenous dose, the half-life of the drug in plasma is relatively short (about 50 minutes in adults), due to rapid metabolic degradation by xanthine oxidase and by thiopurine methyltransferase. Restricted brain distribution of mercaptopurine results from an efficient efflux transport system in the blood-brain barrier (Deguchi *et al.*, 2000). In addition to the HGPRT-catalyzed anabolism of mercaptopurine, there are two other pathways for its metabolism. The first involves methylation of the sulfhydryl group and subsequent oxidation of the methylated derivatives. Expression of the enzyme thiopurine methyltransferase reflects the inheritance of polymorphic alleles (Relling *et al.*, 1999); up to 15% of the Caucasian population have decreased enzyme activity. Low levels of erythrocyte thiopurine methyltransferase activity are associated with increased drug toxicity in individual patients and a lower risk of relapse (Pui *et al.*, 2004). High concentrations of 6-methylmercaptopurine nucleotides are formed following 6-MP administration. Substantial amounts of the mono-, di-, and triphosphate nucleotides of 6-methylmercaptopurine ribonucleoside (6-MMPR) have been identified in cells in the blood and bone marrow of patients treated with mercaptopurine or azathioprine. They are less potent than 6-MP nucleotides as metabolic inhibitors, and their significance in contributing to the activity of 6-MP is not known. A relatively large percentage of the administered sulfur is excreted as inorganic sulfate, the result of enzymatic desulfuration.

The second major pathway for 6-MP metabolism involves its oxidation by xanthine oxidase to 6-thiouric acid, an inactive metabolite. Oral doses of 6-MP should be reduced by 75% in patients receiving the xanthine oxidase inhibitor allopurinol.

Therapeutic Uses. The initial average daily oral dose of mercaptopurine (6-mercaptopurine; PURINETHOL) is 50 to 100 mg/m², and

is adjusted according to white blood cell count and platelet count. The total dose required to produce depression of the bone marrow in patients with nonhematological malignancies is about 45 mg/kg and may range from 18 to 100 mg/kg.

Hyperuricemia with hyperuricosuria may occur during treatment; the accumulation of uric acid presumably reflects the destruction of cells with release of purines that are oxidized by xanthine oxidase and an inhibition of the conversion of inosinic acid to nucleic acid precursors. This circumstance may be an indication for the use of allopurinol. Special caution must be employed if mercaptopurine or its imidazolyl derivative, azathioprine, is used with allopurinol, because the associated delay in catabolism of the purine analog (*see above*) increases the likelihood of severe toxicity. Patients treated simultaneously with both drugs should receive approximately 25% of the usual dose of mercaptopurine.

The combination of methotrexate and 6-MP appears to be synergistic, based on the effects of methotrexate inhibition of purine synthesis. By inhibiting the earliest steps in purine synthesis, methotrexate elevates the intracellular concentration of PRPP, which is required for 6-MP activation.

Clinical Toxicities. The principal toxicity of 6-MP is bone marrow depression, although in general this side effect develops more gradually than with folic acid antagonists; accordingly, thrombocytopenia, granulocytopenia, or anemia may not be encountered for several weeks. When depression of normal bone marrow elements occurs, dose reduction usually results in prompt recovery. Anorexia, nausea, or vomiting is seen in approximately 25% of adults, but stomatitis and diarrhea are rare; manifestations of gastrointestinal effects are less frequent in children than in adults. Jaundice and hepatic enzyme elevations occur in up to one-third of adult patients treated with 6-MP, and usually resolve upon discontinuation of therapy. Their appearance has been associated with bile stasis and hepatic necrosis on biopsy. The long-term complications associated with the use of 6-MP and its derivative, azathioprine, are opportunistic infection and an increased incidence of squamous cell malignancies of skin (Korelitz *et al.*, 1999). Teratogenic effects during the first trimester are associated with chronic 6-MP, and AML has been reported after prolonged use of 6-MP for Crohn's disease (Heizer and Peterson, 1998).

Fludarabine Phosphate

A fluorinated deamination-resistant nucleotide analog of the antiviral agent vidarabine (9- β -D-arabinofuranosyl-adenine), this compound is active in CLL and low-grade lymphomas (Zinzani *et al.*, 2000). After rapid extracellular dephosphorylation to the nucleoside fludarabine, it is rephosphorylated intracellularly by deoxycytidine kinase to the active triphosphate derivative. This antimetabolite inhibits DNA polymerase, DNA primase, DNA ligase, and ribonucleotide reductase, and is incorporated into DNA and RNA. The triphosphate nucleotide is an effective chain terminator when incorporated into DNA (Kamiya *et al.*, 1996), and the incorporation of fludarabine into RNA inhibits RNA function, RNA processing, and mRNA translation (Plunkett

and Gandhi, 1993). A major effect of this drug may be its activation of apoptosis, which may explain its activity against indolent lymphoproliferative disease, where only a small fraction of cells are in S phase (Dighiero, 1996). In experimental tumors, resistance to fludarabine is associated with decreased activity of deoxycytidine kinase, the enzyme that phosphorylates the drug (Mansson *et al.*, 2003).

The structural formulas of fludarabine phosphate and a related adenosine analog, cladribine, are:

Absorption, Fate, and Excretion. Fludarabine phosphate is administered intravenously and is rapidly converted to fludarabine in the plasma. The terminal half-life of fludarabine is approximately 10 hours. The compound is primarily eliminated by renal excretion, and approximately 23% appears in the urine as fludarabine because of its relative resistance to deamination by adenosine deaminase.

Therapeutic Uses. Fludarabine phosphate (FLUDARA) is available for intravenous use. The recommended dose of fludarabine phosphate is 20 to 30 mg/m² daily for 5 days. The drug is administered intravenously by infusion during a period of 30 minutes to 2 hours. Dosage may need to be reduced in renal impairment. Treatment may be repeated every 4 weeks, and at these doses gradual improvement usually occurs during a period of two to three cycles.

Fludarabine phosphate is used primarily for the treatment of patients with CLL, although experience is accumulating that suggests effectiveness in B-cell lymphomas refractory to standard therapy. In CLL patients previously refractory to a regimen containing a standard alkylating agent, response rates of 32% to 48% have been reported. Activity also has been seen with indolent non-Hodgkin's lymphoma, promyelocytic leukemia, cutaneous T-cell lymphoma, and Waldenström's macroglobulinemia. In patients with previously untreated low-grade lymphomas, fludarabine phosphate in combination with either cyclophosphamide or with dexamethasone and mitoxantrone, has resulted in a high rate of response. (Emmanouilides *et al.*, 1998). There is growing interest in its use as a potent immunosuppressive agent, with high-dose alkylators, in nonmyeloablative stem cell transplantation (Taussig *et al.*, 2003).

Clinical Toxicities. Toxic manifestations include myelosuppression, nausea and vomiting, chills and fever, malaise, anorexia, and weakness. Lymphopenia and thrombocytopenia are dose limiting and possibly cumulative (Malspeis *et al.*, 1990). CD4-positive T cells are depleted with therapy. Opportunistic infections and tumor lysis syndrome have been reported (Cheson *et al.*, 1999). Peripheral neuropathy may occur at standard doses. Altered mental status, seizures, optic neuritis, and coma have been observed at higher doses and in older patients. Rarely, CLL patients may develop an acute hemolytic anemia or pure red cell aplasia during fludarabine treatment. Severe pneumonitis that is responsive to corticosteroids has been encountered (Stoica *et al.*, 2002). Because a significant fraction of drug (about one-quarter) is eliminated in the urine, patients with compromised renal function should be treated with caution, and initial doses should be reduced in proportion to serum creatinine levels.

Cladribine

An adenosine deaminase-resistant purine analog, cladribine (2-chlorodeoxyadenosine; 2-CdA) has demonstrated potent activity in hairy cell leukemia, CLL, and low-grade lymphomas. After intracellular phosphorylation by deoxycytidine kinase and conversion to cladribine triphosphate, it is incorporated into DNA. It produces DNA strand breaks and depletion of NAD and ATP, as well as apoptosis, and is a potent inhibitor of ribonucleotide reductase (Beutler, 1992). The drug does not require cell division to be cytotoxic. Resistance is associated with loss of the activating enzyme, deoxycytidine kinase, or escape of ribonucleotide reductase from inhibition (Cardoen *et al.*, 2001).

The structural formula of cladribine is shown above with that of fludarabine-5'-phosphate.

Absorption, Fate, and Excretion. Cladribine is moderately well absorbed orally (55%), but is routinely administered intravenously. The drug is excreted by the kidneys, with a terminal half-life in plasma of 6.7 hours (Liliemark and Juliusson, 1991). Cladribine crosses the blood-brain barrier and reaches CSF concentrations of about 25% of those seen in plasma. In patients with meningeal involvement, however, CSF concentrations can approach those in plasma.

Therapeutic Uses. Cladribine (LEUSTATIN) is administered as a single course of 0.09 mg/kg per day for 7 days by continuous intravenous infusion.

Cladribine is considered the drug of choice in hairy cell leukemia. Eighty percent of patients achieve a complete response after a single course of therapy (Dearden *et al.*, 1999). The drug also is active in CLL, and is a secondary agent in other leukemias and low-grade lymphomas, Langerhans cell histiocytosis, cutaneous T-cell lymphomas including mycosis fungoides and the Sézary syndrome, and Waldenström's macroglobulinemia (Tondini *et al.*, 2000; Saven and Burian, 1999).

Clinical Toxicities. The major dose-limiting toxicity of cladribine is myelosuppression. Cumulative thrombocytopenia may occur with

repeated courses. Opportunistic infections are common and are correlated with decreased CD4⁺ cell counts. Other toxic effects include nausea, infections, high fever, headache, fatigue, skin rashes, and tumor lysis syndrome. Neurological and immunosuppressive adverse effects are less evident than with pentostatin at clinically active doses.

Pentostatin (2'-Deoxycoformycin)

Pentostatin, a transition-state analog of the intermediate in the adenosine deaminase (ADA) reaction, is a potent inhibitor of ADA. Its effects mimic the phenotype of genetic ADA deficiency, which is associated with severe immunodeficiency affecting both T- and B-cell functions. It was isolated from fermentation cultures of *Streptomyces antibioticus*. Inhibition of ADA by pentostatin leads to accumulation of intracellular adenosine and deoxyadenosine nucleotides, which can block DNA synthesis by inhibiting ribonucleotide reductase. Deoxyadenosine also inactivates *S*-adenosyl homocysteine hydrolase. The resulting accumulation of *S*-adenosyl homocysteine is particularly toxic to lymphocytes. Pentostatin also can inhibit RNA synthesis, and its triphosphate derivative is incorporated into DNA, resulting in strand breakage (Stoica *et al.*, 2002). In combination with 2'-deoxyadenosine, it is capable of inducing apoptosis in human monocytoid leukemia cells (Niitsu *et al.*, 1998). Although the precise mechanism of cytotoxicity is not known, it is probable that the imbalance in purine nucleotide pools accounts for its antineoplastic effect in hairy cell leukemia and T-cell lymphomas.

The structural formula of pentostatin (2'-deoxycoformycin) is shown in Figure 51-13.

Absorption, Fate, and Excretion. Pentostatin is administered intravenously, and a single dose of 4 mg/m² has been reported to have a mean terminal half-life of 5.7 hours. The drug is eliminated almost entirely by renal excretion. Proportional reduction of dosage is recommended in patients with renal impairment as measured by reduced creatinine clearance.

Therapeutic Uses. Pentostatin (NIPENT) is available for intravenous use. The recommended dosage is 4 mg/m² administered every other week. After hydration with 500 to 1000 ml of 5% dextrose in half-normal (0.45%) saline, the drug is administered by rapid intravenous injection or by infusion during a period of up to 30 minutes, followed by an additional 500 ml of fluids. Extravasation does not produce tissue necrosis.

Pentostatin is extremely effective in producing complete remissions in hairy cell leukemia (Grever *et al.*, 2003). Complete responses of 58% and partial responses of 28% have been reported, even in patients who were refractory to interferon- α . Activity also is seen against CLL, CML, promyelocytic leukemia, cutaneous T-cell lymphoma, non-Hodgkin's lymphoma, and Langerhans cell histiocytosis (Dillman, 1994; Cortes *et al.*, 1997). Pentostatin has no significant activity against solid tumors or multiple myeloma.

Clinical Toxicities. Toxic manifestations include myelosuppression, gastrointestinal symptoms, skin rashes, and abnormal liver function studies at standard (4 mg/m²) doses. Depletion of normal T cells occurs at these doses, and neutropenic fever and opportunistic infections have been reported (Steis *et al.*, 1991). Immunosuppression may persist for several years after discontinuation of pentostatin therapy. At higher doses (10 mg/m²), major renal and neurological complications are encountered. The use of pentostatin in combination with fludarabine phosphate may result in severe or even fatal pulmonary toxicity.

III. NATURAL PRODUCTS

ANTIMITOTIC DRUGS

Vinca Alkaloids

History. The beneficial properties of the Madagascar periwinkle plant, *Catharanthus roseus* (formerly called *Vinca rosea*), a species of myrtle, have been described in medicinal folklore. While exploring claims that extracts of the periwinkle might have beneficial effects in diabetes mellitus, Noble and coworkers observed granulocytopenia and bone marrow suppression in rats. Purified alkaloids caused regression of an acute lymphocytic leukemia in mice. These extracts yielded four active dimeric alkaloids: vinblastine, vincristine, *vinleurosine*, and *vinrosidine*. Vinblastine and vincristine are important clinical agents for treatment of leukemias, lymphomas, and testicular cancer. A closely related derivative, *vinorelbine*, has important activity against lung cancer and breast cancer (Budman, 1997).

Chemistry. The vinca alkaloid antimitotic agents are asymmetrical dimeric compounds; the structures of vinblastine, vincristine, vindesine, and vinorelbine are:

	R ₁	R ₂	R ₃
Structure A			
VINBLASTINE	—CH ₃	—C(=O)—OCH ₃	—O—C(=O)—CH ₃
VINCRIStINE	—CH(=O)	—C(=O)—OCH ₃	—O—C(=O)—CH ₃
VINDESINE	—CH ₃	—C(=O)—NH ₂	—OH
Structure B			
VINORELBINE	—CH ₃	—C(=O)—OCH ₃	—O—C(=O)—CH ₃

Mechanism of Action. The vinca alkaloids are cell-cycle-specific agents, and in common with other drugs such as *colchicine*, *podophyllotoxin*, and taxanes, block cells in mitosis. The biological activities of the vincas can be explained by their ability to bind specifically to β -tubulin and to block its ability to polymerize with α -tubulin into microtubules. When cells are incubated with vinblastine, the microtubules dissolve and highly regular crystals form, containing 1 mole of bound vinblastine per mole of tubulin. Cell division is arrested in metaphase. In the absence of an intact mitotic spindle, duplicated chromosomes cannot align along the division plate. They disperse throughout the cytoplasm (exploded mitosis) or may clump in unusual groupings, such as balls or stars. Cells blocked in mitosis undergo changes characteristic of apoptosis (Smets, 1994).

In addition to their key role in the formation of mitotic spindles, microtubules are found in high concentration in the brain and are essential to other cellular functions such as movement, phagocytosis, and axonal transport. Side effects of the vinca alkaloids, such as their neurotoxicity, may be due to disruption of these functions.

Drug Resistance. Despite their structural similarity, the vinca alkaloids have unique individual patterns of clinical effectiveness (*see below*). However, in most experimental systems, they share cross-resistance. Their antitumor effects are blocked by multidrug resistance, in which tumor cells become cross-resistant to a wide range of chemically dissimilar agents after exposure to a single (natural product) drug. Such multidrug-resistant tumor cells display cross-resistance to vinca alkaloids, the epipodophyllotoxins, anthracyclines, and taxanes. Chromosomal abnormalities consistent with gene amplification have been observed in resistant cells in culture, and the cells contain markedly increased levels of the P-glycoprotein, a membrane efflux pump that transports drugs from the cells (Endicott and Ling, 1989). Calcium channel block-

ers such as *verapamil* can reverse resistance of this type. Other membrane transporters such as the multidrug resistance–associated protein (MRP) (Kuss *et al.*, 1994), and the closely related breast cancer resistance protein, may mediate multidrug resistance. Still other forms of resistance to vinca alkaloids stem from mutations in β -tubulin or in the relative expression of isoforms of β -tubulin; both changes prevent the effective binding of the inhibitors to their target.

Cytotoxic Actions. Vincristine is a standard component of regimens for treating pediatric leukemias, lymphomas, and solid tumors. In large-cell non-Hodgkin's lymphomas, vincristine remains an important agent, particularly when used in the CHOP regimen with cyclophosphamide, doxorubicin, and prednisone. As mentioned previously, vincristine is more useful for remission induction in lymphocytic leukemia. Vincristine also is a standard component of a number of regimens used to treat pediatric solid tumors such as Wilms' tumor, neuroblastoma, and rhabdomyosarcoma.

Vinblastine is employed in treating bladder cancer, testicular carcinomas, and Hodgkin's disease. Vinorelbine has activity against non–small cell lung cancer and breast cancer. The very limited myelosuppressive action of vincristine makes it a valuable component of a number of combination therapy regimens for leukemia and lymphoma, while the lack of neurotoxicity of vinblastine is a decided advantage in lymphomas and in combination with cisplatin against testicular cancer. Vinorelbine, which causes a mild neurotoxicity as well as myelosuppression, has an intermediate toxicity profile.

Myelosuppression. The nadir of leukopenia following vinblastine or vinorelbine occurs 7 to 10 days following drug administration. Vincristine in standard doses, 1.4 to 2 mg/m², causes little reduction of formed elements in the blood. All three agents cause hair loss and local cellulitis if extravasated. A syndrome of hyponatremia due to inappropriate secretion of antidiuretic hormone occurs rarely after vincristine administration (*see* Chapter 29).

Neurological Toxicity. While all three derivatives may cause neurotoxic symptoms, vincristine has predictable cumulative effects. Numbness and tingling of the extremities and loss of deep tendon reflexes constitute the most common and earliest signs and are followed by motor weakness. The sensory changes do not usually warrant an immediate reduction in drug dose, but loss of motor function should lead to a reevaluation of the therapeutic plan, and under most circumstances, discontinuation of the drug. Rarely, patients may experience vocal cord paralysis or loss of extraocular muscle function. High-dose vincristine causes severe constipation or obstipation. Inadvertent intrathecal vincristine administration produces devastating and invariably fatal central neurotoxicity, with seizures and irreversible coma (Williams *et al.*, 1983).

Absorption, Fate, and Excretion. The liver extensively metabolizes all three agents, and the conjugates and metabolites are excreted in the bile (Zhou and Rahmani, 1992; Robieux *et al.*, 1996). Only a small fraction of a dose (less than 15%) is found in the urine unchanged. In patients with hepatic dysfunction (bilirubin >3 mg/dl), a 75% reduction in dose of any of the vinca alkaloids is advisable, although firm guidelines for dose adjustment have not been established. The pharmacokinetics of each of the three drugs are similar, with elimination half-lives of 1 and 20 hours for vincristine,

3 and 23 hours for vinblastine, and 1 and 45 hours for vinorelbine (Marquet *et al.*, 1992).

Vinblastine

Therapeutic Uses. Vinblastine sulfate (VELBAN, others) is given intravenously; special precautions must be taken against subcutaneous extravasation, since this may cause painful irritation and ulceration. The drug should not be injected into an extremity with impaired circulation. After a single dose of 0.3 mg/kg of body weight, myelosuppression reaches its maximum in 7 to 10 days. If a moderate level of leukopenia (approximately 3000 cells per mm³) is not attained, the weekly dose may be increased gradually by increments of 0.05 mg/kg of body weight. In regimens designed to cure testicular cancer, vinblastine is used in doses of 0.3 mg/kg every 3 weeks.

The most important clinical use of vinblastine is with bleomycin and cisplatin (*see* below) in the curative therapy of metastatic testicular tumors (Williams and Einhorn, 1985), although it has been supplanted by etoposide or ifosfamide in this disease. It is a component of the standard curative regimen for Hodgkin's disease, (ABVD; dacarbazine, vinblastine, doxorubicin, and bleomycin). It also is active in Kaposi's sarcoma, neuroblastoma, and Letterer-Siwe disease (histiocytosis X), as well as in carcinoma of the breast and choriocarcinoma.

Clinical Toxicities. The nadir of the leukopenia that follows the administration of vinblastine usually occurs within 7 to 10 days, after which recovery ensues within 7 days. Other toxic effects of vinblastine include neurological manifestations as described above. Gastrointestinal disturbances including nausea, vomiting, anorexia, and diarrhea may be encountered. The syndrome of inappropriate secretion of antidiuretic hormone has been reported. Loss of hair, stomatitis, and dermatitis occur infrequently. Extravasation during injection may lead to cellulitis and phlebitis. Local injection of hyaluronidase and application of moderate heat to the area may be of help by dispersing the drug.

Vincristine

Therapeutic Uses. Vincristine sulfate (ONCOVIN, VINCASAR PFS, others) used together with glucocorticoids is the treatment of choice to induce remissions in childhood leukemia; common dosages for these drugs are vincristine, intravenously, 2 mg/m² of body surface area weekly, and prednisone, orally, 40 mg/m² daily. Adult patients with Hodgkin's disease or non-Hodgkin's lymphomas usually receive vincristine as part of a complex protocol. When used in the MOPP regimen (*see* below), the recommended dose of vincristine is 1.4 mg/m². Vincristine seems to be tolerated better by children than by adults, who may experience severe, progressive neurological toxicity. Administration of the drug more frequently than every 7 days or at higher doses seems to increase the toxic manifestations without proportional improvement in the response rate. Maintenance therapy with vincristine is not recommended in children with leukemia. Precautions also should be used to avoid extravasation during intravenous administration of vincristine.

In large-cell lymphoma, a liposomal formulation of vincristine (ONCO-TCS), given in doses of 2 mg/m², appears to have less neurotoxicity and retains activity in patients who relapse after vincristine therapy. It has the expected pharmacokinetic advantage of slower

elimination and greater tissue distribution as compared to the unmodified drug (Krishna *et al.*, 2001).

Clinical Toxicities. The clinical toxicity of vincristine is mostly neurological, as described above. The more severe neurological manifestations may be avoided or reversed by either suspending therapy or reducing the dosage upon occurrence of motor dysfunction. Severe constipation, sometimes resulting in colicky abdominal pain and obstruction, may be prevented by a prophylactic program of laxatives and hydrophilic (bulk-forming) agents and usually is a problem only with doses above 2 mg/m².

Alopecia occurs in about 20% of patients given vincristine; however, it is always reversible, frequently without cessation of therapy. Although less common than with vinblastine, leukopenia may occur with vincristine, and thrombocytopenia, anemia, polyuria, dysuria, fever, and gastrointestinal symptoms have been reported occasionally. The syndrome of inappropriate secretion of antidiuretic hormone occasionally has been observed during vincristine therapy. In view of the rapid action of the vinca alkaloids, it is advisable to prevent hyperuricemia by the administration of allopurinol.

Vinorelbine

Vinorelbine (NAVELBINE, others) is administered in normal saline as an intravenous infusion of 30 mg/m² given over 6 to 10 minutes. A lower dose (20 to 25 mg/m²) may be required for patients who have received prior chemotherapy. When used alone, it is initially given every week until progression of disease or dose-limiting toxicity. When used with cisplatin for the treatment of non-small cell lung carcinoma, it is given every 3 weeks. Like the other vincas, it is eliminated by hepatic metabolism, and has an elimination half-life of 24 hours. Its primary toxicity is granulocytopenia, with only modest thrombocytopenia and less neurotoxicity than other vinca alkaloids. It may cause allergic reactions and mild, reversible changes in liver enzymes. In experimental studies, it has been given in an oral capsule, but bioavailability is only 30% to 40% (Fumoleau *et al.*, 1993). As with the other vincas, doses should be reduced in patients with elevated bilirubin or with >75% liver replacement by metastatic disease.

Taxanes

The first compound of this series, paclitaxel (TAXOL), was isolated from the bark of the Western yew tree in 1971 (Wani *et al.*, 1971). It and its congeneric, the semisynthetic docetaxel (TAXOTERE), exhibit unique pharmacological actions as inhibitors of mitosis, differing from the vinca alkaloids and colchicine derivatives in that they bind to a different site on β -tubulin and promote rather than inhibit microtubule formation. The drugs have a central role in the therapy of ovarian, breast, lung, esophageal, bladder, and head and neck cancers (Rowinsky and Donehower, 1995). Their optimal dose, schedule, and use in drug combinations still are evolving.

Chemistry. Paclitaxel is a diterpenoid compound that contains a complex 8-member taxane ring as its nucleus (Figure 51-14). The

side chain linked to the taxane ring at C13 is essential for its anti-tumor activity. Modification of the side chain has led to identification of the more potent analog, docetaxel (Figure 51-14), which shares the same spectrum of clinical activity as paclitaxel, but differs in its spectrum of toxicity. Originally purified as the parent molecule from yew bark, paclitaxel now can be obtained for commercial purposes by semisynthesis from 10-desacetylbaaccatin, a precursor found in yew leaves. It also has been successfully synthesized (Nicolaou *et al.*, 1994) in a complex series of reactions. Paclitaxel has very limited solubility and must be administered in a vehicle of 50% ethanol and 50% polyethoxylated castor oil (CREMOPHOR EL), a formation likely responsible for a high rate of hypersensitivity reactions. Patients receiving this formulation are protected by pretreatment with a histamine H₁ receptor antagonist such as *diphenhydramine*, an H₂ receptor antagonist such as *cimetidine* (see Chapter 24), and a glucocorticoid such as dexamethasone (see Chapter 59).

Docetaxel, somewhat more soluble, is administered in polysorbate 80 and causes a lower incidence of hypersensitivity reactions. Pretreatment with dexamethasone is required to prevent progressive, and often disabling, fluid retention. A variety of new taxanes, including some with oral bioavailability, are undergoing clinical testing.

Mechanism of Action. Interest in paclitaxel was stimulated by the finding that the drug possessed the unique ability to promote microtubule formation at cold temperatures and in the absence of GTP. It binds specifically to the β -tubulin subunit of microtubules and antagonizes the disassembly of this key cytoskeletal protein, with the result that bundles of microtubules and aberrant struc-

Figure 51-14. Chemical structures of paclitaxel and its more potent analog, docetaxel.

tures derived from microtubules appear in the mitotic phase of the cell cycle. Arrest in mitosis follows. Cell killing is dependent on both drug concentration and duration of cell exposure. Drugs that block cell-cycle progression prior to mitosis antagonize the toxic effects of taxanes.

Schedules for optimal use alone or in combination with other drugs, including doxorubicin and cisplatin, still are evolving. Drug interactions have been noted; the sequence of cisplatin preceding paclitaxel decreases paclitaxel clearance and produces greater toxicity than the opposite schedule (Rowinsky and Donehower, 1995). Paclitaxel decreases doxorubicin clearance and enhances cardiotoxicity, while docetaxel has no apparent effect on anthracycline pharmacokinetics (Holmes and Rowinsky, 2001).

In cultured tumor cells, resistance to taxanes is associated in some lines with increased expression of the *mdr-1* gene and its product, the P-glycoprotein; other resistant cells have β -tubulin mutations, and these latter cells may display heightened sensitivity to vinca alkaloids (Cabral, 1983). Other cell lines display an increase in survivin, an anti-apoptotic factor (Zaffaroni *et al.*, 2002) or aurora kinase, an enzyme that promotes completion of mitosis (Anand *et al.*, 2003). The basis of clinical drug resistance is not known. Cell death occurs by apoptosis, but the effectiveness of paclitaxel against experimental tumors does not depend on an intact p53 gene product.

Absorption, Fate, and Excretion. Paclitaxel is administered as a 3-hour infusion of 135 to 175 mg/m² every 3 weeks, or as a weekly 1-hour infusion of 80 to 100 mg/m². Longer infusions (96 hours) have yielded significant response rates in breast cancer patients in preliminary trials (Wilson *et al.*, 1994), but this form of treatment has serious practical limitations. The drug undergoes extensive CYP-mediated hepatic metabolism (primarily CYP2C8 with a contribution of CYP3A4), and less than 10% of a dose is excreted in the urine intact. The primary metabolite identified thus far is 6-OH paclitaxel, which is inactive, but multiple additional hydroxylation products are found in plasma (Creteuil *et al.*, 1994).

Paclitaxel clearance is nonlinear and decreases with increasing dose or dose rate, possibly related to its dissolution in the vehicle of 50% ethanol and 50% polyethoxylated castor oil, and the non-linearity of concentrations of the diluent (Henningsson *et al.*, 2001). In studies of 96-hour infusion of 35 mg/m² per day, the presence of hepatic metastases greater than 2 cm in diameter decreased clearance and led to high drug concentrations in plasma and greater myelosuppression. Paclitaxel disappears from the plasma compartment with a half-life of 10 to 14 hours and a clearance of 15 to 18 L/hour per square meter. The critical plasma concentration for inhibiting bone marrow elements depends on duration of exposure, but likely lies in the range of 50 to 100 nM (Huizing *et al.*, 1993).

Docetaxel pharmacokinetics are similar to those of paclitaxel. Its elimination half-life is approximately 12 hours, and its clear-

ance is 22 L/hour per square meter. Clearance is primarily through CYP3A4- and CYP3A5-mediated hydroxylation, leading to inactive metabolites (Clark and Rivory, 1999). In contrast to paclitaxel, the pharmacokinetics of docetaxel are linear up to doses of 115 mg/m².

Dose reductions in patients with abnormal hepatic function have been suggested and 50% to 75% doses of taxanes should be used in the presence of hepatic metastases >2 cm in size or in patients with abnormal serum bilirubin. Drugs that induce CYP2C8 or CYP3A4, such as phenytoin and phenobarbital, or those that inhibit the same cytochromes, such as antifungal imidazoles, significantly alter drug clearance and toxicity.

Paclitaxel clearance is markedly delayed by *cyclosporine A* and a number of other drugs employed experimentally as inhibitors of the P-glycoprotein. This inhibition may be due to a block of CYP-mediated metabolism or effects on biliary excretion of parent drug or metabolites (Kang *et al.*, 2001).

Therapeutic Uses. Docetaxel and paclitaxel have become central components of regimens for treating metastatic ovarian, breast, lung, and head and neck cancers (McGuire *et al.*, 1996; Seidman, 1998). Docetaxel has significant activity with *estramustine* for treatment of hormone-refractory prostate cancer. In current regimens, either drug is administered once weekly or once every 3 weeks, with comparable response rates and somewhat different patterns of toxicity. Docetaxel produces greater leukopenia and peripheral edema, while paclitaxel causes a higher incidence of hypersensitivity, muscle aching, and neuropathy (particularly when used in combination with a platinum analog). The optimal schedule of taxane administration, alone or in combination with other drugs, is still under evaluation.

Clinical Toxicities. Paclitaxel exerts its primary toxic effects on the bone marrow. Neutropenia usually occurs 8 to 11 days after a dose and reverses rapidly by days 15 to 21. Used with *filgrastim* (granulocyte-colony stimulating factor; G-CSF), doses as high as 250 mg/m² over 24 hours are well tolerated, and peripheral neuropathy becomes dose limiting (Kohn *et al.*, 1994). Many patients experience myalgias for several days after receiving paclitaxel. In high-dose schedules, or with prolonged use, a stocking-glove sensory neuropathy can be disabling, particularly in patients with underlying diabetic alcoholic neuropathy or concurrent cisplatin therapy. Mucositis is prominent in 72- or 96-hour infusions and in the weekly schedule.

Hypersensitivity reactions occurred in patients receiving paclitaxel infusions of short duration (1 to 6 hours), but have largely been averted by pretreatment with dexamethasone, diphenhydramine, and histamine H₂ receptor antagonists, as noted above. Pre-medication is not necessary with 96-hour infusions. Many patients experience asymptomatic bradycardia, and occasional episodes of silent ventricular tachycardia also occur and resolve spontaneously during 3- or 24-hour infusions.

Docetaxel tends to cause more severe, but short-lived, neutropenia than does paclitaxel. It causes less severe peripheral neuropathy and asthenia, and less frequent hypersensitivity. Fluid retention is a progressive problem with multiple cycles of therapy, leading to peripheral edema, pleural and peritoneal fluid, and pulmonary edema in extreme cases. Oral dexamethasone, 8 mg/day, begun 1 day prior to drug infusion and continuing for 3 days, greatly ameliorates fluid retention. In rare cases, docetaxel may cause a progres-

sive interstitial pneumonitis, with respiratory failure supervening if the drug is not discontinued (Read *et al.*, 2002).

CAMPTOTHECIN ANALOGS

The camptothecins are potent, cytotoxic antineoplastic agents that target the nuclear enzyme topoisomerase I. The lead compound in this class, *camptothecin*, was isolated from the Chinese tree *Camptotheca acuminata* in 1966. Initial efforts to develop the compound as a sodium salt were compromised, despite evidence of promising preclinical and clinical antitumor activity, by severe and unpredictable toxicity, principally myelosuppression and hemorrhagic cystitis. Elucidation of the mechanism of action and a better understanding of its physicochemical properties during the 1980s led to the development of more soluble and less toxic analogs. Irinotecan and *topotecan*, currently the only camptothecin analogs approved for clinical use, have established activity in colorectal, ovarian, and small cell lung cancer (Garcia-Carbonero and Supko, 2002).

Chemistry. All camptothecins have a fused five-ring backbone beginning with a weakly basic quinoline moiety and terminating with a lactone ring (Figure 51–15). The hydroxyl group and S-conformation of the chiral center at C20 in the lactone ring to which it is attached are absolute requirements for biological activity. Appropriate substitutions on the A and B rings of the quinoline subunit can enhance water solubility and increase potency for inhibiting topoisomerase I. Topotecan [(S)-9-dimethylaminoethyl-10-hydroxycamptothecin hydrochloride] is a semisynthetic molecule with a basic dimethylamino group that increases its water solubility. Irinotecan (7-ethyl-10-[4-(1-piperidino)-1-piperidino]carbonyloxycamptothecin, or CPT-11) differs from topotecan in that it is a prodrug. The carbamate bond between the camptothecin moiety and the dibasic bispiperidine side chain at position C10, which makes the molecule water soluble, is cleaved by a carboxylesterase to form the biologically active metabolite known as SN-38.

Figure 51–15. Chemical structures of camptothecin and its analogs.

Although an intact lactone ring is necessary for the biological activity of the camptothecins, it is nevertheless unstable, undergoing reversible, nonenzymatic, pH-dependent hydrolysis in aqueous solution. Consequently, the camptothecins exist as an equilibrium mixture of the intact lactone and opened-ring carboxylate forms in biological fluids. Substituents on the A and B rings can modulate the equilibrium position between the closed and opened lactone ring forms of the molecule through effects on their relative affinities for binding to plasma proteins. For instance, the carboxylate form of camptothecin binds to serum albumin with a 200 times greater affinity than the intact lactone, and it is the predominant form in plasma and whole blood. In contrast, the lactone form of SN-38 binds preferentially to serum albumin, thereby shifting the equilibrium in the opposite direction.

Mechanism of Action. The DNA topoisomerases are nuclear enzymes that reduce torsional stress in supercoiled DNA, allowing selected regions of DNA to become sufficiently untangled and relaxed to permit its replication, recombination, repair, and transcription. Two classes of topoisomerase (I and II) are known to mediate DNA strand breakage and resealing, and both have become the target of cancer chemotherapies. Camptothecin analogs inhibit the function of topoisomerase I, while a number of different chemical entities (*e.g.*, anthracyclines, epipodophyllotoxins, acridines) inhibit topoisomerase II. Topoisomerase I binds covalently to double-stranded DNA through a reversible trans-esterification reaction. This reaction yields an intermediate complex in which the tyrosine of the enzyme is bound to the 3'-phosphate end of the DNA strand, creating a single-strand DNA break. This "cleavable complex" allows for relaxation of the DNA torsional strain, either by passage of the intact single-strand through the nick, or by free rotation of the DNA about the noncleaved strand. Once the DNA torsional strain has been relieved, the topoisomerase I reseals the cleavage and dissociates from the newly relaxed double helix.

The camptothecins bind to and stabilize the normally transient DNA-topoisomerase I cleavable complex (Hsiang *et al.*, 1985). Although the initial cleavage action of topoisomerase I is not affected, the religation step is inhibited, leading to the accumulation of single-stranded breaks in DNA. These lesions are reversible and not by themselves toxic to the cell. However, the collision of a DNA replication fork with this cleaved strand of DNA causes an irreversible double-strand DNA break, ultimately leading to cell death (Tsao *et al.*, 1993). Camptothecins are therefore S-phase-specific drugs, because ongoing DNA synthesis is necessary for cytotoxicity. This has important clinical implications, because S-phase-specific cytotoxic agents generally require prolonged exposures of tumor cells to drug concentrations above a minimum threshold to optimize therapeutic efficacy. In fact, preclinical studies of low-dose, protracted administration of camptothecin analogs have shown less toxicity, and equal or greater antitumor activity, than shorter more intense courses.

The precise sequence of events that lead from drug-induced DNA damage to cell death has not been fully elucidated. *In vitro* studies have shown that camptothecin-induced DNA damage abolishes the activation of the p34^{cdc2}/cyclin B complex, leading to cell-cycle arrest at the G2 phase (Tsao *et al.*, 1993). It also has been observed that treatment with camptothecins can induce the transcription of *c-fos* and *c-jun* early-response genes, and this occurs in association with internucleosomal DNA fragmentation, a characteristic of programmed cell death (Kharbanda *et al.*, 1991). Interesting-

ly, camptothecin-induced cytotoxicity also has been observed in cells not actively synthesizing DNA. Replication-independent mechanisms of cytotoxicity may involve the induction of serine proteases and endonucleases.

Mechanisms of Resistance. A variety of mechanisms of resistance to topoisomerase I-targeted agents have been characterized *in vitro*, although little is known about their significance in the clinical setting. Decreased intracellular drug accumulation has been observed in several cell lines resistant to camptothecin analogs. Topotecan, but not SN-38 or the intact lactone form of irinotecan, is a substrate for P-glycoprotein. However, the clinical relevance of P-glycoprotein-mediated efflux as a mechanism of resistance against topotecan remains unclear, as the magnitude of the effect in preclinical studies was found to be substantially lower than that observed with other MDR substrates, such as etoposide or doxorubicin. Other reports have associated topotecan or irinotecan resistance with the MRP class of transporters (Miyake *et al.*, 1999). Preclinical studies suggest drug metabolism could have a role in resistance to the prodrug irinotecan, as cell lines that lack carboxylesterase activity demonstrate resistance to irinotecan (Van Ark-Otte *et al.*, 1998), but in patients the liver and red blood cells may have sufficient carboxylesterase activity to convert irinotecan to SN-38. Camptothecin resistance also may result from decreased expression or mutation of topoisomerase I. Although a good correlation has been found in certain tumor cell lines between sensitivity to camptothecin analogs and topoisomerase I levels (Sugimoto *et al.*, 1990), clinical studies have not confirmed this association. Chromosomal deletions or hypermethylation of the topoisomerase I gene are possible mechanisms of decreased topoisomerase I expression in resistant cells. A transient downregulation of topoisomerase I has been demonstrated following prolonged exposure to camptothecins *in vitro* and *in vivo*. Moreover, an association between the degree of topoisomerase I downregulation in peripheral blood mononuclear cells and the area under the plasma concentration-time curve (AUC) or neutrophil nadir has been observed in ovarian cancer patients treated with a 21-day continuous intravenous infusion of topotecan. Mutations leading to reduced topoisomerase I enzyme catalytic activity or DNA binding affinity have been described *in vitro* in association with camptothecin resistance (Tamura *et al.*, 1991). In addition, some posttranscriptional events, such as enzyme phosphorylation (Pommier *et al.*, 1990) or poly-ADP ribosylation (Kasid *et al.*, 1989), may have a significant impact on the activity of topoisomerase I and on its susceptibility to inhibition. Finally, exposure of cells to topoisomerase I-targeted agents leads to increased expression of topoisomerase II, providing a rationale for sequential therapy with topoisomerase I and II inhibitors.

Very little is known about how the cell deals with the stabilized DNA-topoisomerase complexes. As cleavable complexes normally are present in the untreated cell, cellular repair processes may not readily recognize the drug-enzyme-DNA complex. However, an enzyme with specific tyrosyl-DNA phosphodiesterase activity may be involved in the disassembly of topoisomerase I-DNA complexes (Yang *et al.*, 1996). Since entry into S phase is required to kill tumor cells exposed to camptothecins, drugs that abolish the G₁-S checkpoint enhance lethality of camptothecins (Shao *et al.*, 1997). The fact that cell-cycle arrest in G₂ has been correlated with drug resistance to topoisomerase I-targeted drugs in colon cancer and leukemia cell lines *in vitro* suggests that enhanced DNA repair activity can lead to camptothecin resistance.

The role of p53 in mediating cell death due to camptothecins is unclear. These drugs induce p53 expression, but cells without functional p53 also can undergo apoptosis following exposure to camptothecins.

Absorption, Fate, and Excretion. **Topotecan.** Topotecan is only approved for intravenous administration. However, there has been interest in developing an oral dosage form for the drug, which has a bioavailability of 30% to 40% in cancer patients. Topotecan exhibits linear pharmacokinetics and it is rapidly eliminated from systemic circulation. The biological half-life of total topotecan, which ranges from 3.5 to 4.1 hours, is relatively short as compared with other camptothecins. Only 20% to 35% of the total drug in plasma is found to be in the active lactone form. Elimination of the lactone form appears to result mainly from rapid hydrolysis to the carboxylate species followed by renal excretion, with 30% to 40% of the administered dose excreted in the urine within 24 hours. Doses should be reduced in proportion to reductions in creatinine clearance. Although several oxidative metabolites have been identified, hepatic metabolism appears to be a relatively minor route of drug elimination. Unlike most other camptothecins considered for clinical development, plasma protein binding of topotecan is low, being only 7% to 35%, which may explain its relatively greater CNS penetration.

Irinotecan. The conversion of irinotecan to SN-38 is mediated predominantly by carboxylesterases in the liver (*see* Figure 3-5). Although SN-38 can be measured in plasma shortly after beginning an intravenous infusion of irinotecan, the AUC of SN-38 is only about 4% of the AUC of irinotecan, suggesting that only a relatively small fraction of the dose is ultimately converted to the active form of the drug. Irinotecan exhibits linear pharmacokinetics at doses evaluated in cancer patients. In comparison to topotecan, a relatively large fraction of both irinotecan and SN-38 are present in plasma as the biologically active intact lactone form. Another potential advantage of this analog is that the biological half-life of SN-38 is 11.5 hours, which is much longer than topotecan. Oral administration does not appear to be feasible because the bioavailability of irinotecan is only 8%. Plasma protein binding is at least 43% for irinotecan and 92% to 96% for SN-38. CSF penetration of SN-38 in humans has not been characterized yet, although in rhesus monkeys it is only 14%, significantly lower than that observed for topotecan.

In contrast to topotecan, hepatic metabolism represents an important route of elimination for both irinotecan and SN-38 (*see* Figures 3-7 and 3-8). Several oxidative metabolites have been identified in plasma, all of which result from CYP3A-mediated reactions directed at the bispiperidine side chain. These metabolites are not significantly converted to SN-38. The total body clearance of irinotecan was found to be two times greater in brain cancer patients who were concurrently taking antiseizure drugs that induce hepatic CYPs, further attesting to the importance of oxidative hepatic metabolism as a route of elimination for this drug (Gilbert *et al.*, 2003).

Conjugation of SN-38 with glucuronic acid, through the hydroxyl group at position C10 resulting from cleavage of the bispiperidine moiety, is the only known metabolite of SN-38. Biliary excretion appears to be the primary elimination route of irinotecan, SN-38, and their metabolites, although urinary excretion also contributes significantly (14% to 37%). Uridine diphosphate-glucuronosyltransferase (UGT), particularly the UGT1A1 isoform, converts SN-38 to its inactive glucuronidated derivative (Iyer *et al.*, 1998). The extent of SN-38 glucuronidation has been

inversely correlated with the risk of severe diarrhea after irinotecan therapy. UGT1A1 also glucuronidates bilirubin. Polymorphisms of this enzyme (see Figure 3–6) are associated with familial hyperbilirubinemia syndromes such as Crigler-Najjar syndrome and Gilbert syndrome. Crigler-Najjar syndrome is rare (1 in a million births), but Gilbert syndrome occurs in up to 15% of the general population, and results in a mild hyperbilirubinemia that may be clinically silent. The existence of UGT enzyme polymorphisms may have a major impact on the clinical use of irinotecan. A positive correlation has been found between baseline serum unconjugated bilirubin concentration and both severity of neutropenia and the AUC of irinotecan and SN-38 in patients treated with irinotecan. Moreover, severe irinotecan toxicity has been observed in cancer patients with Gilbert syndrome, presumably due to decreased glucuronidation of SN-38. The presence of bacterial glucuronidase in the intestinal lumen potentially can contribute to irinotecan's GI toxicity by releasing unconjugated SN-38 from the inactive glucuronide metabolite excreted in the bile.

Therapeutic Uses. Topotecan. Topotecan (HYCAMTIN) is indicated for previously treated patients with ovarian (Herzog, 2002) and small cell lung cancer (Huang and Treat, 2001). Its significant hematological toxicity, though, has limited its use in combination with other active agents in these diseases (e.g., cisplatin). Promising antitumor activity also has been observed in hematological malignancies, particularly in CML and in myelodysplastic syndromes.

The recommended dosing regimen of topotecan is a 30-minute infusion of 1.5 mg/m² per day for 5 consecutive days every 3 weeks. Since a significant fraction of the topotecan administered is excreted in the urine, severe toxicities have been observed in patients with decreased creatinine clearance (O'Reilly *et al.*, 1996). Therefore, the dose of topotecan should be reduced to 0.75 mg/m² per day in patients with moderate renal dysfunction (creatinine clearance 20 to 40 ml/minute), and topotecan should not be administered to patients with severe renal impairment (creatinine clearance <20 ml/minute). Topotecan clearance and toxicity are not significantly altered in patients with hepatic dysfunction, and therefore no dose reduction is necessary in these patients.

Irinotecan. Approved dosage schedules of irinotecan (CAMP-TOSAR) in the United States include: 125 mg/m² as a 90-minute infusion administered weekly for 4 out of 6 weeks; 350 mg/m² given every 3 weeks; 100 mg/m² every week; or 150 mg/m² every other week. Irinotecan has significant clinical activity in patients with advanced colorectal cancer. It now is the treatment of choice in combination with fluoropyrimidines for advanced colorectal cancer in patients who have not received chemotherapy previously (Douillard *et al.*, 2000) or as a single agent following failure on a 5-FU regimen (Rothenberg, 2001). Encouraging results from different phase II studies suggest that irinotecan may have an increasing role in the treatment of other solid tumors, including small cell and non-small cell lung cancer, cervical cancer, ovarian cancer, gastric cancer, and brain tumors.

Clinical Toxicities. Topotecan. The dose-limiting toxicity with all schedules is neutropenia, with or without thrombocytopenia. The

incidence of severe neutropenia at the recommended phase II dose of 1.5 mg/m² daily for 5 days every 3 weeks may be as high as 81%, with a 26% incidence of febrile neutropenia. In patients with hematological malignancies, gastrointestinal side effects such as mucositis and diarrhea become dose limiting. Other less common and generally mild topotecan-related toxicities include nausea and vomiting, elevated liver transaminases, fever, fatigue, and rash.

Irinotecan. The dose-limiting toxicity with all schedules is delayed diarrhea, with or without neutropenia. In the initial studies, up to 35% of patients experienced severe diarrhea. Adoption of an intensive loperamide (see Chapter 38) regimen (4 mg of loperamide starting at the onset of any loose stool beginning more than a few hours after receiving therapy, followed by 2 mg every 2 hours) has effectively reduced this incidence by more than half. However, once severe diarrhea does occur, standard doses of antidiarrheal agents tend to be ineffective, although the diarrhea episode generally resolves within a week and, unless associated with fever and neutropenia, is rarely fatal.

The second most common irinotecan-associated toxicity is myelosuppression. Severe neutropenia occurs in 14% to 47% of the patients treated with the every-3-week schedule, and is less frequently encountered among patients treated with the weekly schedule. Febrile neutropenia is observed in 3% of patients, and may be fatal, particularly when associated with concomitant diarrhea. A cholinergic syndrome resulting from the inhibition of acetylcholinesterase activity by irinotecan may occur within the first 24 hours after irinotecan administration. Symptoms include acute diarrhea, diaphoresis, hypersalivation, abdominal cramps, visual accommodation disturbances, lacrimation, rhinorrhea, and less often, asymptomatic bradycardia. These effects are short lasting and respond within minutes to atropine. Atropine may be prophylactically administered to patients who have previously experienced a cholinergic reaction, prior to the administration of additional cycles of irinotecan. Other common and generally manageable toxicities include nausea and vomiting, fatigue, vasodilation or skin flushing, mucositis, elevation in liver transaminases, and alopecia. Finally, there have been case reports of dyspnea and interstitial pneumonitis associated with irinotecan therapy in Japanese patients with lung cancer (Fukuoka *et al.*, 1992).

ANTIBIOTICS

Dactinomycin (Actinomycin D)

The first anticancer antibiotics to be isolated from a culture broth of a species of *Streptomyces* were the series of actinomycins discovered by Waksman and colleagues in 1940. The most important of these, actinomycin D, has beneficial effects in the treatment of solid tumors in children and choriocarcinoma.

Chemistry and Structure–Activity Relationship. The actinomycins are chromopeptides. Most contain the same chromophore, the planar phenoxazone actinosin, which is responsible for their yellow-red color. The differences among naturally occurring actinomycins are confined to variations in the structure of the amino acids of the pep-

side chains. By varying the amino acid content of the growth medium, it is possible to alter the types of actinomycins produced and the biological activity of the molecule (Crooke, 1983). The chemical structure of dactinomycin is as follows:

Mechanism of Action. The capacity of actinomycins to bind with double-helical DNA is responsible for their biological activity and cytotoxicity. X-ray studies of a crystalline complex between dactinomycin and deoxyguanosine permitted formulation of a model that appears to explain the binding of the drug to DNA (Sobell, 1973). The planar phenoxazine ring intercalates between adjacent guanine–cytosine base pairs of DNA, while the polypeptide chains extend along the minor groove of the helix. The summation of these interactions provides great stability to the dactinomycin–DNA complex, and as a result of the binding of dactinomycin, the transcription of DNA by RNA polymerase is blocked. The DNA-dependent RNA polymerases are much more sensitive to the effects of dactinomycin than are the DNA polymerases. In addition, dactinomycin causes single-strand breaks in DNA, possibly through a free-radical intermediate or as a result of the action of topoisomerase II (Goldberg *et al.*, 1977).

Cytotoxic Action. Dactinomycin inhibits rapidly proliferating cells of normal and neoplastic origin, and on a molar basis is among the most potent antitumor agents known. The drug may produce alopecia, and when extravasated subcutaneously, causes marked local inflammation. Erythema, sometimes progressing to necrosis, has been noted in areas of the skin exposed to x-ray radiation before, during, or after administration of dactinomycin.

Absorption, Fate, and Excretion. Dactinomycin is administered by intravenous injection. The drug is excreted both in bile and in the urine and disappears from plasma with a terminal half-life of 36 hours. Metabolism of the drug is minimal. Dactinomycin does not cross the blood–brain barrier.

Therapeutic Uses. The usual daily dose of dactinomycin (actinomycin D; COSMEGEN) is 10 to 15 $\mu\text{g}/\text{kg}$; this is given intravenously for 5 days; if no manifestations of toxicity are encountered, additional courses may be given at intervals of 2 to 4 weeks. In other regimens, 3 to 6 $\mu\text{g}/\text{kg}$ per day, for a total of 125 $\mu\text{g}/\text{kg}$, and weekly maintenance doses of 7.5 $\mu\text{g}/\text{kg}$ have been used. If infiltrated during administration, the drug is extremely corrosive to soft tissues.

The most important clinical use of dactinomycin is in the treatment of rhabdomyosarcoma and Wilms' tumor in children, where it is curative in combination with primary surgery, radiotherapy, and other drugs, particularly vincristine and cyclophosphamide (Pinkel and Howarth, 1985). Antineoplastic activity has been noted in Ewing's tumor, Kaposi's sarcoma, and soft tissue sarcomas. Dactinomycin can be effective in women with advanced cases of choriocarcinoma in combination with methotrexate. Dactinomycin also has been used as an immunosuppressant in renal transplants.

Clinical Toxicities. Toxic manifestations include anorexia, nausea, and vomiting, usually beginning a few hours after administration. Hematopoietic suppression with pancytopenia may occur in the first week after completion of therapy. Proctitis, diarrhea, glossitis, cheilitis, and ulcerations of the oral mucosa are common; dermatological manifestations include alopecia, as well as erythema, desquamation, and increased inflammation and pigmentation in areas previously or concomitantly subjected to X-ray radiation. Severe injury may occur as a result of local toxic extravasation.

Daunorubicin, Doxorubicin, Epirubicin, Idarubicin, and Mitoxantrone

These anthracycline antibiotics are among the most important antitumor agents. They are derived from the fungus *Streptococcus peucetius* var. *caesius*. *Idarubicin* and *epirubicin* are analogs of the naturally produced anthracyclines, differing only slightly in chemical structure, but having somewhat distinct patterns of clinical activity. *Daunorubicin* and *idarubicin* have been used primarily in the acute leukemias, whereas *doxorubicin* and *epirubicin* display broader activity against human solid tumors. These agents, which all possess potential for generating free radicals, cause an unusual and often irreversible cardiomyopathy, the occurrence of which is related to the total dose of the drug. The structurally similar agent *mitoxantrone* has useful activity against prostate cancer and AML, and is used in high-dose chemotherapy. *Mitoxantrone*, an anthracenedione, has significantly less cardiotoxicity than do the anthracyclines.

Chemistry. The anthracycline antibiotics have a tetracyclic ring structure attached to an unusual sugar, daunosamine. Cytotoxic agents of this class all have quinone and hydroquinone moieties on adjacent rings that permit the gain and loss of electrons. Although there are marked differences in the clinical use of *daunorubicin* and *doxorubicin*, their chemical structures differ only by a single hydroxyl group on C14. *Idarubicin* is 4-demethoxydaunorubicin, a synthetic derivative of *daunorubicin*, while *epirubicin* is an epimer at the 4'-position of the sugar. *Mitoxantrone* lacks a glycosidic side group. The chemical structures of *doxorubicin*, *daunorubicin*, *epirubicin*, and *idarubicin* are as follows:

	DOXORUBICIN	DAUNORUBICIN	EPIRUBICIN	IDARUBICIN
R ₁ =	OCH ₃	OCH ₃	OCH ₃	H
R ₂ =	H	H	OH	H
R ₃ =	OH	OH	H	OH
R ₄ =	OH	H	OH	H

Mechanism of Action. A number of important biochemical effects have been described for the anthracyclines and anthracenediones, all of which could contribute to their therapeutic and toxic effects. These compounds can intercalate with DNA, directly affecting transcription and replication. A more important action is the ability of these drugs to form a tripartite complex with topoisomerase II and DNA. Topoisomerase II is an ATP-dependent enzyme that binds to DNA and produces double-strand breaks at the 3' phosphate backbone, allowing strand passage and uncoiling of supercoiled DNA. Following strand passage, topoisomerase II religates the DNA strands. This enzymatic function is essential for DNA replication and repair. Formation of the tripartite complex with anthracyclines and with etoposide inhibits the re-ligation of the broken DNA strands, leading to apoptosis (Rubin and Hait, 2000). Defects in DNA double-strand break repair sensitize cells to damage by these drugs, while overexpression of transcription-linked DNA repair may contribute to resistance. Anthracyclines, by virtue of their quinone groups, also generate free radicals in solution and in both normal and malignant tissues (Myers, 1988; Gewirtz, 1999). Anthracyclines can form semiquinone radical intermediates, which in turn can react with oxygen to produce superoxide anion radicals. These can generate both hydrogen peroxide and hydroxyl radicals (-OH), which attack DNA (Serrano *et al.*, 1999) and oxidize DNA bases. The production of free radicals is significantly stimulated by the interaction of doxorubicin with iron (Myers, 1988). Enzymatic defenses such as superoxide dismutase and catalase are believed to have an important role in protecting cells against the toxicity of the anthracyclines, and these defenses can be augmented by exogenous antioxidants such as *alpha tocopherol* or by an iron chelator, *dexrazoxane* (ZINECARD), which protects against cardiac toxicity (Swain *et al.*, 1997).

Exposure of cells to anthracyclines leads to apoptosis; mediators of this process include the p53 DNA-damage sensor and activated caspases (proteases), although ceramide, a lipid breakdown product, and the fas receptor-ligand system also have been implicated in selected tumor cells (Friesen *et al.*, 1996; Jaffrezou *et al.*, 1996).

As discussed above, the phenomenon of multidrug resistance is observed in tumor cell populations exposed to anthracyclines. Attempts to reverse or prevent the emergence of resistance through the simultaneous use of inhibitors of the P-glycoprotein, such as calcium channel blockers, steroidal compounds, and others, have yielded inconclusive results, primarily because of the effects of these inhibitors on anthracycline pharmacokinetics and metabolism. Anthracyclines also are exported from tumor cells by members of

the MRP transporter family and by the breast cancer resistance protein, a "half" transporter (Doyle *et al.*, 1998). Other biochemical changes in resistant cells include increased glutathione peroxidase activity (Sinha *et al.*, 1989), decreased activity or mutation of topoisomerase II (Jarvinen *et al.*, 1998), and enhanced ability to repair DNA strand breaks.

Absorption, Fate, and Excretion. Daunorubicin, doxorubicin, epirubicin, and idarubicin usually are administered intravenously and are cleared by a complex pattern of hepatic metabolism and biliary excretion. The plasma disappearance curve for doxorubicin is multiphasic, with elimination half-lives of 3 hours and about 30 hours. All anthracyclines are converted to an active alcohol intermediate that plays a variable role in their therapeutic activity. Idarubicin has a half-life of about 15 hours, and its active metabolite, idarubicinol, has a half-life of about 40 hours. There is rapid uptake of the drugs in the heart, kidneys, lungs, liver, and spleen. They do not cross the blood-brain barrier.

Daunorubicin and doxorubicin are eliminated by metabolic conversion to a variety of aglycones and other inactive products. Idarubicin is primarily metabolized to idarubicinol, which accumulates in plasma and likely contributes significantly to its activity. Clearance is delayed in the presence of hepatic dysfunction, and at least a 50% initial reduction in dose should be considered in patients with abnormal serum bilirubin levels (Twelves *et al.*, 1998).

Idarubicin. The recommended dosage for idarubicin (IDAMYCIN) is 12 mg/m² daily for 3 days by intravenous injection in combination with cytarabine. Slow injection with care over 10 to 15 minutes is recommended to avoid extravasation, as with other anthracyclines.

Daunorubicin. Therapeutic Uses. Daunorubicin (daunomycin, rubidomycin; CERUBIDINE, others) is available for intravenous use. The recommended dosage is 30 to 60 mg/m² daily for 3 days. The agent is administered with appropriate care to prevent extravasation, since severe local vesicant action may result. Total doses of greater than 1000 mg/m² are associated with a high risk of cardiotoxicity. A daunorubicin citrate liposomal product (DAUNOXOME) is indicated for the treatment of AIDS-related Kaposi's sarcoma. It is given in a dose of 40 mg/m² infused over 60 minutes and repeated every 2 weeks. Patients should be advised that the drug may impart a red color to the urine.

Daunorubicin is primarily used in the treatment of AML in combination with Ara-C and has largely been replaced by idarubicin.

Clinical Toxicities. The toxic manifestations of daunorubicin as well as idarubicin include bone marrow depression, stomatitis, alopecia, GI disturbances, and dermatological manifestations. Cardiac toxicity is a peculiar adverse effect observed with these agents. It is characterized by tachycardia, arrhythmias, dyspnea, hypotension, pericardial effusion, and congestive heart failure that is poorly responsive to digitalis (*see below*).

Doxorubicin. Therapeutic Uses. Doxorubicin (ADRIAMYCIN, others) is available for intravenous use. The recommended dose is 50 to 75 mg/m², administered as a single rapid intravenous infusion that is repeated after 21 days. Care should be taken to avoid extravasation, since severe local vesicant action and tissue necrosis may result. A doxorubicin liposomal product (DOXIL) is available for treatment of AIDS-related Kaposi's sarcoma and is given intravenously in a dose of 20 mg/m² over 30 minutes and repeated every 3 weeks. As for

daunorubicin, patients should be advised that the drug may impart a red color to the urine.

Doxorubicin is effective in malignant lymphomas; however, in contrast to daunorubicin, it also is active in a number of solid tumors, particularly breast cancer. Used in combination with cyclophosphamide, vinca alkaloids, and other agents, it is an important ingredient for the successful treatment of lymphomas. It is a valuable component of various regimens of chemotherapy for adjuvant and metastatic carcinoma of the breast and small cell carcinoma of the lung. The drug also is particularly beneficial in a wide range of pediatric and adult sarcomas, including osteogenic, Ewing's, and soft tissue sarcomas.

Clinical Toxicities. The toxic manifestations of doxorubicin are similar to those of daunorubicin. Myelosuppression is a major dose-limiting complication, with leukopenia usually reaching a nadir during the second week of therapy and recovering by the fourth week; thrombocytopenia and anemia follow a similar pattern but usually are less pronounced. Stomatitis, GI disturbances, and alopecia are common but reversible. Erythematous streaking near the site of infusion ("ADRIAMYCIN flare") is a benign local allergic reaction and should not be confused with extravasation. Facial flushing, conjunctivitis, and lacrimation may occur rarely. The drug may produce severe local toxicity in irradiated tissues (*e.g.*, the skin, heart, lung, esophagus, and gastrointestinal mucosa). Such reactions may occur even when the two therapies are not administered concomitantly.

Cardiomyopathy is the most important long-term toxicity. Two types of cardiomyopathies may occur:

1. An acute form is characterized by abnormal electrocardiographic changes, including ST- and T-wave alterations and arrhythmias. This is brief and rarely a serious problem. An acute reversible reduction in ejection fraction is observed in some patients in the 24 hours after a single dose, and elevation of troponin T, a cardiac enzyme released with myocardial damage, is found in a minority of patients in the first few days following drug administration (Lipshultz *et al.*, 2004). An exaggerated manifestation of acute myocardial damage, the "pericarditis–myocarditis syndrome," may be characterized by severe disturbances in impulse conduction and frank congestive heart failure, often associated with pericardial effusion.
2. Chronic, cumulative dose-related toxicity (usually at or above total doses of 550 mg/m²) is manifested by congestive heart failure that is unresponsive to digitalis. The mortality rate in patients with congestive failure approaches 50%. Total dosage of doxorubicin as low as 250 mg/m² can cause pathologic changes in the myocardium, as demonstrated by subendocardial biopsies. Nonspecific alterations, including a decrease in the number of myocardial fibrils, mitochondrial changes, and cellular degeneration, are visible by electron microscopy. The most promising noninvasive techniques used to detect the early development of drug-induced congestive heart failure are radionuclide cineangiography, which assesses ejection fraction, and echocardiography, which reveals abnormalities in contractility and ventricular dimensions. Sequential echocardiograms have detected structural abnormalities in 25% of children who received up to 300 mg/m² of doxorubicin, although fewer than 10% have clinical manifestations of cardiac disease in long-term follow-up. Although no completely practical and reliable predictive tests are available, the frequency of clinically apparent cardiomyopathy is 1% to 10% at total doses below 450 mg/m². The risk increases markedly (to >20% of patients) at total doses higher than 550 mg/m²,

and this total dosage should be exceeded only under exceptional circumstances or with the concomitant use of dexrazoxane, a cardioprotective iron-chelating agent that appears not to compromise the anticancer activity of the drug (Speyer *et al.*, 1988; Swain *et al.*, 1997). Cardiac irradiation, administration of high doses of cyclophosphamide or another anthracycline, or concomitant *herceptin* (Slamon *et al.*, 2001) increases the risk of cardiotoxicity. Late-onset cardiac toxicity, with congestive heart failure years after treatment, may occur in both pediatric and adult populations (Lipshultz *et al.*, 2004). In children treated with anthracyclines, there is a three- to tenfold elevated risk of arrhythmias, congestive heart failure, and sudden death in adult life. A total dose limit of 300 mg/m² is advised for pediatric cases, and there is preliminary evidence that concomitant administration of dexrazoxane may reduce troponin T elevations that predict later cardiotoxicity (Lipshultz *et al.*, 2004).

Newer Analogs of Doxorubicin. *Valrubicin* (VALSTAR) was approved in 1998 for intravesical therapy of bacille Calmette-Guérin–refractory urinary bladder carcinoma *in situ* in patients for whom immediate cystectomy would be associated with unacceptable morbidity or mortality. *Epirubicin* (4'-epidoxorubicin, ELLENCE) was approved by the FDA in 1999 as a component of adjuvant therapy following resection of early lymph-node–positive breast cancer.

A related anthracenedione, mitoxantrone, has been approved for use in AML. Mitoxantrone has limited ability to produce quinone-type free radicals and causes less cardiac toxicity than does doxorubicin. It produces acute myelosuppression, cardiac toxicity, and mucositis as its major toxicities; the drug causes less nausea and vomiting and alopecia than does doxorubicin. It also is used as a component of experimental high-dose chemotherapy regimens, with uncertain efficacy.

Mitoxantrone (NOVANTRONE) is supplied for intravenous infusion. To induce remission in acute nonlymphocytic leukemia in adults, the drug is given in a daily dose of 12 mg/m² for 3 days as a component of a regimen that also includes cytosine arabinoside. Mitoxantrone also is used in advanced hormone-resistant prostate cancer in a dose of 12 to 14 mg/m² every 21 days. Mitoxantrone has been approved by the FDA for the treatment of late-stage, secondary progressive multiple sclerosis.

EPIPODOPHYLLOTOXINS

Podophyllotoxin, extracted from the mandrake plant (may-apple; *Podophyllum peltatum*), was used as a folk remedy by the American Indians and early colonists for its emetic, cathartic, and anthelmintic effects. Two of the many derivatives synthesized during the past 20 years show significant therapeutic activity in several human neoplasms, including pediatric leukemia, small cell carcinomas of the lung, testicular tumors, Hodgkin's disease, and large cell lymphomas.

These derivatives, shown below, are etoposide (VP-16-213) and teniposide (VM-26). Although podophyllotoxin binds to tubulin at a site distinct from that for interaction with the vinca alkaloids, etoposide and teniposide have no effect on microtubular structure or function at usual concentrations (for reviews of the epipodophyllotoxins, see Hande, 1998; Pommier *et al.*, 2001).

Mechanism of Action. Etoposide and teniposide are similar in their actions and in the spectrum of human tumors affected. Unlike podophyllotoxin, but like the anthracyclines, they form a ternary complex with topoisomerase II and DNA and prevent resealing of the break that normally follows topoisomerase binding to DNA. The enzyme remains bound to the free end of the broken DNA strand, leading to an accumulation of DNA breaks and cell death (Pommier *et al.*, 2001). Cells in the S and G₂ phases of the cell cycle are most sensitive to etoposide and teniposide. Resistant cells demonstrate amplification of the *mdr-1* gene that encodes the P-glycoprotein drug efflux transporter, mutation or decreased expression of topoisomerase II, or mutations of the p53 tumor suppressor gene, a required component of the apoptotic pathway (Lowe *et al.*, 1993).

Etoposide

Absorption, Fate, and Excretion. Oral administration of etoposide results in variable absorption that averages about 50%. After intravenous injection, peak plasma concentrations of 30 µg/ml are achieved; there is a biphasic pattern of clearance with a terminal half-life of about 6 to 8 hours in patients with normal renal function. Approximately 40% of an administered dose is excreted intact in the urine. In patients with compromised renal function, dosage should be reduced in proportion to the reduction in creatinine clearance (Arbuck *et al.*, 1986). In patients with advanced liver disease, low serum albumin and elevated bilirubin (which displaces etoposide from albumin) tend to increase the unbound fraction of drug, increasing the toxicity of any given dose. However, guidelines for dose reduction in this circumstance have not been defined (Stewart *et al.*, 1991). Drug concentrations in the cerebrospinal fluid average 1% to 10% of those in plasma.

Therapeutic Uses. The intravenous dose of etoposide (VEPESID, TOPOSAR, ETOPOPHOS) for testicular cancer in combination therapy is 50 to 100 mg/m² for 5 days, or 100 mg/m² on alternate days for three doses. For small cell carcinoma of the lung, the dose in combination therapy is 50 to 120 mg/m² per day intravenously for 3 days, or 50 mg per day orally for 21 days. Cycles of therapy usually are repeated every 3 to 4 weeks. When given intravenously, the drug should be administered slowly during a 30- to 60-minute infusion to avoid hypotension and bronchospasm, which likely result from the additives used to dissolve etoposide, a relatively insoluble compound.

A disturbing complication of etoposide therapy has emerged in long-term follow-up of patients with childhood acute lymphoblastic leukemia, who develop an unusual form of acute nonlymphocytic leukemia with a translocation in chromosome 11 at 11q23. At this locus is found a gene(s) (the MLL or mixed-lineage leukemia gene) that regulates the proliferation of pluripotent stem cells. The leukemic cells have the cytological appearance of acute monocytic or monomyelocytic leukemia. Another distinguishing feature of etoposide-related leukemia is the short time interval between the end of treatment and onset of leukemia (1 to 3 years), as compared to the 4- to 5-year interval for secondary leukemias related to alkylating agents, and the absence of a myelodysplastic period preceding leukemia (Levine and Bloomfield, 1992; Pui *et al.*, 1995; Sandler *et al.*, 1997; Smith *et al.*, 1999). Patients receiving weekly or twice-weekly doses of etoposide, with cumulative doses above 2000 mg/m², seem to be at higher risk of leukemia.

Etoposide is used primarily for treatment of testicular tumors, in combination with bleomycin and cisplatin, and in combination with cisplatin and ifosfamide for small cell carcinoma of the lung (Nemati *et al.*, 2000). It also is active against non-Hodgkin's lymphomas, acute nonlymphocytic leukemia, and Kaposi's sarcoma associated with acquired immunodeficiency syndrome (AIDS) (Chao *et al.*, 2000; Tung *et al.*, 2000). Etoposide has a favorable toxicity profile for dose escalation in that its primary acute toxicity is myelosuppression. In combination with ifosfamide and carboplatin, it is frequently used for high-dose chemotherapy in total doses of 1500 to 2000 mg/m² (Josting *et al.*, 2000).

Clinical Toxicities. The dose-limiting toxicity of etoposide is leukopenia, with a nadir at 10 to 14 days and recovery by 3 weeks. Thrombocytopenia occurs less often and usually is not severe. Nausea, vomiting, stomatitis, and diarrhea occur in approximately 15% of patients treated intravenously and in about 55% of patients who receive the drug orally. Alopecia is common but reversible. Fever, phlebitis, dermatitis, and allergic reactions including anaphylaxis have been observed. Hepatic toxicity is particularly evident after high-dose treatment. For both etoposide and teniposide, toxicity is increased in patients with decreased serum albumin, an effect related to decreased protein binding of the drug (Stewart *et al.*, 1991).

Teniposide

Teniposide (VUMON) is administered intravenously. It has a multiphasic pattern of clearance from plasma. After distribution, half-lives of 4 hours and 10 to 40 hours are observed. Approximately 45% of the drug is excreted in the urine, but in contrast to etoposide, as much as 80% is recovered as metabolites. Anticonvulsants such as phenytoin increase the hepatic metabolism of teniposide and reduce systemic exposure (Baker *et al.*, 1992). Dosage need not be reduced for patients with impaired renal function (Pommier

Figure 51–16. Chemical structures of bleomycin A₂ and B₂.

et al., 2001). Less than 1% of the drug crosses the blood–brain barrier. However, teniposide has produced responses in small cell and non–small cell lung cancer metastases in the brain (Boogerd *et al.*, 1999).

Teniposide is available for treatment of refractory ALL in children and appears to be synergistic with cytarabine. It is administered by intravenous infusion in doses that range from 50 mg/m² per day for 5 days to 165 mg/m² per day twice weekly. The clinical spectrum of activity includes acute leukemia in children, particularly monocytic leukemia in infants, as well as glioblastoma, neuroblastoma, and brain metastases from small cell carcinomas of the lung (Odom and Gordon, 1984; Postmus *et al.*, 1995; Boogerd *et al.*, 1999). Myelosuppression, nausea, and vomiting are its primary toxic effects.

Bleomycins

The bleomycins are an important group of DNA-cleaving antibiotics discovered by Umezawa and colleagues as fermentation products of *Streptococcus verticillus*. The drug currently employed clinically is a mixture of the two copper-chelating peptides, bleomycins A₂ and B₂. The bleomycins differ only in their terminal amino acid (*see* below), which can be altered by the amino acids added to the fermentation medium.

Bleomycins have attracted interest both because of their significant antitumor activity against squamous carcinoma of the cervix, and against lymphomas and testicular tumors. They are minimally myelo- and immunosuppressive but cause unusual cutaneous side effects and pulmonary fibrosis. Because their toxicities do not overlap with those of other drugs, and because of their unique mechanism of action, bleomycins maintain an important role in combination chemotherapy.

Chemistry. The bleomycins are water-soluble, basic glycopeptides (Figure 51–16). The core of the bleomycin molecule is a complex metal-binding structure containing a pyrimidine chromophore linked to propionamide, a β -aminoalanine amide side chain, and the sugars L-gulose and 3-*O*-carbamoyl-D-mannose. Attached to this core are a tripeptide chain and a terminal bithiazole carboxylic acid; this latter segment binds to DNA. The bleomycins form equimolar complexes with metal ions, including Cu²⁺ and Fe²⁺.

Mechanism of Action. Although bleomycin has a number of interesting biochemical properties, its cytotoxic action results from their ability to cause oxidative damage to the deoxyribose of thymidylate and other nucleotides, leading to single- and double-stranded breaks in DNA. Studies *in vitro* indicate that bleomycin causes accumulation of cells in the G₂ phase of the cell cycle, and many of these cells display chromosomal aberrations, including chromatid breaks, gaps, and fragments, as well as translocations (Twentyman, 1983).

Bleomycin causes scission of DNA by interacting with O₂ and Fe²⁺. In the presence of O₂ and a reducing agent, such as dithiothreitol, the metal–drug complex becomes activated and functions mechanistically as a ferrous oxidase, transferring electrons from Fe²⁺ to molecular oxygen to produce activated species of oxygen (Burger, 1998). Metallobleomycin complexes can be activated by reaction with the flavin enzyme, NADPH-cytochrome P450 reductase. Bleomycin binds to DNA through its amino-terminal peptide, and the activated complex generates free radicals that are responsible for scission of the deoxyribose backbone of the DNA chain. Bleomycin is degraded by a specific hydrolase found in various normal tissues, including liver; however, hydrolase activity is low in skin and lung, perhaps contributing to the toxicity at those sites (Sebti *et al.*, 1987). Some bleomycin-resistant cells contain high levels of hydrolase activity (Sebti *et al.*, 1991). In other cell lines resistance has been attributed to decreased uptake, cleavage by the hydrolase, repair of strand breaks, or drug inactivation by thiols or thiol-rich proteins (Zuckerman *et al.*, 1986).

Absorption, Fate, and Excretion. Bleomycin is administered parenterally, either intravenously or intramuscularly, or instilled into the bladder for local treatment of bladder cancer (Bracken *et al.*, 1977). After intravenous infusion, relatively high drug concentrations are detected in the skin and lungs of experimental animals, and these organs become major sites of toxicity. Having a high molecular mass, bleomycin crosses the blood–brain barrier poorly.

After intravenous administration of a bolus dose of 15 units/m², peak concentrations of 1 to 5 units/ml are achieved in plasma. The half-time for elimination is approximately 3 hours. The average steady-state concentration of bleomycin in plasma of patients receiving continuous intravenous infusions of 30 units daily for 4 to 5 days is approximately 0.15 units/ml. About two-thirds of the drug normally is excreted in the urine. Concentrations in plasma are greatly elevated if usual doses are given to patients with renal impairment, and such patients are at high risk of developing pulmonary toxicity. Doses of bleomycin should be reduced in the presence of a creatinine clearance lower than 60 ml/min (Dalglish *et al.*, 1984).

Therapeutic Uses. The recommended dose of bleomycin (BLENOXANE, others) is 10 to 30 units/m² given weekly by the intravenous or intramuscular route. It also may be administered as a subcutaneous injection or as an intrapleural or intracystic instillation. Total courses exceeding 250 units should be given with great caution because of a marked increase in pulmonary toxicity above this total dose. However, pulmonary toxicity may occur at lower doses (*see below*).

Bleomycin is highly effective against germ cell tumors of the testis and ovary. In testicular cancer it is curative when used with cisplatin and vinblastine or cisplatin and etoposide. It is used as a component of the standard ABVD regimen for Hodgkin's disease, although its contribution to this curative therapy is uncertain (Duggan *et al.*, 2003). Bleomycin also is given intrapleurally (60 units) for malignant pleural effusions.

Clinical Toxicities. Because bleomycin causes little myelosuppression, it has significant advantages in combination with other cytotoxic drugs. However, it does cause significant cutaneous toxicity, including hyperpigmentation, hyperkeratosis, erythema, and even ulceration. These changes may begin with tenderness and swelling of the distal digits and progress to erythematous, ulcerating lesions over the elbows, knuckles, and other pressure areas. Skin changes often leave a residual hyperpigmentation at these points and may recur when patients are treated with other antineoplastic drugs.

The most serious adverse reaction to bleomycin is pulmonary toxicity, which begins with a dry cough, fine rales, and diffuse basilar infiltrates on x-ray and may progress to life-threatening pulmonary fibrosis. Radiologic changes may be indistinguishable from interstitial infection or tumor, but may progress to dense fibrosis, cavitation, atelectasis or lobar collapse, or even apparent consolidation. Approximately 5% to 10% of patients receiving bleomycin develop clinically apparent pulmonary toxicity, and about 1% die of this complication. Most who recover experience a significant improvement in pulmonary function, but fibrosis may be irreversible (Van Barneveld *et al.*, 1987). Pulmonary function tests are not of predictive value for detecting early onset of this complication. The CO diffusion capacity declines in patients receiving doses above 250 units. The risk is related to total dose, with a significant increase above total doses of 250 units and in patients over 70 years of age and in those with underlying pulmonary disease; sin-

gle doses of 30 units/m² or more also are associated with an increased risk of pulmonary toxicity. Administration of high inspired oxygen concentrations during anesthesia or respiratory therapy may aggravate or precipitate pulmonary toxicity in patients previously treated with the drug. There is no known specific therapy for bleomycin lung injury except for standard symptomatic management and pulmonary care. Steroids are of uncertain benefit. The etiology of bleomycin pulmonary toxicity has been the subject of intense investigation in rodent models. These studies implicate cytokine (transforming growth factor- β [TGF- β] and tumor necrosis factor [TNF]) and chemokine (CXCL12) secretion by macrophages in response to epithelial apoptosis in the pulmonary fibrosis (Munger *et al.*, 1999). Recruitment of bone marrow derived fibrocytes to the site of injury may contribute to the evolution of pulmonary fibrosis (Garanziotis *et al.*, 2004).

Other toxic reactions to bleomycin include hyperthermia, headache, nausea and vomiting, and a peculiar acute fulminant reaction observed in patients with lymphomas. This is characterized by profound hyperthermia, hypotension, and sustained cardiorespiratory collapse; it does not appear to be a classical anaphylactic reaction and possibly may be related to release of an endogenous pyrogen. Because this reaction has occurred in approximately 1% of patients with lymphomas and has resulted in deaths, it is recommended that patients receive a test dose of bleomycin (1 unit), followed by a 1-hour period of observation, before administration of the drug on standard dosage schedules. Unexplained exacerbations of rheumatoid arthritis also have been reported during bleomycin therapy. Raynaud's phenomenon and coronary artery occlusive events have been reported in patients with testicular tumors treated with bleomycin in combination with other chemotherapeutic agents.

Mitomycin

This antibiotic was isolated from *Streptococcus caespitosus* by Wakaki and associates in 1958. It has limited clinical utility, having been replaced by less toxic and more effective drugs in lung, colorectal, and anal cancers. However, it remains of considerable pharmacologic interest.

Mitomycin contains an azauridine group and a quinone group in its structure, as well as a mitosane ring, and each of these participates in the alkylation reactions with DNA. Its structural formula is:

MITOMYCIN

Mechanism of Action. After intracellular enzymatic or spontaneous chemical reduction of the quinone and loss of the methoxy group, mitomycin becomes a bifunctional or trifunctional alkylating agent (Verweij *et al.*, 2001). Reduction occurs preferentially in hypoxic cells in some experimental systems. The drug inhibits DNA synthesis and cross-links DNA at the N6 position of adenine and at the O⁶

and N7 positions of guanine. In addition, single-strand breakage of DNA and chromosomal breaks are caused by mitomycin. Mitomycin is a potent radiosensitizer and is teratogenic and carcinogenic in rodents. Resistance has been ascribed to deficient activation, intracellular inactivation of the reduced quinone, and P-glycoprotein-mediated drug efflux (Dorr, 1988).

Absorption, Fate, and Excretion. Mitomycin is administered intravenously. It disappears rapidly from the blood after injection, with a half-life of 25 to 90 minutes. Peak concentrations in plasma are 0.4 $\mu\text{g}/\text{ml}$ after doses of 20 mg/m^2 (Dorr, 1988). The drug is widely distributed throughout the body but is not detected in the CNS. Inactivation occurs by metabolism or chemical conjugation. Less than 10% of the active drug is excreted in the urine or the bile.

Therapeutic Uses. Mitomycin (mitomycin-C; MUTAMYCIN) is administered by intravenous infusion; extravasation may result in severe local injury. The usual dose (6 to 10 mg/m^2) is given as a single bolus every 6 weeks. Dosage is modified based on hematological recovery. Mitomycin also may be used by direct instillation into the bladder to treat superficial carcinomas (Boccardo *et al.*, 1994).

Mitomycin is used with decreasing frequency in combination with 5-FU, cisplatin, or doxorubicin in carcinomas of the cervix, stomach, breast, bladder, anus, head and neck, and lung.

Clinical Toxicities. The major toxic effect is myelosuppression, characterized by marked leukopenia and thrombocytopenia; after higher doses, the nadirs may be delayed and cumulative, with recovery only after 6 to 8 weeks of pancytopenia. Nausea, vomiting, diarrhea, stomatitis, dermatitis, fever, and malaise also are observed. A hemolytic uremic syndrome represents the most dangerous toxic manifestation of mitomycin and is believed to result from drug-induced endothelial damage. Patients who have received more than 50 mg/m^2 total dose may acutely develop hemolysis, neurological abnormalities, interstitial pneumonia, and glomerular damage resulting in renal failure. The incidence of renal failure increases to 28% in patients who receive total doses of 70 mg/m^2 or higher (Valavaara and Nordman, 1985). There is no effective treatment for the disorder; blood transfusion may cause pulmonary edema. Mitomycin causes interstitial pulmonary fibrosis, and total doses above 30 mg/m^2 have infrequently led to congestive heart failure. It also may potentiate the cardiotoxicity of doxorubicin when used in conjunction with this drug.

ENZYMES

L-Asparaginase

In 1953, Kidd reported that guinea pig serum had anti-leukemic activity and identified *L-asparaginase* (L-asp) as the source of this activity (Kidd, 1953). Fifteen years later, the enzyme was introduced into cancer chemotherapy in an effort to exploit a distinct, qualitative difference between normal and malignant cells (Broome, 1981). It remains a standard agent for treating lymphocytic leukemia.

Mechanism of Action. While most normal tissues are able to synthesize L-asparagine in amounts sufficient for protein synthesis, some types of lymphoid malignancies derive the required amino acid from plasma. L-asp, by catalyzing the hydrolysis of circulating asparagine to aspartic acid and ammonia, deprives these malignant cells of the asparagine necessary for protein synthesis, leading to cell death. L-asp commonly is used in combination with other agents, including methotrexate, doxorubicin, vincristine, and prednisone for the treatment of ALL and for high-grade lymphomas. The sequence of drug administration in these combinations may be critical; for example, synergistic cytotoxicity results when methotrexate precedes the enzyme, but the reverse sequence leads to abrogation of methotrexate cytotoxicity. The latter outcome is a consequence of the inhibition of protein synthesis by L-asp, an effect that stops the progression of cells through the cell cycle and negates the effect of methotrexate, a drug that exerts its greatest effect during the DNA synthetic phase of the cell cycle (Capizzi and Handschumacher, 1982).

Resistance arises through induction of asparagine synthetase in tumor cells. For unknown reasons, hyperdiploid ALL cells are particularly sensitive to L-asp (Pui *et al.*, 2004).

Absorption, Fate, Excretion, and Therapeutic Use. L-Asparaginase (ELSPAR) is given parenterally. Three different preparations of L-asp are used clinically. Their pharmacokinetics and immunogenicity differ significantly. After intravenous administration, *E. coli*-derived L-asp has a clearance rate from plasma of 0.035 ml/minute per kg, a volume of distribution that approximates the volume of plasma in humans, and a half-life of 14 to 24 hours (Asselin *et al.*, 1993). It is given in doses of 6000 to 10,000 international units every third day for 3 to 4 weeks, although doses up to 25,000 international units once per week have been employed in experimental ALL protocols. Enzyme levels are maintained above 0.03 international units/ml in plasma to abolish asparagine in the bloodstream. An *Erwinia* preparation (*see below*), used in patients hypersensitive to the enzyme from *E. coli*, has a shorter half-life of 16 hours and thus requires administration of higher doses. *Pegaspargase* (PEG-L-ASPARAGINASE; ONCAS-PAR), is a preparation in which the enzyme is conjugated to 5000-dalton units of monomethoxy polyethylene glycol and is cleared much less rapidly. Its plasma half-life is 6 days, and it is administered in doses of 2500 international units/ m^2 intramuscularly every week. Pegaspargase has much reduced immunogenicity (fewer than 20% of patients develop antibodies) (Hawkins *et al.*, 2004).

Intermittent dosage regimens have an increased risk of inducing anaphylaxis. In hypersensitive patients, circulating antibodies lead to immediate inactivation of the enzyme and L-asp levels rapidly become immeasurable after drug administration. Not all patients with neutralizing antibodies experience hypersensitivity, although enzyme may be inactivated and therapy may be ineffective. In previously untreated ALL, pegaspargase produces more rapid clearance of lymphoblasts from bone marrow than does the *E. coli* preparation and circumvents the rapid antibody-mediated clearance seen with *E. coli* enzyme in relapsed patients (Avramis *et al.*, 2002). Only partial depletion of CSF asparagine is achieved by the various asparaginase preparations in clinical use.

Clinical Toxicity. L-Asparaginase has minimal effects on bone marrow and gastrointestinal mucosa. Its most serious toxicities result from its antigenicity as a foreign protein and its inhibition of protein synthesis. Hypersensitivity reactions occur in 5% to 20% of patients and may be fatal. These reactions are heralded by the appearance of circulating neutralizing antibody in some, but not all, hypersensitive

patients. In these patients, pegaspargase is a safe alternative, and the *Erwinia* enzyme may be used with caution.

Other toxicities result from inhibition of protein synthesis in normal tissues and include hyperglycemia due to insulin deficiency, clotting abnormalities due to deficient clotting factors, and hypalbuminemia. The clotting problems may take the form of spontaneous thrombosis related to deficient factor S, factor C, or antithrombin III, or less frequently, hemorrhagic episodes. Thrombosis of cortical sinus vessels frequently goes unrecognized. Brain magnetic resonance imaging studies should be considered in patients treated with L-asp who present with seizures, headache, or altered mental status (Bushara and Rust, 1997). L-Asparaginase-induced thromboses occur with greater frequency in patients with underlying inherited disorders of coagulation, such as factor V Leiden, elevated serum homocysteine, protein C or S deficiency, antithrombin III deficiency, or the 620210A variant of prothrombin (Nowak-Gottl *et al.*, 1999). Intracranial hemorrhage in the first week of L-asp treatment is an infrequent but devastating complication. L-Asparaginase suppresses immune function as well.

In addition to these side effects, coma may rarely result and has been attributed to ammonia toxicity resulting from L-asparagine hydrolysis. Pancreatitis also has been observed; its cause is uncertain.

IV. MISCELLANEOUS AGENTS

HYDROXYUREA

Dresler and Stein originally synthesized hydroxyurea in 1869, but its potential biological significance was not recognized until 1928, when leukopenia and megaloblastic anemia were observed in experimental animals treated with this compound. In the 1950s, the drug was evaluated in a large number of experimental murine tumor models and was found to have broad antitumor activity against both leukemia and solid tumors. Clinical trials with hydroxyurea began in the 1960s. Since then this drug has attracted interest, as it has unique and surprisingly diverse biological effects that have led to exploration of its clinical utility as an antileukemic drug, radiation sensitizer, and an inducer of fetal hemoglobin in patients with sickle cell disease. Its use has been encouraged because the drug is orally administered and its toxicity in most patients is modest and limited to myelosuppression (Paz-Ares and Donehower, 2001). The structural formula of hydroxyurea is:

Cytotoxic Action. Hydroxyurea (HU) inhibits the enzyme ribonucleoside diphosphate reductase. This enzyme, which catalyzes the reductive conversion of ribonucleotides to deoxyribonucleotides, is a crucial rate-limiting step in the biosynthesis of DNA, and it represents a logical target for the design of chemotherapeutic agents. HU destroys a tyrosyl free radical that binds iron in the catalytic center of the human ribonucleotide reductase subunit hRRM2. Iron is an essential mediator of the reduction of nucleotides, providing an electron for this reaction. The drug is specific for the S phase of the cell cycle, in which concentrations of the target reductase are maximal, and causes cells to arrest at or near the G₁-S interface. Cell-cycle arrest by HU is mediated by both p53-dependent and p53-independent mechanisms (Zhou *et al.*, 2003). Since cells are highly sensitive to irradiation in the G₁-S boundary, combinations of HU and irradiation cause synergistic toxicity (Schilsky *et al.*, 1992). Through depletion of deoxynucleotides, HU also may potentiate the antiproliferative effects of DNA-damaging agents such as cisplatin, alkylating agents, or topoisomerase II inhibitors, and facilitates the incorporation of drugs such as Ara-C, gemcitabine, or fludarabine into DNA. HU also induces the expression of a number of genes (*e.g.*, TNF, interleukin-6) and accelerates the loss of extrachromosomally amplified genes present in double-minute chromosomes formed in response to methotrexate therapy. The role of nitric oxide release in its differentiating activity and in its antitumor effects is uncertain, but intriguing (Cokic *et al.*, 2003).

HU reduces vaso-occlusive events in patients with sickle cell disease. It does so *via* several potential mechanisms. Increased expression of fetal hemoglobin and synthesis of fetal hemoglobin may result from suppression of erythroid precursor proliferation with compensatory stimulation of a distinct set of fetal Hb-producing cells. An alternative mechanism (Steinberg, 2003) has been offered because of the ability of HU to generate nitric oxide both *in vitro* and *in vivo*, causing nitrosylation of small-molecular-weight GTPases that stimulate γ -globin production in erythroid precursors. Through the induction of HbF, it promotes solubility of hemoglobin within red cells. It also reduces adhesion of red cells to vascular endothelium, and by suppressing the production of neutrophils, decreases their contribution to vascular occlusion. It specifically lowers the expression of adhesion molecules such as L-selectin in neutrophils (Halsey and Roberts, 2003).

The principal mechanism by which cells achieve resistance to HU is increased synthesis of the hRRM2 subunit of ribonucleoside diphosphate reductase, thus restoring enzyme activity. HU reduces the frequency of painful events, acute chest syndrome, and secondary strokes in patients.

Absorption, Fate, and Excretion. The oral bioavailability of hydroxyurea is excellent (80% to 100%), and comparable plasma concentrations are seen after oral or intravenous dosing (Rodríguez *et al.*, 1998). Peak plasma concentrations are reached 1 to 1.5 hours after oral doses of 15 to 80 mg/kg. Hydroxyurea disappears from plasma with a half-life from 3.5 to 4.5 hours. The drug readily crosses the blood-brain barrier, and it appears in significant quantities in human breast milk. From 40% to 80% of the drug is recovered in the urine within 12 hours after either intravenous or oral administration. Although precise guidelines are not available, it seems prudent to modify doses for patients with abnormal renal function until individual tolerance can be assessed. Data from several experimental animal systems suggest that metabolism of hydroxyurea does occur, but the extent and significance of metabolism of the drug in humans have not been established.

Therapeutic Uses. In cancer treatment, two dosage schedules for hydroxyurea (HYDREA, DROXIA, others), alone or in combination with other drugs, are most commonly used in a variety of clinical situations: (1) intermittent therapy with 80 mg/kg administered orally as a single dose every third day; or (2) continuous therapy with 20 to 30 mg/kg administered as a single daily dose. In patients with essential thrombocythemia and in sickle cell disease, HU is given in daily dose of 15 to 30 mg/kg, depending on tolerance and myelosuppression (Halsey and Roberts, 2003). Dosage should be adjusted according to the number of leukocytes in the peripheral blood. Treatment is typically continued for a period of 6 weeks in malignant diseases to determine its effectiveness; if satisfactory results are obtained, therapy can be continued indefinitely, although leukocyte counts at weekly intervals are advisable.

The principal use of HU has been as a myelosuppressive agent in various myeloproliferative syndromes, particularly CML, polycythemia vera, and essential thrombocytosis. In essential thrombocythemia, it is the drug of choice for patients with a platelet count over 1.5 million cells per mm³, or with a history of arterial or venous thrombosis. In this disease it dramatically lowers the risk of thrombosis by lowering the platelet count, but also through its effect on neutrophil and red cell counts, and by reducing expression of L-selectin and increasing nitric oxide production of neutrophils (Finazzi *et al.*, 2003).

In CML, HU has been largely replaced by imatinib (Silver *et al.*, 1999). Thus, HU cannot be considered to be standard therapy, although it has produced anecdotal, temporary remissions in patients with advanced cancers (*e.g.*, head and neck or genitourinary carcinomas, melanoma). HU has been incorporated into several schedules with concurrent irradiation, as it is able to synchronize cells into a radiation-sensitive phase of the cell cycle. This combination has shown promise in several diseases, including cervical carcinoma, primary brain tumors, head and neck cancer, and non-small cell lung cancer, although it has not been proven to be superior to regimens including cisplatin and irradiation.

HU (DROXIA) has been approved by the FDA for the treatment of adult patients with sickle cell disease. Hydroxyurea also appears to be effective in children with sickle cell disease and in patients with sickle cell- α -thalassemia and sickle cell-hemoglobin C disease (Zimmerman *et al.*, 2004).

Clinical Toxicity. Hematopoietic depression—involving leukopenia, megaloblastic anemia, and occasionally thrombocytopenia—is the major toxic effect; recovery of the bone marrow usually is prompt if the drug is discontinued for a few days. Other adverse reactions include a desquamative interstitial pneumonitis, gastrointestinal disturbances, and mild dermatological reactions; more rarely, stomatitis, alopecia, and neurological manifestations have been encountered. Increased skin and fingernail pigmentation may occur, as well as painful leg ulcers. Hydroxyurea has uncertain effect on the risk of secondary leukemia in patients with myeloproliferative disorders and should be used with caution in nonmalignant diseases. Hydroxyurea is a potent teratogen in all animal species tested and should not be used in women with childbearing potential.

DIFFERENTIATING AGENTS

One of the hallmarks of malignant transformation is a block in differentiation. In some malignancies, the trans-

forming genetic change directly confers this block, an example being the t(15;17) translocation in APL. This translocation involves the retinoic acid receptor- α , which forms a heterodimeric retinoid binding protein critical for differentiation, and the PML gene, which encodes a transcription factor important in inhibiting proliferation and promoting myeloid differentiation. The product of the new gene, a fusion protein of portions of RAR- α and PML, binds retinoids with much decreased affinity, lacks PML inhibitory function, and blocks the function of transcription factors such as C/EBP, which promote myeloid differentiation (Jing, 2003). The fusion gene also promotes expression of genes that increase leukemic stem cell renewal, and suppresses expression of DNA repair functions, thereby enhancing mutability of APL cells (Alcalay *et al.*, 2003). A number of chemical entities, including vitamin D and its analogs, retinoids, benzamides and other inhibitors of histone deacetylase, various cytotoxics and biological agents, and inhibitors of DNA methylation, can induce differentiation in tumor cell lines *in vitro*. Fittingly, the first and best example of differentiating therapy has been discovered in the treatment of APL.

Retinoids

Tretinoin. The biology and pharmacology of retinoids and related compounds are discussed in detail in Chapter 62. The most important of these for cancer treatment is *tretinoin* (all-trans retinoic acid; ATRA), which induces a high rate of complete remission in APL as a single agent, and in combination with anthracyclines, has become part of a curative regimen for this disease (Huang *et al.*, 1988).

Under physiologic conditions, the RAR- α receptor dimerizes with the retinoid X receptor to form a complex that binds ATRA tightly, displacing a repressor of differentiation. In APL cells, physiologic concentrations of retinoid are inadequate to displace the repressor. Pharmacologic concentrations, however, are effective in displacing the repressor, activating the differentiation program, and promoting degradation of the PML-RAR- α fusion gene. Resistance to ATRA arises by further mutation of the fusion gene, abolishing ATRA binding or by loss of expression of the fusion gene (Roussel and Lanotte, 2001). Sensitivity can be restored by transfection of a functional RAR- α gene.

Clinical Pharmacology. The usual dosing regimen of orally administered ATRA is 45 mg/m² per day until remission is achieved. ATRA as a single agent reverses the hemorrhagic diathesis associated with APL and induces a high rate of temporary remission. However, clinical trials have clearly established the benefit of giving ATRA in combination with an anthracycline for remission induction, achieving 70% or greater relapse-free long-term survival (Tallman *et al.*, 1997, Sanz *et al.*, 1999).

ATRA concentrations reach 400 ng/ml in plasma, and are cleared by a CYP-mediated elimination with a half-life of less than 1 hour. Treatment with inducers of CYP leads to more rapid drug disappearance, and in some patients, resistance to ATRA (Gallagher, 2002). Remission rate and time to remission induction improve with the inclusion of other chemotherapy. Corticosteroids and chemotherapy decrease the occurrence of “retinoic acid syndrome,” which is characterized by fever, dyspnea, weight gain, pulmonary infiltrates, and pleural or pericardial effusions. When used as a single agent for remission induction, especially in patients with >5000 leukemic cells per mm³ in the peripheral blood, ATRA induces an outpouring of cytokines and mature appearing neutrophils of leukemic origin. These cells express high concentrations of integrins and other adhesion molecules on their surface, and clog small vessels in the pulmonary circulation, leading to significant morbidity in 15% to 20% of patients. The syndrome includes respiratory distress, pleural and pericardial effusions, mental status changes, and death.

Toxicity. Retinoids as a class, including ATRA, cause dry skin, cheilitis, reversible hepatic enzyme abnormalities, bone tenderness, and hyperlipidemia, and as mentioned above, the retinoic acid syndrome.

Arsenic Trioxide (ATO)

Although recognized as a heavy metal toxin for centuries, *arsenic trioxide* (ATO) attracted interest as a medicinal agent nearly a century ago for syphilis and parasitic disease, and eventually CML. Through the efforts of Shen and colleagues in Shanghai (Shen *et al.*, 1997), it was shown to be a highly effective treatment for relapsed APL, producing complete responses in more than 85% of such patients. The chemistry and toxicity of arsenic is considered in detail in Chapter 65.

The mechanism of pharmacological action of ATO remains uncertain (Miller *et al.*, 2002). It causes differentiation of APL cells in culture and in clinical use, and also promotes apoptosis. ATO is highly reactive with sulfhydryls of glutathione and with cysteine-rich proteins. It generates free radicals and inhibits angiogenesis, both of which may be relevant to its antileukemic effects (Miller *et al.*, 2002). Cells exposed to ATO upregulate p53, Jun kinase, and caspases associated with the intrinsic pathway of apoptosis (Davison *et al.*, 2004). It promotes the phosphorylation, sumoylation, and the degradation of the fusion protein, as well as promoting degradation of NF- κ B, a transcription factor that stimulates angiogenesis and dampens apoptotic responses in cells with DNA damage (Hayakawa and Privalsky, 2004).

Clinical Pharmacology. ATO is administered as a 2-hour intravenous infusion in doses of 0.15 mg/kg per day for up to 60 days, until remission is documented. Further consolidation therapy resumes after a 3-week break. The primary mechanism of elimination is through enzymatic methylation (Miller *et al.*, 2002). Methylated metabolites have uncertain biological effects. Peak concentrations of ATO in plasma reach 5 to 7 μ M with rapid conversion to metabolites. Little drug appears in the urine. No dose reductions are indicated for hepatic or renal dysfunction.

Toxicity. Pharmacological doses of ATO are well tolerated. Patients may experience reversible side effects including hyperglycemia, hepatic enzyme elevations, fatigue, dysesthesias, and lightheadedness. Ten percent or fewer of patients will experience a leukocyte maturation syndrome similar to that seen with ATRA, including pulmonary distress, effusions, and mental status changes. Oxygen, corticosteroids, and temporary discontinuation of ATO leads to full reversal of this syndrome (Soignet *et al.*, 1998). Another important and potentially dangerous side effect is lengthening of the QT interval on the electrocardiogram in 40% of patients. The basis for this conduction defect appears to be an enhancement of Ca²⁺ flux and an inhibition of K⁺ channels in myocardial tissue by As₂O₃. This change leads to atrial or ventricular arrhythmias in a small minority of patients, but daily monitoring of the ECG and repletion of serum K⁺ in patients with hypokalemia are standard measures in ATO therapy.

PROTEIN TYROSINE KINASE INHIBITORS

Protein kinases are ubiquitous and critical components of signal transduction pathways that transmit information concerning extracellular or cytoplasmic conditions to the nucleus, thereby influencing gene transcription and/or DNA synthesis. The human genome contains approximately 550 protein kinases and an additional 130 protein phosphatases that regulate the activity of the various protein kinases. The protein kinases can be classified into three different categories: tyrosine kinases, with specific activity for tyrosine residues only, serine/threonine kinases, with activity for serine and threonine residues only, and kinases with activity for all three residues. Tyrosine kinases can be further subdivided into proteins that have an extracellular ligand binding domain (receptor tyrosine kinases) and enzymes that are confined to the cytoplasm and/or nuclear cellular compartment (nonreceptor tyrosine kinases) (Hubbard and Till, 2000). Abnormal activation of specific protein tyrosine kinases has been demonstrated in many human neoplasms (Blume-Jensen and Hunter, 2001), making them attractive molecular targets for cancer therapy. There currently are three small-molecular-weight protein tyrosine kinase inhibitors that are FDA approved and many others are in clinical trials.

Imatinib

Chemistry. Imatinib mesylate (STI 571, GLEEVEC, GLIVEC) was identified through the combined use of high throughput screening and medicinal chemistry and is 4-[(4-methyl-1-piperazinyl)methyl]-N-[4-methyl-3-[[4-(3-pyridinyl)-2-pyrimidinyl] amino]-phenyl]benzamide-methanesulfonate. The lead compound of this series, a 2-phenylaminopyrimidine, had low potency and poor specificity, inhibiting both

serine/threonine and tyrosine kinases (Buchdunger *et al.*, 2001). The addition of a 3'-pyridyl group at the 3'-position of the pyrimidine enhanced the cellular activity of the derivatives. A number of chemical modifications resulted in improved activity against the platelet-derived growth factor receptor (PDGFR) tyrosine kinase and loss of serine/threonine kinase inhibition. These compounds also were found to possess inhibitory activity toward the cytoplasmic ABL tyrosine kinase and receptor tyrosine kinase, KIT. Introduction of N-methylpiperazine as a polar side chain greatly improved water solubility and oral bioavailability, yielding imatinib, whose chemical structure is:

Mechanism of Action. Imatinib has inhibitory activity against ABL and its activated derivatives v-ABL, BCR-ABL, and EVT6-ABL (Buchdunger *et al.*, 1996; Druker *et al.*, 1996). IC_{50} values are in the range of 0.025 μM using *in vitro* kinase assays with immunoprecipitated or purified proteins. Activity against the PDGFR and KIT are in a similar range. In contrast, the IC_{50} values for a large number of other tyrosine and serine/threonine kinases generally are at least 100 times higher, demonstrating that imatinib exhibits a high level of selectivity (Buchdunger *et al.*, 2001).

Cellular studies showed that imatinib specifically inhibited the proliferation of myeloid cell lines that express the BCR-ABL fusion protein associated with CML (Druker *et al.*, 1996). The IC_{50} for BCR-ABL phosphorylation in intact cells is between 0.25 and 0.5 μM (Buchdunger *et al.*, 2001). Complete inhibition of proliferation with cell death through apoptotic mechanisms occurs between 0.5- and 1- μM concentrations of imatinib. Similar concentrations of imatinib inhibit the proliferation of cells dependent on KIT or PDGFR for proliferation. This includes cells expressing mutant KIT isoforms associated with gastrointestinal stromal tumors (GISTs) (Heinrich *et al.*, 2000), the ETV6-PDGFR fusion associated with a subset of chronic myelomonocytic leukemia (CMML) (Carroll *et al.*, 1997), and the FIP1L1-PDGFR fusion associated with hypereosinophilic syndrome (HES) (Cools *et al.*, 2003).

Mechanisms of Resistance. Resistance to imatinib can be primary, that is, failure to achieve a specific desired response, or secondary (acquired), that is, loss of a desired response. The acquired resistance predominantly results from mutations in the kinase domain (Shah *et al.*, 2002), although some patients have amplification of BCR-ABL (Hochhaus *et al.*, 2002). Interestingly, in CML patients in whom the malignancy is driven by the BCR-ABL tyrosine kinase, mutations have only been observed in the ABL kinase, whereas in GIST and HES, only KIT and PDGFR mutations have been observed, respectively (Cools *et al.*, 2003; Wakai *et al.*, 2004). These data demonstrate the critical tumor dependence on the specific mutated kinase. ABL mutations are scattered throughout the kinase domain and variably render the kinase less sensitive to imatinib (Corbin *et al.*, 2003). Mutations affect sites that are direct contact points between the kinase and imatinib or affect residues that are required for the kinase to adopt a conformation to which imatinib can bind (Deininger and Druker,

2004; Shah *et al.*, 2002). Alternate kinase inhibitors that can inhibit the imatinib-resistant mutations are currently in clinical development (Deininger and Druker, 2004).

In contrast to acquired resistance, the mechanisms mediating primary resistance are unknown. Hypotheses include alternate pathways that allow tumors to escape the antiapoptotic effects of an agent targeting a single pathway, quiescence of a population of cells in the tumors that are not susceptible to the antiproliferative effects of this class of agents, or inadequate drug levels due to poor tumor penetration of the drug, drug efflux, protein binding, or unappreciated mutations that affect drug sensitivity.

Pharmacokinetics. Imatinib is well absorbed after oral administration with maximum plasma concentrations (C_{max}) achieved within 2 to 4 hours (Peng *et al.*, 2004). Mean absolute bioavailability for the capsule formulation is 98%. Following oral administration in healthy volunteers, the elimination half-lives of imatinib and its major active metabolite, the N-desmethyl derivative, are approximately 18 and 40 hours, respectively. Mean imatinib AUC increases proportionally with increasing dose in the range 25 to 1000 mg (Peng *et al.*, 2004). There is no significant change in the pharmacokinetics of imatinib on repeated dosing or with administration of food. Doses >300 mg per day achieve trough levels of 1 μM , which corresponds to *in vitro* levels required to kill BCR-ABL-expressing cells. Pharmacodynamic inhibition of the BCR-ABL tyrosine kinase can be demonstrated in white blood cells from patients with CML with a plateau in inhibition between doses of 250 and 750 mg (Druker *et al.*, 2001). Nonrandomized studies suggest that improved responses may be observed with doses of 600 or 800 mg per day as opposed to 400 mg per day (Kantarjian *et al.*, 2004; Talpaz *et al.*, 2002), consistent with dose-dependent inhibition of the kinase.

CYP3A4 is the major enzyme responsible for metabolism of imatinib. Other cytochrome P450 enzymes, such as CYP1A2, CYP2D6, CYP2C9, and CYP2C19, play a minor role in its metabolism. Plasma levels of drugs that are substrates for these cytochromes may increase if coadministered with imatinib due to competition for biotransformation pathways, and those that are enzyme inhibitors or inducers may increase or decrease the plasma levels of imatinib, respectively. A single dose of *ketoconazole* increases mean C_{max} and AUC of imatinib by 26% and 40%, respectively, confirming that imatinib is a CYP3A4 substrate (Dutreix *et al.*, 2004). Imatinib increased the C_{max} and AUC of *simvastatin* by 2 and 3.5 times, respectively, indicating inhibition of CYP3A4 (O'Brien *et al.*, 2003). Coadministration with *rifampin*, an inducer of CYP3A4, reduces plasma imatinib AUC by approximately 70% (Bolton *et al.*, 2004). Elimination of imatinib occurs predominantly in the feces, mostly as metabolites.

Therapeutic Uses. Imatinib has efficacy in diseases in which the ABL, KIT, or PDGFR have dominant roles in driving the proliferation of the tumor. This dominant role is defined by the presence of a mutation that results in constitutive activation of the kinase, either by fusion with another protein or point mutations. Thus, imatinib shows remarkable therapeutic benefits in patients with CML (BCR-ABL), GIST (KIT mutation positive), CMML (EVT6-PDGFR), HES (FIP1L1-PDGFR), and dermatofibrosarcoma protuberans (constitutive production of the ligand for PDGFR) (Druker, 2004). The situation in GIST is particularly instructive, as patients with an exon 11 mutation of KIT have a significantly higher partial response rate (72%) than those with no detectable KIT mutations (9%) (Heinrich *et al.*, 2003). Thus, KIT mutational status predicts response. The currently recommended dose of imatinib is 400 to 600 mg per day.

Clinical Toxicity. The most frequently reported drug-related adverse events are nausea, vomiting, edema, and muscle cramps (Deininger *et al.*, 2003). Most events are of mild-to-moderate grade, and only 2% to 5% of patients permanently discontinue therapy, most commonly because of skin rashes and elevations of transaminases (each in <1% of patients). Edema can manifest at any site, most commonly in the ankles and periorbital tissues. Severe fluid retention (pleural effusion, pericardial effusion, pulmonary edema, and ascites) is reported in 1% to 2% of patients taking imatinib. The probability of edema increases with higher imatinib doses and in persons >65 years old. Neutropenia and thrombocytopenia are consistent findings in all studies in leukemia patients, with a higher frequency at doses ≥ 750 mg. The occurrence of cytopenias also is dependent on the stage of CML, with a frequency of grade 3 or 4 neutropenia and thrombocytopenia between two- and threefold higher in blast crisis and accelerated phase compared to chronic phase. In solid tumor patients, grade 4 neutropenia has been reported in <5% of patients. Thrombocytopenia is much less common.

Gefitinib

The epidermal growth factor receptor (EGFR) belongs to a family of four receptor tyrosine kinases. The EGFR type 1 (ErbB1 or HER1) is overexpressed in many common malignancies, and may be activated by autocrine loops in many others. A truncated version of the EGFR (EGFRvIII) that has lost a portion of the extracellular ligand-binding domain and is constitutively activated, is found in a subset of patients with glioblastoma. Based on these data, the EGFR is viewed as a particularly attractive molecular target for anticancer drugs (Grunwald and Hidalgo, 2003).

Chemistry. Gefitinib (ZD1839, IRESSA, [4-(3-chloro-4-fluoroanilino)-7-methoxy-6-(3-morpholinopropoxy)quinazoline]) is a low-molecular-weight quinazoline derivative discovered through the screening of a compound library with the EGFR tyrosine kinase, which identified 4-anilinoquinazolines as lead compounds (Barker *et al.*, 2001). Structure-activity relationships reveal that the quinazoline moiety was absolutely required for activity with electron-donating substituents at the 6- and 7-positions leading to increased potency. Other chemical modifications improved potency and pharmacokinetics of these compounds. A wide variety of compounds were generated from this foundation and gefitinib was selected as the lead candidate for clinical development based on its superior *in vivo* antitumor activity and pharmacokinetic properties (Barker *et al.*, 2001). The chemical structure of gefitinib is displayed below.

Mechanism of Action. Gefitinib is a specific inhibitor of the EGFR tyrosine kinase that competitively inhibits ATP binding. Gefitinib inhibits the EGFR with an IC_{50} of 2.7 nM. It is 100 times less potent against highly related tyrosine kinases such as HER2 (ErbB2/neu) and does not inhibit a variety of serine/threonine kinases (Wakeling *et al.*, 2002). Preclinical studies showed that gefitinib inhibits the growth of a variety of cell lines that are dependent on EGFR activity for growth (Baselga and Averbuch, 2000; Grunwald and Hidalgo, 2003). Treatment with gefitinib was associated with cell-cycle arrest at the G_0/G_1 boundary. *In vivo* studies showed significant antitumor activity in a variety of human xenograft tumor models with EGFR overexpression. In these preclinical studies, although gefitinib treatment resulted in rapid tumor regression, the tumors regrew when the drug was discontinued, suggesting that long-term administration would be required to maintain activity. Interestingly, in xenograft models, expression levels of EGFR did not correlate with responses, suggesting that factors other than EGFR expression may be more predictive of response. Preclinical studies showed that combinations of gefitinib with chemotherapy or radiation therapy improves therapeutic outcome (Grunwald and Hidalgo, 2003).

Mechanisms of Resistance. The predominant problem with the clinical use of gefitinib has been relatively low response rates (Dancey and Freidlin, 2003). Consistent with the preclinical studies, levels of EGFR expression do not correlate with responses. As with KIT mutational status in GIST, patients whose non-small cell lung tumors have point mutations in the EGFR respond dramatically to gefitinib (Lynch *et al.*, 2004; Paez *et al.*, 2004). Thus, primary resistance could be due to the fact that tumors are not uniquely dependent on EGFR activity for survival. Although target inhibition by gefitinib has been demonstrated in normal skin (Albanell *et al.*, 2002), it is possible that poor tumor penetration of the drug could lead to incomplete inhibition of the EGFR. Alternatively, drug efflux, unappreciated mutations that affect drug sensitivity, or a variety of other factors that could affect target inhibition may have a role in mediating lack of responsiveness.

Pharmacokinetics. Following oral administration of gefitinib, peak plasma concentrations are achieved within 3 to 7 hours (Baselga *et al.*, 2002; Ranson *et al.*, 2002). Mean absolute bioavailability of the oral formulation is 59%. Exposure to gefitinib is not significantly altered by food; however, coadministration of drugs that cause sustained elevations in gastric pH to ≥ 5 reduce mean gefitinib AUC by 47%. Administration of gefitinib once daily results in two- to eightfold accumulation with steady-state exposures achieved after 7 to 10 doses. At steady state, circulating plasma concentrations typically are maintained within a two- to threefold range over the 24-hour dosing interval. The mean terminal half-life is 41 hours (Thomas and Grandis, 2004).

In vitro studies showed that the metabolism of gefitinib is predominantly via CYP3A4 (Cohen *et al.*, 2004). The major metabolite identified in human plasma is O-desmethyl gefitinib. It is 14 times less potent than gefitinib at inhibiting EGFR-stimulated cell growth and is unlikely to contribute significantly to the clinical activity of gefitinib. Substances that are inducers of CYP3A4 activity may increase metabolism and decrease gefitinib plasma concentrations. Therefore, CYP3A4 inducers (*e.g.*, phenytoin, carbamazepine, rifampin, barbiturates, or *St. John's wort*) may reduce efficacy. Coadministration with *rifampin* (a known potent CYP3A4

inducer) in healthy volunteers reduced mean gefitinib AUC by 83%. Coadministration with *itraconazole* (a CYP3A4 inhibitor) resulted in an 80% increase in the mean AUC of gefitinib in healthy volunteers (Cohen *et al.*, 2004). This increase may be clinically relevant since adverse experiences are related to dose and exposure. Elimination of gefitinib is primarily by metabolism and excretion in feces.

Therapeutic Uses. Gefitinib is approved for the treatment of patients with non–small cell lung cancer who have failed standard chemotherapy. Single-agent responses in these heavily pretreated patients are in the 12% to 18% range (Fukuoka *et al.*, 2003; Kris *et al.*, 2003). However, there is a subset of patients who responded dramatically to gefitinib and these are predominantly non-smoking women with bronchoalveolar tumors (Miller *et al.*, 2004). It has been shown that this subset of patients has EGFR mutations that render the EGFR hypersensitive to ligand and to gefitinib (Lynch *et al.*, 2004; Paez *et al.*, 2004). Tumors from patients responding to other EGFR inhibitors in clinical development, such as *erlotinib* (TARCEVA), display EGFR mutations. The recommended dose of gefitinib is one 250-mg tablet daily, taken with or without food.

Clinical Toxicity. The most commonly reported adverse drug reactions are diarrhea, rash, acne, pruritus, dry skin, nausea, vomiting, and anorexia (Baselga *et al.*, 2002; Ranson *et al.*, 2002). A higher rate of most of these adverse events is observed in patients treated with 500 mg per day of gefitinib as compared to treatment with 250 mg per day. Most adverse events are of mild-to-moderate grade. Less than 2% of patients have permanently discontinued therapy. Adverse drug reactions usually occur within the first month of therapy and generally are reversible. Asymptomatic increases in liver transaminases have been observed and periodic liver function testing should be performed. Interstitial lung disease, which may be acute in onset, has been observed uncommonly in patients receiving gefitinib, and some cases have been fatal. The overall frequency of interstitial lung disease is approximately 0.3% outside of Japan (39,000 patients exposed) and approximately 2% in Japan (27,000 patients exposed) (Cohen *et al.*, 2004).

Erlotinib

Pharmacology and Cytotoxic Effects. Erlotinib (TARCEVA) is a human HER1/EGFR tyrosine kinase inhibitor with the following chemical formula: N-(3-ethynylphenyl)-6,7-bis(2-methoxyethoxy)-4-quinazolinamine. It is indicated for treatment of patients with locally advanced or metastatic non–small cell lung cancer.

FDA approval was based on a 731-patient double-blind, multinational, randomized trial comparing oral erlotinib 150 mg daily to placebo. An analysis of EGFR protein expression status on treatment survival effect was performed; however, EGFR status was known for only one-third of patients. In the EGFR-positive subgroup, erlotinib prolonged survival compared to placebo by a median of 6.9 months. No apparent survival benefit for erlotinib was observed in the EGFR-negative subgroup. However, the confidence intervals for the two subgroups did not allow an erlotinib survival

effect in the EGFR-negative subgroup to be excluded. The chemical structure of erlotinib is shown below.

Absorption, Fate, and Excretion. Erlotinib is about 60% absorbed after oral administration and its bioavailability is substantially increased to almost 100% by food. Peak plasma levels occur 4 hours after an oral dose. Following absorption, erlotinib is approximately 93% protein-bound to albumin and α_1 -acid glycoprotein. Its half-life is ~36 hours. Erlotinib is metabolized primarily by CYP3A4 and to a lesser extent by CYP1A2 and CYP1A1.

Clinical Toxicities. The most common adverse reactions in patients receiving erlotinib were diarrhea and rash. Serious interstitial lung disease also has been reported. Other adverse effects include elevated liver enzymes and bleeding, especially in patients receiving warfarin. Coadministration of CYP3A4 inhibitors is expected to increase toxicity to erlotinib.

THALIDOMIDE

Thalidomide originally was developed in the 1950s for the treatment of pregnancy-associated morning sickness, but withdrawn from the market due to the tragic consequences of teratogenicity and dysmyelia (stunted limb growth) (Franks *et al.*, 2004). However, it has since been reintroduced to clinical practice, initially because of its clinical efficacy as an oral agent for the management of erythema nodosum leprosum, which the FDA approved in 1998 (*see* Chapter 47). Meanwhile, the realization of thalidomide's antiangiogenic and immunomodulatory effects, including the inhibition of TNF- α signaling, triggered an expansion of thalidomide uses in other disease settings, most notably multiple myeloma (MM) (Franks *et al.*, 2004). Indeed, significant clinical experience has been acquired on the activity of thalidomide in both newly diagnosed and heavily pretreated relapsed/refractory MM patients. In addition, thalidomide has shown clinical activity in patients with myelodysplastic syndromes and ongoing clinical studies are addressing the potential role of thalidomide in the therapeutic management of other neoplasias. Although the precise mechanism(s) of antitumor activity of thalidomide remain(s) to

be fully elucidated, substantial insight has been generated by extensive preclinical studies in MM. New analogs derived from thalidomide now are in clinical trials for MM and myelodysplasia.

Chemistry and Pharmacology of Thalidomide and Its Derivatives.

Thalidomide (Figure 51–17) exists at physiologic pH as a nonpolar racemic mixture of cell permeable and rapidly interconverting S(–) and R(+) isomers, the former being associated with the teratogenic, and the latter with the sedative properties of thalidomide. Thalidomide absorption from the GI tract is slow and highly variable (4 hours mean time to reach peak concentration [t_{max}], with a range of 1 to 7 hours) (Figg *et al.*, 1999). Thalidomide is widely distributed throughout most tissues and organs, without significant binding to plasma proteins, and with a large apparent volume of distribution (V_d). Importantly, thalidomide is detected in the semen of patients after a period of 4 weeks of therapy, with levels that correlate with serum levels. Thalidomide metabolism *via* the hepatic CYP system is limited, and no induction of its own metabolism is noted with prolonged use. However, thalidomide undergoes rapid and spontaneous nonenzymatic hydrolytic cleavage at physiologic pH, generating >50 metabolites, most of which are unstable *in vitro* or *in vivo*. Importantly, there are substantial species-specific differences in the patterns and profiles of thalidomide metabolites in mice compared with humans, which likely explains why teratogenicity of thalidomide was not detected in preclinical murine models (Lenz, 1962).

Elimination of thalidomide is mainly by spontaneous hydrolysis, which occurs in all body fluids, with an apparent mean clearance of 10 L/hour for the (R)-enantiomer and 21 L/hour for the (S)-enantiomer in adult subjects. This leads to higher blood concentrations of the (R)-enantiomer compared to those of the (S)-enantiomer. Thalidomide and its metabolites appear to be rapidly excreted in the urine, while the nonabsorbed portion of the drug is excreted unchanged in feces, but clearance is primarily nonrenal. Studies of both single and multiple dosing of thalidomide in elderly prostate cancer patients showed significantly longer half-life at higher doses (1200 mg daily) *versus* lower doses (200 mg daily) (Figg *et al.*, 1999). Conversely, no effect of increased age on elimination half-life was identified in the age range of 55 to 80 years. The impact of renal or hepatic dysfunction on thalidomide clearance remains to be fully elucidated.

Thalidomide's interactions with other drugs have not been systematically addressed, except for lack of significant interaction with oral contraceptives (Franks *et al.*, 2004) and thalidomide's effect in enhancing the sedative effects of barbiturates and alcohol and the catatonic effects of *chlorpromazine* and *reserpine*. Conversely, CNS stimulants (such as *methamphetamine* and *methylphenidate*) counteract the depressant effects of thalidomide.

Figure 51–17. Structures of thalidomide and lenalidomide. The asterisk denotes the chiral center.

Pharmacology of Thalidomide Derivatives. *Lenalidomide* (Figure 51–17) constitutes a lead compound in the new class of immunomodulatory thalidomide derivatives (IMiDs) and exhibits a constellation of pharmacological properties, including stimulation of T cells and NK cells, inhibition of angiogenesis and tumor cell proliferation, and modulation of hematopoietic stem cell differentiation (Corral and Kaplan, 1999; Hideshima *et al.*, 2000; Davies *et al.*, 2001). This orally administered agent has been tested in MM, myelodysplastic syndrome, and an expanding array of other clinical settings, because of preclinical data suggesting more potent activity than its parent compound, as well as less toxicity and a lack of teratogenic effects as compared to thalidomide (Franks *et al.*, 2004). Lenalidomide is rapidly absorbed following oral administration, with peak plasma levels occurring between 0.6 and 1.5 hours postdose. The C_{max} and AUC values increased proportionately with increasing dose, both over a single-dose range of 5 to 400 mg and after multiple dosing with 100 mg daily. The half-life increases with dose, from approximately 3 hours at the 5-mg dose, to approximately 9 hours at the 400-mg dose (the higher dose is believed to provide a better estimate of the half-life due to the prolonged elimination phase). Approximately 70% of the orally administered dose of lenalidomide is excreted by the kidney. Ongoing studies are characterizing the adverse-effect profile of lenalidomide use and are addressing the potential for drug interactions with other agents. More extensive clinical experience is required to determine whether lenalidomide is completely devoid of some of thalidomide's side effects.

Mechanism(s) of Action of Thalidomide and Its Immunomodulatory Derivatives. The precise mechanisms responsible for thalidomide's clinical activity remain to be completely elucidated. Its enantiomeric interconversion and spontaneous cleavage to multiple short-lived and poorly characterized metabolites, as well as its species-specific *in vivo* metabolic activation, confound the interpretation of preclinical *in vitro* and *in vivo* mechanistic studies. At least four distinct, but potentially complementary, mechanisms (Figure 51–18) have been proposed to explain the antitumor activity of thalidomide and its derivatives: (1) direct antiproliferative/proapoptotic antitumor effects (Hideshima *et al.*, 2000), probably mediated by one or more metabolites of thalidomide, that include inhibition of the transcriptional activity of NF- κ B and its antiapoptotic target genes, including the caspase inhibitors FLIP, cIAP-2 (cellular inhibitor of apoptosis-2), or the antiapoptotic Bcl-2 family member A1/Bfl-1 (Mitsiades *et al.*, 2002a); (2) indirect targeting of tumor cells by abrogation of the protection conferred to tumor cells by their cell adhesion molecule- or cytokine (*e.g.*, IL-6)-mediated interactions with bone marrow stromal cells (Hideshima *et al.*, 2000); (3) inhibition of cytokine production, release, and signaling, leading to antiangiogenic effects (D'Amato *et al.*, 1994); and (4) immunomodulatory effects, including enhanced natural killer (NK) cell-mediated cytotoxicity against tumor cells (Davies *et al.*, 2001), contributing to potentiated antitumor immune response. It is conceivable that because NF- κ B protects MM cells from the proapoptotic effects of steroids or cytotoxic chemotherapeutics (Mitsiades *et al.*, 2002b), the inhibitory effect of thalidomide and its derivatives on NF- κ B activity could account for the ability of its combination with dexamethasone or cytotoxic chemotherapeutics to achieve synergistic antitumor responses (Weber *et al.*, 2003).

Adverse Effects. Generally, thalidomide is well tolerated at doses below 200 mg daily. The most common adverse effects reported in

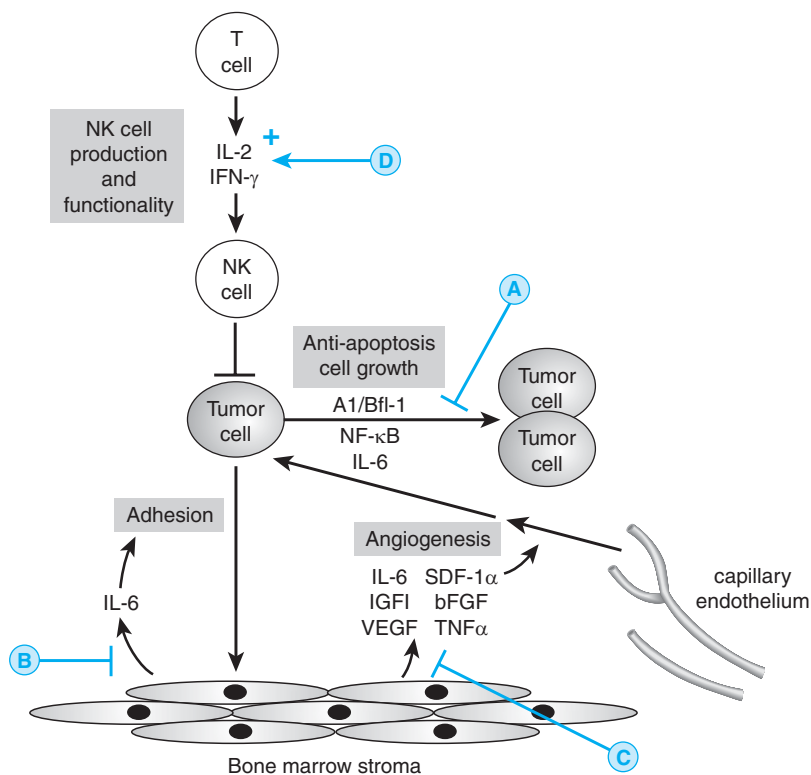

Figure 51–18. Schematic overview of proposed mechanisms of antimyeloma activity of thalidomide and its derivatives. Some biological hallmarks of the malignant phenotype are indicated in light gray boxes. The proposed sites of action for thalidomide (dark blue letters within circles) are hypothesized to be operative for thalidomide derivatives also. **A.** Direct anti-MM effect on tumor cells including G1 growth arrest and/or apoptosis, even against MM cells resistant to conventional therapy. This is due to the disruption of the anti-apoptotic effect of Bcl-2 family members, blocking NF- κ B signaling, and inhibition of the production of IL-6. **B.** Inhibition of MM cell adhesion to bone marrow stromal cells due partially to the reduction in IL-6 release. **C.** Decreased angiogenesis due to the inhibition of cytokine and growth factor production and release. **D.** Enhanced T-cell production of cytokines, such as IL-2 and IFN- γ , that increase the number and cytotoxic functionality of natural killer (NK) cells.

cancer patients are sedation and constipation (Franks *et al.*, 2004), while the most serious one is treatment-emergent peripheral sensory neuropathy, which occurs in 10% to 30% of patients with MM or other malignancies in a dose- and time-dependent manner (Richardson *et al.*, 2004). Thalidomide-related neuropathy is an asymmetric, painful, peripheral paresthesia with sensory loss, commonly presenting with numbness of toes and feet, muscle cramps, weakness, signs of pyramidal tract involvement, and carpal tunnel syndrome. The incidence of peripheral neuropathy increases with higher cumulative doses of thalidomide, especially in elderly patients. Although clinical improvement typically occurs upon prompt drug discontinuation, long-standing residual sensory loss can occur. Particular caution should be applied in cancer patients with preexisting neuropathy (*e.g.*, related to diabetes) or prior exposure to drugs that can cause peripheral neuropathy (*e.g.*, vinca alkaloids or *bortezomib*), especially since there has been little progress in defining effective strategies to alleviate neuropathic symptoms. An increasing incidence of thromboembolic events in thalidomide-treated patients has been reported, but mostly in the context of thalidomide combinations with other drugs, including steroids and particularly anthracycline-based chemotherapy (Zangari *et al.*, 2001), and with very low incidence with single-agent thalidomide treatment.

ESTRAMUSTINE

Pharmacology and Cytotoxic Effects. Estramustine (EMCYT) is a combination of *estradiol* coupled to *normustine* (nornitrogen mustard) by a carbamate link. Respectively, estramustine has weaker estrogenic and antineoplastic activity than estradiol and other alkylating agents. While the intent of the combination was to enhance the uptake of the alkylating agent into estradiol-sensitive prostate cancer cells, estramustine does not appear to function *in vivo* as an alkylating agent. Rather, estramustine binds to β -tubulin and microtubule-associated proteins, causing microtubule disassembly and antimitotic actions.

Resistance to estramustine has been described (Laing *et al.*, 1998). Estramustine is used for the treatment of metastatic or progressive prostate cancer (Kitamura, 2001) at a usual initial dose of 10 to 16 mg/kg daily in three or four divided doses.

Absorption, Fate, and Excretion. Following oral administration, at least 75% of a dose of estramustine is absorbed from the gastrointestinal tract and rapidly dephosphorylated. Estramustine is found in the body mainly as its oxidized 17-keto analog isomer, estromustine; both forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. Estramustine and estromustine have plasma half-lives of 10 to 20 hours, respectively, and are excreted with their metabolites, mainly in the feces (Bergenheim and Henriksson, 1998).

Clinical Toxicities. In addition to myelosuppression, estramustine also possesses estrogenic side effects (gynecomastia, impotence, and elevated risk of thrombosis, and fluid retention) and is associated with hypercalcemia, acute attacks of porphyria, impaired glucose tolerance, and hypersensitivity reactions including angioedema.

Bortezomib

Chemistry. Bortezomib (VELCADE) is [(1R)-3-methyl-1-[[[(2S)-1-oxo-3-phenyl-2-[(pyrazinylcarbonyl)amino]propyl]amino]butyl]boronic acid, and its structure is:

BORTEZOMIB

Mechanism of Action. Bortezomib binds to the 20S core of the 26S proteasome and is a reversible inhibitor of its chymotrypsin-like activity (Orlowski *et al.*, 2002). Inhibition of the proteasome disrupts multiple signaling cascades within the cell, often leading to cell death. Most important consequences of proteasome inhibition are believed to result from downregulation of NF- κ B, a key transcription factor that promotes cell survival. Generally, NF- κ B is bound to I κ B in the cytosol, thus preventing transfer to the nucleus and binding to DNA. In response to “environmental” stress such as hypoxia, chemotherapy, and DNA damage, I κ B becomes ubiquitinated, resulting in its degradation *via* the proteasome and subsequent release of NF- κ B to the nucleus. NF- κ B is thought to be responsible for the activation of cell adhesion proteins E-selectin, ICAM-1, VCAM-1, and VEGF. NF- κ B also activates cyclin-D1, cIAPs, IL-6, and BCL-2, promoting cell proliferation and survival (Aghajanian *et al.*, 2002). Bortezomib blocks degradation of I κ B so that NF- κ B is silenced. In a similar manner, bortezomib disrupts the ubiquitin-proteasome regulation of p21, p27, and p53, which are key regulatory proteins in the cell cycle and initiators of apoptosis. The antineoplastic activity of bortezomib in tumors is likely due to a greater dependence on certain cell proliferating and promoting pathways in cancer relative to normal tissues.

General Toxicity and Cytotoxic Action. Animal and human toxicity studies have shown that escalating doses of bortezomib have resulted in dose-limiting toxicities in the following organ systems: gastrointestinal, hematopoietic, lymphatic, and renal.

Absorption, Fate, and Excretion. After intravenous administration of 1 to 1.3 mg/m² of bortezomib in animals and patients without renal or hepatic impairment, there is a rapid distribution phase (<10 minutes), followed by a longer elimination phase of 5 to 15 hours (Papandreou *et al.*, 2001). The median peak plasma concentration was 509 ng/ml after a 1.3-mg/m² bolus injection. Plasma protein binding averaged 83%. The mean terminal elimination in phase I and II studies was 5.45 hours, with an average clearance of 65.9 L/hour following a 2-compartment model. Peak pharmacodynamic activity (proteasome inhibition) occurred at 1 hour with a mean of 61% inhibition and a half-life of approximately 24 hours (Aghajanian *et al.*, 2002; Orlowski *et al.*, 2002). Inhibition of the 20S subunit was 10% to 30% at 96 hours. Proteasome inhibition is very sensitive to bortezomib concentrations, inhibition being 0% to 60% over a range of concentrations of 0.5 to 2 ng/ml.

In vivo studies and work with human liver microsomes has shown that bortezomib is primarily metabolized to an inactive metabolite by the CYP system and not by glucuronidation or sulfation. Deboronation accounts for greater than 90% of total metabolism, with CYP3A4 being more active than CYP2D6. Studies in patients with hepatic or renal impairment are being conducted and should help guide dose reduction in such patients, and pathways of elimination in humans. No formal drug interaction studies have been performed, but bortezomib is known to be a poor inhibitor of human liver microsome cytochrome P450 enzymes.

Preparations. Bortezomib is available for intravenous injection only. Each vial contains 3.5 mg of bortezomib as a sterile lyophilized powder and 35 mg of mannitol. Prior to use, the contents of each vial must be reconstituted with 3.5 ml of normal (0.9%) saline. The reconstituted product should be clear and colorless, and should be administered to patients within 8 hours.

Dosage and Routes of Administration. The recommended starting dose of bortezomib is 1.3 mg/m² given as an intravenous bolus, and this should be given on days 1, 4, 8, and 11 of every 21-day cycle (10-day rest period per cycle). At least 72 hours should elapse between doses. For grade 3 nonhematologic toxicities and grade 4 hematologic toxicities, drug administration should be held until resolution and subsequent doses should be reduced 25%. In clinical trials some patients have received 2 mg/m² without severe toxicity, and extravasation of bortezomib has occurred without tissue damage.

Therapeutic Uses and Clinical Toxicity. Bortezomib was approved by the FDA in 2003 for use in patients with MM who have received two prior therapies and are progressing on their current therapy (Kane *et al.*, 2003). In a phase II trial in such patients the complete response rate was 4%, the partial response rate was 24%, and the minor response rate was 7% (Richardson *et al.*, 2003). The drug currently is being studied in combination with other drugs in MM as well as other hematologic neoplasms and solid tumors.

Toxicities from the use of bortezomib have been well characterized (Orlowski *et al.*, 2002; Richardson *et al.*, 2003). At the stan-

standard dose and schedule, grade 4 toxicities were rare (<4%) and grade 3 toxicities encountered in >5% of patients were as follows: thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), neutropenia (11%), anemia (8%), vomiting (8%), diarrhea (7%), limb pain (7%), dehydration (7%), nausea (6%), and weakness (5%). Peripheral neuropathy was encountered more frequently in patients with a prior history of neuropathy or preexisting numbness, pain, or burning. Dose reductions of bortezomib are recommended for these patients. Usually, the neuropathy improves or resolves completely after several months off treatment. Hypotension associated with the injection of bortezomib has been rarely encountered, and caution should be taken with patients who are volume-depleted, have a history of syncope, or who are on antihypertensive medications. Cardiac toxicity in the form of hypotension and failure has been encountered in animal studies at twice the recommended dose. Very little cardiac toxicity has been encountered in human studies.

Zoledronic Acid

Zoledronic acid (ZOMETA) is a bisphosphonate (see Chapter 61) indicated both for the treatment of patients with bony metastases and for patients with multiple myeloma. A direct antitumor effect on myeloma cells has been suggested (Aparicio *et al.*, 1998) and preclinical data suggest the possibility that inhibition of bone matrix-degrading proteinases may inhibit tumor cell invasion in breast and prostate cancers (Bossier *et al.*, 2000).

Mitotane

The principal application of *mitotane* (*o,p'*-DDD), a compound chemically similar to the insecticides DDT and DDD, is in the treatment of neoplasms derived from the adrenal cortex. In studies of the toxicology of related insecticides in dogs, it was noted that the adrenal cortex was severely damaged, an effect caused by the presence of the *o,p'* isomer of DDD, whose structural formula is as follows:

Cytotoxic Action. The mechanism of action of mitotane has not been elucidated, but its relatively selective attack on adrenocortical cells, normal or neoplastic, is well established. Thus, administration of the drug causes a rapid reduction in the levels of adrenocorticosteroids and their metabolites in blood and urine, a response that is useful both in guiding dosage and in following the course of hyperadrenocorticism (Cushing's syndrome) resulting from an adrenal

tumor or adrenal hyperplasia. Damage to the liver, kidneys, or bone marrow has not been encountered.

Absorption, Fate, and Excretion. Approximately 40% of mitotane is absorbed after oral administration. After daily doses of 5 to 15 g, concentrations of 10 to 90 $\mu\text{g}/\text{ml}$ of unchanged drug and 30 to 50 $\mu\text{g}/\text{ml}$ of a metabolite are present in the blood. After discontinuation of therapy, plasma concentrations of mitotane are still measurable for 6 to 9 weeks. Although the drug is found in all tissues, fat is the primary site of storage. A water-soluble metabolite of mitotane is found in the urine; approximately 25% of an oral or parenteral dose is recovered in this form. About 60% of an oral dose is excreted unchanged in the stool.

Therapeutic Uses. Mitotane (LYSODREN) is administered in initial daily oral doses of 2 to 6 g, usually given in three or four divided portions, but the maximal tolerated dose may vary from 2 to 16 g per day. Treatment should be continued for at least 3 months; if beneficial effects are observed, therapy should be maintained indefinitely. *Spirolactone* should not be administered concomitantly, since it interferes with the adrenal suppression produced by mitotane (Wortsman and Soler, 1977).

Treatment with mitotane is indicated for the palliation of inoperable adrenocortical carcinoma, producing symptomatic benefit in 30% to 50% of such patients.

Clinical Toxicity. Although the administration of mitotane produces anorexia and nausea in approximately 80% of patients, somnolence and lethargy in about 34%, and dermatitis in 15% to 20%, these effects do not contraindicate the use of the drug at lower doses. Since this drug damages the adrenal cortex, administration of adrenocorticosteroids is indicated, particularly in patients with evidence of adrenal insufficiency, shock, or severe trauma (Hogan *et al.*, 1978).

BIOLOGICAL RESPONSE MODIFIERS

In contrast to small molecules, biological response modifiers include biological agents or approaches that beneficially affect the patient's biological response to a neoplasm. Included are agents that act indirectly to mediate their antitumor effects (*e.g.*, by enhancing the immunologic response to neoplastic cells) or directly on the tumor cells (*e.g.*, differentiating agents). Recombinant DNA technology has greatly facilitated the identification and production of a number of human proteins with potent effects on the function and growth of both normal and neoplastic cells. Proteins that currently are in clinical trials include the interferons (see Chapters 49 and 52), interleukins (see Chapter 52), hematopoietic growth factors (see Chapter 53) such as *erythropoietin*, filgrastim (granulocyte colony-stimulating factor [G-CSF]), and *sargramostim* (granulocyte-macrophage colony-stimulating factor [GM-CSF]), *tumor necrosis factor* (TNF), and

monoclonal antibodies such as trastuzumab, *cetuximab*, and rituximab.

Among the agents now approved for clinical use because of their activity in specific neoplastic diseases are *interferon-alfa* for use in hairy cell leukemia, condyromata acuminata, CML, and Kaposi's sarcoma associated with AIDS; *interleukin-2* (IL-2) for kidney cancer; trastuzumab for breast cancer; and rituximab for B-cell lymphomas.

Interleukin-2 (IL-2, ALDESLEUKIN, PROLEUKIN)

The isolation of a cytokine initially named T-cell growth factor, subsequently renamed IL-2, allowed the first attempts to treat cancer by producing lymphocytes specifically cytolytic for the malignant cell (Morgan *et al.*, 1976). IL-2 is not directly cytotoxic; rather, it induces and expands a T-cell response cytolytic for tumor cells. Clinical trials have studied the antitumor activity of IL-2 both as a single agent and with adoptive cellular therapy using IL-2-stimulated autologous lymphocytes obtained by leukopheresis, termed *lymphokine-activated killer* (LAK) cells. Randomized trials have not shown that the addition of LAK cells to the treatment regimen improves overall response rates (Rosenberg *et al.*, 1989). Later studies in adoptive cellular therapy have used expanded populations of lymphocytes obtained from tumor biopsies and expanded *in vitro*, so-called tumor-infiltrating lymphocytes (Rosenberg *et al.*, 1994).

Because the half-life of IL-2 in humans is short (13 minutes for α and 85 minutes for β) (Konrad *et al.*, 1990), most clinical schedules have explored either continuous infusion or multiple intermittent dosing. Others have explored the use of liposome-encapsulated IL-2 or conjugation of IL-2 with polyethylene glycol to extend the half-life of IL-2 and to enhance its delivery to immune cells in tumors. These alternative forms of IL-2 therapy are experimental at this time (Bukowski *et al.*, 2001). The most significant antitumor activity has been demonstrated with the most intense dosing schedules: continuous intravenous infusion for 5 days every other week for 2 cycles, or intravenous bolus dosing every 8 hours daily for 5 days every other week.

The toxicities of IL-2 are likely related to the activation and expansion of cytotoxic lymphocytes in organs and within vessels, resulting in inflammation and vascular leak, and to the secondary release by activated cells of other cytokines, such as tumor necrosis factor and interferon. When given at maximally tolerated doses of 600,000 units/kg every 8 hours for up to 5 days, IL-2 causes hypotension, arrhythmias, peripheral edema, prerenal azotemia, elevated liver transaminases, anemia, thrombocytopenia, nausea, vomiting, diarrhea, confusion, and fever (Rosenberg *et al.*, 1989).

Reproducible antitumor activity has been reported in advanced MM and renal cell cancer, where response rates (partial and complete) are seen in 20% to 30% of patients. Complete responses,

seen in approximately 5% to 10% of patients, appear to be durable, with some patients now free of disease beyond 5 years of treatment.

IL-2 currently is being studied in the treatment of AML, where it is capable of inducing remission in relapsed patients (Meloni *et al.*, 1994). In some studies where IL-2 is given following bone marrow transplantation, it appears that IL-2 can lengthen the remission duration as compared to historical controls (Fefer *et al.*, 1993). Randomized trials are in progress to test this hypothesis prospectively.

Monoclonal Antibodies

Since the discovery of methods for fusing mouse myeloma cells with B lymphocytes, it has been possible to produce a single species of antibody that recognizes a specific antigen. Cancer cells express a variety of antigens that are attractive targets for monoclonal antibody-based therapy (Table 51-3). The development of monoclonal antibodies against specific targets has been largely accomplished by the empiric method of immunizing mice against human tumor cells and screening the hybridomas for antibodies of interest. This technology has led to the production of therapeutic monoclonal antibodies for the treatment of cancer. Because murine antibodies have a short half-life and induce a human anti-mouse antibody immune response, they usually are chimerized or humanized when used as therapeutic reagents. Presently, several monoclonal antibodies have received FDA approval for lymphoid and solid tumor malignancies, and include rituximab and *alemtuzumab* for lymphoid malignancies, and trastuzumab for breast cancer (Keating *et al.*, 2002; Vogel *et al.*, 2002; Cobleigh *et al.*, 1999). The nomenclature adopted for naming therapeutic monoclonal antibodies is to terminate the name in *-ximab* for chimeric antibodies and *-umab* for humanized antibodies. A variety of mechanism(s) of cell killing have been described for monoclonal antibodies, including antibody-dependent cellular cytotoxicity (ADCC), complement-dependent cytotoxicity (CDC) and direct induction of apoptosis, but the clinically relevant mechanisms remain uncertain (Shan *et al.*, 1998).

Monoclonal antibodies also may be engineered to combine the antibody with a toxin (immunotoxins), such as *gemtuzumab ozogamicin* (MYLOTARG) or *denileukin diftitox* (ONTAK), or combined with a radioactive isotope, as in the case of *90Y-ibritumomab tiuxetan* (ZEVOLIN) (Table 51-3). More recently, antibodies have been engineered to contain a second specificity, known as bispecific antibodies (Onda *et al.*, 2004; Silverman *et al.*, 2004). For example, an antibody with specificity to B-cell lymphomas and to CD3, which binds to and acti-

Table 51-3*Monoclonal Antibodies Approved for Hematopoietic and Solid Tumors*

ANTIGEN AND TUMOR CELL TARGETS	ANTIGEN FUNCTION	NAKED ANTIBODIES	RADIOISOTOPE-BASED ANTIBODIES	TOXIN-BASED ANTIBODIES
Antigen: CD20 Tumor type: B-cell lymphoma and CLL	Proliferation/differentiation	Rituximab (chimeric)	¹³¹ I-tositumomab; ⁹⁰ Y-ibritumomab tiuxetan	None
Antigen: CD52 Tumor type: B-cell CLL and T-cell lymphoma	Unknown	Alemtuzumab (humanized)	None	None
Antigen: CD25 α subunit Tumor type: T-cell mycosis fungoides	Activation antigen	Daclizumab (humanized)	None	Denileukin diftitox (diphtheria toxin)
Antigen: CD33 Tumor type: acute myeloid leukemia	Unknown	Gemtuzumab (humanized)	None	Gemtuzumab ozogamicin
Antigen: HER2/neu (ErbB-2) Tumor type: breast cancer	Tyrosine kinase	Trastuzumab (humanized)	None	None
Antigen: EGFR (ErbB-1) Tumor type: colorectal; NSCLC; pancreatic, breast	Tyrosine kinase	Cetuximab (chimeric)	None	None
Antigen: VEGF Tumor type: colorectal cancer	Angiogenesis	Bevacizumab (humanized)	None	None

Abbreviations: CLL, chronic lymphocytic leukemia; EGFR, epidermal growth factor receptor; NSCLC, non-small cell lung cancer; VEGF, vascular-endothelial growth factor.

vates normal T cells, may enhance T-cell mediated lysis of the lymphoma cell. Monoclonal antibodies raised against the immunoglobulin idiotype on a B-cell lymphoma represent another therapeutic strategy (Miller *et al.*, 1982).

Naked Monoclonal Antibodies

Rituximab. Rituximab (RITUXAN) is a chimeric monoclonal antibody that targets the CD20 B-cell antigen (Tables 51–3 and 51–4) (Maloney *et al.*, 1997a; Maloney *et al.*, 1994; Maloney *et al.*, 1997b). CD20 is found on cells from the pre-B-cell stage through terminal differentiation to plasma cells and is expressed on 90% of B-cell neoplasms (Stashenko *et al.*, 1980; Bhan, 1981). The biological functions of CD20 are uncertain, although incubation of B cells with anti-CD20 antibody has variable effects on cell-cycle progression, depending on the monoclonal antibody type (Tedder *et al.*, 1986; Smeland *et al.*, 1985). Monoclonal antibody binding to CD20 generates transmembrane signals that produce autophosphorylation and activation of serine/tyrosine protein kinases, and induction of c-myc oncogene expression and major histocompatibility complex class II molecules (Deans *et al.*, 1993). Studies have shown that CD20 also is associated with transmembrane Ca^{2+} conductance, through its possible function as a Ca^{2+} channel (Deans *et al.*, 1993). These studies demonstrate the importance of CD20 in B-cell regulation, but do not in themselves indicate how ligation of the receptor produces cell death independent of ADCC or complement-mediated pathways.

Rituximab is the first monoclonal antibody to receive FDA approval and initially was approved for relapsed indolent lymphomas. However, it has shown activity in a wide variety of clinical settings (Coiffier *et al.*, 1998; Foran *et al.*, 2000). In the initial phase II study of rituximab in 37 patients with relapsed low-grade lymphoma, 46% responded with a median time to progression of 10 months (Maloney *et al.*, 1997a). Notably, rituximab also was shown to be effective in 40% of patients who had previously responded to rituximab, but has a longer median time to progression of 18 months (Davis *et al.*, 2000). Recent studies also have demonstrated significant activity of rituximab in mantle cell lymphoma, relapsed aggressive B-cell lymphomas, and CLL (Coiffier *et al.*, 1998; O'Brien *et al.*, 2001). The use of maintenance rituximab has gained increased acceptance, based on demonstration of delayed time to progression, but effects on survival have not been demonstrated (Hainsworth, 2004). Increasingly evident are the synergistic effects of rituximab and chemotherapy, suggesting it sensitizes lymphoma cells to the apoptotic effects of chemotherapy by directly acting on tumor cells (Maloney *et al.*, 2002). Based on *in vitro* studies showing synergistic effects of chemotherapy and rituximab, rituximab is being clinically combined with agents such as fludarabine and combinations

such as CHOP (Savage *et al.*, 2003). Of great importance is the recent finding that the addition of rituximab to CHOP chemotherapy significantly improves the event-free survival of diffuse large B-cell lymphoma (Coiffier *et al.*, 2002; Wilson *et al.*, 2003).

Rituximab demonstrates dose-dependent pharmacokinetics. At a dose of 375 mg/m², the mean serum half-life was 76.3 hours (range, 32 to 153 hours) after one dose and 205.8 hours (range, 84 to 407 hours) after the last dose (Maloney *et al.*, 1997a; Maloney *et al.*, 1997b). The wide range of half-lives likely reflects differences in patient tumor burden and normal B-cell populations. Rituximab toxicities are mostly related to infusion reactions, although there are increasing reports of late-onset neutropenia and rare reports of severe skin toxicity (Table 51–4) (Maloney *et al.*, 1994; Lemieux, 2004).

Alemtuzumab. Alemtuzumab (CAMPATH) is a humanized monoclonal antibody targeting the CD52 antigen present on normal neutrophils and lymphocytes as well as most B- and T-cell lymphomas (Tables 51–3 and 51–4) (Kumar *et al.*, 2003). CD52 is expressed at reasonable levels and does not modulate with antibody binding, making it a good target for unconjugated monoclonal antibodies. Mechanistically, alemtuzumab can induce tumor cell death through antibody-dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC) (Table 51–4) (Villamor *et al.*, 2003). Clinical activity has been demonstrated in low-grade lymphomas and CLL, including in patients with purine analog–refractory disease (Keating *et al.*, 2002; Rai *et al.*, 2002). In refractory CLL, response rates from 33% to 59% have been described, with higher rates in untreated CLL patients (Osterborg *et al.*, 1997).

Alemtuzumab demonstrates dose-dependent pharmacokinetic behavior. In clinical studies, alemtuzumab had a mean half-life of 12 days and steady-state levels were reached at approximately week 6 of treatment, although there was significant interpatient variability. The most concerning side effects are from acute infusion reactions and the depletion of hematopoietic cells and T cells (Table 51–4). Patients also may develop severe pancytopenia and death. Opportunistic infections are a serious side effect, particularly in patients who have received purine analogs, and have resulted in patient deaths (Tang *et al.*, 1996). The broad expression of CD52 in T cells has led to the testing of alemtuzumab in T-cell lymphomas. Recent studies have shown a high response rate in mycosis fungoides, and combination chemotherapy trials are being conducted in aggressive T-cell lymphomas (Kennedy *et al.*, 2003).

Trastuzumab. Trastuzumab (HERCEPTIN) is a humanized monoclonal antibody against the HER2/neu (ErbB-2) member of the epidermal growth factor family of cellular receptors (Noonberg and Benz, 2000). The internal domain of the HER2/neu glycoprotein encodes a tyrosine kinase that activates downstream signals and enhances metastatic potential and inhibits apoptosis.

Table 51-4**Dose and Toxicity of Monoclonal Antibody–Based Drugs**

DRUG	MECHANISM	DOSE AND SCHEDULE	MAJOR TOXICITY
Rituximab ^{12, 25}	ADCC; CDC; apoptosis	375 mg/m ² IV infusion weekly for 4 weeks	Infusion-related toxicity with fever, rash, and dyspnea; B-cell depletion; late-onset neutropenia
Alemtuzumab ⁸⁸	ADCC; CDC; apoptosis	Escalation 3, 10, 30 mg/m ² IV 3 times per week followed by 30 mg/m ² 3 times per week for 4 to 12 weeks	Infusion-related toxicity, T-cell depletion with increased infection; hematopoietic suppression; pancytopenia
Trastuzumab ^{3, 43}	ADCC; apoptosis; inhibition of HER2 signaling with G ₁ arrest	Loading dose of 4 mg/kg infusion followed by 2 mg/kg weekly	Cardiomyopathy; infusion-related toxicity
Cetuximab ⁵⁸	Inhibition of EGFR signaling; apoptosis; ADCC	Loading dose of 400 mg/kg infusion followed by 250 mg/kg weekly	Infusion-related toxicity; skin rash in 75%
Bevacizumab ⁶⁸	Inhibition of angiogenesis/neovascularization	5 mg/kg IV every 14 days until disease progression	Hypertension; pulmonary hemorrhage; gastrointestinal perforation; proteinuria; congestive heart failure
Denileukin diftitox ⁷³	Targeted diphtheria toxin with inhibition of protein synthesis	9–18 μg/kg per day IV for the first 5 days every 3 weeks	Fever; arthralgia; asthenia; hypotension
Gemtuzumab ozogamicin ⁸²	Double DNA strand breaks and apoptosis	2 doses of 9 mg/m ² IV separated by 14 days	Infusion-related toxicity; hematopoietic suppression; mucosal hepatic (VOD); and skin toxicity
⁹⁰ Y-ibritumomab tiuxetan ⁸⁹	Targeted radiotherapy	0.4 mCi/kg IV	Hematologic toxicity; myelodysplasia
¹³¹ I-tositumomab ⁸⁶	Targeted radiotherapy	Patient-specific dosimetry	Hematologic toxicity; myelodysplasia

Abbreviations: ADCC, antibody-dependent cellular cytotoxicity; CDC, complement-dependent cytotoxicity; EGFR, epidermal growth factor receptor; VOD, veno-occlusive disease.

HER2/neu is overexpressed in up to 30% of breast cancers and is associated with clinical resistance to cytotoxic and hormone therapy (Slamon *et al.*, 1989). A number of mechanisms of action have been proposed, which may lead to both cytostatic and cytotoxic effects (Nahta and Esteva, 2003). Downregulation of HER2/neu expression may inhibit cell proliferation, potentially through induction of p27 and reduction of cyclin D1, and is associated with antiangiogenic effects (Izumi *et al.*, 2002). Trastuzumab also can initiate FC γ -receptor-mediated antibody-dependent cellular cytotoxicity and directly induce apoptosis.

Trastuzumab is the first monoclonal antibody to be approved for the treatment of a solid tumor. Currently, trastuzumab is approved for HER2/neu overexpressing metastatic breast cancer in combination with paclitaxel as initial treatment or as monotherapy following chemotherapy relapse (Vogel *et al.*, 2002; Cobleigh *et al.*, 1999). Trastuzumab also is synergistic with other cytotoxic agents, but expectedly, this is only observed in HER2/neu-overexpressing cancers (Slamon *et al.*, 2001; Seidman *et al.*, 2001; Baselga *et al.*, 1998; Baselga, 2000). Phase III studies are randomizing patients between chemotherapy with or without trastuzumab to assess the optimum regimen (Hinoda *et al.*, 2004). HER2/neu expression also is found in other solid tumors and responses have been reported in colorectal and non-small cell lung cancer (Vogel *et al.*, 2002; Langer *et al.*, 2004). Clinical trials of trastuzumab in other tumors that express HER2/neu at relatively high frequency, such as pancreas and stomach, are likely.

Trastuzumab has dose-dependent pharmacokinetics with a mean half-life of 5.8 days at the 2-mg/kg maintenance dose. Steady-state levels were achieved between the 16th and the 32nd weeks with mean trough and peak concentrations of approximately 79 and 123 $\mu\text{g/ml}$, respectively (Cobleigh *et al.*, 1999; Baselga, 2000). The infusional effects of trastuzumab are typical of other monoclonal antibodies and include fever, chills, nausea, dyspnea, and rashes. Allergic reactions also may be observed. Cardiac dysfunction is an unexpected and potentially serious side effect that was observed in the pivotal trial of trastuzumab and chemotherapy (Seidman *et al.*, 2002). Left ventricular dysfunction was seen most commonly in those patients who received doxorubicin and cyclophosphamide. In a murine model, mice with a ventricular-restricted deletion of the HER2/neu gene developed cardiomyopathy, indicating that HER2/neu signaling is important for cardiac muscle (Crone *et al.*, 2002).

Cetuximab. Cetuximab (ERBITUX) is a chimeric monoclonal antibody that recognizes the epidermal growth factor receptor (EGFR; also ERBB1 or HER1) (Mendelsohn and Baselga, 2000; Grunwald and Hidalgo, 2003). Activation of EGF receptor signaling through its intercellular tyrosine kinase domain produces multiple cellular events associated with proliferation, survival, and angiogenesis (Kim *et al.*, 2001). EGFR expression is found in 60% to 75% of colorectal cancers, where it has been linked to tumor progression and a poor prognosis

(Mayer *et al.*, 1993). Multiple epithelial cancers, such as breast, lung, kidney, prostate, brain, pancreas, bladder, and head and neck malignancies, also express EGFR and are potential therapeutic targets of cetuximab (Mendelsohn and Baselga, 2000; Kim *et al.*, 2001). Although the mechanism of tumor cell kill for cetuximab is uncertain, it is likely to involve inhibition of EGF binding and signaling, which may lead to inhibition of pro-angiogenic factors and apoptosis (Petit *et al.*, 1997). The role of more classical immune mechanisms, such as ADCC, is unclear.

Cetuximab was approved by the FDA in 2004 for the treatment of EGFR-positive metastatic colorectal cancer as a single agent in patients who could not tolerate irinotecan-based therapy, or in combination with irinotecan for refractory patients (Saltz *et al.*, 2004; Cunningham *et al.*, 2004). In part, this approval was based on a randomized study of cetuximab alone *versus* cetuximab and irinotecan in patients with refractory colorectal cancer. The combined therapy group had a significantly higher response rate (22.9%) compared to the monotherapy group (10.8%), and a longer median time to progression (4.1 vs. 1.5 months). However, the median survival times of 8.6 months and 6.9 months, respectively, were not significantly different (Cunningham *et al.*, 2004). Studies in head and neck cancer in combination with radiation therapy suggest that cetuximab improves local control.

Cetuximab displays nonlinear characteristics (Thomas and Grandis, 2004). Following the recommended dose regimen, steady-state levels were achieved by the third weekly infusion, with mean peak and trough concentrations ranging from 168 to 235 and 41 to 85 $\mu\text{g/ml}$, respectively. The mean half-life was 114 hours (range, 75 to 188 hours). Toxic side effects observed with cetuximab are typical of other monoclonal antibodies and include infusion reactions. The incidence of skin rash is significantly greater than that observed with other monoclonal antibodies; it may occur in 75% of patients, and may be severe in 16% (Saltz *et al.*, 2004). Interestingly, there is a correlation between development of a rash and its intensity with duration of benefit from cetuximab.

Bevacizumab. Bevacizumab (AVASTIN) is a humanized monoclonal antibody against vascular-endothelial growth factor (VEGF) and inhibits its interaction with the VEGFR1 and VEGFR2 receptors (Rosen, 2002). Functionally, VEGF is an angiogenic growth factor that regulates vascular proliferation and permeability and inhibits apoptosis of new blood vessels (Ferrara *et al.*, 1992; Aotake *et al.*, 1999). VEGF expression is increased in a variety of tumor types, including breast, ovarian, non-small cell lung, and colorectal cancer, and its expression correlates with neovascularization within tumor masses (Vermeulen *et al.*, 1999). Furthermore, in colorectal cancer, microvessel density is associated with progression of adenomas to carcinomas and with metastatic potential and a poor prognosis (Vermeulen, 1999; Choi *et al.*, 1998).

Bevacizumab is approved by the FDA for treatment of metastatic colorectal cancer in combination with 5-FU (Kabbinnar *et al.*, 2003; Hurwitz *et al.*, 2004). A phase III study of irinotecan/5-FU/leucovorin with or without bevacizumab for the initial treatment of advanced colorectal cancer showed a significant, albeit modest, benefit in median survival (20.3 vs. 15.6 months) and progression-free survival (10.6 vs. 6.2 months) for patients receiving bevacizumab (Hurwitz *et al.*, 2004). There also is evidence of biological activity of bevacizumab in clear-cell renal cancer as a single agent and in non-small cell lung cancer and breast cancer in combination with chemotherapy (Yang *et al.*, 2003; Cobleigh *et al.*, 2003).

The pharmacokinetics of bevacizumab vary by sex, body weight, and tumor burden. Clearance is higher in patients with greater tumor burden, but the relationship with clinical outcome has not been explored. Bevacizumab has an estimated half-life of 20 days (range, 11 to 50 days) and a predicted time to reach steady state of 100 days at the therapeutic dose (Zondor and Medina, 2004). Infusion-related toxicities are relatively uncommon. However, this agent has a number of unique and potentially serious toxicities including severe hypertension, proteinuria, and congestive heart failure (Hurwitz *et al.*, 2004). It also has been reported to cause hemorrhage and gastrointestinal perforation.

Monoclonal Antibody-Cytotoxic Conjugates

Gemtuzumab Ozogamicin. Gemtuzumab ozogamicin (MYLOTARG) comprises a humanized monoclonal antibody against CD33 that is covalently linked to a semisynthetic derivative of *calicheamicin*, a potent enediyne antitumor antibiotic (Bernstein, 2000). The CD33 antigen is found on most hematopoietic cells and on more than 80% of AML and in most myelodysplasias (Wellhausen and Peiper, 2002). However, it has little expression on other cell types, making it attractive for targeted therapy. The function of CD33 is unknown, although monoclonal antibody cross-linking inhibits normal and myeloid leukemia cell proliferation (Bernstein, 2000). Following binding to CD33, gemtuzumab ozogamicin undergoes endocytosis with cleavage of calicheamicin within the lysosome, which then enters the nucleus (van Der Velden *et al.*, 2001) and causes double-strand DNA breaks and cell death (Zein *et al.*, 1988).

Gemtuzumab ozogamicin is approved by the FDA for the treatment of CD33-positive AML in first relapse, which occurs in patients at least 60 years old and who are not candidates for conventional cytotoxic therapy. The approval was based on its single-agent activity in refractory AML, where 20% of patients had reductions in blast counts (Sievers *et al.*, 2001). However, there are no controlled studies demonstrating clinical benefit compared with other treatments. There are multiple studies exploring new roles for gemtuzumab ozogamicin, such as in combination with chemotherapy or stem cell transplant and as maintenance treatment. These studies are being conducted in a variety of clinical settings including refractory and previously untreated AML (Amadori *et al.*, 2004; Damle, 2004).

Pharmacokinetics of gemtuzumab ozogamicin at the standard 9 mg/m² dose showed a half-life of total and unconjugated calicheamicin of 41 and 143 hours, respectively (Dowell *et al.*, 2001). Following a second dose, the half-life increased to 64 hours and the area under the curve was twice that of the initial dose. Serious toxicities may occur with gemtuzumab ozogamicin. Like other monoclonal antibodies, infusion-related toxicities occur with the first infusion but are ameliorated by glucocorticoids. The primary toxicities are bone marrow suppression and hepatic toxicity. Hepatic toxicity can be serious and may lead to fatal veno-occlusive disease. In the phase II study, grade 3 or 4 hyperbilirubinemia was observed in 23% of patients and may represent subclinical veno-occlusive disease in some cases (Sievers *et al.*, 2001).

Radioimmuno-Conjugates

Radioimmuno-conjugates provide monoclonal antibody targeted delivery of radioactive particles to tumor cells (Tables 51-3 and 51-4) (Kaminski *et al.*, 2001). ¹³¹Iodine (¹³¹I) is a commonly used radioisotope, as it is readily available, relatively inexpensive, and easily conjugated to a monoclonal antibody. The gamma particles emitted by ¹³¹I can be used for both imaging and therapy, but have the drawbacks of releasing free ¹³¹I and ¹³¹I-tyrosine into the blood, presenting a potential health hazard to caregivers. The β -emitter, ⁹⁰Yttrium (⁹⁰Y), has emerged as an attractive alternative to ¹³¹I, based on its higher energy and longer path length, which may be more effective in tumors with larger diameters. It also has a short half-life and remains conjugated, even after endocytosis, providing a safer profile for outpatient use. However, disadvantages include its inability to image, limited availability, and its expense.

Clinically, radioimmuno-conjugates have been developed with murine monoclonal antibodies against CD20 conjugated with ¹³¹I (¹³¹I-*tositumomab* or BEXXAR) and ⁹⁰Y-*ibritumomab* tiuxetan (ZEVALIN). Both drugs have shown response rates in relapsed lymphoma of 65% to 80% (Kaminski *et al.*, 2001). These agents have been well tolerated with most toxicity attributable to bone marrow suppression. However, there have been worrisome reports of secondary leukemias (Table 51-4).

Pretargeting has been used to increase the therapeutic index of radioimmuno-conjugates by taking advantage of the high binding affinity of avidin and biotin. Patients initially are treated with avidin-labeled monoclonal antibody, followed 1 to 2 days later, after maximal binding of the monoclonal antibody to the target, by administration of yttrium-conjugated biotin. This technique may improve the specificity of radioisotope delivery to tumor cells and increase the therapeutic index.

Immunotoxin

Denileukin Diftitox. Denileukin diftitox (ONTAK) is an immunotoxin made from the genetic recombination of IL-2 and the catalytically active fragment of diphtheria

toxin (Foss, 2001). The human IL-2 receptor (IL-2R) consists of three discrete subunits, CD25 (α chain, Tac, p55), CD122 (β chain, p70), and CD132 (γ chain, p64), assembled as a trimolecular complex to generate the high-affinity IL-2R. CD25, the low-affinity IL-2R, is incapable of internalizing IL-2, whereas CD122, the β chain of the IL-2R, internalizes IL-2 and has an intermediate affinity. In a complex with CD25, CD122 produces the high-affinity IL-2R with an affinity 100-fold greater than that of the intermediate-affinity receptor. The high affinity IL-2R is not expressed on resting T cells, but is upregulated by antigen activation and is constitutively expressed on malignant lymphocytes of both T-cell and B-cell origin. The limited tissue expression of the high-affinity IL-2R makes this an attractive target for cancer treatments, as cells that do not express the IL-2R or express only the intermediate- or low-affinity types are significantly less sensitive to this agent.

Denileukin diftitox is FDA approved for the treatment of recurrent/refractory cutaneous T-cell lymphomas. Response rates of 30% to 37% have been achieved in such patients with denileukin diftitox, with a median response duration of 6.9 months in one study (Olsen *et al.*, 2001). A larger proportion of patients showed clinical benefit but did not meet the objective criteria for response. Denileukin diftitox is being evaluated in patients with CD25-negative tumors and modulators of CD25 expression are being combined in an attempt to increase response rates. This latter approach may allow higher levels of intracellular toxin to be delivered. *Bexarotene* increases the level of CD25 expression on malignant T cells and provides a rationale for combining these agents (Gorgun and Foss, 2002).

The systemic exposure to denileukin diftitox is variable but proportional to dose (LeMaistre *et al.*, 1998). It has a distribution half-life of 2 to 5 minutes with a terminal half-life of approximately 70 minutes. Immunologic reactivity to denileukin diftitox can be detected in virtually all patients after treatment but does not preclude clinical benefit with continued treatment. Denileukin diftitox clearance in later cycles of treatment is accelerated by two- to threefold as a result of development of antibodies, but serum levels are greater than that required to produce cell death in IL-2R-expressing cell lines (1 to 10 ng/ml for more than 90 minutes). Patients with a history of hypersensitivity reactions to diphtheria toxin or IL-2 should not be treated. Significant toxicities associated with denileukin diftitox are typically acute hypersensitivity reactions, a vascular leak syndrome, and constitutional toxicities; glucocorticoid premedication significantly decreases toxicity (Table 51-4) (Foss, 2001).

Colony-Stimulating Factors

As noted above, many agents used for cancer chemotherapy suppress the production of multiple types of hematopoietic cells, and bone marrow suppression often has limited the delivery of chemotherapy on schedule

and at prescribed doses. The availability of recombinant growth factors for erythrocytes (*i.e.*, erythropoietin), granulocytes (*i.e.*, granulocyte colony-stimulating factor), and granulocytes and macrophages (*i.e.*, granulocyte-macrophage colony-stimulating factor) have enormously advanced the ability to use combination therapy or high-dose therapy with diminished complications such as febrile neutropenia. Whether this will result in improved survival rates for specific cancers remains to be determined by clinical trials. The individual growth factors and specifics of therapy are described in detail in Chapter 53.

V. HORMONES AND RELATED AGENTS

GLUCOCORTICIDS

The pharmacology, major therapeutic uses, and toxic effects of the glucocorticoids are discussed in Chapter 59. Only the applications of the hormones in the treatment of neoplastic disease are considered here. Because of their lympholytic effects and their ability to suppress mitosis in lymphocytes, the greatest value of these steroids as cytotoxic agents is in the treatment of acute leukemia in children and malignant lymphoma in children and adults.

In acute lymphoblastic or undifferentiated leukemia of childhood, glucocorticoids may produce prompt clinical improvement and objective hematological remissions in up to 30% of children. Although these responses frequently are characterized by complete disappearance of all detectable leukemic cells from the peripheral blood and bone marrow, the duration of remission is brief. Remissions occur more rapidly with glucocorticoids than with antimetabolites, and there is no evidence of cross-resistance to unrelated agents. For these reasons, therapy is initiated with prednisone and vincristine, often followed by an anthracycline or methotrexate, and L-asparaginase. Glucocorticoids are a valuable component of curative regimens for Hodgkin's disease and non-Hodgkin's lymphoma, as well as for treatment of multiple myeloma and CLL. Glucocorticoids are extremely helpful in controlling autoimmune hemolytic anemia and thrombocytopenia associated with CLL.

The glucocorticoids, particularly dexamethasone, are used in conjunction with radiotherapy to reduce edema related to tumors in critical areas such as the superior mediastinum, brain, and spinal cord. Doses of 4 to 6 mg every 6 hours have dramatic effects in restoring neurological function in patients with cerebral metastases, but these effects are temporary. Acute changes in dexamethasone dosage can lead to a rapid recrudescence of symptoms. Dex-

amethasone should not be discontinued abruptly in patients receiving radiotherapy or chemotherapy for brain metastases. Gradual tapering of the dosage may be undertaken if a clinical response to definitive antitumor therapy has been achieved. The antitumor effects of glucocorticoids are mediated by their binding to the glucocorticoid receptor, which activates a program of gene expression that leads to apoptosis.

Several glucocorticoids are available and at equivalent dosages exert similar effects (*see* Chapter 59). Prednisone, for example, usually is administered orally in doses as high as 60 to 100 mg, or even higher, for the first few days and gradually reduced to levels of 20 to 40 mg/day. A continuous attempt should be made to establish the lowest possible dosage required to control the manifestations of the disease. These agents, when used chronically, exert a wide range of side effects, including glucose intolerance, immunosuppression, osteoporosis, and psychosis (*see* Chapter 59).

PROGESTINS

Progestational agents (*see* Chapter 57) have been used as second-line hormonal therapy for metastatic hormone-dependent breast cancer and in the management of endometrial carcinoma previously treated by surgery and radiotherapy. In addition, progestins stimulate appetite and restore a sense of well-being in cachectic patients with advanced stages of cancer and AIDS. While progesterone itself is poorly absorbed when given orally and must be used with an oil carrier when given intramuscularly, there are synthetic progesterone preparations.

Hydroxyprogesterone usually is administered intramuscularly in doses of 1000 mg one or more times weekly; *medroxyprogesterone* (DEPO-PROVERA) can be administered intramuscularly in doses of 400 to 1000 mg weekly. An alternative and more commonly used oral agent is *megestrol acetate* (MEGACE, others; 40 to 320 mg daily, in divided doses). Beneficial effects have been observed in approximately one-third of patients with endometrial cancer. The response of breast cancer to megestrol is predicted by both the presence of hormonal receptors and the evidence of response to a prior hormonal treatment. The effect of progestin therapy in breast cancer appears to be dose-dependent, with patients demonstrating second responses following escalation of megestrol to 1600 mg/day. Clinical use of progestins in breast cancer has been largely superseded by the advent of the aromatase inhibitors (*see* below). Responses to progestational agents have also been reported in metastatic carcinomas of the prostate and kidney.

ESTROGENS AND ANDROGENS

Discussions of the pharmacology of the estrogens and androgens appear in Chapters 57 and 58, respectively.

They are of value in certain neoplastic diseases, notably those of the prostate and the mammary gland, because these organs are dependent upon hormones for their growth, function, and morphological integrity. Carcinomas arising from these organs often retain some of the hormonal responsiveness of their normal counterparts for varying periods of time. By changing the hormonal environment of such tumors, it is possible to alter the course of the neoplastic process.

Androgen-Control Therapy of Prostatic Carcinoma

The development of anti-androgenic therapy for prostatic carcinoma is largely the contribution of Huggins and associates. Although the hormonal treatment of metastatic prostate carcinoma is palliative, life expectancy is increased and thousands of patients have enjoyed its benefit.

Localized prostate cancer is curable with surgery or radiation therapy. However, when distant metastases already are present, hormonal therapy becomes the primary treatment. Standard approaches to reduce the concentrations of endogenous androgens or inhibit their effects include bilateral orchiectomy, antiandrogens, or most commonly, the administration of gonadotropin-releasing hormone (GnRH) agonists or antagonists with or without antiandrogens (*see* below).

Subjective and objective improvements rapidly follow the institution of androgen-control therapy of prostatic carcinoma in the majority of patients with metastatic disease, and these benefits last an average of 1 year. From the patient's point of view, the most gratifying may be relief of bone pain. This is associated with an increase in appetite, weight gain, and a feeling of well-being. Objectively, there are regressions of the primary tumor and soft tissue metastases, but neoplastic cells do not disappear completely. The concentration of prostate-specific antigen (PSA) in plasma is a useful marker of response. Eventually prostatic tumors become insensitive to androgen deprivation through loss or mutation of the androgen receptor, which in some patients recognizes androgen antagonists such as *flutamide* as agonists (*see* below and Chapter 58). In such cases, withdrawal of the antagonist may lead to a response.

Estrogens and Androgens in the Treatment of Mammary Carcinoma

Despite remissions of disease being noted with pharmacologic doses of estrogen therapy in breast cancer patients, unwanted side effects prompted the development of alternate strategies. Paradoxically, antagonizing the effects of estrogen also is frequently effective as exemplified by

remission of disease achieved with oophorectomy. Thus, because of a relative paucity of side effects and equivalence of efficacy, the use of anti-estrogens such as *tamoxifen* replaced treatment with estrogens or androgens as hormonal therapy of breast cancer. The detection of the estrogen receptors (ER) and progesterone receptors (PR) by monoclonal antibodies has led to improved selection of patients for hormone therapies. A significant minority of patients with ER- or PR-positive tumors have a response to hormonal therapy, and furthermore have a better overall prognosis independent of the type of therapy. In contrast, ER- and PR-negative carcinomas do not respond to hormonal therapy.

Clinically detectable responses to hormone therapy can be slow and usually take 8 to 12 weeks to detect. If the disease responds or remains stable on a given treatment, the medication typically is continued indefinitely until the disease progresses or unwanted toxicities develop. The duration of an induced remission averages 6 to 12 months but sometimes can last for many years.

Anti-Estrogen Therapy

Anti-estrogen approaches for the therapy of hormone-receptor positive breast cancer include the use of selective estrogen-receptor modulators (SERMs), selective estrogen-receptor downregulators (SERDs), and aromatase inhibitors (AIs).

Selective Estrogen-Receptor Modulators. Tamoxifen citrate is the lead compound of the SERM class. These agents bind to the estrogen receptor and exert either estrogenic or anti-estrogenic effects depending on the specific organ. Tamoxifen is the most widely studied anti-estrogenic treatment in breast cancer. The recent decline in breast cancer mortality in Western countries is believed to be in part due to the widespread utilization of tamoxifen (Hermon and Beral, 1996). However, in addition to its estrogen antagonist effects on breast cancer, tamoxifen also exerts estrogenic agonist effects in nonbreast tissues, which influences the overall therapeutic index of the drug. Therefore several novel anti-estrogen compounds have been developed that offer the potential for enhanced efficacy and reduced toxicity compared with tamoxifen. These novel antiestrogens can be divided into tamoxifen analogues (*e.g.*, *toremifene*, *droloxifene*, and *idoxifene*), “fixed ring” compounds (*e.g.*, *raloxifene*, *lasofoxifene*, *arzofoxifene*, *miproxifene*, *levormeloxifene*, and EM652), and the selective estrogen-receptor downregulators (SERDs) (*e.g.*, *fulvestrant*, SR 16234, and ZK 191703, the latter also termed “pure antiestrogens”) (Howell *et al.*, 2004a).

Tamoxifen. Tamoxifen is the most broadly used anti-estrogen therapy. It was first synthesized in 1966 and initially developed as an oral contraceptive but was found to induce ovulation. For over three decades, tamoxifen has been studied and developed for use in various stages of breast cancer. Its broad use is related to its anticancer activity and good tolerability profile to allow for chronic daily dosing. Tamoxifen is prescribed for the prevention of breast cancer in high-risk patients, for the adjuvant therapy of early-stage breast cancer, and for the therapy of advanced breast cancer.

Mechanism of Action. Tamoxifen is a competitive inhibitor of estradiol binding to the ER. There are two subtypes of estrogen receptors: ER α and ER β , which have different tissue distributions and can either homodimerize or heterodimerize. Binding of estradiol and SERMs to the estrogen-binding sites of the ERs initiates a series of events that includes change in altered conformation of the ER, dissociation of heat-shock proteins, and ER dimerization. Dimerization facilitates the binding of the ER to specific DNA estrogen-response elements (EREs) in the vicinity of estrogen-regulated genes. As detailed in Chapter 57, many coregulator proteins interact with the receptor to act as corepressors or coactivators, while at least 50 transcriptional activating factors modulate the effects of estrogen on target genes. Differences in tissue distribution of ER subtypes, the function of coregulator proteins, and the various transcriptional activating factors may explain the variable response to tamoxifen in hormone-receptor positive breast cancer. Other organs that are affected by the administration of tamoxifen include the uterine endometrium (endometrial hypertrophy, vaginal bleeding, and endometrial cancer), the coagulation system (thromboembolism), bone metabolism (modulation of bone mineral density), and liver function (alterations of blood lipid profile) (Ellis and Swain, 2001).

Absorption, Fate, and Excretion. Tamoxifen is readily absorbed following oral administration, with peak concentrations measurable after 3 to 7 hours and steady-state levels being reached at 4 to 6 weeks (Jordan, 1982). The drug is metabolized predominantly to *N*-desmethyltamoxifen and to 4-hydroxytamoxifen, a more potent metabolite. Both of these metabolites can be further converted to 4-hydroxy-*N*-desmethyltamoxifen, which retains high affinity for the ER. The parent drug has a terminal half-life of 7 days, while the half-lives of *N*-desmethyltamoxifen and 4-hydroxytamoxifen are significantly longer at about 14 days (Ellis and Swain, 2001). After enterohepatic circulation, glucuronides and other metabolites are excreted in the stool; excretion in the urine is minimal.

Therapeutic Uses. The usual oral dose of tamoxifen (NOLVADEX) in the United States is 10 mg twice a day. Doses as high as 200 mg per day have been used in the therapy of breast cancer, but high doses are associated with retinal degeneration.

Tamoxifen is used for the endocrine treatment of women with ER-positive metastatic breast cancer or following primary tumor excision as adjuvant therapy, where it is used either alone or in sequence with adjuvant chemotherapy.

Tamoxifen also is used in premenopausal women with ER-positive tumors. Disease response rates are similar to those seen in postmenopausal patients. Alternative or additional antiestrogen strategies

in premenopausal women include oophorectomy or gonadotropin-releasing hormone analogs (see Chapter 55). The combined use of tamoxifen and a gonadotropin-releasing hormone analog (to reduce high estrogen levels resulting from tamoxifen effects on the gonad-pituitary axis) has been shown to yield better response rates and improved overall survival than has either drug alone (Klijn *et al.*, 2000).

The NOLVADEX Adjuvant Trial Organization (NATO) study indicated an overall disease-free survival advantage for patients receiving tamoxifen. Five years of adjuvant therapy with tamoxifen yielded superior results compared to 1 or 2 years of therapy (Swedish Breast Cancer Cooperative Group, 1996; Early Breast Cancer Trialists' Collaborative Group, 1998). Therefore, although the optimal duration of tamoxifen has not been fully determined, randomized trials have demonstrated superiority of 5 years over shorter durations. One clinical trial evaluating the administration of tamoxifen for more than 5 years failed to show benefit of continued therapy, and a trend toward worse outcomes in women who received a longer duration (Fisher *et al.*, 2001).

Tamoxifen also has shown effectiveness in initial trials for preventing breast cancer in women at increased risk (Strasser-Weippl and Goss, 2004). These studies were prompted by preclinical experiments showing prevention of tumors in animal models and also by the observation of reduced contralateral new primary breast tumors in women receiving adjuvant tamoxifen for early-stage breast cancer (Early Breast Cancer Trialists' Collaborative Group, 1998; Fisher *et al.*, 2001). Tamoxifen only reduces ER-positive tumors without affecting ER-negative tumors, which contribute disproportionately to breast cancer mortality. Additional clinical studies are ongoing (Riggs and Hartmann, 2003).

Clinical Toxicity. The common adverse reactions to tamoxifen include vasomotor symptoms (hot flashes), atrophy of the lining of the vagina, hair loss, nausea, and vomiting. These may occur in as many as 25% of patients and are rarely sufficiently severe to require discontinuation of therapy. Menstrual irregularities, vaginal bleeding and discharge, pruritus vulvae, and dermatitis occur frequently, depending on the menopausal state of the patient. Although side effects are common in women taking tamoxifen, overall quality of life appears not to be impaired (Day *et al.*, 1999).

Tamoxifen also increases the incidence of endometrial cancer by two- to threefold, particularly in older postmenopausal women who receive 20 mg per day for 2 years or longer. In general, tamoxifen-associated endometrial cancers are reported as low-grade and early-stage tumors (O'Regan and Jordan, 2001). Standard practice guidelines from the National Comprehensive Cancer Network recommend monitoring and reporting of abnormal vaginal bleeding with prompt evaluation for endometrial cancer in women with an intact uterus (National Comprehensive Cancer Network Clinical Practice Guidelines in Oncology, 2004).

Tamoxifen increases the risk of thromboembolic events, but this is age dependent and also frequently related to operative procedures. Hence, it is recommended to discontinue tamoxifen prior to elective surgery. Because tamoxifen is associated with thromboembolism, consideration of screening evaluation of factor V Leiden and activated protein C levels has been suggested for women considering tamoxifen, though this has not become a standard of clinical practice (Cushman *et al.*, 2003). Like estrogen, tamoxifen is a hepatic carcinogen in animals, although increases in primary hepatocellular carcinoma have not been reported in

patients on the drug. Tamoxifen causes retinal deposits, decreased visual acuity, and cataracts in occasional patients, although the frequency of these changes is uncertain.

In addition to its ability to prevent recurrence or the development of primary breast cancer, tamoxifen has other end-organ benefits related to its partial estrogenic action. For example, it may slow the development of osteoporosis in postmenopausal women (Fornander *et al.*, 1990). In addition, like certain estrogens, tamoxifen lowers total serum cholesterol, LDL cholesterol, and lipoproteins, and raises apolipoprotein A-I levels, potentially decreasing the risk of myocardial infarction (Love *et al.*, 1994).

Toremifene. Toremifene (FARESTON) is a triphenylethylene derivative of tamoxifen and has a similar pharmacological profile. Toremifene is indicated for the treatment of breast cancer in women with tumors that are ER-positive or of unknown receptor status.

In preclinical models, toremifene has activity against breast cancer cells *in vitro* and *in vivo* similar to that of tamoxifen. Unlike tamoxifen, however, toremifene is not hepatocarcinogenic in experimental animals. Two adjuvant studies were initiated to compare efficacy of these two agents, and in particular long-term tolerability and safety, in early-stage breast cancer. In the largest of these studies, 1480 postmenopausal patients with lymph node-positive disease were randomized to receive adjuvant tamoxifen (20 mg daily) or toremifene (40 mg daily) for 5 years. Although longer follow-up is needed, there were no significant differences in efficacy or tolerability after a median follow-up of 4.4 years, and the number of subsequent second cancers was similar (Howell *et al.*, 2004a). Other head-to-head comparisons of toremifene and tamoxifen in prospective, randomized clinical trials have shown that toremifene has generally similar efficacy and adverse events to tamoxifen (Riggs and Hartmann, 2003). However, *in vitro* in a low-estrogen environment, toremifene has approximately 40 times lower estrogen agonist effect than tamoxifen. This may make toremifene more effective in combination with an aromatase inhibitor than tamoxifen (Di Salle *et al.*, 1990) and this is the subject of ongoing clinical trials.

Selective Estrogen-Receptor Downregulators

SERDs, also termed "pure anti-estrogens," include compounds such as fulvestrant, RU 58668, SR 16234, ZD 164384, and ZK 191703. SERDs, unlike SERMs, are devoid of any estrogen agonist activity. The lead compound of this class currently approved for the treatment of advanced breast cancer is fulvestrant.

Fulvestrant. Fulvestrant (FASLODEX) is the first FDA approved agent in the new class of estrogen-receptor downregulators, which were hypothesized to have an improved safety profile, faster onset, and longer duration of action than the SERMs due to their pure ER antagonist activity (Robertson, 2002). Fulvestrant was approved in

2002 for postmenopausal women with hormone receptor-positive metastatic breast cancer that has progressed despite antiestrogen therapy.

Mechanism of Action. Fulvestrant is a steroidal antiestrogen that binds to the ER with an affinity more than 100 times that of tamoxifen, inhibits its dimerization, and increases its degradation. This appears to occur because fulvestrant's long, bulky side-chain at the 7 α position sterically hinders receptor dimerization, leading to increased ER turnover and disruption of nuclear localization. Unlike tamoxifen, which stabilizes or even increases ER expression, fulvestrant reduces the number of ER molecules in cells, both *in vitro* and *in vivo* (Howell *et al.*, 2004b).

Preclinical studies suggest that as a consequence of this ER "downregulation," ER-mediated transcription is abolished, completely suppressing the expression of estrogen-dependent genes (Howell *et al.*, 2004b). This difference in the activity of fulvestrant likely explains why fulvestrant demonstrates efficacy against tamoxifen-resistant breast cancer. However, the hypothesis that fulvestrant provides more effective antiestrogen activity than tamoxifen was not confirmed by a clinical trial comparing fulvestrant (250 mg intramuscularly monthly) with tamoxifen (20 mg orally daily) as first-line therapy in metastatic breast cancer (Howell *et al.*, 2004a).

Absorption, Fate, and Excretion. Maximum plasma concentrations are reached about 7 days after intramuscular administration of fulvestrant and are maintained over a period of 1 month. The plasma half-life is approximately 40 days. Steady-state concentrations are reached after 3 to 6 monthly injections. There is extensive and rapid distribution, predominantly to the extravascular compartment.

Various pathways, similar to those of steroid metabolism including oxidation, aromatic hydroxylation, and conjugation, extensively metabolize fulvestrant. CYP3A4 appears to be the only CYP isoenzyme involved in the oxidation of fulvestrant. Several preclinical and clinical studies have confirmed that fulvestrant is not subject to CYP3A4 interactions that might affect the safety or efficacy of the drug. The putative metabolites possess no estrogenic activity and only the 17-keto compound demonstrates a level of antiestrogenic activity about 4.5 times less than that of fulvestrant. The major route of excretion is *via* the feces, with less than 1% being excreted in the urine (Robertson and Harrison, 2004).

Therapeutic Uses. Fulvestrant typically is administered as a 250-mg intramuscular injection at monthly intervals. It is used in postmenopausal women as antiestrogen therapy of hormone receptor-positive metastatic breast cancer after progression on first-line antiestrogen therapy such as tamoxifen (Strasser-Weippl and Goss, 2004). Fulvestrant is at least as effective in this setting as the third-generation aromatase inhibitor *anastrozole*.

Fulvestrant 250 mg (administered as a once-monthly 5-ml intramuscular injection) also has been compared with tamoxifen 20 mg (orally once daily) in a trial of postmenopausal women with ER-positive and/or progesterone receptor (PR)-positive or ER/PR-unknown metastatic breast cancer who had not previously received endocrine or chemotherapy. There was no difference between fulvestrant and tamoxifen in time to disease progression in either the entire study population or the subset of patients with ER- and/or PR-positive disease. Observed differences in other efficacy endpoints favored tamoxifen, and fulvestrant equivalence was not

demonstrated (Vergote and Robertson, 2004). The long time to steady-state plasma levels for fulvestrant has brought into question the results of existing studies, and trials are in progress to test the relative efficacy of giving an initial loading dose followed by regular monthly injections.

Clinical Toxicity. Fulvestrant generally is well tolerated with the most common adverse events being nausea, asthenia, pain, vasodilation (hot flushes), and headache. Injection site reactions, seen in about 7% of patients, are reduced by giving the injection slowly. In the study comparing anastrozole and fulvestrant, quality-of-life outcome measures were maintained over time with no significant difference between the drugs (Vergote and Robertson, 2004).

AROMATASE INHIBITORS

Aromatase is the product of the *CYP19* gene. CYP19 is highly expressed in human placenta and in granulosa cells of ovarian follicles, where its expression depends on cyclical gonadotropin stimulation. Aromatase also is present, at lower levels, in several nonglandular tissues, including subcutaneous fat, liver, muscle, brain, normal breast, and breast-cancer tissue (Smith and Dowsett, 2003). The aromatase enzyme is responsible for the conversion of androstenedione and testosterone to the estrogens, estrone (E1) and estradiol (E2), respectively. In postmenopausal women, this conversion occurs primarily in peripheral tissues while estrogen production in premenopausal women is primarily from the ovary.

Aromatase inhibitors (AIs) are a newer class of drugs that inhibit the function of the aromatase enzyme. In postmenopausal women, AIs can suppress most of the peripheral aromatase activity, leading to profound estrogen deprivation. This strategy of estrogen deprivation of ER-positive breast cancer cells is in contrast to the ER-binding antagonistic activity that SERMs and SERDs exert.

Based on when they were developed, AIs are classified as first-, second-, or third-generation. In addition, they are further classified as type 1 (steroidal aromatase inactivator) or type 2 (nonsteroidal aromatase inhibitor) inhibitors according to their mechanism of action. Type 1 inhibitors are steroidal analogs of androstenedione. Androstenedione analogs bind to the same site on the aromatase molecule, but unlike androstenedione, they bind irreversibly because of their conversion to reactive intermediates by aromatase. Thus, they commonly are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal and bind reversibly to the heme group of the enzyme by way of a basic nitrogen atom (Smith and Dowsett, 2003) (Figure 51–19).

Figure 51–19. Structure of the main aromatase inhibitors and the natural substrate androstenedione.

First- and Second-Generation Aromatase Inhibitors

Aminoglutethimide (CYTADREN; AG), a first-generation type 2 AI, originally was developed as an anticonvulsant but was subsequently found to inhibit the synthesis of adrenocortical steroids (*see* Chapter 59). AG is a nonspecific weak AI, administered as a 250-mg dose four times daily with *hydrocortisone* supplementation because of unwanted adrenal suppression. Because of significant toxicities related to its anticonvulsant structure and its relatively weak inhibition of aromatase, its use has declined considerably with the advent of newer AIs.

Second-generation AIs include *formestane* (4-hydroxyandrostenedione; LENTARON), a type 1 steroidal inactivator; *fadrozole*, a type 2 imidazole; and *rogletimide* (pyridoglutethimide), a type 2 inhibitor structurally similar to aminoglutethimide. Formestane was the first steroidal aromatase inactivator widely used for the treatment of breast cancer patients (Goss, 1986). Because of better aromatase inhibition *in vivo* following parenteral administration, it is administered as an intramuscular

depot injection. However, formestane has also been shown to be active when given orally. It suppresses plasma sex hormone-binding globulin (SHBG), which is interpreted as an androgenic side effect. The response rates in phase II and III trials were about 25% to 40%. Due to the introduction of novel compounds, especially *exemestane*, formestane is not widely used today (Geisler, 2003).

Third-Generation Aromatase Inhibitors

The third-generation inhibitors, developed in the 1990s, include the type 1 steroidal agent *exemestane* and the type 2 nonsteroidal imidazoles *anastrozole* and *letrozole*. Currently, third-generation AIs are most commonly used for the treatment of early-stage and advanced breast cancer.

Anastrozole. Mechanism of Action. Anastrozole is a potent and selective triazole AI. Anastrozole, like letrozole, binds competitively and specifically to the heme of the CYP19. Anastrozole 1 or 10 mg administered once daily for 28 days reduces total body aromatization by

96.7% and 98.1%, respectively. In addition, anastrozole reduces local aromatization in large, ER-positive breast tumors.

Anastrozole has no clinically significant effect on adrenal glucocorticoid or mineralocorticoid synthesis in postmenopausal women. Anastrozole also has no effect on the adrenocorticotrophic hormone-stimulated release of cortisol or aldosterone, or on plasma concentrations of luteinizing hormone or follicle-stimulating hormone. Anastrozole, unlike AG, has no effect on thyroid-stimulating hormone (Wellington and Faulds, 2002).

Absorption, Fate, and Excretion. Anastrozole is absorbed rapidly after oral administration with maximal plasma concentration occurring after 2 hours. Repeated dosing increases plasma concentrations of anastrozole and steady-state is attained after 7 days. Although the rate of absorption is delayed after a high-fat breakfast, steady-state concentrations are not generally affected upon multiple dosing. Anastrozole is metabolized by *N*-dealkylation, hydroxylation, and glucuronidation. The main metabolite of anastrozole is a triazole. In addition, several other metabolites with no pharmacological activity are formed. Less than 10% of the drug is excreted as the unmetabolized parent compound. The principal excretory pathway is *via* the liver. The pharmacokinetics of anastrozole, which can be affected by drug interactions *via* the CYP system, is unaffected by coadministration of tamoxifen or cimetidine (Köberle and Thürlimann, 2001).

Therapeutic Uses. Anastrozole (ARIMIDEX), 1 mg oral daily dose, has shown efficacy in the treatment of postmenopausal women with early-stage or advanced, hormone-receptor positive breast cancer. In early-stage breast cancer, anastrozole was significantly more effective than tamoxifen in terms of time to tumor recurrence and odds of a primary contralateral tumor (Baum *et al.*, 2002).

In the setting of advanced breast cancer, the results of two large, randomized trials in postmenopausal women with disease progression while taking tamoxifen showed a statistically significant survival advantage for anastrozole 1 mg/day over megestrol acetate 40 mg four times daily. In another phase III clinical trial involving >1000 postmenopausal women with advanced breast cancer, anastrozole showed a statistically significant advantage over tamoxifen in median time to disease progression in >600 patients who were known to have ER- or PR-positive disease.

Clinical Toxicity. Anastrozole has been associated with a significantly lower incidence of vaginal bleeding, vaginal discharge, hot flushes, endometrial cancer, ischemic cerebrovascular events, venous thromboembolic events, and deep vein thrombosis, including pulmonary embolism. Tamoxifen is associated with a lower incidence of musculoskeletal disorders and fracture. In the advanced disease setting, anastrozole is as well tolerated as megestrol, while weight gain is significantly increased by megestrol compared to anastrozole. In addition, anastrozole is as well tolerated as tamoxifen, with a low rate of withdrawal due to drug-related adverse events (2%). In addition, anastrozole is associated with fewer thromboembolic events and episodes of vaginal bleeding than tamoxifen (Wellington and Faulds, 2002; Nabholz and Reese, 2002).

Letrozole. Mechanism of Action. In postmenopausal women with primary breast cancer, letrozole inhibits whole body aromatization and reduces local aromatiza-

tion within the tumors. The drug has no significant effect on the synthesis of adrenal steroids or thyroid hormone and does not alter levels of a range of other hormones. Letrozole also reduces cellular markers of proliferation to a significantly greater extent than tamoxifen in human estrogen-dependent tumors that overexpress human epidermal growth factor receptors (HER)1 and/or HER2/neu.

Letrozole increases the levels of bone resorption markers in healthy postmenopausal women and in those with a history of breast disease but without current active disease. Letrozole has not demonstrated a consistent effect on serum lipid levels in healthy women or postmenopausal women with breast cancer (Simpson *et al.*, 2004).

Absorption, Fate, and Excretion. Letrozole is rapidly absorbed after oral administration and maximum plasma levels are reached about 1 hour after ingestion. Letrozole has a bioavailability of 99.9%. Steady-state plasma concentrations of letrozole are reached after 2 to 6 weeks of treatment. Following metabolism by CYP2A6 and CYP3A4, letrozole is eliminated as an inactive carbinol metabolite mainly *via* the kidneys. Due to the low total body clearance (2.21 L/h), the elimination half-life is about 40 to 42 hours (Geisler, 2003).

Therapeutic Uses. Letrozole (FEMARA), 2.5 mg administered orally once daily, has shown efficacy in the treatment of postmenopausal women with early-stage or advanced, hormone-receptor positive breast cancer.

In early-stage disease, extending adjuvant endocrine therapy with letrozole (beyond the standard 5-year period of tamoxifen) improved disease-free survival compared with placebo (Goss *et al.*, 2003) and improved overall survival in the subset of patients with positive axillary nodes (Goss *et al.*, 2004).

In advanced breast cancer, letrozole is superior to tamoxifen as first-line treatment; time to disease progression is significantly longer and objective response rate is significantly greater with letrozole, but median overall survival is similar between groups. As second-line therapy of advanced breast cancer that has progressed on antiestrogen therapy, letrozole shows efficacy equivalent to that of anastrozole and similar to or better than that of megestrol (Simpson *et al.*, 2004).

Clinical Toxicity. Similarly to tamoxifen, letrozole generally is well tolerated; the most common treatment-related adverse events are hot flushes, nausea, and hair thinning. In patients with tumors that progressed on antiestrogen therapy, letrozole was tolerated at least as well as, or better than, megestrol. In the trial of extended adjuvant therapy, adverse events reported more frequently with letrozole than placebo were hot flushes, arthralgia, myalgia, and arthritis, but cessation of letrozole was no more frequent than placebo in this double-blind trial. A greater number of new diagnoses of osteoporosis occurred among women receiving letrozole, but the long-term effects on bone mineral density or lipid metabolism have yet to be determined.

Exemestane. Mechanism of Action. Exemestane (AROMASIN) is a more potent, orally administered analog of the natural substrate androstenedione that lowers estrogen

levels more effectively than does formestane. In contrast to the reversible competitive inhibitors, anastrozole and letrozole, exemestane irreversibly inactivates the enzyme, and therefore is referred to as a “suicide substrate.” Doses of 25 mg per day inhibit aromatase activity by 98% and lower plasma estrone and estradiol levels by about 90%. It has less androgenic activity than formestane, but otherwise has a similar toxicity profile.

Absorption, Fate, and Excretion. Exemestane is rapidly absorbed from the gastrointestinal tract, reaching maximum plasma levels after 2 hours. Its absorption is increased by 40% after a high-fat meal. Exemestane is extensively protein-bound in plasma and has a terminal half-life of approximately 24 hours. It is extensively metabolized in the liver to inactive metabolites. A key metabolite, 17-hydroxyexemestane, which is formed by reduction of the 17-oxo group via 17- β -hydroxysteroid dehydrogenase, has weak androgenic activity, which also could contribute to antitumor activity (Lønning *et al.*, 2000). Excretion is distributed almost equally between the urine and feces. Since significant quantities of active metabolites are excreted in the urine, exemestane doses should be adjusted in patients with renal dysfunction.

Therapeutic Uses. Exemestane has been tested in a randomized clinical trial in postmenopausal women with estrogen-receptor positive breast cancer. Women who had completed 2 to 3 years of adjuvant tamoxifen were randomized to complete a total of 5 years of adjuvant treatment with tamoxifen or exemestane (Coombes *et al.*, 2004). The unadjusted hazard ratio in the exemestane group vs. the tamoxifen group was 0.68, representing a 32% reduction in risk and corresponding to an absolute benefit in terms of disease-free survival of 4.7% at 3 years after randomization. Overall survival was not significantly different in the two groups.

In advanced breast cancer, exemestane has been evaluated in a phase III trial against megestrol in women with disease progressing on prior antiestrogen therapy. Patients receiving exemestane had a similar response rate but improved time to disease progression, time to treatment failure, and longer duration of survival compared with those taking megestrol acetate. Responses to treatment also have been shown in women with disease progressing on prior nonsteroidal aromatase inhibitors.

Clinical Toxicity. Exemestane generally is well tolerated. Discontinuations due to toxicity are not common (2.8%). Hot flushes, nausea, fatigue, increased sweating, peripheral edema, and increased appetite have been reported. In the trial comparing exemestane to tamoxifen in early-stage breast cancer, exemestane was associated with more frequent arthralgia and diarrhea, but gynecologic symptoms, vaginal bleeding, and muscle cramps were more frequent with tamoxifen. Visual disturbances and clinical fractures were more common with exemestane (Coombes *et al.*, 2004).

ANTI-ANDROGEN THERAPY IN PROSTATE CANCER

Carcinoma of the prostate is uniquely dependent upon hormonal stimulation with androgens. Huggins and col-

leagues pioneered the use of anti-androgenic therapy in treating prostate cancer more than half a century ago. Early studies noted that either surgical castration (bilateral orchiectomy) or the administration of injectable hormonal therapies that induced medical castration were effective forms of treatment. Androgen deprivation therapy (ADT) through either surgical or medical castration has been the mainstay of treatment for advanced prostate cancer since that time.

Among men with metastatic prostate cancer, >90% have an initial favorable response to primary hormonal therapy with ADT. This is manifest as disease regression or stabilization and relief of cancer-related symptoms. The average time to progression is 18 to 36 months, making ADT one of the longest-lasting beneficial treatments in any advanced solid tumor. A large trial found a survival benefit to ADT (Byar and Corle, 1988; Seidenfeld *et al.*, 2000). In numerous trials of ADT, its positive effects were diluted to some extent by increased cardiovascular toxicity in men receiving high doses of estrogen as the primary form of ADT (Seidenfeld *et al.*, 2000; Hedlund and Henriksson, 2000).

Disease progression after ADT signifies an androgen-independent state, with subsequent median survival of only 12 months. However, many men will respond to secondary hormonal therapy even after failure of ADT. Secondary hormonal treatments include androgen receptor (AR) blockers, adrenal androgen synthesis inhibitors, and estrogenic agents. Responses are more variable than to primary hormonal therapy, but a substantial portion of men benefit from these well-tolerated forms of treatment. When patients become refractory to any form of hormonal therapy, their management usually involves chemotherapeutic agents.

Common side effects of all forms of antiandrogen hormonal therapy include vasomotor flushing, loss of libido, gynecomastia, increased weight, loss of bone mineral density (BMD), and loss of muscle mass. There is variability to these side effects. For example, AR blockers compared with GnRH agonists cause more gynecomastia, but less bone loss, vasomotor flushing, and loss of BMD (Spetz *et al.*, 2001; Smith *et al.*, 2004). Importantly, the increased cardiovascular toxicity observed with high doses of estrogen is not observed with other forms of ADT.

Gonadotropin-Releasing Hormone Agonists and Antagonists

The most common form of ADT involves chemical suppression of the pituitary with gonadotropin-releasing hormone (GnRH) agonists. GnRH agonists cause an initial surge in levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), followed by inhibition of gonadotropin release (*see* Chapter 55). This results in reduction of testicular production of testosterone to castrate levels. GnRH agonists in common use include *leuprolide* (LUPRON, others), *goserelin* (ZOLADEX), *triptorelin* (TRELSTAR), and *buserelin* (SUPREFACT; not

available in the United States). Randomized trials have shown that GnRH analogs are as effective as *diethylstilbestrol* and bilateral orchiectomy in the treatment of men with prostate cancer (Seidenfeld *et al.*, 2000). One important side effect, a transient flare of disease, may result from the initial surge of gonadotropins, and can be avoided by temporary (2 to 4 weeks) administration of AR blockers or by the use of GnRH antagonists (*see below*).

Complete androgen blockade (CAB) refers to combination therapy with androgen-receptor blockers and GnRH agonists. However, the advantages of long-term CAB over GnRH agonists alone are questionable. Large meta-analyses of numerous trials show a small advantage to CAB that is clinically insignificant (Prostate Cancer Trialists' Collaborative Group, 2000; Samson *et al.*, 2002).

Treatment with GnRH antagonists rapidly reduces serum testosterone levels, without the transient initial increase observed after GnRH agonists (Tomera *et al.*, 2001). One such compound is *abarelix* (PLENAXIS), which effectively reduces serum testosterone to castrate levels within a week in most men (Trachtenberg *et al.*, 2002). Other than avoidance of the initial flare, GnRH antagonist therapy offers no advantage compared with GnRH agonists, and GnRH antagonists currently are available only in the 1-month depot formulation.

Androgen Receptor Blockers

Compounds that competitively inhibit the natural ligands of the androgen receptor (AR) are called AR blockers, often referred to simply as anti-androgens. As discussed above, when given with GnRH agonists, the combination therapy is called CAB, since androgens from the adrenals are blocked, in addition to gonad-derived androgens. Currently, AR blockers as monotherapy are not indicated as routine, first-line treatment for patients with advanced prostate cancer, although some evidence points to reduced adverse effects of AR blockers relative to GnRH agonists on bone density and body composition (Smith *et al.*, 2004).

From a structural standpoint, AR blockers are classified as steroidal, including *cyproterone* (ANDROCUR) and *megestrol*, or nonsteroidal, including *flutamide* (EULEXIN, others), *nilutamide* (NILANDRON), and *bicalutamide* (CASODEX) (Reid *et al.*, 1999). The nonsteroidal AR blockers (Figure 51–20) are more commonly used in clinical practice. They inhibit ligand binding and consequent AR translocation from the cytoplasm to the nucleus. Unlike

Figure 51–20. Nonsteroidal androgen-receptor blockers.

the steroidal agents, nonsteroidal AR blockers interrupt the negative feedback of testosterone to the pituitary-hypothalamic axis, resulting in increased serum testosterone levels, thus attenuating the loss of libido and potency (Knuth *et al.*, 1984).

All of the nonsteroidal AR blockers may cause vasomotor flushing, gynecomastia, mastodynia, and variable degrees of decreased libido and potency. Bicalutamide has a serum half-life of 5 to 6 days, and is administered at a dose of 50 mg/day when given in combination with GnRH agonist therapy. Bicalutamide is well tolerated at higher doses as well, with rare additional side effects. Both enantiomers of bicalutamide undergo glucuronidation to inactive metabolites, and the parent compounds and metabolites are eliminated in bile and urine. The elimination half-life of bicalutamide is increased in severe hepatic insufficiency and is unchanged in renal insufficiency. Flutamide is administered at 250 mg three times a day, and may cause diarrhea, nausea, and reversible liver abnormalities. It has one major metabolite, hydroxyflutamide, that is biologically active, and at least five other minor metabolites. The parent compound and metabolites are mainly excreted in the urine. Nilutamide causes less diarrhea than flutamide, but causes diminished adaptation to darkness and other visual disturbances in 25% to 40%, alcohol intolerance in 5% to 20%, and idiopathic allergic pneumonitis in 1% to 2% of patients. It is extensively metabolized, with five known metabolites. At least one of these is biologically active, and all are excreted in the urine. The elimination half-life of nilutamide is 38 to 40 hours, which allows once-daily dosing at 150 mg/day.

CLINICAL SUMMARY

The therapy of cancer has improved dramatically during the past half century. This improvement can be traced to a number of factors: a better understanding of cancer's causes and natural history, better technologies for early detection and diagnosis, improved control of primary tumors through better surgery and radiation therapy, and more effective drugs. It is instructive to remember that at the end of World War II, there were no drugs to treat this group of diseases (Chabner and Roberts, 2005). The evolution of drug therapy for cancer has progressed rapidly, from alkylating agents and antimetabolites to natural products, and most recently, molecularly targeted drugs such as imatinib and gefitinib. As our understanding of the biology of cancer improves, new targets for therapy are being identified daily, and small molecules and monoclonal antibodies are being developed to test the validity of these targets in human cancer.

Although imatinib has been a spectacular success in controlling the chronic phase of CML, it clearly does not eradicate the disease. CML cells develop resistance through point mutations in the target protein or through amplification of the expression of the target gene, the BCR-ABL kinase gene. Importantly, these resistance mutations exist prior to drug exposure and reflect the inherent mutability of cancer cells, as previously reflected in the experience with cytotoxic agents. Thus, it seems likely that single agents, whether cytotoxic or molecularly targeted, will not cure cancer. Future endeavors will include determining how to use the growing list of potential agents in combination, the only strategy that can address the inherent ability of cancer to escape single agents.

There are two challenges standing in the way of more effective cancer treatment. The first is the search for better drugs based on our rapidly evolving knowledge of cancer biology. The second challenge, one that has never been adequately addressed in the age of cytotoxic chemotherapy, is to identify the determinants of response (Roberts and Chabner, 2004) and to select drugs for individual patients. Traditionally, cytotoxic therapies were administered based on regimens devised for broad histologic categories of cancer, such as lung, breast, or colon cancer. Single-agent response rates rarely exceeded 30% for these tumors. Increasingly, however, with the advent of technologies for measurement of targets in tumor samples, it has become possible to select patients

with higher rates of response to hormonal agents, monoclonal antibodies, and now targeted therapies such as gefitinib. Thus, in the future, therapies will be selected based both on histology and on the molecular features of the tumor. Furthermore, through characterization of genetic polymorphisms, it also will be possible to predict individual susceptibility to toxicity. Thus, drug selection will be guided by molecular testing of both patient and tumor. The result will be more effective, less wasteful, and less toxic therapy for cancer.

Immunomodulators

CHAPTER

52

IMMUNOSUPPRESSANTS, TOLEROGENS, AND IMMUNOSTIMULANTS

Alan M. Krensky, Flavio Vincenti, and William M. Bennett

THE IMMUNE RESPONSE

The immune system evolved to discriminate self from nonself. Multicellular organisms were faced with the problem of destroying infectious invaders (microbes) or dysregulated self (tumors) while leaving normal cells intact. These organisms responded by developing a robust array of receptor-mediated sensing and effector mechanisms broadly described as innate and adaptive. Innate, or natural, immunity is primitive, does not require priming, and is of relatively low affinity, but is broadly reactive. Adaptive, or learned, immunity is antigen-specific, depends upon antigen exposure or priming, and can be of very high affinity. The two arms of immunity work closely together, with the innate immune system being most active early in an immune response and adaptive immunity becoming progressively dominant over time. The major effectors of innate immunity are complement, granulocytes, monocytes/macrophages, natural killer cells, mast cells, and basophils. The major effectors of adaptive immunity are B and T lymphocytes. B lymphocytes make antibodies; T lymphocytes function as helper, cytolytic, and regulatory (suppressor) cells. These cells are important in the

normal immune response to infection and tumors, but also mediate transplant rejection and autoimmunity (Janeway *et al.*, 2001; Paul, 1999). Immunoglobulins (antibodies) on the B lymphocyte surface are receptors for a large variety of specific structural conformations. In contrast, T lymphocytes recognize antigens as peptide fragments in the context of self major histocompatibility complex (MHC) antigens (called human leukocyte antigens [HLA] in human beings) on the surface of antigen-presenting cells, such as dendritic cells, macrophages, and other cell types expressing MHC class I (HLA-A, -B, and -C) and class II antigens (HLA-DR, -DP, and -DQ) in human beings. Once activated by specific antigen recognition *via* their respective clonally restricted cell-surface receptors, both B and T lymphocytes are triggered to differentiate and divide, leading to release of soluble mediators (cytokines, lymphokines) that perform as effectors and regulators of the immune response.

The impact of the immune system in human disease is enormous. Developing vaccines against emerging infectious agents such as human immunodeficiency virus (HIV) and Ebola virus is among the most critical challenges facing the research community. Immune system-mediated diseases are significant medical problems.

Immunological diseases are growing at epidemic proportions that require aggressive and innovative approaches to develop new treatments. These diseases include a broad spectrum of autoimmune diseases such as rheumatoid arthritis, type I diabetes mellitus, systemic lupus erythematosus, and multiple sclerosis; solid tumors and hematologic malignancies; infectious diseases; asthma; and various allergic conditions. Furthermore, one of the great therapeutic opportunities for the treatment of many disorders is organ transplantation. However, immune system-mediated graft rejection remains the single greatest barrier to widespread use of this technology. An improved understanding of the immune system has led to the development of new therapies to treat immune system-mediated diseases.

This chapter briefly reviews drugs used to modulate the immune response in three ways: immunosuppression, tolerance, and immunostimulation. Four major classes of immunosuppressive drugs are discussed: glucocorticoids (see Chapter 59), calcineurin inhibitors, antiproliferative and antimetabolic agents (see Chapter 51), and antibodies. The “holy grail” of immunomodulation is the induction and maintenance of immune tolerance, the active state of antigen-specific nonresponsiveness. Approaches expected to overcome the risks of infections and tumors with immunosuppression are reviewed. These include costimulatory blockade, donor-cell chimerism, soluble human leukocyte antigens (HLA), and antigen-based therapies. A general discussion of the limited number of immunostimulant agents is presented, followed by an overview of active and passive immunization, and concluding with a brief case study of immunotherapy for multiple sclerosis.

IMMUNOSUPPRESSION

Immunosuppressive drugs are used to dampen the immune response in organ transplantation and autoimmune disease. In transplantation, the major classes of immunosuppressive drugs used today are: (1) *glucocorticoids*, (2) *calcineurin inhibitors*, (3) *antiproliferative/antimetabolic agents*, and (4) *biologics (antibodies)*. These drugs have met with a high degree of clinical success in treating conditions such as acute immune rejection of organ transplants and severe autoimmune diseases. However, such therapies require life-long use and nonspecifically suppress the entire immune system, exposing patients to considerably higher risks of infection and cancer. The calcineurin inhibitors and glucocorticoids, in particular, are nephrotoxic and diabetogenic,

respectively, thus restricting their usefulness in a variety of clinical settings.

Monoclonal and polyclonal antibody preparations directed at reactive T cells are important adjunct therapies and provide a unique opportunity to target specifically immune-reactive cells. Finally, newer small molecules and antibodies have expanded the arsenal of immunosuppressives. In particular, mTOR (*mammalian target of rapamycin*) inhibitors (*sirolimus*, *everolimus*) and anti-CD25 [interleukin (IL)-2 receptor] antibodies (*basiliximab*, *daclizumab*) target growth factor pathways, substantially limiting clonal expansion and thus potentially promoting tolerance. Immunosuppressive drugs used more commonly today are described below. Many more selective therapeutic agents under development are expected to revolutionize immunotherapy in the next decade.

General Approach to Organ Transplantation Therapy

Organ transplant therapy is organized around five general principles. The first principle is careful patient preparation and selection of the best available ABO blood type-compatible HLA match for organ donation. Second, a multitiered approach to immunosuppressive drug therapy, similar to that in cancer chemotherapy, is employed. Several agents are used simultaneously, each of which is directed at a different molecular target within the allograft response (Table 52-1; Hong and Kahan, 2000a). Synergistic effects permit use of the various agents at relatively low doses, thereby limiting specific toxicities while maximizing the immunosuppressive effect. The third principle is that greater immunosuppression is required to gain early engraftment and/or to treat established rejection than to maintain long-term immunosuppression. Therefore, intensive induction and lower-dose maintenance drug protocols are employed. Fourth, careful investigation of each episode of transplant dysfunction is required, including evaluation for rejection, drug toxicity, and infection, keeping in mind that these various problems can and often do coexist. Organ-specific problems (*e.g.*, obstruction in the case of kidney transplants) must also be considered. The fifth principle, which is common to all drugs, is that a drug should be reduced or withdrawn if its toxicity exceeds its benefit.

Biologic Induction Therapy. Induction therapy with polyclonal and monoclonal antibodies (mAbs) has been an important component of immunosuppression dating back to the 1960s, when Starzl and colleagues demonstrated the beneficial effect of antilymphocyte globulin (ALG) in the prophylaxis of rejection in renal transplant recipients. Over the past 40 years, several polyclonal antilymphocyte preparations have been used in renal transplantation; however, only 2 preparations are currently FDA approved: *lymphocyte immune globulin* (ATGAM) and *antithymocyte globulin* (THYMOGLOBULIN) (Howard *et al.*, 1997; Monaco, 1999). Another important milestone in biologic therapy was the development of mAbs and the introduction of the murine anti-CD3 mAb (*muromonab-CD3* or OKT3) (Ortho Multicenter Transplant Study Group, 1985).

In many transplant centers, induction therapy with biologic agents is used to delay the use of the nephrotoxic calcineurin inhibitors or to intensify the initial immunosuppressive therapy in patients at high risk of rejection (*i.e.*, repeat transplants, broadly presensi-

Table 52–1
Sites of Action of Selected Immunosuppressive Agents on T-Cell Activation

DRUG	SITE OF ACTION
Glucocorticoids	Glucocorticoid response elements in DNA (regulate gene transcription)
Muromonab-CD3	T-cell receptor complex (blocks antigen recognition)
Cyclosporine	Calcineurin (inhibits phosphatase activity)
Tacrolimus	Calcineurin (inhibits phosphatase activity)
Azathioprine	Deoxyribonucleic acid (false nucleotide incorporation)
Mycophenolate Mofetil	Inosine monophosphate dehydrogenase (inhibits activity)
Daclizumab, Basiliximab	IL-2 receptor (block IL-2-mediated T-cell activation)
Sirolimus	Protein kinase involved in cell-cycle progression (mTOR) (inhibits activity)

tized patients, African-American patients, or pediatric patients). Most of the limitations of murine-based mAbs generally were overcome by the introduction of chimeric or humanized mAbs that lack antigenicity and have prolonged serum half-lives. The anti-interleukin-2 receptor (IL-2R) mAbs (frequently referred to as anti-CD25) were the first biologics proven to be effective as induction agents in randomized double-blind prospective trials (Vincenti *et al.*, 1998; Nashan *et al.*, 1997; Nashan *et al.*, 1999; Kahan *et al.*, 1999b).

Biologic agents for induction therapy in the prophylaxis of rejection currently are used in approximately 70% of *de novo* transplant patients and have been propelled by several factors, including the introduction of the safe anti-IL-2R antibodies and the emergence of antilymphocyte globulin as a safer and more effective alternative to lymphocyte immune globulin or muromonab-CD3 mAb. Biologics for induction can be divided into 2 groups: the depleting agents and the immune modulators. The depleting agents consist of lymphocyte immune globulin, antilymphocyte globulin, and muromonab-CD3 mAb (the latter also produces immune modulation); their efficacy derives from their ability to deplete the recipient's CD3-positive cells at the time of transplantation and antigen presentation. The second group of biologic agents, the anti-IL-2R mAbs, do not deplete T lymphocytes, but rather block IL-2-mediated T-cell activation by binding to the α chain of IL-2R.

For patients with high levels of anti-HLA antibodies, humoral rejection mediated by B cells can be modified by plasmapheresis, usually given every other day for 4 to 5 treatments followed by intravenous immunoglobulin to suppress antibody production (Akalın *et al.*, 2003; Zachary *et al.*, 2003).

Maintenance Immunotherapy. The basic immunosuppressive protocols in most transplant centers use multiple drugs simultaneously.

Therapy typically involves a calcineurin inhibitor, glucocorticoids, and mycophenolate mofetil (a purine metabolism inhibitor; *see* below), each directed at a discrete site in T-cell activation (Suthanthiran *et al.*, 1996; Perico and Remuzzi, 1997). Glucocorticoids, azathioprine, cyclosporine, tacrolimus, mycophenolate mofetil, sirolimus, and various monoclonal and polyclonal antibodies are all approved for use in transplantation. Glucocorticoid-free regimens have achieved special prominence in recent successes in using pancreatic islet transplants to treat patients with type I diabetes mellitus. Protocols employing steroid withdrawal or steroid avoidance are being evaluated in many transplant centers. Short-term results are good, but the effects on long-term graft function are unknown (Hricik *et al.*, 2003). Recent data suggest that calcineurin inhibitors may shorten graft half-life by their nephrotoxic effects (Ojo *et al.*, 2003; Colvin, 2003). Protocols under evaluation include calcineurin dose reduction or switching from calcineurin to sirolimus-based immunosuppressive therapy at 3 to 4 months (Oberbauer *et al.*, 2003).

Therapy for Established Rejection. Although low doses of prednisone, calcineurin inhibitors, purine metabolism inhibitors, or sirolimus are effective in preventing acute cellular rejection, they are less effective in blocking activated T lymphocytes, and thus are not very effective against established, acute rejection or for the total prevention of chronic rejection (Monaco *et al.*, 1999). Therefore, treatment of established rejection requires the use of agents directed against activated T cells. These include glucocorticoids in high doses (pulse therapy), polyclonal antilymphocyte antibodies, or muromonab-CD3 mAb.

Adrenocortical Steroids

The introduction of glucocorticoids as immunosuppressive drugs in the 1960s played a key role in making organ transplantation possible. Their chemistry, pharmacokinetics, and drug interactions are described in Chapter 59. Prednisone, prednisolone, and other glucocorticoids are used alone and in combination with other immunosuppressive agents for treatment of transplant rejection and autoimmune disorders.

Mechanism of Action. The immunosuppressive effects of glucocorticoids have long been known, but the specific mechanism(s) of their immunosuppressive action remains somewhat elusive. Glucocorticoids lyse (in some species) and induce the redistribution of lymphocytes, causing a rapid, transient decrease in peripheral blood lymphocyte counts. To effect longer-term responses, steroids bind to receptors inside cells; either these receptors, glucocorticoid-induced proteins, or interacting proteins regulate the transcription of numerous other genes (*see* Chapter 59). Additionally, glucocorticoid-receptor complexes increase I κ B expression, thereby curtailing activation of NF- κ B, which increases apoptosis of activated cells (Auphan *et al.*, 1995). Of central importance, key proinflammatory cytokines such as IL-1 and IL-6 are downregulated. T cells are inhibited from making IL-2 and proliferating. The activation of cytotoxic T lymphocytes is inhibited. Neutrophils and monocytes display poor chemotaxis and decreased lysosomal enzyme release. Therefore, glucocorticoids have broad antiinflammatory effects on multiple components of cellular immunity. In contrast, they have relatively little effect on humoral immunity.

Therapeutic Uses. There are numerous indications for glucocorticoids (Zoorob and Cender, 1998). They commonly are combined with other immunosuppressive agents to prevent and treat transplant rejection. High dose pulses of intravenous *methylprednisolone sodium succinate* (SOLU-MEDROL, A-METHAPRED) are used to reverse acute transplant rejection and acute exacerbations of selected autoimmune disorders (Shinn *et al.*, 1999; Laan *et al.*, 1999). Glucocorticoids also are efficacious for treatment of graft-versus-host disease in bone-marrow transplantation. Glucocorticoids are used routinely to treat autoimmune disorders such as rheumatoid and other arthritides, systemic lupus erythematosus, systemic dermatomyositis, psoriasis and other skin conditions, asthma and other allergic disorders, inflammatory bowel disease, inflammatory ophthalmic diseases, autoimmune hematologic disorders, and acute exacerbations of multiple sclerosis (*see below*). In addition, glucocorticoids limit allergic reactions that occur with other immunosuppressive agents and are used in transplant recipients to block first-dose cytokine storm caused by treatment with muromonad-CD3 and to a lesser extent thymoglobulin (*see below*).

Toxicity. Unfortunately, the extensive use of steroids often results in disabling and life-threatening adverse effects. These effects include growth retardation in children, avascular necrosis of bone, osteopenia, increased risk of infection, poor wound healing, cataracts, hyperglycemia, and hypertension (*see Chapter 59*). The advent of combined glucocorticoid/cyclosporine regimens has allowed reduced doses of steroids, but steroid-induced morbidity remains a major problem in many transplant patients.

Calcineurin Inhibitors

Perhaps the most effective immunosuppressive drugs in routine use are the calcineurin inhibitors, *cyclosporine* and *tacrolimus*, which target intracellular signaling pathways induced as a consequence of T-cell-receptor activation (Schreiber and Crabtree, 1992). Although they are structurally unrelated (Figure 52–1) and bind to distinct, albeit related molecular targets, they inhibit normal T-cell signal transduction essentially by the same mechanism (Figure 52–2). Cyclosporine and tacrolimus do not act *per se* as immunosuppressive agents. Instead, these drugs bind to an immunophilin (cyclophilin for cyclosporine or FKBP-12 for tacrolimus), resulting in subsequent interaction with calcineurin to block its phosphatase activity. Calcineurin-catalyzed dephosphorylation is required for movement of a component of the nuclear factor of activated T lymphocytes (NFAT) into the nucleus (Figure 52–2).

NFAT, in turn, is required to induce a number of cytokine genes, including that for interleukin-2 (IL-2), a prototypic T-cell growth and differentiation factor.

Cyclosporine. Chemistry. Cyclosporine (cyclosporin A), a cyclic polypeptide consisting of 11 amino acids, is produced by the fungus species *Beauveria nivea*. Of note, all amide nitrogens are either hydrogen bonded or methylated, the single D-amino acid is at position 8, the methyl amide between residues 9 and 10 is in the *cis* configuration, and all other methyl amide moieties are in the *trans* form (Figure 52–1). Because cyclosporine is lipophilic and highly hydrophobic, it is formulated for clinical administration using castor oil or other strategies to ensure solubilization.

Mechanism of Action. Cyclosporine suppresses some humoral immunity, but is more effective against T-cell-dependent immune mechanisms such as those underlying transplant rejection and some forms of autoimmunity (Kahan, 1989). It preferentially inhibits antigen-triggered signal transduction in T lymphocytes, blunting expression of many lymphokines including IL-2, and the expression of antiapoptotic proteins. Cyclosporine forms a complex with cyclophilin, a cytoplasmic receptor protein present in target cells. This complex binds to calcineurin, inhibiting Ca^{2+} -stimulated dephosphorylation of the cytosolic component of NFAT (Schreiber and Crabtree, 1992). When cytoplasmic NFAT is dephosphorylated, it translocates to the nucleus and complexes with nuclear components required for complete T-cell activation, including transactivation of IL-2 and other lymphokine genes. Calcineurin phosphatase activity is inhibited after physical interaction with the cyclosporine/cyclophilin complex. This prevents NFAT dephosphorylation such that NFAT does not enter the nucleus, gene transcription is not activated, and the T lymphocyte fails to respond to specific antigenic stimulation. Cyclosporine also increases expression of transforming growth factor- β (TGF- β), a potent inhibitor of IL-2-stimulated T-cell proliferation and generation of cytotoxic T lymphocytes (CTL) (Khanna *et al.*, 1994).

Disposition and Pharmacokinetics. Cyclosporine can be administered intravenously or orally. The intravenous preparation (SANDIMMUNE Injection) is provided as a solution in an ethanol-polyoxyethylated castor oil vehicle that must be further diluted in 0.9% sodium chloride solution or 5% dextrose solution before injection. The oral dosage forms include soft gelatin capsules and oral solutions. Cyclosporine supplied in the original soft gelatin capsule (SANDIMMUNE) is absorbed slowly with 20% to 50% bioavailability. A modified microemulsion formulation (NEORAL) is available (Noble and Markham, 1995). It has more uniform and slightly increased bioavailability compared to SANDIMMUNE and is provided as 25-mg and 100-mg soft gelatin capsules and a 100-mg/ml oral solution. Since SANDIMMUNE and NEORAL are not bioequivalent, they cannot be used interchangeably without supervision by a physician and monitoring of drug concentrations in plasma. Comparison of blood concentrations in published literature and in clinical practice must be performed with a detailed knowledge of the assay system employed.

Figure 52–1. Chemical structures of immunosuppressive drugs: azathioprine, mycophenolate mofetil, cyclosporine, tacrolimus, and sirolimus.

Generic preparations of both NEORAL and SANDIMMUNE are available that are bioequivalent by FDA criteria. The generic preparations for NEORAL have been shown to be bioequivalent in normal volunteers, and, in some studies, also in transplant recipients. A consensus conference held under the auspices of the American Society of Transplantation recommended that generic preparations of cyclosporine could be used *de novo* in transplantation to substitute for NEORAL (Alloway *et al.*, 2003). However, when

switching between generic and NEORAL formulations, increased surveillance is recommended to ensure that drug levels remain in the therapeutic range. This need for increased monitoring is based on anecdotal experience rather than validated differences. In fact the generic preparations were comparable to NEORAL for immunosuppressive purposes in most studies. *Since SANDIMMUNE and NEORAL differ in terms of their pharmacokinetics and are definitely not bioequivalent, their generic versions cannot*

Figure 52–2. Mechanisms of action of cyclosporine, tacrolimus, and sirolimus on T cells. Both cyclosporine and tacrolimus bind to immunophilins (cyclophilin and FK506-binding protein [FKBP], respectively), forming a complex that binds the phosphatase calcineurin and inhibits the calcineurin-catalyzed dephosphorylation essential to permit movement of the nuclear factor of activated T cells (NFAT) into the nucleus. NFAT is required for transcription of interleukin-2 (IL-2) and other growth and differentiation-associated cytokines (lymphokines). Sirolimus (rapamycin) works at a later stage in T-cell activation, downstream of the IL-2 receptor. Sirolimus also binds FKBP, but the FKBP-sirolimus complex binds to and inhibits the mammalian target of rapamycin (mTOR), a kinase involved in cell-cycle progression (proliferation). TCR, T-cell receptor. (From Pattison *et al.*, 1997, with permission.)

be used interchangeably. This has been a source of confusion to pharmacists and patients. Transplant units need to educate patients that SANDIMMUNE and its generics are not the same as NEORAL and its generics, such that one preparation cannot be substituted for another without risk of inadequate immunosuppression or increased toxicity.

Both radioimmunoassays and high-performance liquid chromatography assays for cyclosporine and tacrolimus are available. Because these methods differ, the prescribing physician should ensure that the methods are consistent when monitoring an individual patient. Blood is most conveniently sampled before the next dose, namely a C_0 or trough level. While this is convenient, it has been shown repeatedly that C_0 concentrations do not reflect the area under the curve (AUC) for cyclosporine exposure in individual patients. As a practical solution to this problem and

to better measure the overall exposure of a patient to the drug, it has been proposed that levels be taken 2 hours after a dose administration, so-called C_2 levels (Cole *et al.*, 2003). Some studies have shown a better correlation of C_2 with the AUC, but no single time point can simulate the exposure as measured by more frequent drug sampling. In complex patients with delayed absorption, such as diabetics, the C_2 level may underestimate the peak cyclosporine level obtained, and in others who are rapid absorbers the C_2 level may have peaked before the blood sample is drawn. In practice if a patient has clinical signs or symptoms of toxicity, or there is unexplained rejection or renal dysfunction, a pharmacokinetic profile can be used to estimate that person's exposure to the drug. Many clinicians, particularly those caring for transplant patients some time after the transplant, monitor cyclosporine blood levels only when a clini-

cal event (e.g., renal dysfunction or rejection) occurs. In that setting, either a C_0 or C_2 level helps to ascertain whether inadequate immunosuppression or drug toxicity is present. As described above, cyclosporine absorption is incomplete following oral administration and varies with the individual patient and the formulation used. The elimination of cyclosporine from the blood is generally biphasic, with a terminal half-life of 5 to 18 hours (Faulds *et al.*, 1993; Noble and Markham, 1995). After intravenous infusion, clearance is approximately 5 to 7 ml/min per kg in adult recipients of renal transplants, but results differ by age and patient populations. For example, clearance is slower in cardiac transplant patients and more rapid in children. Thus, the intersubject variability is so large that individual monitoring is required (Faulds *et al.*, 1993; Noble and Markham, 1995).

After oral administration of cyclosporine (as NEORAL), the time to peak blood concentrations is 1.5 to 2 hours (Faulds *et al.*, 1993; Noble and Markham, 1995). Administration with food delays and decreases absorption. High- and low-fat meals consumed within 30 minutes of administration decrease the AUC by approximately 13% and the maximum concentration by 33%. This makes it imperative to individualize dosage regimens for outpatients.

Cyclosporine is distributed extensively outside the vascular compartment. After intravenous dosing, the steady-state volume of distribution is reportedly as high as 3 to 5 L/kg in solid-organ transplant recipients.

Only 0.1% of cyclosporine is excreted unchanged in urine (Faulds *et al.*, 1993). Cyclosporine is extensively metabolized in the liver by CYP3A and to a lesser degree by the gastrointestinal tract and kidneys (Fahr, 1993). At least 25 metabolites have been identified in human bile, feces, blood, and urine (Christians and Sewing, 1993). Although the cyclic peptide structure of cyclosporine is relatively resistant to metabolism, the side chains are extensively metabolized. All of the metabolites have reduced biological activity and toxicity compared to the parent drug. Cyclosporine and its metabolites are excreted principally through the bile into the feces, with only about 6% being excreted in the urine. Cyclosporine also is excreted in human milk. In the presence of hepatic dysfunction, dosage adjustments are required. No adjustments generally are necessary for dialysis or renal failure patients.

Therapeutic Uses. Clinical indications for cyclosporine are kidney, liver, heart, and other organ transplantation; rheumatoid arthritis; and psoriasis (Faulds *et al.*, 1993). Its use in dermatology is discussed in Chapter 62. Cyclosporine generally is recognized as the agent that ushered in the modern era of organ transplantation, increasing the rates of early engraftment, extending kidney graft survival, and making cardiac and liver transplantation possi-

ble. Cyclosporine usually is combined with other agents, especially glucocorticoids and either azathioprine or mycophenolate mofetil, and most recently, sirolimus. The dose of cyclosporine varies, depending on the organ transplanted and the other drugs used in the specific treatment protocol(s). The initial dose generally is not given before the transplant because of the concern about nephrotoxicity. Especially for renal transplant patients, therapeutic algorithms have been developed to delay cyclosporine introduction until a threshold renal function has been attained. The amount of the initial dose and reduction to maintenance dosing is sufficiently variable that no specific recommendation is provided here. Dosage is guided by signs of rejection (too low a dose), renal or other toxicity (too high a dose), and close monitoring of blood levels. Great care must be taken to differentiate renal toxicity from rejection in kidney transplant patients. Ultrasound-guided allograft biopsy is the best way to assess the reason for renal dysfunction. Because adverse reactions have been ascribed more frequently to the intravenous formulation, this route of administration is discontinued as soon as the patient is able to take the drug orally.

In rheumatoid arthritis, cyclosporine is used in severe cases that have not responded to *methotrexate*. Cyclosporine can be combined with methotrexate, but the levels of both drugs must be monitored closely (Baraldo *et al.*, 1999). In psoriasis, cyclosporine is indicated for treatment of adult immunocompetent patients with severe and disabling disease for whom other systemic therapies have failed (Linden and Weinstein, 1999). Because of its mechanism of action, there is a theoretical basis for the use of cyclosporine in a variety of other T-cell-mediated diseases (Faulds *et al.*, 1993). Cyclosporine reportedly is effective in Behçet's acute ocular syndrome, endogenous uveitis, atopic dermatitis, inflammatory bowel disease, and nephrotic syndrome, even when standard therapies have failed.

Toxicity. The principal adverse reactions to cyclosporine therapy are renal dysfunction, tremor, hirsutism, hypertension, hyperlipidemia, and gum hyperplasia (Burke *et al.*, 1994). Hyperuricemia may lead to worsening of gout, increased P-glycoprotein activity, and hypercholesterolemia. Nephrotoxicity occurs in the majority of patients treated and is the major indication for cessation or modification of therapy. Hypertension occurs in approximately 50% of renal transplant and almost all cardiac transplant patients. Combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic, although this apparently is more problematic in patients treated with tacrolimus (*see below*). Especially at risk are obese patients, African-American or Hispanic recipients, or

those with family history of type II diabetes or obesity. Cyclosporine, as opposed to tacrolimus, is more likely to produce elevations in LDL cholesterol (Artz *et al.*, 2003; Kramer *et al.*, 2003; Tanabe, 2003).

Drug Interactions. Cyclosporine interacts with a wide variety of commonly used drugs, and close attention must be paid to drug interactions. Any drug that affects microsomal enzymes, especially the CYP3A system, may impact cyclosporine blood concentrations (Faulds *et al.*, 1993). Substances that inhibit this enzyme can decrease cyclosporine metabolism and increase blood concentrations. These include Ca²⁺ channel blockers (*e.g.*, *verapamil*, *nicardipine*), antifungal agents (*e.g.*, *fluconazole*, *ketoconazole*), antibiotics (*e.g.*, *erythromycin*), glucocorticoids (*e.g.*, methylprednisolone), HIV-protease inhibitors (*e.g.*, *indinavir*), and other drugs (*e.g.*, *allopurinol*, *metoclopramide*). Grapefruit and grapefruit juice block CYP3A and the multidrug efflux pump and should be avoided by patients taking cyclosporine; these effects can increase cyclosporine blood concentrations. In contrast, drugs that induce CYP3A activity can increase cyclosporine metabolism and decrease blood concentrations. Such drugs include antibiotics (*e.g.*, *nafcillin*, *rifampin*), anticonvulsants (*e.g.*, *phenobarbital*, *phenytoin*), and other drugs (*e.g.*, *octreotide*, *ticlopidine*). In general, close monitoring of cyclosporine blood levels and the levels of other drugs is required when such combinations are used.

Interactions between cyclosporine and sirolimus (*see below*) have led to the recommendation that administration of the two drugs be separated by time. Sirolimus aggravates cyclosporine-induced renal dysfunction, while cyclosporine increases sirolimus-induced hyperlipidemia and myelosuppression. Other drug interactions of concern include additive nephrotoxicity when cyclosporine is coadministered with nonsteroidal antiinflammatory drugs and other drugs that cause renal dysfunction; elevation of methotrexate levels when the two drugs are coadministered; and reduced clearance of other drugs, including *prednisolone*, *digoxin*, and statins.

Tacrolimus. Tacrolimus (PROGRAF, FK506) is a macrolide antibiotic produced by *Streptomyces tsukubaensis* (Goto *et al.*, 1987). Its formula is shown in Figure 52–1.

Mechanism of Action. Like cyclosporine, tacrolimus inhibits T-cell activation by inhibiting calcineurin (Schreiber and Crabtree, 1992). Tacrolimus binds to an intracellular protein, FK506-binding protein–12 (FKBP-12), an immunophilin structurally related to cyclophilin. A complex of tacrolimus-FKBP-12, Ca²⁺, calmodulin, and calcineurin then forms, and calcineurin phosphatase activity is inhibited. As described for cyclosporine and depicted in Figure 52–2, the inhibition of phosphatase activity prevents dephosphorylation

and nuclear translocation of NFAT and inhibits T-cell activation. Thus, although the intracellular receptors differ, cyclosporine and tacrolimus target the same pathway for immunosuppression (Plosker and Foster, 2000).

Disposition and Pharmacokinetics. Tacrolimus is available for oral administration as capsules (0.5, 1, and 5 mg) and as a sterile solution for injection (5 mg/ml). Immunosuppressive activity resides primarily in the parent drug. Because of intersubject variability in pharmacokinetics, individualized dosing is required for optimal therapy (Fung and Starzl, 1995). Whole blood, rather than plasma, is the most appropriate sampling compartment to describe tacrolimus pharmacokinetics. For tacrolimus, the C₀ level seems to correlate better with clinical events than it does for cyclosporine. Target concentrations in many centers are 200 to 400 ng/ml in the early preoperative period and 100 to 200 ng/ml 3 months after transplantation. Unlike cyclosporine, more frequent tacrolimus dosing has not been formally evaluated. Gastrointestinal absorption is incomplete and variable. Food decreases the rate and extent of absorption. Plasma protein binding of tacrolimus is 75% to 99%, involving primarily albumin and α_1 -acid glycoprotein. Its half-life is about 12 hours. Tacrolimus is extensively metabolized in the liver by CYP3A, with a half-life of ~12 hours; at least some of the metabolites are active. The bulk of excretion of the parent drug and metabolites is in the feces. Less than 1% of administered tacrolimus is excreted unchanged in the urine.

Therapeutic Uses. Tacrolimus is indicated for the prophylaxis of solid-organ allograft rejection in a manner similar to cyclosporine and as rescue therapy in patients with rejection episodes despite “therapeutic” levels of cyclosporine (Mayer *et al.*, 1997; The U.S. Multicenter FK506 Liver Study Group, 1994). The recommended starting dose for tacrolimus injection is 0.03 to 0.05 mg/kg per day as a continuous infusion. Recommended initial oral doses are 0.15 to 0.2 mg/kg per day for adult kidney transplant patients, 0.1 to 0.15 mg/kg per day for adult liver transplant patients, and 0.15 to 0.2 mg/kg per day for pediatric liver transplant patients in two divided doses 12 hours apart. These dosages are intended to achieve typical blood trough levels in the 5- to 15-ng/ml range. Pediatric patients generally require higher doses than do adults (Shapiro, 1998).

Toxicity. Nephrotoxicity, neurotoxicity (tremor, headache, motor disturbances, seizures), GI complaints, hypertension, hyperkalemia, hyperglycemia, and diabetes are all associated with tacrolimus use (Plosker and Foster, 2000). As with cyclosporine, nephrotoxicity is limiting (Mihatsch *et al.*, 1998; Henry, 1999). Tacrolimus has a negative effect on pancreatic islet beta cells, and glucose intolerance and diabetes mellitus are well-recognized complications of tacrolimus-based immunosuppression. As with other immunosuppressive agents, there is an increased risk of secondary tumors and opportunistic infections. Notably, tacrolimus does not adversely affect uric acid or LDL cholesterol.

Drug Interactions. Because of its potential for nephrotoxicity, tacrolimus blood levels and renal function should be monitored closely, especially when tacrolimus is used with other potentially nephrotoxic drugs. Coadministration with cyclosporine results in additive or synergistic nephrotoxicity; therefore a delay of at least 24 hours is required when switching a patient from cyclosporine to tacrolimus. Since tacrolimus is metabolized mainly by CYP3A, the potential interactions described above for cyclosporine also apply for tacrolimus (Venkataramanan *et al.*, 1995; Yoshimura *et al.*, 1999).

Antiproliferative and Antimetabolic Drugs

Sirolimus. Sirolimus (*rapamycin*; RAPAMUNE) is a macrocyclic lactone produced by *Streptomyces hygroscopicus* (Vezina *et al.*, 1975). Its structure is shown in Figure 52–1.

Mechanism of Action. Sirolimus inhibits T-lymphocyte activation and proliferation downstream of the IL-2 and other T-cell growth factor receptors (Figure 52–2) (Kuo *et al.*, 1992). Like cyclosporine and tacrolimus, therapeutic action of sirolimus requires formation of a complex with an immunophilin, in this case FKBP-12. However, the sirolimus–FKBP-12 complex does not affect calcineurin activity. It binds to and inhibits a protein kinase, designated *mammalian target of rapamycin* (mTOR), which is a key enzyme in cell-cycle progression (Brown *et al.*, 1994). Inhibition of mTOR blocks cell-cycle progression at the G₁ → S phase transition. In animal models, sirolimus not only inhibits transplant rejection, graft-versus-host disease, and a variety of autoimmune diseases, but its effect also lasts several months after discontinuing therapy, suggesting a tolerizing effect (*see* Tolerance, below; Groth *et al.*, 1999). A newer indication for sirolimus is the avoidance of calcineurin inhibitors, even when patients are stable, to protect kidney function (Stegall *et al.*, 2003).

Disposition and Pharmacokinetics. After oral administration, sirolimus is absorbed rapidly and reaches a peak blood concentration within about 1 hour after a single dose in healthy subjects and within about 2 hours after multiple oral doses in renal transplant patients (Napoli and Kahan, 1996; Zimmerman and Kahan, 1997). Systemic availability is approximately 15%, and blood concentrations are proportional to doses between 3 and 12 mg/m². A high-fat meal decreases peak blood concentration by 34%; sirolimus therefore should be taken consistently either with or without food, and blood levels should be monitored closely. About 40% of sirolimus in plasma is protein bound, especially to albumin. The drug partitions into formed elements of blood, with a blood-to-plasma ratio of 38 in renal transplant patients. Sirolimus is extensively metabolized by CYP3A4 and is transported by P-glycoprotein. Seven major metabolites have been identified in whole blood (Salm *et al.*, 1999). Metabolites also are detectable in feces and urine, with the bulk of total excretion being in feces. Although some of its metabolites are active, sirolimus itself is the major active component in whole blood and contributes more than 90% of the immunosuppressive effect. The blood half-life after multiple doses in stable renal transplant patients is 62 hours (Napoli and Kahan, 1996; Zimmerman and Kahan, 1997). A loading dose of three times the maintenance dose will provide nearly steady-state concentrations within 1 day in most patients.

Therapeutic Uses. Sirolimus is indicated for prophylaxis of organ transplant rejection in combination with a calcineurin inhibitor and glucocorticoids (Kahan *et al.*,

1999a). In patients experiencing or at high risk for calcineurin inhibitor–associated nephrotoxicity, sirolimus has been used with glucocorticoids and mycophenolate mofetil to avoid permanent renal damage. The initial dosage in patients 13 years or older who weigh less than 40 kg should be adjusted based on body surface area (1 mg/m² per day) with a loading dose of 3 mg/m². Data regarding doses for pediatric and geriatric patients are lacking at this time (Kahan, 1999). It is recommended that the maintenance dose be reduced by approximately one-third in patients with hepatic impairment (Watson *et al.*, 1999). Sirolimus also has been incorporated into stents to inhibit local cell proliferation and blood vessel occlusion.

Toxicity. The use of sirolimus in renal transplant patients is associated with a dose-dependent increase in serum cholesterol and triglycerides that may require treatment (Murgia *et al.*, 1996). While immunotherapy with sirolimus *per se* is not nephrotoxic, patients treated with cyclosporine plus sirolimus have impaired renal function compared to patients treated with cyclosporine and either *azathioprine* or placebo. Sirolimus also may prolong delayed graft function in deceased donor kidney transplants, presumably because of its antiproliferative action (Smith *et al.*, 2003; McTaggart *et al.*, 2003). Renal function therefore must be monitored closely in such patients. Lymphocele, a known surgical complication associated with renal transplantation, is increased in a dose-dependent fashion by sirolimus, requiring close postoperative follow-up. Other adverse effects include anemia, leukopenia, thrombocytopenia (Hong and Kahan, 2000b), hypokalemia or hyperkalemia, fever, and gastrointestinal effects. Delayed wound healing may occur with sirolimus use. As with other immunosuppressive agents, there is an increased risk of neoplasms, especially lymphomas, and infections. Prophylaxis for *Pneumocystis carinii* pneumonia and cytomegalovirus is recommended (Groth *et al.*, 1999).

Drug Interactions. Since sirolimus is a substrate for CYP3A4 and is transported by P-glycoprotein, close attention to interactions with other drugs that are metabolized or transported by these proteins is required (Yoshimura *et al.*, 1999). As noted above, cyclosporine and sirolimus interact, and their administration should be separated by time. Dose adjustment may be required when sirolimus is coadministered with *diltiazem* or rifampin. The combination of sirolimus plus tacrolimus probably is more nephrotoxic than cyclosporine plus sirolimus. Dose adjustment apparently is not required when sirolimus is coadministered with *acyclovir*, digoxin, *glyburide*, *nifedipine*, *norgestrel/ethinyl estradiol*, prednisolone, or *trimethoprim-sulfamethoxazole*. This list is incomplete, and blood

levels and potential drug interactions must be monitored closely.

Everolimus. Everolimus (40-*O*-[2-hydroxy] ethyl-rapamycin) is closely related chemically and clinically to sirolimus but has distinct pharmacokinetics. The main difference is a shorter half-life and thus a shorter time to achieve steady-state concentrations of the drug. Dosage on a milligram per kilogram basis is similar to sirolimus. Aside from the shorter half-life, no studies have compared everolimus with sirolimus in standard immunosuppressive regimens (Eisen *et al.*, 2003). As with sirolimus, the combination of a calcineurin inhibitor and an mTOR inhibitor produces worse renal function at 1 year than does calcineurin inhibitor therapy alone, suggesting a drug interaction between the mTOR inhibitors and the calcineurin inhibitors to enhance toxicity and to reduce rejection. The toxicity of everolimus and the drug interactions reported to date seem to be the same as with sirolimus.

Azathioprine. Azathioprine (IMURAN) is a purine anti-metabolite. It is an imidazolyl derivative of 6-mercaptopurine (Figure 52–1).

Mechanism of Action. Following exposure to nucleophiles such as glutathione, azathioprine is cleaved to 6-mercaptopurine, which in turn is converted to additional metabolites that inhibit *de novo* purine synthesis (see Chapter 51). 6-Thio-IMP, a fraudulent nucleotide, is converted to 6-thio-GMP and finally to 6-thio-GTP, which is incorporated into DNA. Cell proliferation is thereby inhibited, impairing a variety of lymphocyte functions. Azathioprine appears to be a more potent immunosuppressive agent than 6-mercaptopurine, which may reflect differences in drug uptake or pharmacokinetic differences in the resulting metabolites.

Disposition and Pharmacokinetics. Azathioprine is well absorbed orally and reaches maximum blood levels within 1 to 2 hours after administration. The half-life of azathioprine is about 10 minutes, while that of its metabolite 6-mercaptopurine is about an hour. Other metabolites have half-lives of up to 5 hours. Blood levels have limited predictive value because of extensive metabolism, significant activity of many different metabolites, and high tissue levels attained. Azathioprine and *mercaptopurine* are moderately bound to plasma proteins and are partially dialyzable. Both are rapidly removed from the blood by oxidation or methylation in the liver and/or erythrocytes. Renal clearance has little impact on biological effectiveness or toxicity, but the dose should be reduced in patients with renal failure.

Therapeutic Uses. Azathioprine was first introduced as an immunosuppressive agent in 1961, helping to make allogeneic kidney transplantation possible. It is indicated as an adjunct for prevention of organ transplant rejection and in severe rheumatoid arthritis (Hong and Kahan,

2000a; Gaffney and Scott, 1998). Although the dose of azathioprine required to prevent organ rejection and minimize toxicity varies, 3 to 5 mg/kg per day is the usual starting dose. Lower initial doses (1 mg/kg per day) are used in treating rheumatoid arthritis. Complete blood count and liver function tests should be monitored.

Toxicity. The major side effect of azathioprine is bone marrow suppression, including leukopenia (common), thrombocytopenia (less common), and/or anemia (uncommon). Other important adverse effects include increased susceptibility to infections (especially varicella and herpes simplex viruses), hepatotoxicity, alopecia, GI toxicity, pancreatitis, and increased risk of neoplasia.

Drug Interactions. Xanthine oxidase, an enzyme of major importance in the catabolism of azathioprine metabolites, is blocked by allopurinol. If azathioprine and allopurinol are used concurrently, the azathioprine dose must be decreased to 25% to 33% of the usual dose; it is best not to use these two drugs together. Adverse effects resulting from coadministration of azathioprine with other myelosuppressive agents or angiotensin-converting enzyme inhibitors include leukopenia, thrombocytopenia, and anemia as a result of myelosuppression.

Mycophenolate Mofetil. *Mycophenolate mofetil* (CELL-CEPT) is the 2-morpholinoethyl ester of mycophenolic acid (MPA) (Allison and Eugui, 1993). Its structure is shown in Figure 52–1.

Mechanism of Action. Mycophenolate mofetil is a prodrug that is rapidly hydrolyzed to the active drug, mycophenolic acid (MPA), a selective, noncompetitive, and reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH) (Natsumeda and Carr, 1993), an important enzyme in the *de novo* pathway of guanine nucleotide synthesis. B and T lymphocytes are highly dependent on this pathway for cell proliferation, while other cell types can use salvage pathways; MPA therefore selectively inhibits lymphocyte proliferation and functions, including antibody formation, cellular adhesion, and migration.

Disposition and Pharmacokinetics. Mycophenolate mofetil undergoes rapid and complete metabolism to MPA after oral or intravenous administration. MPA, in turn, is metabolized to the inactive phenolic glucuronide MPAG. The parent drug is cleared from the blood within a few minutes. The half-life of MPA is about 16 hours. Negligible (<1%) amounts of MPA are excreted in the urine (Bardsley-Elliott *et al.*, 1999). Most (87%) is excreted in the urine as MPAG. Plasma concentrations of MPA and MPAG are increased in patients with renal insufficiency. In early renal transplant patients (<40 days posttransplant), plasma concentrations of MPA after a single dose of mycophenolate mofetil are about half of those found in healthy volunteers or stable renal transplant patients. Studies in children are

limited, and safety and effectiveness have not been established (Butani *et al.*, 1999).

Therapeutic Uses. Mycophenolate mofetil is indicated for prophylaxis of transplant rejection, and it typically is used in combination with glucocorticoids and a calcineurin inhibitor, but not with azathioprine (Kimball *et al.*, 1995; Ahsan *et al.*, 1999; Kreis *et al.*, 2000). Combined treatment with sirolimus is possible, although potential drug interactions necessitate careful monitoring of drug levels. For renal transplants, 1 g is administered orally or intravenously (over 2 hours) twice daily (2 g per day). A higher dose, 1.5 g twice daily (3 g per day), is recommended for African-American renal transplant patients and all cardiac transplant patients. Use of mycophenolate mofetil in other clinical settings is under investigation.

Toxicity. The principal toxicities of mycophenolate mofetil are gastrointestinal and hematologic (Fulton and Markham, 1996; Bardsley-Elliott *et al.*, 1999). These include leukopenia, diarrhea, and vomiting. There also is an increased incidence of some infections, especially sepsis associated with cytomegalovirus. Tacrolimus in combination with mycophenolate mofetil has been associated with devastating viral infections including polyoma nephritis (Zavos *et al.*, 2004; Elli *et al.*, 2002).

Drug Interactions. Potential drug interactions between mycophenolate mofetil and several other drugs commonly used by transplant patients have been studied (Bardsley-Elliott *et al.*, 1999). There appear to be no untoward effects produced by combination therapy with cyclosporine, trimethoprim-sulfamethoxazole, or oral contraceptives. Unlike cyclosporine, tacrolimus delays elimination of mycophenolate mofetil by impairing the conversion of MPA to MPAG. This may enhance GI toxicity. Mycophenolate mofetil has not been tested with azathioprine. Coadministration with antacids containing aluminum or magnesium hydroxide leads to decreased absorption of mycophenolate mofetil; thus, these drugs should not be administered simultaneously. Mycophenolate mofetil should not be administered with *cholestyramine* or other drugs that affect enterohepatic circulation. Such agents decrease plasma MPA concentrations, probably by binding free MPA in the intestines. Acyclovir and *ganciclovir* may compete with MPAG for tubular secretion, possibly resulting in increased concentrations of both MPAG and the antiviral agents in the blood, an effect that may be compounded in patients with renal insufficiency.

Other Antiproliferative and Cytotoxic Agents. Many of the cytotoxic and antimetabolic agents used in cancer chemotherapy (*see* Chapter 51) are immunosuppressive due to their action on lymphocytes and other cells of the immune system. Other cytotoxic drugs that have been used as

immunosuppressive agents include methotrexate, *cyclophosphamide* (CYTOXAN), *thalidomide*, and *chlorambucil* (LEUKERAN). Methotrexate is used for treatment of graft-versus-host disease, rheumatoid arthritis, and psoriasis, as well as in anticancer therapy (*see* Chapter 51) (Grosflam and Weinblatt, 1991). Cyclophosphamide and chlorambucil are used in treating childhood nephrotic syndrome (Neuhaus *et al.*, 1994) and a variety of malignancies (*see* Chapter 51). Cyclophosphamide also is used widely for treatment of severe systemic lupus erythematosus (Valeri *et al.*, 1994) and other vasculitides such as Wegener's granulomatosis. *Leflunomide* (ARAVA) is a pyrimidine-synthesis inhibitor indicated for the treatment of adults with rheumatoid arthritis (Prakash and Jarvis, 1999). This drug has found utility in the treatment of polyomavirus nephropathy seen in immunosuppressed renal transplant recipients and is increasingly being used for that purpose. There are no studies showing efficacy, however, compared with control patients treated with withdrawal or reduction of immunosuppression alone in BK virus nephropathy. The drug inhibits dihydroorotate dehydrogenase in the *de novo* pathway of pyrimidine synthesis. It is hepatotoxic and can cause fetal injury when administered to pregnant women.

FTY720

FTY720 (*see* Figure 52-1), an S1P receptor prodrug, is the first agent in a new class of small molecules, sphingosine 1-phosphate receptor (S1P-R) agonists, which reduce recirculation of lymphocytes from the lymphatic system to the blood and peripheral tissues, including inflammatory lesions and organ grafts.

Therapeutic Uses. FTY720 may have an important role in combination immunosuppression therapy in the prevention of acute rejection. FTY720 is not effective as monotherapy; it has demonstrated efficacy in clinical trials with cyclosporine and *prednisone* or in combination with the mTOR inhibitor everolimus and steroids. In Phase II trials with cyclosporine, FTY720 at daily doses of 2.5 and 5 mg showed comparable efficacy in the prevention of acute rejection in *de novo* renal transplant patients when compared to immunosuppression with cyclosporine, mycophenolate mofetil, and *prednisone*. FTY720 now is in Phase III trials.

Mechanism of Action. Unlike other immunosuppressive agents, FTY720 acts via "lymphocyte homing." It specifically and reversibly sequesters host lymphocytes into the lymph nodes and Peyer's patches, and thus away from the circulation. This protects the graft from T-cell-mediated attack. FTY720 sequesters lymphocytes but does not impair either T or B cell functions. FTY720 is phosphorylated by sphingosine kinase-2 and the FTY720-phosphate product is

a potent agonist of S1P receptors. Altered lymphocyte traffic induced by FTY720 clearly results from its effect on S1P receptors.

Toxicity. Lymphopenia, the most common side effect of FTY720, is predicted from its pharmacologic effect and is fully reversible upon drug discontinuation. Of greater concern is the negative chronotropic effect of FTY720 on the heart, which has been observed with the first dose of FTY720 in up to 30% of patients. In most patients, the heart rate returns to baseline within 48 hours after the administration of the first dose of FTY720, with the remainder returning to baseline thereafter. The negative chronotropic effect of FTY720 likely is related to the presence of S1P-R on human atrial myocytes, thus affecting S1P signaling pathways. This effect can be functionally antagonized by β_1 -receptor agonists or by the muscarinic receptor antagonist *atropine*. Importantly, cardiac rhythm was not affected in patients treated chronically with FTY720; however, the safety of the first-dose response of FTY720 on the heart rate in patients with underlying coronary artery disease remains to be determined.

Antibodies

Both polyclonal and monoclonal antibodies against lymphocyte cell-surface antigens are widely used for preven-

tion and treatment of organ transplant rejection. Polyclonal antisera are generated by repeated injections of human thymocytes (antithymocyte globulin, ATG) or lymphocytes (antilymphocyte globulin, ALG) into animals such as horses, rabbits, sheep, or goats, and then purifying the serum immunoglobulin fraction. Although highly effective immunosuppressive agents, these preparations vary in efficacy and toxicity from batch to batch. The advent of hybridoma technology to produce monoclonal antibodies was a major advance in immunology (Kohler and Milstein, 1975). It is now possible to make essentially unlimited amounts of a single antibody of a defined specificity (Figure 52–3). These monoclonal reagents have overcome the problems of variability in efficacy and toxicity seen with the polyclonal products, but they are more limited in their target specificity. The first-generation murine monoclonal antibodies have been replaced by newer chimeric or humanized monoclonal antibodies that lack antigenicity, have prolonged half-lives, and can be mutagenized to alter their affinity to Fc receptors. Thus, both polyclonal and monoclonal products have a place in immunosuppressive therapy.

Antithymocyte Globulin. Antithymocyte globulin is a purified gamma globulin from the serum of rabbits immu-

Figure 52–3. Generation of monoclonal antibodies. Mice are immunized with the selected antigen, and spleen or lymph node is harvested and B cells separated. These B cells are fused to a suitable B-cell myeloma that has been selected for its inability to grow in medium supplemented with hypoxanthine, aminopterin, and thymidine (HAT). Only myelomas that fuse with B cells can survive in HAT-supplemented medium. The hybridomas expand in culture. Those of interest based upon a specific screening technique are then selected and cloned by limiting dilution. Monoclonal antibodies can be used directly as supernatants or ascites fluid experimentally but are purified for clinical use. HPRT, hypoxanthine-guanine phosphoribosyl transferase. (From Krensky, 1999, with permission.)

nized with human thymocytes (Regan *et al.*, 1999). It is provided as a sterile, freeze-dried product for intravenous administration after reconstitution with sterile water.

Mechanism of Action. Antithymocyte globulin contains cytotoxic antibodies that bind to CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, and HLA class I and II molecules on the surface of human T lymphocytes (Bourdage and Hamlin, 1995). The antibodies deplete circulating lymphocytes by direct cytotoxicity (both complement and cell-mediated) and block lymphocyte function by binding to cell surface molecules involved in the regulation of cell function.

Therapeutic Uses. Antithymocyte globulin is used for induction immunosuppression, although the only approved indication is in the treatment of acute renal transplant rejection in combination with other immunosuppressive agents (Mariat *et al.*, 1998). Antilymphocyte-depleting agents (THYMOGLOBULIN, ATGAM, and OKT3) have been neither rigorously tested in clinical trials nor registered for use as induction immunosuppression. However, a meta-analysis (Szczzech *et al.*, 1997) showed that antilymphocyte induction improves graft survival. A course of antithymocyte-globulin treatment often is given to renal transplant patients with delayed graft function to avoid early treatment with the nephrotoxic calcineurin inhibitors and thereby aid in recovery from ischemic reperfusion injury. The recommended dose for acute rejection of renal grafts is 1.5 mg/kg per day (over 4 to 6 hours) for 7 to 14 days. Mean T-cell counts fall by day 2 of therapy. Antithymocyte globulin also is used for acute rejection of other types of organ transplants and for prophylaxis of rejection (Wall, 1999).

Toxicity. Polyclonal antibodies are xenogeneic proteins that can elicit major side effects, including fever and chills with the potential for hypotension. Premedication with corticosteroids, *acetaminophen*, and/or an antihistamine and administration of the antiserum by slow infusion (over 4 to 6 hours) into a large-diameter vessel minimize such reactions. Serum sickness and glomerulonephritis can occur; anaphylaxis is a rare event. Hematologic complications include leukopenia and thrombocytopenia. As with other immunosuppressive agents, there is an increased risk of infection and malignancy, especially when multiple immunosuppressive agents are combined. No drug interactions have been described; anti-ATG antibodies develop, although they do not limit repeated use.

Monoclonal Antibodies. Anti-CD3 Monoclonal Antibodies. Antibodies directed at the ϵ chain of CD3, a trimeric molecule adjacent to the T-cell receptor on the surface of human T lymphocytes, have been used with

considerable efficacy since the early 1980s in human transplantation. The original mouse IgG_{2a} antihuman CD3 monoclonal antibody, muromonab-CD3 (OKT3, ORTHOCLONE OKT3), still is used to reverse glucocorticoid-resistant rejection episodes (Cosimi, *et al.*, 1981).

Mechanism of Action. Muromonab-CD3 binds to the ϵ chain of CD3, a monomorphic component of the T-cell receptor complex involved in antigen recognition, cell signaling, and proliferation (Hooks *et al.*, 1991). Antibody treatment induces rapid internalization of the T-cell receptor, thereby preventing subsequent antigen recognition. Administration of the antibody is followed rapidly by depletion and extravasation of a majority of T cells from the bloodstream and peripheral lymphoid organs such as lymph nodes and spleen. This absence of detectable T cells from the usual lymphoid regions is secondary both to cell death following complement activation and activation-induced cell death and to margination of T cells onto vascular endothelial walls and redistribution of T cells to nonlymphoid organs such as the lungs. Muromonab-CD3 also reduces function of the remaining T cells, as defined by lack of IL-2 production and great reduction in the production of multiple cytokines, perhaps with the exception of IL-4 and IL-10.

Therapeutic Uses. Muromonab-CD3 is indicated for treatment of acute organ transplant rejection (Ortho Multicenter Transplant Study Group, 1985; Woodle *et al.*, 1999; Rostaing *et al.*, 1999). Muromonab-CD3 is provided as a sterile solution containing 5 mg per ampule. The recommended dose is 5 mg/day (in adults; less for children) in a single intravenous bolus (less than 1 minute) for 10 to 14 days. Antibody levels increase over the first 3 days and then plateau. Circulating T cells disappear from the blood within minutes of administration and return within approximately 1 week after termination of therapy. Repeated use of muromonab-CD3 results in the immunization of the patient against the mouse determinants of the antibody, which can neutralize and prevent its immunosuppressive efficacy (Jaffers *et al.*, 1983). Thus, repeated treatment with the muromonab-CD3 or other mouse monoclonal antibodies generally is contraindicated. The use of muromonab-CD3 for induction and rejection therapy has diminished substantially in the past 5 years because of its toxicity and the availability of antithymocyte globulin.

Toxicity. The major side effect of anti-CD3 therapy is the “cytokine release syndrome” (Wilde and Goa, 1996; Ortho Multicenter Transplant Study Group, 1985). The syndrome typically begins 30 minutes after infusion of the antibody (but can occur later) and may persist for hours. Antibody binding to the T-cell receptor complex combined with Fc receptor (FcR)-mediated crosslinking is the basis for the initial activating properties of this agent. The syndrome is associated with and attributed to increased serum levels of cytokines (including tumor necrosis factor [TNF]- α , IL-2, IL-6, and interferon- γ),

which are released by activated T cells and/or monocytes. In several studies, the production of TNF- α has been shown to be the major cause of the toxicity (Herbelin *et al.*, 1995). The symptoms usually are worst with the first dose; frequency and severity decrease with subsequent doses. Common clinical manifestations include high fever, chills/rigor, headache, tremor, nausea/vomiting, diarrhea, abdominal pain, malaise, myalgias, arthralgias, and generalized weakness. Less common complaints include skin reactions and cardiorespiratory and CNS disorders, including aseptic meningitis. Potentially fatal severe pulmonary edema, acute respiratory distress syndrome, cardiovascular collapse, cardiac arrest, and arrhythmias have been described.

Administration of glucocorticoids before the injection of muromonab-CD3 prevents the release of cytokines and reduces first-dose reactions considerably and is now a standard procedure. Volume status of patients also must be monitored carefully before therapy; steroids and other premedications should be given, and a fully competent resuscitation facility must be immediately available for patients receiving their first several doses of this therapy.

Other toxicities associated with anti-CD3 therapy include anaphylaxis and the usual infections and neoplasms associated with immunosuppressive therapy. "Rebound" rejection has been observed when muromonab-CD3 treatment is stopped (Wilde and Goa, 1996). Anti-CD3 therapies may be limited by anti-idiotypic or anti-murine antibodies in the recipient.

New-Generation Anti-CD3 Antibodies. Recently, genetically altered anti-CD3 monoclonal antibodies have been developed that are "humanized" to minimize the occurrence of anti-antibody responses and mutated to prevent binding to FcRs (Friend *et al.*, 1999). The rationale for developing this new generation of anti-CD3 monoclonal antibodies is that they could induce selective immunomodulation in the absence of toxicity associated with conventional anti-CD3 monoclonal antibody therapy. In initial clinical trials, a humanized anti-CD3 monoclonal antibody that does not bind to FcRs reversed acute renal allograft rejection without causing the first-dose cytokine-release syndrome (Woodle *et al.*, 1999). Clinical efficacy of these agents in autoimmune diseases is being evaluated (Herold *et al.*, 2002).

Anti-IL-2 Receptor (Anti-CD25) Antibodies. Daclizumab (ZENAPAX), a humanized murine complementarity-determining region (CDR)/human IgG₁ chimeric monoclonal antibody, and basiliximab (SIMULECT), a murine-human chimeric monoclonal antibody, have been produced by recombinant DNA technology (Wiseman and Faulds, 1999). The composite daclizumab antibody consists of human (90%) constant domains of IgG₁ and variable

framework regions of the Eu myeloma antibody and murine (10%) CDR of the anti-Tac antibody.

Mechanism of Action. Daclizumab has a somewhat lower affinity than does basiliximab, but a longer half-life (20 days). The exact mechanism of action of the anti-CD25 mAbs is not completely understood, but likely results from the binding of the anti-CD25 mAbs to the IL-2 receptor on the surface of activated, but not resting, T cells (Vincenti *et al.*, 1998; Amlot *et al.*, 1995). Significant depletion of T cells does not appear to play a major role in the mechanism of action of these mAbs. However, other mechanisms of action may mediate the effect of these antibodies. In a study of daclizumab-treated patients, there was a moderate decrease in circulating lymphocytes staining with 7G7, a fluorescein-conjugated antibody that binds a different α -chain epitope than that recognized and bound by daclizumab (Vincenti *et al.*, 1998). Similar results were obtained in studies with basiliximab (Amlot *et al.*, 1995). These findings indicate that therapy with the anti IL-2R mAbs results in a relative decrease of the expression of the α chain, either from depletion of coated lymphocytes or modulation of the α chain secondary to decreased expression or increased shedding. There is also recent evidence that the β chain may be down-regulated by the anti-CD25 antibody.

Therapeutic Uses. Anti-IL-2-receptor monoclonal antibodies are used for prophylaxis of acute organ rejection in adult patients. There are two anti-IL-2R preparations for use in clinical transplantation: daclizumab and basiliximab (Vincenti *et al.*, 1998; Nashan *et al.*, 1999). In Phase III trials, daclizumab was administered in five doses (1 mg/kg given intravenously over 15 minutes in 50 ml to 100 ml of normal saline) starting immediately preoperatively, and subsequently at biweekly intervals. The half-life of daclizumab was 20 days, resulting in saturation of the IL-2R α on circulating lymphocytes for up to 120 days after transplantation. In these trials, daclizumab was used with maintenance immunosuppression regimens (cyclosporine, azathioprine, and steroids; cyclosporine and steroids). Subsequently, daclizumab was successfully used with a maintenance triple-therapy regimen—either with cyclosporine or tacrolimus, steroids, and mycophenolate mofetil (MMF) substituting for azathioprine (Ciancio *et al.*, 2003; Pescovitz *et al.*, 2003). In Phase III trials, basiliximab was administered in a fixed dose of 20 mg preoperatively and on days 0 and 4 after transplantation (Nashan *et al.*, 1997; Kahan *et al.*, 1999a). This regimen of basiliximab resulted in a concentration of ≥ 0.2 $\mu\text{g/mL}$, sufficient to saturate IL-2R on circulating lymphocytes for 25 to 35 days after transplantation. The half-life of basiliximab was 7 days. In the Phase III trials, basiliximab was used with a maintenance regimen consisting of cyclosporine and prednisone. In one randomized trial, basiliximab was safe and effective when used in a maintenance regimen consisting of cyclosporine, MMF, and prednisone (Lawen *et al.*, 2000).

There presently is no marker or test to monitor the effectiveness of anti-IL-2R therapy. Saturation of α chain on circulating lymphocytes during anti-IL-2R mAb therapy does not predict rejection. The duration of IL-2R blockade by basiliximab was similar in patients with or without acute rejection episodes (34 ± 14 days vs. 37 ± 14 days, mean + SD) (Kovarik *et al.*, 1999). In another daclizumab trial, patients with acute rejection were found to have circulating and intragraft lymphocytes with saturated IL-2R (Vincenti *et al.*, 2001). A possible explanation is that those patients who reject despite anti-IL-2R blockade do so through a mechanism that bypasses the IL-2 pathway due to cytokine-cytokine receptor redundancy (*i.e.*, IL-7, IL-15).

Toxicity. No cytokine-release syndrome has been observed with these antibodies, but anaphylactic reactions can occur. Although lymphoproliferative disorders and opportunistic infections may occur, as with the depleting antilymphocyte agents, the incidence ascribed to anti-CD25 treatment appears remarkably low. No significant drug interactions with anti-IL-2-receptor antibodies have been described (Hong and Kahan, 1999).

Campath-1H. *Campath-1H* (ALEMTUZUMAB) is a humanized mAb that has been approved for use in chronic lymphocytic leukemia. The antibody targets CD52, a glycoprotein expressed on lymphocytes, monocytes, macrophages, and natural killer cells; thus, the drug causes extensive lympholysis by inducing apoptosis of targeted cells. It has achieved some use in renal transplantation because it produces prolonged T- and B-cell depletion and allows drug minimization. Large controlled studies of efficacy or safety are not available. Although short-term results are promising, further clinical experience is needed before Campath-1H is accepted into the clinical armamentarium for transplantation.

Anti-TNF Reagents. **Infliximab.** *Infliximab* (REMICADE) is a chimeric anti-TNF- α monoclonal antibody containing a human constant region and a murine variable region. It binds with high affinity to TNF- α and prevents the cytokine from binding to its receptors.

Patients with rheumatoid arthritis have elevated levels of TNF- α in their joints, while patients with Crohn's disease have elevated levels of TNF- α in their stools. In one trial, infliximab plus methotrexate improved the signs and symptoms of rheumatoid arthritis more than methotrexate alone. Patients with active Crohn's disease who had not responded to other immunosuppressive therapies also improved when treated with infliximab, including those with Crohn's-related fistulae. Infliximab is approved in the United States for treating the symptoms of rheumatoid arthritis, and is used in combination with methotrexate in patients

who do not respond to methotrexate alone. Infliximab also is approved for treatment of symptoms of moderate to severe Crohn's disease in patients who have failed to respond to conventional therapy, and in treatment to reduce the number of draining fistulae in Crohn's disease patients (*see* Chapter 38). About 1 of 6 patients receiving infliximab experiences an infusion reaction characterized by fever, urticaria, hypotension, and dyspnea within 1 to 2 hours after antibody administration. Serious infections also have occurred in infliximab-treated patients, most frequently in the upper respiratory and urinary tracts. The development of antinuclear antibodies, and rarely a lupuslike syndrome, have been reported after treatment with infliximab.

Although not a monoclonal antibody, *etanercept* (ENBREL) is mechanistically related to infliximab because it also targets TNF- α . Etanercept contains the ligand-binding portion of a human TNF- α receptor fused to the Fc portion of human IgG₁, and binds to TNF- α and prevents it from interacting with its receptors. It is approved in the United States for treatment of the symptoms of rheumatoid arthritis in patients who have not responded to other treatments. Etanercept can be used in combination with methotrexate in patients who have not responded adequately to methotrexate alone. As with infliximab, serious infections have occurred after treatment with etanercept. Injection-site reactions (erythema, itching, pain, or swelling) have occurred in more than one-third of etanercept-treated patients.

Adalimumab (HUMIRA) is another anti-TNF product for intravenous use. This recombinant human IgG₁ monoclonal antibody was created by phage display technology and is approved for use in rheumatoid arthritis.

LFA-1 Inhibition. *Efalizumab* is a humanized IgG₁ mAb targeting the CD11a chain of LFA-1 (lymphocyte function associated antigen). Efalizumab binds to LFA-1 and prevents the LFA-1-ICAM (intercellular adhesion molecule) interaction to block T-cell adhesion, trafficking, and activation (Arnaout, 1990). Pretransplant therapy with anti-CD11a prolonged survival of murine skin and heart allografts and monkey heart allografts (Nakakura *et al.*, 1996). In a randomized, multicenter trial, a murine anti-ICAM-1 mAb (ENLIMOMAB) failed to reduce the rate of acute rejection or to improve delayed graft function of cadaveric renal transplants (Salmela *et al.*, 1999). This may have been due to either the murine nature of the mAb or the redundancy of the ICAMs. Efalizumab also is approved for use in patients with psoriasis. In a Phase I/II open-label, dose-ranging, multidose, multicenter trial, efalizumab (dose 0.5 mg/kg or 2 mg/kg) was administered subcutaneously for 12 weeks after renal transplantation (Vincenti *et al.*, 2001). Both doses of efalizumab decreased the incidence of

acute rejection. Pharmacokinetic and pharmacodynamic studies showed that efalizumab produced saturation and 80% modulation of CD11a within 24 hours of therapy. In a subset of 10 patients who received the higher dose efalizumab (2 mg/kg) with full-dose cyclosporine, MMF, and steroids, 3 patients developed posttransplant lymphoproliferative diseases. While efalizumab appears to be an effective immunosuppressive agent, it may be best used in a lower dose and with an immunosuppressive regimen that spares calcineurin inhibitors.

TOLERANCE

Immunosuppression has concomitant risks of opportunistic infections and secondary tumors. Therefore, the ultimate goal of research on organ transplantation and autoimmune diseases is to induce and maintain immunologic tolerance, the active state of antigen-specific nonresponsiveness (Krensky and Clayberger, 1994; Hackett and Dickler, 1999). Tolerance, if attainable, would represent a true cure for conditions discussed above without the side effects of the various immunosuppressive therapies. The calcineurin inhibitors prevent tolerance induction in some, but not all, preclinical models (Wood, 1991; Van Parijs and Abbas, 1998). In these same model systems, sirolimus does not prevent tolerance and may even promote tolerance induction (Li *et al.*, 1998). Several other promising approaches are being evaluated in clinical trials. Because they remain experimental, they are discussed only briefly here.

Costimulatory Blockade

Induction of specific immune responses by T lymphocytes requires two signals: an antigen-specific signal *via* the T-cell receptor and a costimulatory signal provided by the interaction of molecules such as CD28 on the T lymphocyte and CD80 and CD86 on the antigen-presenting cell (Figure 52-4; Khoury *et al.*, 1999). In preclinical studies, inhibition of the costimulatory signal can induce tolerance (Larsen *et al.*, 1996; Kirk *et al.*, 1997). Experimental approaches to inhibit costimulation include a recombinant fusion protein molecule, CTLA4Ig, and anti-CD80 and/or anti-CD86 mAbs. The antibodies h1F1 and h3D1 are humanized anti-CD80 and anti-CD-86 mAbs, respectively. *In vitro*, h1F1 and h3D1 were shown to block CD28-dependent T-cell proliferation and decrease mixed lymphocyte reactions. These mAbs must be used in tandem since either CD80 or CD86 is sufficient to stimulate T cells *via* CD28. In nonhuman primates, anti CD80 and CD86 mAbs were proven effective in renal transplantation, either as monotherapy or in combination with steroids or cyclosporine (Kirk *et al.*, 2001; Ossevoort *et al.*, 1999), but did not induce durable tolerance. A Phase I study of h1F1 and h3D1 in renal transplant recipients was performed in patients receiving maintenance therapy consisting of cyclosporine, mycophenolate

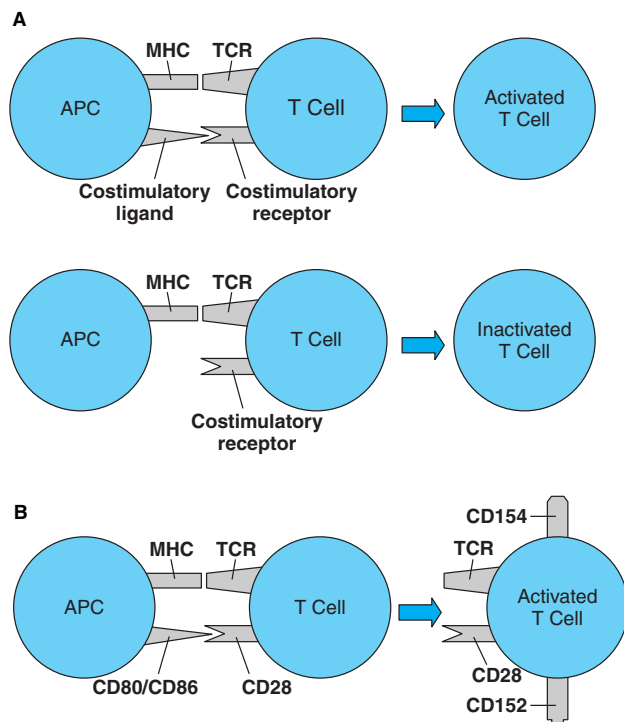

Figure 52-4. Costimulation. **A.** Two signals are required for T-cell activation. Signal 1 is *via* the T-cell receptor (TCR) and signal 2 is *via* a costimulatory receptor-ligand pair. Both signals are required for T-cell activation. Signal 1 in the absence of signal 2 results in an inactivated T cell. **B.** One important costimulatory pathway involves CD28 on the T cell and B7-1 (CD80) and B7-2 (CD86) on the antigen-presenting cell (APC). After a T cell is activated, it expresses additional costimulatory molecules. CD152 is CD40 ligand, which interacts with CD40 as a costimulatory pair. CD154 (CTLA4) interacts with CD80 and CD86 to dampen or down-regulate an immune response. Antibodies against CD80, CD86, and CD152 are being evaluated as potential therapeutic agents. CTLA4-Ig, a chimeric protein consisting of part of an immunoglobulin molecule and part of CD154, also has been tested as a therapeutic agent. (From Clayberger and Krensky, 2001, with permission.)

mofetil, and steroids (Vincenti, 2002). While the results of this study are as yet unpublished, the preliminary results appear to show that these mAbs are safe and possibly effective.

CTLA4Ig contains the binding region of CTLA4, which is a CD28 homolog, and the constant region of the human IgG₁. CTLA4Ig competitively inhibits CD28. Numerous animal studies have confirmed the efficacy of CTLA4Ig in inhibiting alloimmune responses, resulting in successful organ transplantation. More recently, CTLA4Ig was shown to be effective in the treatment of rheumatoid arthritis. However, CTLA4Ig was less effective when utilized in nonhuman primate models of renal transplantation. LEA29Y (*see* Figure 52-5) is a second-generation CTLA4Ig with two amino acid substitutions. LEA29Y has higher affinity for CD80 (twofold) and CD86 (fourfold), yielding a tenfold increase in potency *in vitro* as compared to CTLA4Ig. Preclinical

Figure 52–5. Structure of LEA29Y, a CTLA4Ig congener. For details, see text and Figure 52–4.

renal transplant studies in nonhuman primates showed that LEA29Y did not induce tolerance but did prolong graft survival. LEA29Y (administered intravenously every 4 or 8 weeks) is undergoing clinical trials in calcineurin inhibitor–free immunosuppression regimens.

A second costimulatory pathway involves the interaction of CD40 on activated T cells with CD40 ligand (CD154) on B cells, endothelium, and/or antigen-presenting cells (Figure 52–4). Among the purported activities of anti-CD154 antibody treatment is its blockade of B7 expression induced by immune activation. Two humanized anti-CD154 monoclonal antibodies have been used in clinical trials in renal transplantation and autoimmune diseases. The development of these antibodies, however, is on hold because of associated thromboembolic events. An alternative approach to block the CD154-CD40 pathway is to target CD40 with monoclonal antibodies.

Donor Cell Chimerism

Another promising approach is induction of chimerism (coexistence of cells from two genetic lineages in a single individual) by any of a variety of protocols that first dampen or eliminate immune function in the recipient with ionizing radiation, drugs such as cyclophosphamide, and/or antibody treatment, and then provide a new source of immune function by adoptive transfer (transfusion) of bone marrow or hematopoietic stem cells (Starzl *et al.*, 1997; Fuchimoto *et al.*, 1999; Spitzer *et al.*, 1999; Hale *et al.*, 2000). Upon reconstitution of immune function, the recipient no longer recognizes new antigens provided during a critical period as “nonself.” Such tolerance is long-lived and is less likely to be complicated by the use of calcineurin inhibitors. Although the most promising approaches in this arena have

been therapies that promote the development of mixed or macrochimerism, in which substantial numbers of donor cells are present in the circulation, some microchimerization approaches also have shown promise in the development of long-term unresponsiveness.

Soluble HLA

In the precyclosporine era, blood transfusions were shown to be associated with improved outcomes in renal transplant patients (Opelz and Terasaki, 1978). These findings gave rise to donor-specific transfusion protocols that improved outcomes (Opelz *et al.*, 1997). After the introduction of cyclosporine, however, these effects of blood transfusions disappeared, presumably due to the efficacy of this drug in blocking T-cell activation. Nevertheless, the existence of tolerance-promoting effects of transfusions is irrefutable. It is possible that this effect is due to HLA molecules on the surface of cells or in soluble forms. Recently, soluble HLA and peptides corresponding to linear sequences of HLA molecules have been shown to induce immunologic tolerance in animal models *via* a variety of mechanisms (Murphy and Krensky, 1999).

Antigens

Specific antigens provided in a variety of forms (generally as peptides) induce immunologic tolerance in preclinical models of diabetes mellitus, arthritis, and multiple sclerosis. Clinical trials of such approaches are under way. The past decade has witnessed a revolution in our understanding of the basis for immune tolerance. It is now well established that antigen/MHC complex binding to the T-cell-receptor/CD3 complex coupled with soluble and membrane-bound costimulatory signals initiates a cascade of signaling events that lead to productive immunity. In addition, the immune response is regulated by a number of negative signaling events that control cell survival and expansion. For the first time, *in vitro* and preclinical *in vivo* studies have demonstrated that one can selectively inhibit immune responses to specific antigens without the associated toxicity of established immunosuppressive therapies (Van Parijs and Abbas, 1998). With these new insights comes the enormous promise of specific immune therapies to treat the vast array of immune disorders from autoimmunity to transplant rejection. These new therapies will take advantage of a combination of drugs that target the primary T-cell receptor–mediated signal, either by blocking cell-surface receptor interactions or inhibiting early signal transduction events. The drugs will be combined with therapies that effectively block costimulation to prevent cell expansion and differentiation of those cells that have engaged antigen while maintaining a noninflammatory milieu.

IMMUNOSTIMULATION

General Principles

In contrast to immunosuppressive agents that inhibit the immune response in transplant rejection and autoimmunity, a few immunostimulatory drugs have been developed with applicability to infection, immunodeficiency, and cancer. Problems with such drugs include systemic (generalized) effects at one extreme or limited efficacy at the other.

Immunostimulants

Levamisole. *Levamisole* (ERGAMISOL) was synthesized originally as an anthelmintic but appears to “restore” depressed immune function of B lymphocytes, T lymphocytes, monocytes, and macrophages. Its only clinical indication is as adjuvant therapy with 5-fluorouracil after surgical resection in patients with Dukes’ stage C colon cancer (Moertel *et al.*, 1990; Figueredo *et al.*, 1997), where it occasionally has been associated with fatal agranulocytosis.

Thalidomide. Thalidomide (THALOMID) is best known for the severe, life-threatening birth defects it caused when administered to pregnant women (Smithells and Newman, 1992; Lary *et al.*, 1999). For this reason, it is available only under a restricted distribution program and can be prescribed only by specially licensed physicians who understand the risk of teratogenicity if thalidomide is used during pregnancy. *Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug.* Nevertheless, it is indicated for the treatment of patients with erythema nodosum leprosum (Sampaio *et al.*, 1993; see Chapter 47) and also is used in conditions such as multiple myeloma. Its mechanism of action is unclear (Tseng *et al.*, 1996). Reported immunologic effects vary substantially under different conditions. For example, thalidomide has been reported to decrease circulating TNF- α in patients with erythema nodosum leprosum, but to increase it in patients who are HIV-seropositive (Jacobson *et al.*, 1997). Alternatively, it has been suggested that the drug affects angiogenesis (Miller and Stromland, 1999). The anti-TNF- α effect has led to its evaluation as a treatment for severe, refractory rheumatoid arthritis (Keesal *et al.*, 1999).

Bacillus Calmette-Guérin (BCG). Live *bacillus Calmette-Guérin* (BCG; TICE BCG, THERACYS) is an attenuated, live culture of the bacillus of Calmette and Guérin strain of *Mycobacterium bovis*, that induces a granulomatous reaction at the site of administration. By unclear mechanisms, this preparation is active against tumors and is indicated for treatment and prophylaxis of carcinoma *in situ* of the urinary bladder and for prophylaxis of primary and recurrent stage Ta and/or T1 papillary tumors after transurethral resection (Morales *et al.*, 1981; Paterson and Patel, 1998; Patard *et al.*, 1998). Adverse effects include hypersensitivity, shock, chills, fever, malaise, and immune complex disease.

Recombinant Cytokines. Interferons. Although interferons (alpha, beta, and gamma) initially were identified by their antiviral activity, these agents also have important immunomodulatory activities (Johnson *et al.*, 1994; Tilg and Kaser, 1999; Ransohoff, 1998). The interferons bind to specific cell-surface receptors that initiate a series of intracellular events: induction of certain enzymes, inhibition of cell proliferation, and enhancement of immune activities, including increased phagocytosis by macrophages and augmentation of specific cytotoxicity by T lymphocytes (Tompkins, 1999). Recombinant *interferon alfa-2b* (IFN-alpha 2, INTRON A) is obtained from *Escherichia coli* by recombinant expression. It is a member of a family of naturally occurring small proteins with molecular weights of 15,000 to 27,600 daltons, produced and secreted by cells in response to viral infections and other

inducers. Interferon alfa-2b is indicated in the treatment of a variety of tumors, including hairy cell leukemia, malignant melanoma, follicular lymphoma, and AIDS-related Kaposi’s sarcoma (Punt, 1998; Bukowski, 1999; Sinkovics and Horvath, 2000). It also is indicated for infectious diseases, chronic hepatitis B, and condylomata acuminata. In addition, it is supplied in combination with *ribavirin* (REBETRON) for treatment of chronic hepatitis C in patients with compensated liver function not treated previously with interferon alfa-2b or who have relapsed after interferon alfa-2b therapy (Lo Iacono *et al.*, 2000). Flu-like symptoms, including fever, chills, and headache, are the most common adverse effects after interferon alfa-2b administration. Adverse experiences involving the cardiovascular system (hypotension, arrhythmias, and rarely cardiomyopathy and myocardial infarction) and CNS (depression, confusion) are less-frequent side effects.

Interferon gamma-1b (ACTIMMUNE) is a recombinant polypeptide that activates phagocytes and induces their generation of oxygen metabolites that are toxic to a number of microorganisms. It is indicated to reduce the frequency and severity of serious infections associated with chronic granulomatous disease. Adverse reactions include fever, headache, rash, fatigue, GI distress, anorexia, weight loss, myalgia, and depression.

Interferon beta-1a (AVONEX, REBIF), a 166–amino acid recombinant glycoprotein, and *interferon beta-1b* (BETASERON), a 165–amino acid recombinant protein, have antiviral and immunomodulatory properties. They are FDA approved for the treatment of relapsing and relapsing-remitting multiple sclerosis to reduce the frequency of clinical exacerbations (see below). The mechanism of their action in multiple sclerosis is unclear. Flu-like symptoms (fever, chills, myalgia) and injection-site reactions have been common adverse effects.

Further discussion of the use of these and other interferons in the treatment of viral diseases can be found in Chapter 49.

Interleukin-2. Human recombinant interleukin-2 (*aldesleukin*, PROLEUKIN; des-alanyl-1, serine-125 human IL-2) is produced by recombinant DNA technology in *E. coli* (Taniguchi and Minami, 1993). This recombinant form differs from native IL-2 in that it is not glycosylated, has no amino terminal alanine, and has a serine substituted for the cysteine at amino acid 125 (Doyle *et al.*, 1985). The potency of the preparation is represented in International Units in a lymphocyte proliferation assay such that 1.1 mg of recombinant IL-2 protein equals 18 million International Units. Aldesleukin has the following *in vitro* biologic activities of native IL-2: enhancement of lymphocyte proliferation and growth of IL-2–dependent cell lines; enhancement

of lymphocyte-mediated cytotoxicity and killer cell activity; and induction of interferon- γ activity (Winkelhake *et al.*, 1990; Whittington and Faulds, 1993). *In vivo* administration of aldesleukin in animals produces multiple immunologic effects in a dose-dependent manner. Cellular immunity is profoundly activated with lymphocytosis, eosinophilia, thrombocytopenia, and release of multiple cytokines (*e.g.*, TNF, IL-1, interferon- γ). Aldesleukin is indicated for the treatment of adults with metastatic renal cell carcinoma and melanoma. Administration of aldesleukin has been associated with serious cardiovascular toxicity resulting from capillary leak syndrome, which involves loss of vascular tone and leak of plasma proteins and fluid into the extravascular space. Hypotension, reduced organ perfusion, and death may occur. An increased risk of disseminated infection due to impaired neutrophil function also has been associated with aldesleukin treatment.

Immunization

Immunization may be active or passive. Active immunization involves stimulation with an antigen to develop immunologic defenses against a future exposure. Passive immunization involves administration of preformed antibodies to an individual who is already exposed or is about to be exposed to an antigen.

Vaccines. Active immunization, vaccination, involves administration of an antigen as a whole, killed organism, attenuated (live) organism, or a specific protein or peptide constituent of an organism. Booster doses often are required, especially when killed (inactivated) organisms are used as the immunogen. In the United States, vaccination has sharply curtailed or practically eliminated a variety of major infections, including diphtheria, measles, mumps, pertussis, rubella, tetanus, *Haemophilus influenzae* type b, and pneumococcus (Dorner and Barrett, 1999; The National Vaccine Advisory Committee, 1999).

Although most vaccines have targeted infectious diseases, a new generation of vaccines may provide complete or limited protection from specific cancers or autoimmune diseases (Lee *et al.*, 1998; Del Vecchio and Parmiani, 1999; Simone *et al.*, 1999). Because T cells optimally are activated by peptides and costimulatory ligands that both are present on antigen-presenting cells (APCs), one approach for vaccination has consisted of immunizing patients with APCs expressing a tumor antigen. The first generation of anticancer vaccines used whole cancer cells or tumor-cell lysates as a source of antigen in combination with various adjuvants, relying on host APCs to process and present tumor-specific antigens (Sinkovics and Horvath, 2000).

These anticancer vaccines resulted in occasional clinical responses and are being tested in prospective clinical trials. Second generation anticancer vaccines utilized specific APCs incubated *ex vivo* with antigen or transduced to express antigen and subsequently reinfused into patients. In laboratory animals, immunization with dendritic cells previously pulsed with MHC class I-restricted peptides derived from tumor-specific antigens led to pronounced antitumor cytotoxic T-lymphocyte responses and protective tumor immunity (Tarte and Klein, 1999). Finally, multiple studies have demonstrated the efficacy of DNA vaccines in small- and large-animal models of infectious diseases and cancer (Lewis and Babiuk, 1999; Liljeqvist and Stahl, 1999). The advantage of DNA vaccination over peptide immunization is that it permits generation of entire proteins, enabling determinant selection to occur in the host without having to restrict immunization to patients bearing specific HLA alleles. However, a safety concern about this technique is the potential for integration of the plasmid DNA into the host genome, possibly disrupting important genes and thereby leading to phenotypic mutations or carcinogenicity. A final approach to generate or enhance immune responses against specific antigens consists of infecting cells with recombinant viruses that encode the protein antigen of interest. Different types of viral vectors that can infect mammalian cells, such as vaccinia, avipox, lentivirus, adenovirus or adenovirus-associated virus, have been used.

Immune Globulin. Passive immunization is indicated when an individual is deficient in antibodies because of a congenital or acquired immunodeficiency, when an individual with a high degree of risk is exposed to an agent and there is inadequate time for active immunization (*e.g.*, measles, rabies, hepatitis B), or when a disease is already present but can be ameliorated by passive antibodies (*e.g.*, botulism, diphtheria, tetanus). Passive immunization may be provided by several different products (Table 52-2). Nonspecific immunoglobulins or highly specific immunoglobulins may be provided based upon the indication. The protection provided usually lasts from 1 to 3 months. Immune globulin is derived from pooled plasma of adults by an alcohol-fractionation procedure. It contains largely IgG (95%) and is indicated for antibody-deficiency disorders, exposure to infections such as hepatitis A and measles, and specific immunologic diseases such as immune thrombocytopenic purpura and Guillain-Barré syndrome (Ballow, 1997; Jordan *et al.*, 1998a; Jordan *et al.*, 1998b). In contrast, specific immune globulins ("hyperimmune") differ from other immune globulin preparations in that donors are selected for high titers of the desired antibodies. Specific immune globulin preparations are available

Table 52–2**Selected Immune Globulin Preparations**

Immune globulin intravenous	BAYGAM
	GAMMAGARD S/D
	GAMMAR-P.I.V

	RHOGAM
	others
Tetanus immune globulin	BAYTET
	HYPERTET

for hepatitis B, rabies, tetanus, varicella-zoster, cytomegalovirus, and respiratory syncytial virus. Rho(D) immune globulin is a specific hyperimmune globulin for prophylaxis against hemolytic disease of the newborn due to Rh incompatibility between mother and fetus. All such plasma-derived products carry the theoretical risk of transmission of infectious disease.

Rho(D) Immune Globulin. The commercial forms of Rho(D) immune globulin (Table 52–2) consist of IgG containing a high titer of antibodies against the Rh(D) antigen on the surface of red blood cells. All donors are carefully screened to reduce the risk of transmitting infectious diseases. Fractionation of the plasma is performed by precipitation with cold alcohol followed by passage through a viral clearance system (Bowman, 1998; Contreras, 1998; Lee, 1998).

Mechanism of Action. Rho(D) immune globulin binds Rho antigens, thereby preventing sensitization (Peterec, 1995). Rh-negative women may be sensitized to the “foreign” Rh antigen on red blood cells *via* the fetus at the time of birth, miscarriage, ectopic pregnancy, or any transplacental hemorrhage. If the women go on to have a primary immune response, they will make antibodies to Rh antigen that can cross the placenta and damage subsequent fetuses by lysing

red blood cells. This syndrome, called hemolytic disease of the newborn, is life-threatening. The form due to Rh incompatibility is largely preventable by Rho(D) immune globulin.

Therapeutic Use. Rho(D) immune globulin is indicated whenever fetal red blood cells are known or suspected to have entered the circulation of an Rh-negative mother unless the fetus is known also to be Rh-negative. The drug is given intramuscularly. The half-life of circulating immunoglobulin is approximately 21 to 29 days.

Toxicity. Injection site discomfort and low-grade fever have been reported. Systemic reactions are extremely rare, but myalgia, lethargy, and anaphylactic shock have been reported. As with all plasma-derived products, there is a theoretical risk of transmission of infectious diseases.

Intravenous Immunoglobulin (IVIG). In recent years, indications for the use of intravenous immunoglobulin (IVIG) have expanded beyond replacement therapy for agammaglobulinemia and other immunodeficiencies to include a variety of bacterial and viral infections, and an array of autoimmune and inflammatory diseases as diverse as thrombocytopenic purpura, Kawasaki’s disease, and autoimmune skin, neuromuscular, and neurologic diseases (Dalakas, 2004). Although the mechanism of action of IVIG in immune modulation remains largely unknown, proposed mechanisms include modulation of expression and function of Fc receptors on leukocytes and endothelial cells, interference with complement activation and cytokine production, provision of anti-idiotypic antibodies (Jerne network theory), and effects on the activation and effector function of T and B lymphocytes (Larroche *et al.*, 2002; Rutter and Luger, 2002). Although IVIG is effective in many autoimmune diseases, its spectrum of efficacy and appropriate dosing (especially duration of therapy) are unknown. Additional controlled studies of IVIG are needed to identify proper dosing, cost-benefit, and quality-of-life parameters.

A CASE STUDY: IMMUNOTHERAPY FOR MULTIPLE SCLEROSIS

Clinical Features and Pathology. Multiple sclerosis (MS) is a demyelinating inflammatory disease of the CNS white matter that displays a triad of pathogenic symptoms: mononuclear cell infiltration, demyelination, and scarring (gliosis). The peripheral nervous system is uninvolved. The disease, which may be episodic or progressive, occurs in early to middle adulthood with prevalence increasing from late adolescence to 35 years and then declining. MS is roughly twice as common in females as in males and occurs mainly

in higher latitudes of the temperate climates. Epidemiologic studies suggest a role for environmental factors in the pathogenesis of MS; despite many suggestions, associations with infectious agents have proven inconclusive, even though several viruses can cause similar demyelinating diseases in laboratory animals and humans. A stronger linkage is the genetic one: people of Northern European origin have a higher susceptibility to MS, and studies in twins and siblings suggest a genetic component of susceptibility to MS. The genetic linkage in the pathogenesis of MS is complex. Several studies indicate that one determinant of MS may be the class II (or HLA-DR) domain of the major histocompatibility complex (MHC) on chromosome 6 that encodes the histocompatibility antigens. Other loci under study include polymorphisms for GSH transferase and CD45. There is also substantial evidence of an autoimmune component to MS: in MS patients, there are activated T cells that are reactive to different myelin antigens including myelin basic protein (MBP); in addition, there is evidence for the presence of autoantibodies to myelin oligodendrocyte glycoprotein (MOG) and to MBP that can be eluted from the CNS plaque tissue, though it appears unlikely that high-affinity autoantibodies are present in the circulation. These antibodies may act with pathogenic T cells to produce some of the cellular pathology of MS. The neurophysiological result is altered conduction (both positive and negative) in myelinated fibers within the CNS (cerebral white matter, brain stem, cerebellar tracts, optic nerves, spinal cord); some alterations appear to result from exposure of voltage-dependent K⁺ channels that are normally covered by myelin.

Attacks are classified by type and severity and likely correspond to specific degrees of CNS damage and pathologic processes. Thus, physicians refer to acute MS (an acute attack), relapsing-remitting MS (the form in 85% of younger patients), secondary progressive MS (progressive neurologic deterioration following a long period of relapsing-remitting disease), and primary progressive MS (about 15% of patients, wherein deterioration with relatively little inflammation is apparent at onset). Keegan and Noseworthy (2002) have recently reviewed current concepts of the etiology, natural history, and current therapy of MS.

Pharmacotherapy for MS. Specific therapies are aimed at resolving acute attacks, reducing recurrences and exacerbations, and slowing the progression of disability (Table 52–3). Nonspecific therapies focus on maintaining function and quality of life. For acute attacks, pulse glucocorticoids are often employed (typically, 1 g/day of methylprednisolone administered intravenously for 3 to 5 days). There is no evidence that tapered doses of oral prednisone are useful or even desirable.

For relapsing-remitting attacks, immunomodulatory therapies are approved: beta-1 interferons (interferon beta-1a, interferon beta-1b, and *glatiramer acetate* [COPAXONE]). The interferons suppress the proliferation of T lymphocytes, inhibit their movement into the CNS from the periphery, and shift the cytokine profile from pro- to anti-inflammatory types.

Random polymers that contain amino acids commonly used as MHC anchors and T-cell receptor contact residues have been proposed as possible “universal APLs (altered peptide ligands).” Glatiramer acetate (GA) is a random sequence polypeptide consisting of four amino acids (alanine [A], lysine [K], glutamate [E], and tyrosine [Y]) at a molar ratio of A:K:E:Y of 4.5:3.6:1.5:1) with an average length of 40 to 100 amino acids. Directly labeled GA binds efficiently to different murine H2 I-A molecules, as well as to their human counterparts, the MHC class II DR molecules, but does not bind MHC class II DQ or MHC class I molecules *in vitro*. In Phase III clinical trials, GA, administered subcutaneously to patients with relapsing-remitting MS, decreased the rate of exacerbations by about 30% (Steinman, 2004; Hafler, 2004). *In vivo* administration of GA induces highly cross-reactive CD4⁺ T cells that are immune-deviated to secrete Th2 cytokines and prevents the appearance of new lesions detectable by MRI. This represents one of the first successful uses of an agent that ameliorates autoimmune disease by altering signals through the T-cell receptor complex (Steinman, 2004; Hafler, 2004).

For relapsing-remitting attacks and for secondary progressive MS, the alkylating agent cyclophosphamide (reviewed in Weiner, 2004) and the anthracenedione-derivative *mitoxantrone* (NOVATRONE) are currently used in patients refractory to other immunomodulators. These agents, used primarily for cancer chemotherapy, have significant toxicities (*see* Chapter 51 for structures and pharmacology). While cyclophosphamide in patients with MS may not be limited by an accumulated dose exposure, mitoxantrone can be tolerated only up to an accumulated dose of 100 to 140 mg/m² (Crossley, 1984). The utility of interferon therapy in patients with secondary progressive MS is unclear. In primary progressive MS, with no discrete attacks and less observed inflammation, suppression of inflammation seems to be less helpful. A minority of patients at this stage will respond to high doses of glucocorticoids. Table 52–3 summarizes current immunomodulatory therapies for MS.

Each of the agents mentioned above has side effects and contraindications that may be limiting: infections (for glucocorticoids); hypersensitivity and pregnancy (for immunomodulators); and prior anthracycline/anthracenedione use, mediastinal irradiation, or cardiac disease (mitoxantrone). With all of these agents, it is clear that the

Table 52–3
Pharmacotherapy of Multiple Sclerosis

THERAPEUTIC AGENT	BRAND NAME (DOSE, regimen)	INDICATIONS	RESULTS	MECHANISM OF ACTION
IFN β -1a	AVONEX (30 μ g, IM, weekly) REBIFF (22 or 44 μ g, SC, 3 times weekly)	Treatment of RRMS	Reduction of relapses by one-third Reduction of new MRI T2 lesions and the volume of enlarging T2 lesions Reduction in the number and volume of Gd-enhancing lesions Slowing of brain atrophy	Acts on blood–brain barrier by interfering with T-cell adhesion to the endothelium by binding VLA-4 on T cells or by inhibiting the T cell expression of MMP Reduction in T cell activation by interfering with HLA class II and costimulatory molecules B7/CD28 and CD40:CD40L Immune deviation of Th2 over Th1 cytokine profile Same as IFN β -1a, above
IFN β -1b	BETASERON (0.3 mg, SC, every other day)	Treatment of RRMS	Same as IFN β -1a, above	Same as IFN β -1a, above
Glatiramer acetate	COPAXONE (20 μ g, SC, daily)	Treatment of RRMS	Reduction of relapses by one-third Reduction in the number and volume of Gd-enhancing lesions	Induces T-helper type 2 cells that enter the CNS; mediates bystander suppression at sites of inflammation
Mitoxantrone	NOVANTRONE (12 mg/m ² , as short [5–15 min] IV infusion every 3 months)	Worsening forms of RRMS SPMS	Reduction in relapses by 67% Slowed progression on EDSS, ambulation index, and MRI disease activity	Intercalates DNA (<i>see</i> Chapter 51) Suppresses cellular and humoral immune response

IFN, interferon; IM, intramuscularly; RRMS, relapsing-remitting MS; SC, subcutaneously; SPMS, secondary progressive MS; IV, intravenously. Gd, gadolinium, used in Gd-enhanced MRI to assess number and size of inflammatory brain lesions; EDSS, Expanded Disability Status Scale, a neurologic assessment scale for MS pathology (*see* Ravnborg *et al.*, 2005); MMP, matrix metalloproteinase.

earlier they are used, the more effective they are in preventing disease relapses. What is not clear is whether any of these agents will prevent or diminish the later onset of secondary progressive disease, which causes the more severe form of disability. Given the fluctuating nature of this disease, only long-term studies lasting decades will answer this question.

A number of other new immunomodulatory therapies are completing Phase III trials. One is a monoclonal antibody, *natalizumab* (ANTEGREN), directed against the adhesion molecule α_4 integrin; natalizumab binds to α_4 integrin and antagonizes interactions with integrin heterodimers containing α_4 integrin, such as $\alpha_4\beta_1$ integrin that is expressed on the surface of activated lymphocytes

and monocytes. Preclinical data suggest that an interaction of $\alpha_4\beta_1$ integrin with VCAM-1 (vascular cellular-adhesion molecule 1) is critical for T-cell trafficking from the periphery into the CNS (Steinman, 2004); thus, blocking this interaction would hypothetically inhibit disease exacerbations. In fact, Phase II clinical trials have demonstrated a significant decrease in the number of new lesions as determined by magnetic resonance imaging and clinical attacks in MS patients receiving natalizumab (Miller *et al.*, 2003). Monoclonal antibodies directed against the IL-2 receptor are also entering Phase III clinical trials. The pharmacotherapy of MS has been reviewed by Weiner (2004); the utility of immunotherapy for autoimmune diseases has been reviewed by Steinman (2004).

CLINICAL SUMMARY

Most transplant centers employ some combination of immunosuppressive drugs with antilymphocyte induction therapy with either a monoclonal or polyclonal antibody agent. Maintenance immunosuppression consists of a calcineurin inhibitor (cyclosporine or tacrolimus), glucocorticoids, and an antimetabolite (azathioprine or mycophenolate mofetil). Mycophenolate mofetil has largely replaced azathioprine as part of the standard immunosuppressive regimen after transplantation. At present, a number of centers are conducting trials with new drug combinations including either cyclosporine or tacrolimus in combination with glucocorticoids and mycophenolate mofetil, with or without antibody-induction therapy or FTY70 with cyclosporine. Sirolimus is being used to limit exposure to the nephrotoxic calcineurin inhibitors, while steroid avoidance or minimization strategies increasingly are used. Newer immunosuppressive agents are providing more effective control of rejection and permitting transplantation to become an accepted procedure with a number of different organs, including kidney, liver, pancreas, and heart. The apparent effectiveness of new drug combinations has resulted in a resurgence of interest in glucocorticoid withdrawal.

SECTION XI

Drugs Acting on the Blood and the Blood-Forming Organs

CHAPTER 53

HEMATOPOIETIC AGENTS

Growth Factors, Minerals, and Vitamins

Kenneth Kaushansky and Thomas J. Kipps

The finite life span of most mature blood cells requires their continuous replacement, a process termed hematopoiesis. New cell production must respond to basal needs and states of increased demand. Red blood cell production can increase more than twentyfold in response to anemia or hypoxemia, white blood cell production increases dramatically in response to a systemic infection, and platelet production can increase ten- to twentyfold when platelet consumption results in thrombocytopenia.

The regulation of blood cell production is complex. Hematopoietic stem cells are rare marrow cells that manifest self-renewal and lineage commitment, resulting in cells destined to differentiate into the nine distinct blood-cell lineages. For the most part, this process occurs in the marrow cavities of the skull, vertebral bodies, pelvis, and proximal long bones; it involves interactions among hematopoietic stem and progenitor cells and the cells and complex macromolecules of the marrow stroma, and is influenced by a number of soluble and membrane-bound hematopoietic growth factors. A number of these hormones and cytokines have been identified and cloned, permitting their production in quantities sufficient for therapeutic use. Clinical applications range from the treatment of primary hematological diseases to use as adjuncts in the treatment of severe infections and in the manage-

ment of patients who are undergoing cancer chemotherapy or marrow transplantation.

Hematopoiesis also requires an adequate supply of minerals (*e.g.*, iron, cobalt, and copper) and vitamins (*e.g.*, folic acid, vitamin B₁₂, pyridoxine, ascorbic acid, and riboflavin), and deficiencies generally result in characteristic anemias, or, less frequently, a general failure of hematopoiesis (Hoffbrand and Herbert, 1999). Therapeutic correction of a specific deficiency state depends on the accurate diagnosis of the anemic state and knowledge about the correct dose, the use of these agents in various combinations, and the expected response. This chapter deals with the growth factors, vitamins, minerals, and drugs that affect the blood and blood-forming organs.

I. HEMATOPOIETIC GROWTH FACTORS

History. Modern concepts of hematopoietic cell growth and differentiation arose in the 1950s, when cells from the spleen and marrow were shown to play an important role in the restoration of hematopoietic tissue in irradiated animals. In 1961, Till and McCulloch demonstrated that individual hematopoietic cells could form macroscopic hematopoietic colonies in the spleens of irradiated mice.

Their work established the concept that there exist discrete hematopoietic stem cells, which can be experimentally identified, albeit in retrospect (*i.e.*, the presence of a multilineage clonal splenic colony appearing 11 days after transplantation implied that a single cell lodged and expanded into several cell lineages). This concept now has been expanded to include normal human marrow cells. Moreover, such cells now can be prospectively identified.

The basis for identifying soluble growth factors was provided by Sachs and independently by Metcalf, who developed clonal, *in vitro* assays for hematopoietic progenitor cells. Initially, such hematopoietic colonies developed only in the presence of conditioned culture medium from leukocytes or tumor cell lines. Individual growth factors then were isolated based on their activities in such assays. Many of these same assays were instrumental in purifying a hierarchy of progenitor cells committed to individual and combinations of mature blood cells (Kondo *et al.*, 1997; Akashi *et al.*, 2000; Sawada *et al.*, 1990; Nakorn *et al.*, 2003).

The existence of a circulating growth factor that controls red blood cell development was first suggested by the experiments of Paul Carnot in 1906. He observed an increase in the red cell count in rabbits injected with serum obtained from anemic animals and postulated the existence of a factor that he called *hemopoietine*. However, it was not until the 1950s that Reissmann, Erslev, and Jacobsen and coworkers defined the origin and actions of the hormone, now called *erythropoietin*. Subsequently, extensive studies of erythropoietin were carried out in patients with anemia and polycythemia, leading to the purification of erythropoietin from urine and the subsequent cloning of the erythropoietin gene. The high-level expression of erythropoietin in and purification from cell lines has allowed for its use in humans with anemia.

Similarly, the existence of specific leukocyte growth factors was suggested by the capacity of different conditioned culture media to induce the *in vitro* growth of colonies containing different combinations of granulocytes and monocytes. Using a multistep purification process beginning with conditioned culture medium from fibroblasts, macrophage colony-stimulating factor (M-CSF) was purified and the corresponding gene identified (Wong *et al.*, 1987). An activity that stimulated the production of both granulocytes and monocytes was purified from murine lung-conditioned medium, leading to cloning of its cDNA (Gough *et al.*, 1984), as was an activity that stimulated the exclusive production of neutrophils, permitting the cloning of granulocyte colony-stimulating factor (G-CSF) (Welte *et al.*, 1985). Most recently, a megakaryocyte colony-stimulating factor termed *thrombopoietin* was purified and cloned (Kaushansky, 1998).

The growth factors that support lymphocyte growth were not identified using *in vitro* colony-forming assays, but rather using assays that measured the capacity of the cytokine to promote lymphocyte proliferation *in vitro*. This permitted the identification of the growth-promoting properties of interleukin-7, interleukin-4, or interleukin-15 for all lymphocytes, B cells, or NK cells, respectively (Goodwin *et al.*, 1989; Yokota *et al.*, 1986; Grabstein *et al.*, 1994). Again, recombinant expression of these cDNAs permitted production of sufficient quantities of biologically active growth factors for clinical investigations, allowing for the demonstration of the potential clinical utility of such factors.

Growth Factor Physiology. Steady-state hematopoiesis encompasses the production of more than 400 billion blood cells each day. This production is tightly regulated and can be increased severalfold with increased demand. The hematopoietic organ also is unique in adult physiology

in that several mature cell types are derived from a much smaller number of multipotent progenitors, which develop from a more limited number of pluripotent hematopoietic stem cells. Such cells are capable of maintaining their own number and differentiating under the influence of cellular and humoral factors to produce the large and diverse number of mature blood cells.

Stem cell differentiation can be described as a series of steps that produce so-called burst-forming units (BFU) and colony-forming units (CFU) for each of the major cell lines (Quesenberry and Levitt, 1979). These early progenitors (BFU and CFU) are capable of further proliferation and differentiation, increasing their number by some thirtyfold. Subsequently, colonies of morphologically distinct cells form under the control of an overlapping set of additional growth factors (G-CSF, M-CSF, erythropoietin, and thrombopoietin). Proliferation and maturation of the CFU for each cell line can amplify the resulting mature cell product by another thirtyfold or more, generating more than 1000 mature cells from each committed stem cell.

Hematopoietic and lymphopoietic growth factors are glycoproteins produced by a number of marrow cells and peripheral tissues. They are active at very low concentrations and typically affect more than one committed cell lineage. Most interact synergistically with other factors and also stimulate production of additional growth factors, a process called *networking*. Growth factors generally exert actions at several points in the processes of cell proliferation and differentiation and in mature cell function (Metcalf, 1985). However, the network of growth factors that contributes to any given cell lineage depends absolutely on a nonredundant, lineage-specific factor, such that absence of factors that stimulate developmentally early progenitors is compensated for by redundant cytokines, but loss of the lineage-specific factor leads to a specific cytopenia. Some of the overlapping and nonredundant effects of the more important hematopoietic growth factors are illustrated in Figure 53–1 and listed in Table 53–1.

ERYTHROPOIETINS

While erythropoietin is not the sole growth factor responsible for erythropoiesis, it is the most important regulator of the proliferation of committed progenitors (CFU-E) and their immediate progeny. In its absence, severe anemia is invariably present. Erythropoiesis is controlled by a highly responsive feedback system in which a sensor in the kidney detects changes in oxygen delivery to modu-

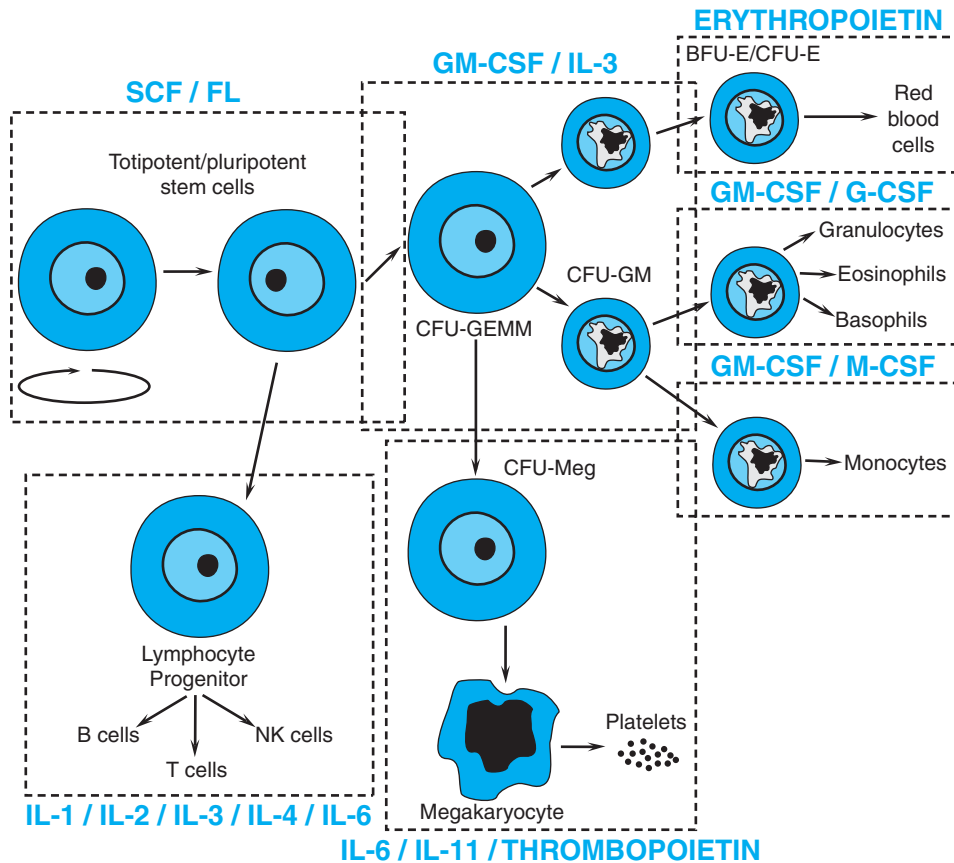

Figure 53–1. Sites of action of hematopoietic growth factors in the differentiation and maturation of marrow cell lines. A self-sustaining pool of marrow stem cells differentiates under the influence of specific hematopoietic growth factors to form a variety of hematopoietic and lymphopoietic cells. Stem cell factor (SCF), ligand (FL), interleukin-3 (IL-3), and granulocyte-macrophage colony-stimulating factor (GM-CSF), together with cell-cell interactions in the marrow, stimulate stem cells to form a series of burst-forming units (BFU) and colony-forming units (CFU): CFU-GEMM (granulocyte, erythrocyte, monocyte and megakaryocyte), CFU-GM (granulocyte and macrophage), CFU-Meg (megakaryocyte), BFU-E (erythrocyte), and CFU-E (erythrocyte). After considerable proliferation, further differentiation is stimulated by synergistic interactions with growth factors for each of the major cell lines—granulocyte colony-stimulating factor (G-CSF), monocyte/macrophage-stimulating factor (M-CSF), thrombopoietin, and erythropoietin. Each of these factors also influences the proliferation, maturation, and in some cases the function of the derivative cell line (see Table 53–1).

late the erythropoietin secretion. The sensor mechanism is now understood at the molecular level (Maxwell *et al.*, 2001). Hypoxia-inducible factor (HIF-1) is a heterodimeric (HIF-1 α and HIF-1 β) transcription factor that enhances expression of multiple hypoxia-inducible genes, such as vascular endothelial growth factor and erythropoietin. HIF-1 α is labile due to its prolyl hydroxylation and subsequent polyubiquitination and degradation, aided by the von Hippel-Lindau (VHL) protein. During states of hypoxia, the prolyl hydroxylase is inactive, allowing the accumulation of HIF-1 α and activating erythropoietin expression, which in turn stimulates a rapid expansion of erythroid progenitors. Specific alteration of VHL leads to an oxygen-sensing defect, characterized by constitutively

elevated levels of HIF-1 α and erythropoietin, with a resultant polycythemia (Gordeuk *et al.*, 2004).

Erythropoietin is encoded by a gene on human chromosome 7 that is expressed primarily in peritubular interstitial cells of the kidney. Erythropoietin contains 193 amino acids, of which the first 27 are cleaved during secretion. The final hormone is heavily glycosylated and has a molecular mass of approximately 30,000 daltons. After secretion, erythropoietin binds to a receptor on the surface of committed erythroid progenitors in the marrow and is internalized. With anemia or hypoxemia, synthesis rapidly increases by one hundredfold or more, serum erythropoietin levels rise, and marrow progenitor cell survival, proliferation, and maturation are dramati-

Table 53–1**Hematopoietic Growth Factors****ERYTHROPOIETIN (EPO)**

- Stimulates proliferation and maturation of committed erythroid progenitors to increase red cell production

STEM CELL FACTOR (SCF, c-kit ligand, Steel factor) and FLT-3 LIGAND (FL)

- Act synergistically with a wide range of other colony-stimulating factors and interleukins to stimulate pluripotent and committed stem cells
- FL also stimulates both dendritic and natural killer cells (anti-tumor response)
- SCF also stimulates mast cells and melanocytes

INTERLEUKINS***IL-1, IL-3, IL-5, IL-6, IL-9, and IL-11***

- Act synergistically with each other and SCF, GM-CSF, G-CSF, and EPO to stimulate BFU-E, CFU-GEMM, CFU-GM, CFU-E, and CFU-Meg growth
- Numerous immunologic roles, including stimulation of B cell and T cell growth
- IL-6 stimulates human myeloma cells to proliferate
- IL-6 and IL-11 stimulate BFU-Meg to increase platelet production

IL-5

- Controls eosinophil survival and differentiation

IL-1, IL-2, IL-4, IL-7, and IL-12

- Stimulate growth and function of T cells, B cells, NK cells, and monocytes
- Co-stimulate B, T, and LAK cells

IL-8 and IL-10

- Numerous immunological activities involving B and T cell functions
- IL-8 acts as a chemotactic factor for basophils and neutrophils

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR (GM-CSF)

- Acts synergistically with SCF, IL-1, IL-3, and IL-6 to stimulate CFU-GM, and CFU-Meg to increase neutrophil and monocyte production
- With EPO may promote BFU-E formation
- Enhances migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils
- Prevents alveolar proteinosis

GRANULOCYTE COLONY-STIMULATING FACTOR (G-CSF)

- Stimulates CFU-G to increase neutrophil production
- Enhances phagocytic and cytotoxic activities of neutrophils

MONOCYTE/MACROPHAGE COLONY-STIMULATING FACTOR (M-CSF, CSF-1)

- Stimulates CFU-M to increase monocyte precursors
- Activates and enhances function of monocyte/macrophages

MACROPHAGE COLONY-STIMULATING FACTOR (M-CSF)

- Stimulates CFU-M to increase monocyte/macrophage precursors
- Acts in concert with tissues and other growth factors to determine the proliferation, differentiation, and survival of a range of cells of the mononuclear phagocyte system

THROMBOPOIETIN (TPO, *Mpl* ligand)

- Stimulates the self-renewal and expansion of hematopoietic stem cells
- Stimulates stem cell differentiation into megakaryocyte progenitors
- Selectively stimulates megakaryocytopoiesis to increase platelet production
- Acts synergistically with other growth factors, especially IL-6 and IL-11

ABBREVIATIONS: BFU, burst-forming unit; CFU, colony-forming unit; E, erythrocyte; G, granulocyte; M, macrophage; Meg, megakaryocyte; NK cells, natural killer cells; LAK cells, lymphokine-activated killer cells.

cally stimulated. This finely tuned feedback loop can be disrupted by kidney disease, marrow damage, or a deficiency in iron or an essential vitamin. With an infection or an inflammatory state, erythropoietin secretion, iron delivery, and progenitor proliferation all are suppressed by inflammatory cytokines, but this accounts for only part of the resultant anemia; interference with iron metabolism also is an effect of inflammatory mediator effects on the hepatic protein hepcidin (Nemeth *et al.*, 2004).

Recombinant human erythropoietin (*epoetin alfa*), produced using engineered Chinese hamster ovary cells, is nearly identical to the endogenous hormone except for two subtle differences. First, the carbohydrate modification pattern of epoetin alfa differs slightly from the native protein, but this difference apparently does not alter kinetics, potency, or immunoreactivity of the drug. However, modern assays can detect these differences (Skibeli *et al.*, 2001), which is of significance for detecting athletes who use the recombinant product for “blood doping.” The second difference probably is related to the manufacturing process, as one commercially available form of the drug was recently associated with the development of anti-recombinant erythropoietin antibodies that cross-react with the patient’s own erythropoietin, potentially causing pure red cell aplasia (Macdougall, 2004). Most of these cases were caused by one preparation of the drug shortly after albumin was removed from the formulation (Casadevall, 2003).

Available preparations of epoetin alfa include EPOGEN, PROCIT, and EXPREX, supplied in single-use vials of from 2000 to 40,000 units/ml for intravenous or subcutaneous administration. When injected intravenously, epoetin alfa is cleared from plasma with a half-life of 4 to 8 hours. However, the effect on marrow progenitors is sufficiently sustained that it need only be given three times a week to achieve an adequate response. Combination of the weekly dose into a single injection also can achieve virtually identical results. No significant allergic reactions have been associated with the intravenous or subcutaneous administration of epoetin alfa, and—except as noted above—antibodies have not been detected even after prolonged administration.

More recently, novel erythropoiesis-stimulating protein (NESP) or darbapoetin alfa (ARANESP) has been approved for clinical use in patients with indications similar to those for epoetin alfa. It is a genetically modified form of erythropoietin in which four amino acids have been mutated such that additional carbohydrate side chains are added during its synthesis, prolonging the circulatory survival of the drug to 24 to 26 hours (Jelkmann, 2002).

Therapeutic Uses, Monitoring, and Adverse Effects. Recombinant erythropoietin therapy, in conjunction with adequate iron intake, can be highly effective in a number of anemias, especially those associated with a poor erythropoietic response. There is a clear dose-response relationship between the epoetin alfa dose and the rise in hematocrit in anephric patients, with eradication of their anemia at higher doses (Eschbach *et al.*, 1987). Epoetin alfa also is effective in the treatment of anemias associated with surgery, AIDS, cancer chemotherapy, prematurity, and certain chronic inflammatory conditions. Darbapoetin alfa also has been approved for use in patients with anemia associated with chronic kidney disease and is under review for several other indications.

During erythropoietin therapy, absolute or functional iron deficiency may develop. Functional iron deficiency (*i.e.*, normal ferritin levels but low transferrin saturation) presumably results from the inability to mobilize iron stores rapidly enough to support the increased erythropoiesis. Virtually all patients eventually will require supplemental iron to increase or maintain transferrin saturation to levels that will adequately support stimulated erythropoiesis. Supplemental iron therapy is recommended for all patients whose serum ferritin is below 100 $\mu\text{g/L}$ or whose serum transferrin saturation is less than 20% (*see below*).

During initial therapy and after any dosage adjustment, the hematocrit is determined once a week (HIV-infected and cancer patients) or twice a week (renal failure patients) until it has stabilized in the target range and the maintenance dose has been established; the hematocrit then is monitored at regular intervals. If the hematocrit increases by more than 4 points in any 2-week period, the dose should be decreased. Due to the time required for erythropoiesis and the erythrocyte half-life, hematocrit changes lag behind dosage adjustments by 2 to 6 weeks. The dose of darbapoetin should be decreased if the hemoglobin increase exceeds 1 g/dl in any two-week period because of the association of excessive rate of rise of hemoglobin with adverse cardiovascular events.

During hemodialysis, patients receiving epoetin alfa or darbapoetin may require increased anticoagulation. Serious thromboembolic events have been reported, including migratory thrombophlebitis, microvascular thrombosis, pulmonary embolism, and thrombosis of the retinal artery and temporal and renal veins. The risk of thrombotic events, including vascular access thromboses, was higher in adults with ischemic heart disease or congestive heart failure receiving epoetin alfa therapy with the goal of reaching a normal hematocrit (42%) than in those with a lower target hematocrit of 30%. The higher risk of cardiovascular events from erythropoietic therapies may be associated with higher hemoglobin or higher rates of rise of hemoglobin. The hemoglobin level should be managed to avoid exceeding a target level of 12 g/dl. Although epoetin alfa is not associated with direct pressor effects, blood pressure may rise, especially during the early phases of therapy when the hematocrit is increasing. Erythropoietins should be withheld in patients with pre-existing uncontrolled hypertension. Patients may require initiation of, or increases in, antihypertensive therapy. Hypertensive encephalopathy and seizures have occurred in chronic renal failure patients treated with epoetin alfa. The incidence of seizures appears to be higher during the first 90 days of therapy with epoetin alfa in patients on dialysis (occurring in about 2.5% of patients) when compared with subsequent 90-day periods. Headache, tachycardia, edema, shortness of breath, nausea, vomiting, diarrhea, injection site stinging, and flu-like symptoms (*e.g.*, arthralgias and myalgias) also have been reported in conjunction with epoetin alfa therapy. Pure red cell

aplasia in association with neutralizing antibodies to native erythropoietin has been observed in patients treated with recombinant erythropoietins (*see above*); underlying infectious, inflammatory, or malignant processes; occult blood loss; underlying hematologic diseases (*e.g.*, thalassemia, refractory anemia, or other myelodysplastic disorders); folic acid or vitamin B₁₂ deficiency; hemolysis; aluminum intoxication; bone marrow fibrosis; and osteitis fibrosa cystica.

Anemia of Chronic Renal Failure. Patients with anemia secondary to chronic kidney disease are ideal candidates for epoetin alfa therapy. The response in predialysis, peritoneal dialysis, and hemodialysis patients is dependent on severity of the renal failure, the erythropoietin dose and route of administration, and iron availability (Eschbach *et al.*, 1989; Kaufman *et al.*, 1998; Besarab *et al.*, 1999). The subcutaneous route of administration is preferred over the intravenous route because absorption is slower and the amount of drug required is reduced by 20% to 40%.

The dose of epoetin alfa should be adjusted to obtain a gradual rise in the hematocrit over a 2- to 4-month period to a final hematocrit of 33% to 36%. Treatment to hematocrit levels greater than 36% is not recommended, as patients treated to a hematocrit above 40% showed a higher incidence of myocardial infarction and death (Besarab *et al.*, 1998). The drug should not be used to replace emergency transfusion in patients who need immediate correction of a life-threatening anemia.

Patients are started on doses of 80 to 120 units/kg of epoetin alfa, given subcutaneously, three times a week. It can be given on a once-a-week schedule, but somewhat more drug is required for an equivalent effect. If the response is poor, the dose should be progressively increased. The final maintenance dose of epoetin alfa can vary from as little as 10 units/kg to more than 300 units/kg, with an average dose of 75 units/kg, three times a week. Children younger than 5 years generally require a higher dose. Resistance to therapy is common in patients who develop an inflammatory illness or become iron deficient, so close monitoring of general health and iron status is essential. Less common causes of resistance include occult blood loss, folic acid deficiency, carnitine deficiency, inadequate dialysis, aluminum toxicity, and osteitis fibrosa cystica secondary to hyperparathyroidism.

The most common side effect of epoetin alfa therapy is aggravation of hypertension, which occurs in 20% to 30% of patients and most often is associated with a rapid rise in hematocrit. Blood pressure usually can be controlled either by increasing antihypertensive therapy or ultrafiltration in dialysis patients or by reducing the epoetin alfa dose to slow the hematocrit response.

Darbapoetin alfa also is approved for use in patients who are anemic secondary to chronic kidney disease. The recommended starting dose is 0.45 $\mu\text{g}/\text{kg}$ administered intravenously or subcutaneously once weekly, with dose adjustments depending on the response. Like epoetin alfa, side effects tend to occur when patients experience a rapid rise in hemoglobin concentration; a rise of less than 1 g/dl every 2 weeks generally has been considered safe.

Anemia in AIDS Patients. Epoetin alfa therapy has been approved for the treatment of HIV-infected patients, especially those on *zidovudine* therapy (Fischl *et al.*, 1990). Excellent responses to doses of 100 to 300 units/kg, given subcutaneously three times a week, generally are seen in patients with zidovudine-induced anemia. In the face of advanced disease, marrow damage, and elevated serum erythropoietin levels (greater than 500 IU/L), therapy is less effective.

Cancer-Related Anemias. Epoetin alfa therapy, 150 units/kg three times a week or 450 to 600 units/kg once a week, can reduce the

transfusion requirement in cancer patients undergoing chemotherapy. Evidence-based guidelines for the therapeutic use of recombinant erythropoietin in patients with cancer have been published (Rizzo *et al.*, 2002). Briefly, the guidelines recommend the use of epoetin alfa in patients with chemotherapy-associated anemia when hemoglobin levels fall below 10 g/dl, basing the decision to treat less severe anemia (hemoglobin between 10 and 12 g/dl) on clinical circumstances. For anemia associated with hematologic malignancies, the guidelines support the use of recombinant erythropoietin in patients with low-grade myelodysplastic syndrome, although the evidence that the drug is effective in anemic patients with multiple myeloma, non-Hodgkin's lymphoma, or chronic lymphocytic leukemia not receiving chemotherapy is less robust. A baseline serum erythropoietin level may help to predict the response; most patients with blood levels of more than 500 IU/L are unlikely to respond to any dose of the drug. Most patients treated with epoetin alfa experienced an improvement in their anemia, sense of well being, and quality of life (Demetri *et al.*, 1998; Littlewood *et al.*, 2001). This improved sense of well being, particularly in cancer patients, may not be solely due to the rise in the hematocrit. Erythropoietin receptors have been demonstrated in cells of the CNS, and erythropoietin has been found to act as a cytoprotectant in several models of CNS ischemia (Juil, 2002; Prass *et al.*, 2003; Martinez-Estrada *et al.*, 2003). Thus, high levels of the hormone may directly affect cancer patients' sense of well-being.

Darbapoetin alfa also has been tested in cancer patients undergoing chemotherapy (Bloomfield *et al.*, 2003; Hesketh *et al.*, 2004), and preliminary studies appear promising. However, recent case reports have suggested a direct effect of both epoetin alfa and darbapoetin alfa in stimulation of tumor cells. For example, patients with cancer of the head and neck randomized to receive recombinant erythropoietin had a statistically significant increase in likelihood of tumor progression during the duration of the study (Henke *et al.*, 2003). This finding is being evaluated by the FDA and warrants serious attention.

Surgery and Autologous Blood Donation. Epoetin alfa has been used perioperatively to treat anemia and reduce the need for transfusion. Patients undergoing elective orthopedic and cardiac procedures have been treated with 150 to 300 units/kg of epoetin alfa once daily for the 10 days preceding surgery, on the day of surgery, and for 4 days after surgery. As an alternative, 600 units/kg can be given on days -21, -14, and -7 before surgery, with an additional dose on the day of surgery. This can correct a moderately severe preoperative anemia (*i.e.*, hematocrit 30% to 36%) and reduce the need for transfusion. Epoetin alfa also has been used to improve autologous blood donation (Goodnough *et al.*, 1989). However, the potential benefit generally is small, and the expense is considerable. Patients treated for 3 to 4 weeks with epoetin alfa (300 to 600 units/kg twice a week) are able to donate only one or two more units than untreated patients, and most of the time this goes unused. Still, the ability to stimulate erythropoiesis for blood storage can be invaluable in the patient with multiple alloantibodies to red blood cells.

Other Uses. Epoetin alfa has received orphan drug status from the FDA for the treatment of the anemia of prematurity, HIV infection, and myelodysplasia. In the latter case, even very high doses of more than 1000 units/kg two to three times a week have had limited success. The utility of very high-dose therapy in other hematological disorders, such as sickle cell anemia, still is under study. Highly competitive athletes have used epoetin alfa to increase their hemoglobin levels ("blood doping") and improve performance. Unfortu-

nately, this misuse of the drug has been implicated in the deaths of several athletes and is strongly discouraged.

MYELOID GROWTH FACTORS

The myeloid growth factors are glycoproteins that stimulate the proliferation and differentiation of one or more myeloid cell lines. They also enhance the function of mature granulocytes and monocytes. Recombinant forms of several growth factors have been produced, including GM-CSF (Wong *et al.*, 1985), G-CSF (Welte *et al.*, 1985), IL-3 (Yang *et al.*, 1986), M-CSF or CSF-1 (Kawasaki *et al.*, 1985), and SCF (Huang *et al.*, 1990) (Table 53-1).

The myeloid growth factors are produced naturally by a number of different cells, including fibroblasts, endothelial cells, macrophages, and T cells (Figure 53-2). They are active at extremely low concentrations and act *via* membrane receptors of the cytokine receptor superfamily to activate the JAK/STAT signal transduction pathway. GM-CSF is capable of stimulating the proliferation, differentiation, and function of a number of the myeloid cell lineages (Figure 53-1). It acts synergistically with other growth factors, including erythropoietin, at the level of the BFU. GM-CSF stimulates the CFU-GEMM, CFU-GM, CFU-M, CFU-E, and CFU-Meg to increase cell production. It also enhances the migration, phagocytosis, superoxide production, and antibody-depend-

ent cell-mediated toxicity of neutrophils, monocytes, and eosinophils (Weisbart *et al.*, 1987).

The activity of G-CSF is restricted to neutrophils and their progenitors, stimulating their proliferation, differentiation, and function. It acts primarily on the CFU-G, although it also can play a synergistic role with IL-3 and GM-CSF in stimulating other cell lines. G-CSF enhances phagocytic and cytotoxic activities of neutrophils. Unlike GM-CSF, G-CSF has little effect on monocytes, macrophages, and eosinophils and reduces inflammation by inhibiting IL-1, tumor necrosis factor, and interferon gamma. G-CSF also mobilizes primitive hematopoietic cells, including hematopoietic stem cells, from the marrow into the peripheral blood (Sheridan *et al.*, 1992). This observation has virtually transformed the practice of stem cell transplantation, such that more than 90% of all such procedures today use G-CSF-mobilized peripheral blood stem cells as the donor product.

Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF). Recombinant human GM-CSF (*sargramostim*) is a 127-amino acid glycoprotein produced in yeast. Except for the substitution of a leucine in position 23 and variable levels of glycosylation, it is identical to endogenous human GM-CSF. While sargramostim, like natural GM-CSF, has a wide range of effects on cells in culture, its primary therapeutic effect is to stimulate myelopoiesis. The initial clinical application of sargramostim was in patients undergoing autologous bone marrow transplantation. By shortening the duration of neutropenia, transplant morbidity was significantly reduced without a change in long-term survival or risk of inducing an early relapse of the malignant process (Brandt *et al.*, 1988; Rabinowe *et al.*, 1993).

The role of GM-CSF therapy in allogeneic transplantation is less clear. Its effect on neutrophil recovery is less pronounced in patients receiving prophylactic treatment for graft-versus-host disease (GVHD), and studies have failed to show a significant effect on transplant mortality, long-term survival, the appearance of GVHD, or disease relapse. However, it may improve survival in transplant patients who exhibit early graft failure (Nemunaitis *et al.*, 1990). It also has been used to mobilize CD34-positive progenitor cells for peripheral blood stem cell collection for transplantation after myeloablative chemotherapy (Haas *et al.*, 1990). Sargramostim has been used to shorten the period of neutropenia and reduce morbidity in patients receiving intensive cancer chemotherapy (Gerhartz *et al.*, 1993). It also stimulates myelopoiesis in some patients with cyclic neutropenia, myelodysplasia, aplastic anemia, or AIDS-associated neutropenia (Groopman *et al.*, 1987).

Figure 53-2. Cytokine-cell interactions. Macrophages, T cells, B cells, and marrow stem cells interact *via* several cytokines (IL-1, IL-2, IL-3, IL-4, IFN [interferon]- γ , GM-CSF, and G-CSF) in response to a bacterial or a foreign antigen challenge. See Table 53-1 for the functional activities of these various cytokines.

Sargramostim (LEUKINE) is administered by subcutaneous injection or slow intravenous infusion at doses of 125 to 500 $\mu\text{g}/\text{m}^2$ per day. Plasma levels of GM-CSF rise rapidly after subcutaneous injection and then decline with a half-life of 2 to 3 hours. When given intravenously, infusions should be maintained over 3 to 6 hours. With the initiation of therapy, there is a transient decrease in the absolute leukocyte count secondary to margination and sequestration in the lungs. This is followed by a dose-dependent, biphasic increase in leukocyte counts over the next 7 to 10 days. Once the drug is discontinued, the leukocyte count returns to baseline within 2 to 10 days. When GM-CSF is given in lower doses, the response is primarily neutrophilic, while monocytosis and eosinophilia are observed at larger doses. After hematopoietic stem cell transplantation or intensive chemotherapy, sargramostim is given daily during the period of maximum neutropenia until a sustained rise in the granulocyte count is observed. Frequent blood counts are essential to avoid an excessive rise in the granulocyte count. The dose may be increased if the patient fails to respond after 7 to 14 days of therapy. However, higher doses are associated with more pronounced side effects, including bone pain, malaise, flu-like symptoms, fever, diarrhea, dyspnea, and rash. An acute reaction to the first dose, characterized by flushing, hypotension, nausea, vomiting, and dyspnea, with a fall in arterial oxygen saturation due to granulocyte sequestration in the pulmonary circulation occurs in sensitive patients. With prolonged administration, a few patients may develop a capillary leak syndrome, with peripheral edema and pleural and pericardial effusions. Other serious side effects have included transient supraventricular arrhythmia, dyspnea, and elevation of serum creatinine, bilirubin, and hepatic enzymes.

Granulocyte Colony-Stimulating Factor (G-CSF).

Recombinant human G-CSF *filgrastim* (NEUPOGEN) is a 175–amino acid glycoprotein produced in *E. coli*. Unlike natural G-CSF, it is not glycosylated and carries an extra N-terminal methionine. The principal action of filgrastim is the stimulation of CFU-G to increase neutrophil production (Figure 53–1). It also enhances the phagocytic and cytotoxic functions of neutrophils.

Filgrastim is effective in the treatment of severe neutropenia after autologous hematopoietic stem cell transplantation and high-dose cancer chemotherapy (Lieschke and Burgess, 1992). Like GM-CSF, filgrastim shortens the period of severe neutropenia and reduces morbidity secondary to bacterial and fungal infections. When used as a part of an intensive chemotherapy regimen, it can decrease the frequency of hospitalization for febrile neutropenia and interruptions in the chemotherapy protocol; a positive impact on patient survival has not been demonstrated. G-CSF also is effective in the treatment of severe congenital neutropenias. In patients with cyclic neutropenia, G-CSF therapy will increase the level of neutrophils and shorten the length of the cycle sufficiently to prevent recurrent bacterial infections (Hammond *et al.*, 1989). Filgrastim therapy can improve neutrophil counts in some

patients with myelodysplasia or marrow damage (moderately severe aplastic anemia or tumor infiltration of the marrow). The neutropenia of AIDS patients receiving zidovudine also can be partially or completely reversed. Filgrastim is routinely used in patients undergoing peripheral blood stem cell (PBSC) collection for stem cell transplantation. It promotes the release of CD34⁺ progenitor cells from the marrow, reducing the number of collections necessary for transplant. Moreover, filgrastim-mobilized PBSCs appear more capable of rapid engraftment. PBSC-transplanted patients require fewer days of platelet and red blood cell transfusions and a shorter duration of hospitalization than do patients receiving autologous bone marrow transplants.

Filgrastim is administered by subcutaneous injection or intravenous infusion over at least 30 minutes at doses of 1 to 20 $\mu\text{g}/\text{kg}$ per day. The usual starting dose in a patient receiving myelosuppressive chemotherapy is 5 $\mu\text{g}/\text{kg}$ per day. The distribution and clearance rate from plasma (half-life of 3.5 hours) are similar for both routes of administration. As with GM-CSF therapy, filgrastim given daily after hematopoietic stem cell transplantation or intensive cancer chemotherapy will increase granulocyte production and shorten the period of severe neutropenia. Frequent blood counts should be obtained to determine the effectiveness of the treatment and guide dosage adjustment. In patients who received intensive myelosuppressive cancer chemotherapy, daily administration of G-CSF for 14 to 21 days or longer may be necessary to correct the neutropenia. With less intensive chemotherapy, fewer than 7 days of treatment may suffice. In AIDS patients on zidovudine or patients with cyclic neutropenia, chronic G-CSF therapy often is required.

One indication for G-CSF presently under investigation is its use to increase the number of peripheral blood neutrophils in leukocyte donors. For many years it had been hoped that, like platelet transfusions for the bleeding associated with severe thrombocytopenia, neutrophil transfusion could diminish the infectious complications of neutropenia. However, given the short circulatory half-life of neutrophils (~6 hours) and the need for large numbers of cells, the practical collection of sufficient cell numbers has eluded hematologists. With few complications of therapy in more than 15 years of clinical experience, G-CSF now has been used to increase peripheral neutrophil counts in prospective donors and neutrophil transfusions (Hubel *et al.*, 2002). While initial results were modest, the therapy is likely to be optimized and greater efficacy is anticipated.

Adverse reactions to filgrastim include mild to moderate bone pain in patients receiving high doses over a protracted period, local skin reactions following subcutaneous injection, and rare cutaneous necrotizing vasculitis. Patients with a history of hypersensitivity to proteins produced by *E. coli* should not receive the drug. Marked granulocytosis, with counts greater than 100,000/ μl , can occur in patients receiving filgrastim over a prolonged period of time. However, this is not associated with any reported clinical morbidity or mortality and rapidly resolves once therapy is discontinued. Mild to moderate splenomegaly has been observed in patients on long-term therapy.

Pegylated recombinant human G-CSF *pegfilgrastim* (NEULASTA) is generated through conjugation of a 20,000-dalton polyethylene glycol moiety to the N-terminal methionyl residue of the 175-amino acid G-CSF glycoprotein produced in *E. coli*. The clearance of pegfilgrastim by glomerular filtration is minimized, thus making neutrophil-mediated clearance the primary route of elimination. Consequently the circulating half-life of pegfilgrastim is longer than that of filgrastim, allowing for more sustained duration of action and less frequent dosing (Waladkhani, 2004). Clinical studies suggest that neutrophil-mediated clearance of pegfilgrastim may be self-regulating and therefore specific to each patient's hematopoietic recovery (Crawford, 2002). As such, the recommended dose for pegfilgrastim is fixed at 6 mg administered subcutaneously.

The therapeutic roles of other growth factors still need to be defined, although IL-3 and IL-6 have been removed from testing due to poor efficacy and/or significant toxicity. M-CSF may play a role in stimulating monocyte and macrophage production, although with significant side effects, including splenomegaly and thrombocytopenia. Stem cell factor (SCF) has been shown to augment peripheral blood mobilization of primitive hematopoietic progenitor cells (Molineux *et al.*, 1991; Moskowitz *et al.*, 1997).

THROMBOPOIETIC GROWTH FACTORS

Interleukin-11. Interleukin-11 was cloned based on its activity to promote proliferation of an IL-6–dependent myeloma cell line (Du *et al.*, 1994). The 23,000-dalton cytokine contains 178 amino acids and stimulates hematopoiesis, intestinal epithelial cell growth, and osteoclastogenesis and inhibits adipogenesis. IL-11 enhances megakaryocyte maturation *in vitro* (Teramura *et al.*, 1992; Debili *et al.*, 1993), and its *in vivo* administration to animals modestly increases peripheral blood platelet counts (Neben *et al.*, 1993; Farese *et al.*, 1994). Clinical trials in patients who previously demonstrated significant chemotherapy-induced thrombocytopenia demonstrated that administration of the recombinant cytokine was associated with less severe thrombocytopenia and reduced use of platelet transfusion (Tepler *et al.*, 1996; Isaacs *et al.*, 1997) leading to its approval for clinical use by the FDA.

Recombinant human interleukin-11 *oprelvekin* (NEUMEGA) is a bacterially derived, 19,000-dalton polypeptide of 177 amino acids that differs from the native protein only because it lacks the amino terminal proline residue

and is not glycosylated. The recombinant protein has a 7-hour half-life after subcutaneous injection. In normal subjects, daily administration of oprelvekin leads to a thrombopoietic response in 5 to 9 days.

The drug is available in single-use vials containing 5 mg and is administered to patients at 25 to 50 $\mu\text{g}/\text{kg}$ per day subcutaneously. Oprelvekin is approved for use in patients undergoing chemotherapy for nonmyeloid malignancies that displayed severe thrombocytopenia (platelet count $<20,000/\mu\text{l}$) on a prior cycle of the same chemotherapy, and is administered until the platelet count returns to more than $100,000/\mu\text{l}$. The major complications of therapy are fluid retention and other associated cardiac symptoms, such as tachycardia, palpitation, edema, and shortness of breath; this is a significant concern in elderly patients and often requires concomitant therapy with diuretics. Fluid retention reverses upon drug discontinuation, but volume status should be carefully monitored in elderly patients, those with a history of heart failure, or those with preexisting fluid collections in the pleura, pericardium, or peritoneal cavity. Also reported are blurred vision, injection-site rash or erythema, and paresthesias.

Thrombopoietin. The cloning and expression of recombinant thrombopoietin, a cytokine that predominantly stimulates megakaryopoiesis, is potentially another milestone in the development of hematopoietic growth factors as therapeutic agents (Lok *et al.*, 1994; de Sauvage *et al.*, 1994; Kaushansky *et al.*, 1994) (Table 53–1). Thrombopoietin is a 45,000- to 75,000-dalton glycoprotein containing 332 amino acids that is produced by the liver, marrow stromal cells, and many other organs. In both humans and mice, genetic elimination of thrombopoietin or its receptor reduces the platelet counts to 10% of normal values. Moreover, blood levels of the hormone are inversely related to the blood platelet count, together indicating that the hormone is the primary regulator of platelet production.

Administration of recombinant thrombopoietin leads to a log-linear increase in the platelet count in mice, rats, dogs, and nonhuman primates (Harker, 1999) that begins on the third day of administration. In a number of human preclinical trials in several models of chemotherapy- and radiation-induced myelosuppression, thrombopoietin accelerated the recovery of platelet counts and other hematologic parameters (Kaushansky, 1998). Of note, however, the agent failed to substantially affect hematopoietic recovery when administered after myeloablative therapy and stem cell transplantation, unless given to the stem cell donor (Fibbe *et al.*, 1995).

Two forms of recombinant thrombopoietin have been developed for clinical use. One is a truncated version of the native polypeptide, termed recombinant *human megakaryocyte growth and development factor* (rHuMGDF), which is produced in bacteria and then covalently modified with polyethylene glycol to increase the circulatory half-life. The second is the full-length polypeptide termed *recombinant human thrombopoietin* (rHuTPO), which is produced in mammalian cells. *In vitro*, both drugs are equally potent in stimulating megakaryocyte growth.

In clinical trials, both drugs are safe in the patient populations selected for study (Basser *et al.*, 1996; Fanucchi *et al.*, 1997; Vadhan-Raj *et al.*, 1997). However, efficacy results using these agents have been mixed. In a small number of patients with gynecological cancers who were receiving *carboplatin* (Vadhan-Raj *et al.*, 2000), recombinant human thrombopoietin therapy reduced the duration of severe thrombocytopenia and the need for platelet transfusions. In a similar study of patients treated with carboplatin plus *cyclophosphamide*, patients receiving a cycle of chemotherapy supplemented with G-CSF plus thrombopoietin had higher platelet counts at nadir and a shorter median duration of severe thrombocytopenia than they did after cycles of therapy supplemented only with G-CSF (Basser *et al.*, 2000). When used to augment peripheral blood counts in preparation for platelet donation, a single dose of thrombopoietin in the platelet donors tripled their platelet counts, allowed for a threefold increase in the number of platelets that could be collected in a single apheresis, and led to a fourfold increase in the mean platelet count increase noted in transfusion recipients (Kuter *et al.*, 2001). However, this particular regimen was associated with several instances of anti-recombinant thrombopoietin antibodies that cross-reacted with the native hormone, resulting in subsequent thrombocytopenia (Li *et al.*, 2001).

In several studies, although the drug was safe, rHuMGDF was not effective. In two studies of patients treated for 7 days with standard, aggressive therapy for acute leukemia, the addition of recombinant thrombopoietin failed to accelerate platelet recovery (Archimbaud *et al.*, 1999; Schiffer *et al.*, 2000). A similar lack of efficacy was seen when the drug was used following autologous peripheral blood stem cell transplantation (Bolwell *et al.*, 2000). Failure to improve hematopoiesis in some of these trials may have resulted from the dosing regimen employed; the optimal dose and schedule of administration in various clinical settings need to be established. After a single bolus injection, platelet counts showed a detectable increase by day 4, peaked by 12 to

14 days, and then returned to normal over the next 4 weeks. The peak platelet response follows a log-linear dose response. Platelet activation and aggregation are not affected, and patients are not at increased risk of thromboembolic disease, unless the platelet count is allowed to rise to very high levels. These kinetics need to be taken into account when planning therapy in cancer chemotherapy patients.

Due to concerns over the immunogenicity of these agents, and to other considerations, efforts now are under way to develop small molecular mimics of recombinant thrombopoietin, discovered either through screening of phage display peptide libraries (Broudy *et al.*, 2004) or of small organic molecules (Kimura *et al.*, 1998). Several of these agents are in clinical trials.

II. DRUGS EFFECTIVE IN IRON DEFICIENCY AND OTHER HYPOCHROMIC ANEMIAS

IRON AND IRON SALTS

Iron deficiency is the most common nutritional cause of anemia in humans. It can result from inadequate iron intake, malabsorption, blood loss, or an increased requirement, as with pregnancy. When severe, it results in a characteristic microcytic, hypochromic anemia. The impact of iron deficiency is not limited to the erythron (Dallman, 1982). Iron also is an essential component of myoglobin; heme enzymes such as the cytochromes, catalase, and peroxidase; and the metalloflavoprotein enzymes, including xanthine oxidase and the mitochondrial enzyme α -glycerophosphate oxidase. Iron deficiency can affect metabolism in muscle independently of the effect of anemia on oxygen delivery. This may reflect a reduction in the activity of iron-dependent mitochondrial enzymes. Iron deficiency also has been associated with behavioral and learning problems in children, abnormalities in catecholamine metabolism, and possibly, impaired heat production. Awareness of the ubiquitous role of iron has stimulated considerable interest in the early and accurate detection of iron deficiency and in its prevention.

History. The modern understanding of iron metabolism began in 1937 with the work of McCance and Widdowson on iron absorption and excretion and Heilmeyer and Plotner's measurement of iron in plasma (Beutler, 2002). In 1947, Laurell described a plas-

ma iron transport protein that he called *transferrin*. Hahn and coworkers first used radioactive isotopes to quantitate iron absorption and define the role of the intestinal mucosa to regulate this function. In the next decade, Huff and associates initiated isotopic studies of internal iron metabolism. The subsequent development of practical clinical measurements of serum iron, transferrin saturation, plasma ferritin, and red cell protoporphyrin permitted the definition and detection of the body's iron store status and iron-deficient erythropoiesis.

Iron and the Environment. Iron exists in the environment largely as ferric oxide or hydroxide or as polymers. In this state, its biological availability is limited unless solubilized by acid or chelating agents. For example, bacteria and some plants produce high-affinity chelating agents that extract iron from the surrounding environment. Most mammals have little difficulty in acquiring iron; this is explained by an ample iron intake and perhaps also by a greater efficiency in absorbing iron. Humans, however, appear to be an exception. Although total dietary intake of elemental iron in human beings usually exceeds requirements, the bioavailability of the iron in the diet is limited.

Metabolism of Iron. The body store of iron is divided between essential iron-containing compounds and excess iron, which is held in storage. Quantitatively, hemoglobin dominates the essential fraction (Table 53–2). This protein, with a molecular weight of 64,500, contains four atoms of iron per molecule, amounting to 1.1 mg of iron per milliliter of red blood cells (20 mmol). Other forms of essential iron include myoglobin and a variety of heme and nonheme iron-dependent enzymes. Ferritin is a protein-iron storage complex that exists as individual molecules or as aggregates. Apoferritin has a molecular weight of about 450,000 and is composed of 24 polypeptide subunits that form an outer shell, within which resides a storage cavity for polynuclear hydrous ferric oxide phosphate. More than 30% of the weight of ferritin may be iron (4000 atoms of iron per ferritin molecule). Ferritin aggregates, referred to as *hemosiderin* and visible by light microscopy, constitute about one-third of normal stores, a fraction that increases as stores enlarge. The two predominant sites of iron storage are the reticuloendothelial system and the hepatocytes, although some storage also occurs in muscle.

Internal exchange of iron is accomplished by the plasma protein transferrin. This 76-kd β_1 -glycoprotein has two binding sites for ferric iron. Iron is delivered from transferrin to intracellular sites by means of specific transferrin receptors in the plasma membrane. The iron–transferrin complex binds to the receptor, and the ternary complex is taken up by receptor-mediated endocytosis. Iron subsequently dissociates in the acidic, intracellular vesicular compartment (the endosomes), and the receptor returns the apotransferrin to the cell surface, where it is

Table 53–2

released into the extracellular environment (Klausner *et al.*, 1983).

Cells regulate their expression of transferrin receptors and intracellular ferritin in response to the iron supply. When iron is plentiful, the synthesis of transferrin receptors is reduced and ferritin production is increased (Rouault, 2002). Conversely, with iron deficiency, cells express a greater number of transferrin receptors and reduce ferritin concentrations to maximize uptake and prevent diversion of iron to storage forms. Apoferritin synthesis is regulated posttranscriptionally by two cytoplasmic binding proteins (IRP-1 and IRP-2) and an iron-regulating element on mRNA (IRE). When iron is in short supply, IRP binds to mRNA IRE and inhibits apoferritin translation. Conversely, when iron is abundant, binding is blocked and apoferritin synthesis increases (Klausner *et al.*, 1993).

The flow of iron through the plasma amounts to a total of 30 to 40 mg per day in the adult (about 0.46 mg/kg of body weight) (Finch and Huebers, 1982). The major internal circulation of iron involves the erythron and reticuloendothelial cells (Figure 53–3). About 80% of the iron in plasma goes to the erythroid marrow to be packaged into new erythrocytes; these normally circulate for about 120 days before being catabolized by the reticuloendothelial system. At that time, a portion of the iron is immediately returned to the plasma bound to transferrin, while another portion is incorporated into the ferritin stores of reticuloendothelial cells and returned to the circulation more gradually. Isotopic studies indicate some degree of iron wastage in this process, wherein defective cells or unused portions of their iron are transferred to the reticuloendothelial cell during maturation, bypassing the circulating blood. With abnormalities in erythrocyte maturation, the predominant portion of iron assimilated by the erythroid marrow may be rap-

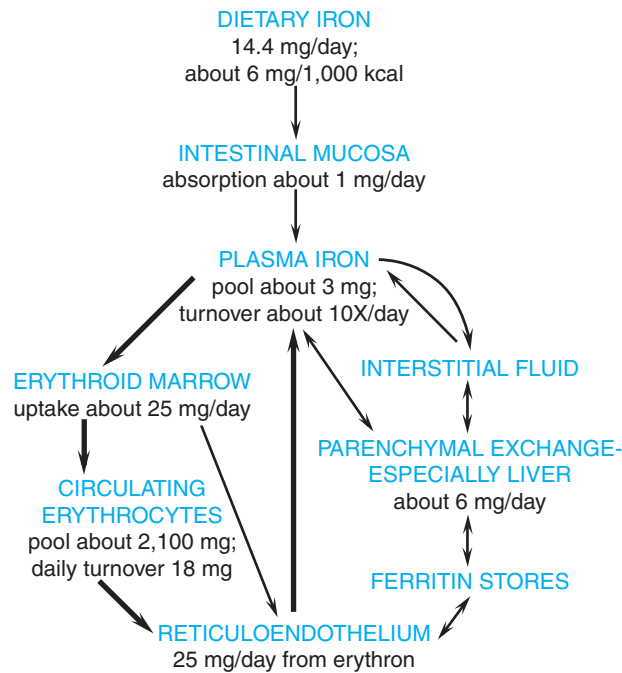

Figure 53-3. Pathways of iron metabolism in human beings (excretion omitted).

idly localized in the reticuloendothelial cells as defective red cell precursors are broken down; this is termed *ineffective erythropoiesis*. The rate of iron turnover in plasma may be reduced by one-half or more with red cell aplasia, with all the iron directed to the hepatocytes for storage.

The most remarkable feature of iron metabolism is the degree to which body stores are conserved. Only 10% of the total is lost per year by normal men, *i.e.*, about 1 mg per day. Two-thirds of this iron is excreted from the gastrointestinal tract as extravasated red cells, iron in bile, and iron in exfoliated mucosal cells. The other third is accounted for by small amounts of iron in desquamated skin and in the urine. Physiological losses of iron in men vary over a narrow range, from 0.5 mg in the iron-deficient individual to 1.5 to 2 mg per day when excessive iron is consumed. Additional losses of iron occur in women due to menstruation. While the average loss in menstruating women is about 0.5 mg per day, 10% of menstruating women lose more than 2 mg per day. Pregnancy and lactation impose an even greater requirement for iron (Table 53-3). Other causes of iron loss include blood donation, the use of antiinflammatory drugs that cause bleeding from the gastric mucosa, and gastrointestinal disease with associated bleeding. Two much rarer causes are the hemosiderinuria that follows

Table 53-3
Iron Requirements for Pregnancy

	AVERAGE, mg	RANGE, mg
External iron loss	170	150–200
Expansion of red cell mass	450	200–600
Fetal iron	270	200–370
Iron in placenta and cord	90	30–170

intravascular hemolysis, and pulmonary siderosis, where iron deposited in the lungs becomes unavailable to the rest of the body.

The limited physiological losses of iron point to the primary importance of absorption in determining of the body's iron content. Unfortunately, this process is understood only in general terms (Roy and Enns, 2000; Morgan and Oates, 2002). After acidification and partial digestion of food in the stomach, iron is presented to the intestinal mucosa as either inorganic iron or heme iron. These fractions are taken up by the absorptive cells of the duodenum and upper small intestine, and the iron is transported either directly into the plasma or stored as mucosal ferritin. Absorption appears to be regulated by two transporters: DCT1, which controls uptake from the intestinal lumen, and a second transporter that governs movement of mucosal cell iron across the basolateral membrane to bind to plasma protein. Mucosal cell iron transport and the delivery of iron to transferrin from reticuloendothelial stores both are determined by the HFE gene, a major histocompatibility complex class I molecule localized to chromosome 6 (Peters *et al.*, 1993; Beutler, 2003). Regulation is finely tuned to prevent iron overload in times of iron excess while allowing for increased absorption and mobilization of iron stores with iron deficiency (Roy and Andrews, 2001; Sheth and Brittenham, 2000). A predominant negative regulator of iron absorption in the small intestine is hepcidin, a 25-amino acid peptide made by hepatocytes (Ganz, 2003). The synthesis of hepcidin is greatly stimulated by inflammation or by iron overload. A deficient hepcidin response to iron

Table 53–4
Daily Iron Intake and Absorption

SUBJECT	IRON REQUIREMENT, mg/kg	AVAILABLE IRON IN POOR DIET–GOOD DIET, mg/kg	SAFETY FACTOR, AVAILABLE IRON/REQUIREMENT
Infant	67	33–66	0.5–1
Child	22	48–96	2–4
Adolescent (male)	21	30–60	1.5–3
Adolescent (female)	20	30–60	1.5–3
Adult (male)	13	26–52	2–4
Adult (female)	21	18–36	1–2
Mid-to-late pregnancy	80	18–36	0.22–0.45

loading can contribute to iron overload and one type of hemochromatosis. In anemia of chronic disease, hepcidin production can be increased up to one hundredfold, potentially accounting for characteristic features of this condition, namely poor gastrointestinal uptake and enhanced sequestration of iron in the reticuloendothelial system.

Normal iron absorption is about 1 mg per day in adult men and 1.4 mg per day in adult women; 3 to 4 mg of dietary iron is the most that normally can be absorbed. Increased iron absorption is seen whenever iron stores are depleted or when erythropoiesis is increased or ineffective. Patients with hereditary hemochromatosis due to HFE mutations demonstrate increased iron absorption and loss of the normal regulation of iron delivery to transferrin by reticuloendothelial cells (Beutler, 2003; Ajioka and Kushner, 2003). The resulting increased saturation of transferrin permits abnormal iron deposition in nonhematopoietic tissues.

Iron Requirements and the Availability of Dietary Iron. Iron requirements are determined by obligatory physiological losses and the needs imposed by growth. Thus, adult men require only 13 $\mu\text{g}/\text{kg}$ per day (about 1 mg), whereas menstruating women require about 21 $\mu\text{g}/\text{kg}$ per day (about 1.4 mg). In the last two trimesters of pregnancy, requirements increase to about 80 $\mu\text{g}/\text{kg}$ per day (5 to 6 mg), and infants have similar requirements due to their rapid growth. These requirements (Table 53–4) must be considered in the context of the amount of dietary iron available for absorption.

In developed countries, the normal adult diet contains about 6 mg of iron per 1000 calories, providing an average daily intake for adult men of between 12 and 20 mg and for adult women of between 8 and 15 mg. Foods high

in iron (>5 mg/100 g) include organ meats such as liver and heart, brewer's yeast, wheat germ, egg yolks, oysters, and certain dried beans and fruits; foods low in iron (<1 mg/100 g) include milk and milk products and most non-green vegetables. The content of iron in food is affected further by the manner of its preparation, since iron may be added from cooking in iron pots.

Although the iron content of the diet obviously is important, of greater nutritional significance is the bioavailability of iron in food. Heme iron, which constitutes only 6% of dietary iron, is far more available and is absorbed independent of the diet composition; it therefore represents 30% of iron absorbed (Conrad and Umbreit, 2002).

The nonheme fraction nonetheless represents by far the largest amount of dietary iron ingested by the economically underprivileged. In a vegetarian diet, nonheme iron is absorbed very poorly because of the inhibitory action of a variety of dietary components, particularly phosphates. Ascorbic acid and meat facilitate the absorption of nonheme iron. Ascorbate forms complexes with and/or reduces ferric to ferrous iron. Meat facilitates the absorption of iron by stimulating production of gastric acid; other effects also may be involved. Either of these substances can increase availability severalfold. Thus, assessment of available dietary iron should include both the amount of iron ingested and an estimate of its availability (Figure 53–4) (Monsen *et al.*, 1978).

A comparison of iron requirements with available dietary iron is seen in Table 53–4. Obviously, pregnancy and infancy represent periods of negative balance. Menstruating women also are at risk, whereas iron balance in adult men and nonmenstruating women is reasonably secure. The difference between dietary supply and require-

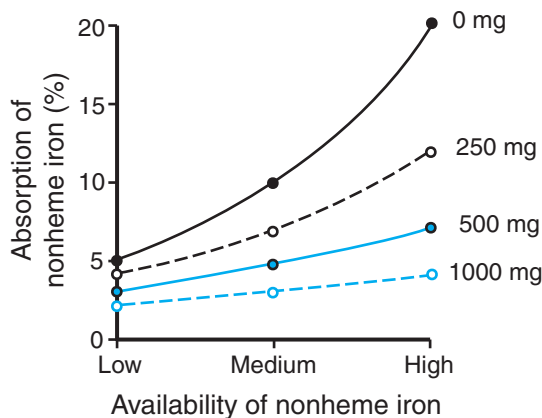

Figure 53-4. Effect of iron status on the absorption of nonheme iron in food. The percentages of iron absorbed from diets of low, medium, and high bioavailability in individuals with iron stores of 0, 250, 500, and 1000 mg are portrayed. (After Monsen *et al.*, 1978; used with permission.)

ments is reflected in the size of iron stores, which are low or absent when iron balance is precarious and high when iron balance is favorable (Table 53-2). Thus, in infants after the third month of life and in pregnant women after the first trimester, stores of iron are negligible. Menstruating women have approximately one-third the stored iron found in adult men, indicative of the extent to which the additional average daily loss of about 0.5 mg of iron affects iron balance.

Iron Deficiency. Iron deficiency is the most common nutritional disorder (World Health Organization, 2003; Hoffbrand and Herbert, 1999). The prevalence of iron-deficiency anemia in the United States is on the order of 1% to 4% (Anonymous, 2002) and depends on the economic status of the population. In developing countries, up to 20% to 40% of infants and pregnant women may be affected. Better iron balance has resulted from the practice of fortifying flour, the use of iron-fortified formulas for infants, and the prescription of medicinal iron supplements during pregnancy.

Iron-deficiency anemia results from dietary intake of iron that is inadequate to meet normal requirements (nutritional iron deficiency), blood loss, or interference with iron absorption. Most nutritional iron deficiency in the United States is mild. More severe iron deficiency is usually the result of blood loss, either from the gastrointestinal tract, or in women, from the uterus. Impaired absorption of iron from food results most often from partial gastrectomy or malabsorption in the small intestine. Finally, treatment of patients with

erythropoietin can result in a functional iron deficiency (Beutler, 2003).

Iron deficiency in infants and young children can lead to behavioral disturbances and can impair development, which may not be fully reversible. Iron deficiency in children also can lead to an increased risk of lead toxicity secondary to pica and an increased absorption of heavy metals. Premature and low-birth-weight infants are at greatest risk for developing iron deficiency, especially if they are not breast-fed and/or do not receive iron-fortified formula. After age 2 to 3, the requirement for iron declines until adolescence, when rapid growth combined with irregular dietary habits again increase the risk of iron deficiency. Adolescent girls are at greatest risk; the dietary iron intake of most girls ages 11 to 18 is insufficient to meet their requirements.

The recognition of iron deficiency rests on an appreciation of the sequence of events that lead to depletion of iron stores (Hillman and Finch, 1997; Beutler, 2003). A negative balance first results in a reduction of iron stores, and eventually a parallel decrease in red-cell iron and iron-related enzymes (Figure 53-5). In adults, depletion of iron stores may be recognized by a plasma ferritin of less than 12 $\mu\text{g/L}$ and the absence of reticuloendothelial hemosiderin in the marrow aspirate. Iron-deficient erythropoiesis is identified by a decreased saturation of transferrin to less than 16% and/or by an increase above normal in red-cell protoporphyrin. Iron-deficiency anemia is associated with a recognizable decrease in the concentration of hemoglobin in blood. However, the physiological variation in hemoglobin levels is so great that only about half the individuals with iron-deficient erythropoiesis are identified from their anemia. Moreover, “normal” hemoglobin and iron values in infancy and childhood are lower because of the more restricted supply of iron in young children (Dallman *et al.*, 1980).

In mild iron deficiency, identifying the underlying cause is more important than any symptoms related to the deficiency state. Because of the frequency of iron deficiency in infants and in menstruating or pregnant women, the need for exhaustive evaluation of such individuals usually is determined by the severity of the anemia. However, iron deficiency in men or postmenopausal women necessitates a search for a site of bleeding.

Although the presence of microcytic anemia is the most common indicator of iron deficiency, laboratory tests—such as quantitation of transferrin saturation, red cell protoporphyrin, and plasma ferritin—are required to distinguish iron deficiency from other causes of microcytosis. Such measurements are particularly useful when circulating red cells are not yet microcytic because of the recent nature of blood loss, but iron supply nonetheless limits erythropoiesis. More difficult is the differentiation of true iron deficiency from iron-deficient erythropoiesis due to inflammation. In the latter condition, iron stores actually are increased, but the release of iron from reticuloendothelial cells is blocked; the concentration of iron in plasma is decreased, and the supply of iron to the erythroid marrow becomes inadequate. The increased stores of iron in this condition may be demonstrated directly by examination of an aspirate of marrow or may be inferred from determination of an elevated plasma concentration of ferritin.

	Normal	Iron Depletion	Iron-Deficient Erythropoiesis	Iron-Deficiency Anemia
Iron Stores				
Erythron Iron

Figure 53–5. Sequential changes (from left to right) in the development of iron deficiency in the adult. Rectangles enclose abnormal test results. RE marrow Fe, reticuloendothelial hemosiderin; RBC, red blood cells. (Adapted from Hillman and Finch, 1997. Used with permission.)

Treatment of Iron Deficiency

General Therapeutic Principles. The response of iron-deficiency anemia to iron therapy is influenced by several factors, including the severity of anemia, the ability of the patient to tolerate and absorb medicinal iron, and the presence of other complicating illnesses. Therapeutic effectiveness is best measured by the resulting increase in the rate of production of red cells. The magnitude of the marrow response to iron therapy is proportional to the severity of the anemia (level of erythropoietin stimulation) and the amount of iron delivered to marrow precursors.

The patient's ability to tolerate and absorb medicinal iron is a key factor in determining the rate of response to therapy. The small intestine regulates absorption, and with increasing doses of oral iron, limits the entry of iron into the bloodstream. This provides a natural ceiling on how much iron can be supplied by oral therapy. In the patient with a moderately severe iron-deficiency anemia, tolerable doses of oral iron will deliver, at most, 40 to 60 mg of iron per day to the erythroid marrow. This is an amount sufficient for production rates of two to three times normal.

Complicating illness also can interfere with the response of an iron-deficiency anemia to iron therapy.

By decreasing the number of red cell precursors, intrinsic disease of the marrow can blunt the response. Inflammatory illnesses suppress the rate of red cell production, both by reducing iron absorption and reticuloendothelial release and by direct inhibition of erythropoietin and erythroid precursors. Continued blood loss can mask the response as measured by recovery of the hemoglobin or hematocrit.

Clinically, the effectiveness of iron therapy is best evaluated by tracking the reticulocyte response and the rise in the hemoglobin or the hematocrit. An increase in the reticulocyte count is not observed for at least 4 to 7 days after beginning therapy. A measurable increase in the hemoglobin level takes even longer. A decision as to the effectiveness of treatment should not be made for 3 to 4 weeks after the start of treatment. An increase of 20 g per liter or more in the concentration of hemoglobin by that time should be considered a positive response, assuming that no other change in the patient's clinical status can account for the improvement and that the patient has not been transfused.

If the response to oral iron is inadequate, the diagnosis must be reconsidered. A full laboratory evaluation should be conducted, and poor compliance by the patient or the presence of a concurrent inflammatory disease must be explored. A source of continued bleeding obviously should be sought. If no other explanation can be found, an evaluation of the patient's ability to absorb oral iron should be considered. There is no justification for merely continuing oral iron therapy beyond 3 to 4 weeks if a favorable response has not occurred.

Once a response to oral iron is demonstrated, therapy should be continued until the hemoglobin returns to normal. Treatment may be extended if it is desirable to replenish iron stores. This may require a considerable period of time, since the rate of absorption of iron by the intestine will decrease markedly as iron stores are reconstituted. The prophylactic use of oral iron should be reserved for patients at high risk, including pregnant women, women with excessive menstrual blood loss, and infants. Iron supplements also may be of value for rapidly growing infants who are consuming substandard diets and for adults with a recognized cause of chronic blood loss. Except for infants, in whom the use of supplemented formulas is routine, the use of over-the-counter mixtures of vitamins and minerals to prevent iron deficiency should be discouraged.

Therapy with Oral Iron. Orally administered *ferrous sulfate* is the treatment of choice for iron deficiency. Ferrous salts are absorbed about three times as well as ferric salts, and the discrepancy becomes even greater at high dosages. Variations in the particular ferrous salt have relatively little effect on bioavailability, and the sulfate, fumarate, succinate, gluconate, and other ferrous salts are absorbed to approximately the same extent.

Ferrous sulfate (FEOSOL, others) is the hydrated salt, $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, which contains 20% iron. *Dried ferrous sulfate* (32% elemental iron) is also available. *Ferrous fumarate* (FEOSTAT, others) contains 33% iron and is moderately soluble in water, stable, and almost tasteless. *Ferrous gluconate* (FERGON, others) also has been successfully used in the therapy of iron-deficiency anemia. The gluconate contains 12% iron. *Polysaccharide-iron complex* (NIFEREX, others), a compound of ferrihydrite and carbohydrate, is another preparation with comparable absorption. The effective dose of all of these preparations is based on iron content.

Other iron compounds have utility in fortification of foods. Reduced iron (metallic iron, elemental iron) is as effective as ferrous sulfate, provided that the material employed has a small particle size. Large-particle *ferrum reductum* and iron phosphate salts have a much lower bioavailability, and their use for the fortification of foods is undoubtedly responsible for some of the confusion concerning effectiveness. *Ferric edetate* has been shown to have good bioavailability and to have advantages for maintenance of the normal appearance and taste of food.

The amount of iron, rather than the mass of the total salt in iron tablets, is important. It also is essential that the coating of the tablet dissolve rapidly in the stomach. Surprisingly, since iron usually is absorbed in the upper small intestine, certain delayed-release preparations have been reported to be effective and have been said to be even more effective than ferrous sulfate when taken with meals. However, reports of absorption from such preparations vary. Because a number of forms of delayed-release preparations are on the market, and information on their bioavailability is limited, the effectiveness of most such preparations must be considered questionable.

A variety of substances designed to enhance the absorption of iron has been marketed, including surface-acting agents, carbohydrates, inorganic salts, amino acids, and vitamins. When present in an amount of 200 mg or more, ascorbic acid increases the absorption of medicinal iron by at least 30%. However, the increased

uptake is associated with a significant increase in the incidence of side effects; therefore, the addition of ascorbic acid seems to have little advantage over increasing the amount of iron administered. It is inadvisable to use preparations that contain other compounds with therapeutic actions of their own, such as vitamin B₁₂, folate, or cobalt, because the patient's response to the combination cannot easily be interpreted.

The average dose for the treatment of iron-deficiency anemia is about 200 mg of iron per day (2 to 3 mg/kg), given in three equal doses of 65 mg. Children weighing 15 to 30 kg can take half the average adult dose, while small children and infants can tolerate relatively large doses of iron—for example, 5 mg/kg. The dose used is a compromise between the desired therapeutic action and the toxic effects. Prophylaxis and mild nutritional iron deficiency may be managed with modest doses. When the object is the prevention of iron deficiency in pregnant women, for example, doses of 15 to 30 mg of iron per day are adequate to meet the 3- to 6-mg daily requirement of the last two trimesters. When the purpose is to treat iron-deficiency anemia, but the circumstances do not demand haste, a total dose of about 100 mg (35 mg three times daily) may be used.

The responses expected for different dosage regimens of oral iron are given in Table 53–5. These effects are modified by the severity of the iron-deficiency anemia and by the time of ingestion of iron relative to meals. Bioavailability of iron ingested with food is probably one-half or one-third of that seen in the fasting subject (Grebe *et al.*, 1975). Antacids also reduce iron absorption if given concurrently. It is always preferable to administer iron in the fasting state, even if the dose must be reduced because of gastrointestinal side effects. For patients who require maximal therapy to encourage a rapid response or to counteract continued bleeding, as much as 120 mg of iron may be administered four times a day. Sustained high rates of red cell production require an uninterrupted supply of iron, and oral doses should be spaced equally to maintain a continuous high concentration of iron in plasma.

The duration of treatment is governed by the rate of recovery of hemoglobin and the desire to create iron stores. The former depends on the severity of the anemia. With a daily rate of repair of 2 g of hemoglobin per liter of whole blood, the red cell mass usually is reconstituted within 1 to 2 months. Thus, an individual with a hemoglobin of 50 g per liter may achieve a normal complement of 150 g per liter in about 50 days, whereas an individual

Table 53–5
Average Response to Oral Iron

TOTAL DOSE, mg of iron per day	ESTIMATED ABSORPTION		INCREASE IN HEMOGLOBIN, g/liter of blood per day
	%	mg	
35	40	14	0.7
105	24	25	1.4
195	18	35	1.9
390	12	45	2.2

with a hemoglobin of 100 g per liter may take only half that time. The creation of stores of iron requires many months of oral iron administration. The rate of absorption decreases rapidly after recovery from anemia, and after 3 to 4 months of treatment, stores may increase at a rate of not much more than 100 mg per month. Much of the strategy of continued therapy depends on the estimated future iron balance. Patients with an inadequate diet may require continued therapy with low doses of iron. If the bleeding has stopped, no further therapy is required after the hemoglobin has returned to normal. With continued bleeding, long-term, high-dose therapy clearly is indicated.

Untoward Effects of Oral Preparations of Iron. Intolerance to oral preparations of iron primarily is a function of the amount of soluble iron in the upper GI tract and of psychological factors. Side effects include heartburn, nausea, upper gastric discomfort, and diarrhea or constipation. A good policy is to initiate therapy at a small dosage, to demonstrate freedom from symptoms at that level, and then gradually to increase the dosage to that desired. With a dose of 200 mg of iron per day divided into three equal portions, symptoms occur in approximately 25% of treated individuals *versus* 13% among those receiving placebo; this increases to approximately 40% when the dosage of iron is doubled. Nausea and upper abdominal pain are increasingly common at high dosage. Constipation and diarrhea, perhaps related to iron-induced changes in the intestinal bacterial flora, are not more prevalent at higher dosage, nor is heartburn. If a liquid is given, one can place the iron solution on the back of the tongue with a dropper to prevent transient staining of teeth.

The normal individual apparently is able to control absorption of iron despite high intake, and it is only individuals with underlying disorders that augment the absorption of iron who run the hazard of developing iron overload (hemochromatosis). However, hemochromatosis is a relatively common genetic disorder, present in 0.5% of the population.

Iron Poisoning. Large amounts of ferrous salts are toxic, but fatalities are rare in adults. Most deaths occur in children, particularly between the ages of 12 and 24 months. As little as 1 to 2 g of iron may cause death, but 2 to 10 g usually is ingested in fatal cases. The frequency of iron poisoning relates to its availability in the household, particularly the supply that remains after a pregnancy. The colored sugar coating of many of the commercially available tablets gives them the appearance of candy. *All iron preparations should be kept in childproof bottles.*

Signs and symptoms of severe poisoning may occur within 30 minutes after ingestion or may be delayed for several hours. They include abdominal pain, diarrhea, or vomiting of brown or bloody stomach contents containing pills. Of particular concern are pallor or cyanosis, lassitude, drowsiness, hyperventilation due to acidosis, and cardiovascular collapse. If death does not occur within 6

hours, there may be a transient period of apparent recovery, followed by death in 12 to 24 hours. The corrosive injury to the stomach may result in pyloric stenosis or gastric scarring. Hemorrhagic gastroenteritis and hepatic damage are prominent findings at autopsy. In the evaluation of a child thought to have ingested iron, a color test for iron in the gastric contents and an emergency determination of the concentration of iron in plasma can be performed. If the latter is less than 63 μmol (3.5 mg per liter), the child is not in immediate danger. However, vomiting should be induced when there is iron in the stomach, and an x-ray should be taken to evaluate the number of pills remaining in the small bowel (iron tablets are radiopaque). Iron in the upper GI tract can be precipitated by lavage with sodium bicarbonate or phosphate solution, although the clinical benefit is questionable. When the plasma concentration of iron is greater than the total iron-binding capacity (63 μmol ; 3.5 mg per liter), *deferoxamine* should be administered; dosage and routes of administration are detailed in Chapter 65. Shock, dehydration, and acid-base abnormalities should be treated in the conventional manner. Most important is the speed of diagnosis and therapy. With early effective treatment, the mortality from iron poisoning can be reduced from as high as 45% to about 1%.

Therapy with Parenteral Iron. When oral iron therapy fails, parenteral iron administration may be an effective alternative (Silverstein and Rodgers, 2004). The rate of response to parenteral therapy is similar to that which follows usual oral doses. Common indications are iron malabsorption (*e.g.*, sprue, short bowel syndrome), severe oral iron intolerance, as a routine supplement to total parenteral nutrition, and in patients who are receiving erythropoietin (Eschbach *et al.*, 1987). Parenteral iron also has been given to iron-deficient patients and pregnant women to create iron stores, something that would take months to achieve by the oral route. *Parenteral iron therapy should be used only when clearly indicated, since acute hypersensitivity, including anaphylactic and anaphylactoid reactions, can occur in 0.2% to 3% of patients.* The belief that the response to parenteral iron, especially *iron dextran*, is faster than oral iron is open to debate. In otherwise healthy individuals, the rate of hemoglobin response is determined by the balance between the severity of the anemia (the level of erythropoietin stimulus) and the delivery of iron to the marrow from iron absorption and iron stores. When a large intravenous dose of iron dextran is given to a severely anemic patient, the hematologic response can exceed that seen with oral iron for 1 to 3 weeks. Subsequently, however, the response is no better than that seen with oral iron.

Three preparations of iron are FDA-approved for parenteral therapy, sodium ferric gluconate complex in sucrose (FERR-LECTIT), iron sucrose (SACCHARATE), and iron dextran (INFED, DEXFERRUM). Unlike iron dextran, which requires processing by

macrophages that may require several weeks, approximately 80% of sodium ferric gluconate is delivered to transferrin with 24 hours. Sodium ferric gluconate also has a much lower risk of inducing serious anaphylactic reactions than iron dextran (Michael *et al.*, 2002). No deaths were reported with 25 million infusions of sodium ferric gluconate, whereas there were 31 infusion-related deaths reported from approximately half the number of patients treated with iron dextran (Faich and Strobos, 1999). Thus, sodium ferric gluconate is the preferred agent for parenteral iron therapy. Currently, iron dextran is reserved for noncompliant patients or for those who are seriously inconvenienced by the multiple infusions that may be required for treatment with sodium ferric gluconate (Beutler, 2003). *Sodium ferric gluconate complex in sucrose* (FERRELECIT) was approved by the FDA for the treatment of iron deficiency in patients undergoing chronic hemodialysis who are receiving supplemental erythropoietin therapy (Eichbaum *et al.*, 2003).

Iron sucrose (SACCHARATE) also is approved for use in the United States, providing yet another form of parenteral iron for treatment of patients with iron deficiency intractable to therapy with oral iron. Like sodium ferric gluconate, iron sucrose appears to be better tolerated than iron dextran (Fishbane and Kowalski, 2000; Michaud, *et al.*, 2002). However, the experience with iron sucrose is much more limited than that with either iron dextran or sodium ferric gluconate.

Iron dextran injection (INFED, DEXFERRUM) is a colloidal solution of ferric oxyhydroxide complexed with polymerized dextran (molecular weight approximately 180,000) that contains 50 mg/ml of elemental iron. It can be administered by either intravenous (preferred) or intramuscular injection. When given by deep intramuscular injection, it is gradually mobilized *via* the lymphatics and transported to reticuloendothelial cells; the iron then is released from the dextran complex. Intravenous administration gives a more reliable response. Given intravenously in a dose of less than 500 mg, the iron dextran complex is cleared exponentially with a plasma half-life of 6 hours. When 1 g or more is administered intravenously as total dose therapy, reticuloendothelial cell clearance is constant at 10 to 20 mg/hour. This slow rate of clearance results in a brownish discoloration of the plasma for several days and an elevation of the serum iron for 1 to 2 weeks.

Once the iron is released from the dextran within the reticuloendothelial cells, it is either incorporated into stores or transported *via* transferrin to the erythroid marrow. While a portion of the processed iron is rapidly made available to the marrow, a significant fraction is only gradually converted to usable iron stores. All of the iron eventually is released, although many months are required before the process is complete. During this time, the iron dextran stores in reticuloendothelial cells can confuse the clinician who attempts to evaluate the iron status of the patient.

Intramuscular injection of iron dextran should only be initiated after a test dose of 0.5 ml (25 mg of iron). If no adverse reactions are observed, the injections can proceed. The daily dose ordinarily should not exceed 0.5 ml (25 mg of iron) for infants weighing less than 4.5 kg (10 lb), 1 ml (50 mg of iron) for children weighing less than 9 kg (20 lb), and 2 ml (100 mg of iron) for other patients. Iron dextran should be injected only into the muscle mass of the upper outer quadrant of the buttock using a z-track technique (displacement of the skin laterally before injection). However, local reactions and the concern about malignant change at the site of injection

(Weinren *et al.*, 1978) make intramuscular administration inappropriate except when the intravenous route is inaccessible.

A test injection of 0.5 ml of undiluted iron dextran or an equivalent amount (25 mg of iron) diluted in saline also should precede intravenous administration of a therapeutic dose of iron dextran. The patient should be observed for signs of immediate anaphylaxis, and for an hour after injection for any signs of vascular instability or hypersensitivity, including respiratory distress, hypotension, tachycardia, or back or chest pain. When widely spaced, total-dose infusion therapy is given, a test dose injection should be given before each infusion because hypersensitivity can appear at any time. Furthermore, the patient should be monitored closely throughout the infusion for signs of cardiovascular instability. Delayed hypersensitivity reactions also are observed, especially in patients with rheumatoid arthritis or a history of allergies. Fever, malaise, lymphadenopathy, arthralgias, and urticaria can develop days or weeks following injection and last for prolonged periods of time. Therefore, iron dextran should be used with extreme caution in patients with rheumatoid arthritis or other connective tissue diseases, and during the acute phase of an inflammatory illness. Once hypersensitivity is documented, iron dextran therapy must be abandoned.

Before initiating iron dextran therapy, the total dose of iron required to repair the patient's iron-deficient state should be calculated. Relevant factors are the hemoglobin deficit, the need to reconstitute iron stores, and continued excess losses of iron, as seen with hemodialysis and chronic GI bleeding. Iron dextran solution (50 mg/ml of elemental iron) can be administered undiluted in daily doses of 2 ml until the total dose is reached or given as a single total-dose infusion. In the latter case, the iron dextran should be diluted in 250 to 1000 ml of 0.9% saline and infused over an hour or more.

When hemodialysis patients are started on erythropoietin, oral iron therapy alone generally is insufficient to guarantee an optimal hemoglobin response. It therefore is recommended that sufficient parenteral iron be given to maintain a plasma ferritin level between 100 and 800 $\mu\text{g/L}$ and a transferrin saturation of between 20% and 50% (Goodnough *et al.*, 2000). One approach is to administer an initial intravenous dose of 200 to 500 mg, followed by weekly or every-other-week injections of 25 to 100 mg of iron dextran to replace ongoing blood loss (Besarab *et al.*, 1999). With repeated doses of iron dextran—especially multiple, total-dose infusions such as those sometimes used in the treatment of chronic GI blood loss—accumulations of slowly metabolized iron dextran stores in reticuloendothelial cells can be impressive. The plasma ferritin level also can rise to levels associated with iron overload. While disease-related hemochromatosis has been associated with an increased risk of infections and cardiovascular disease, this has not been shown to be true in hemodialysis patients treated with iron dextran (Owen, 1999). It seems prudent, however, to withhold the drug whenever the plasma ferritin rises above 800 $\mu\text{g/L}$.

Reactions to intravenous iron include headache, malaise, fever, generalized lymphadenopathy, arthralgias, urticaria, and in some patients with rheumatoid arthritis, exacerbation of the disease. Phlebitis may occur with prolonged infusions of a concentrated solution or when an intramuscular preparation containing 0.5% phenol is used in error. Of greatest concern is the rare anaphylactic reaction, which may be fatal despite treatment (Faich and Strobos, 1999).

COPPER

Copper deficiency is extremely rare because the amount present in food is more than adequate to provide the needed body complement of slightly more than 100 mg. There is no evidence that copper ever needs to be added to a normal diet, either prophylactically or therapeutically. Even in clinical states associated with hypocupremia (sprue, celiac disease, and nephrotic syndrome), effects of copper deficiency usually are not demonstrable. Anemia due to copper deficiency has been described in individuals who have undergone intestinal bypass surgery (Zidar *et al.*, 1977), in those who are receiving parenteral nutrition (Dunlap *et al.*, 1974), in malnourished infants (Graham and Cordano, 1976), and in patients ingesting excessive amounts of zinc (Hoffman *et al.*, 1988). While an inherited disorder affecting the transport of copper in human beings (Menkes' disease; steely hair syndrome) is associated with reduced activity of several copper-dependent enzymes, this disease is not associated with hematological abnormalities.

Copper deficiency in experimental animals interferes with the absorption of iron and its release from reticuloendothelial cells (Lee *et al.*, 1976). The associated microcytic anemia is related to a decrease in the availability of iron to the normoblasts, and perhaps even more importantly, to decreased mitochondrial production of heme. It may be that the specific defect in the latter case is a decrease in the activity of cytochrome oxidase. Other pathological effects involving the skeletal, cardiovascular, and nervous systems have been observed in copper-deficient experimental animals. In human beings, the outstanding findings have been leukopenia, particularly granulocytopenia, and anemia. Concentrations of iron in plasma are variable, and the anemia is not always microcytic. When a low plasma copper concentration is determined in the presence of leukopenia and anemia, a therapeutic trial with copper is appropriate. Daily doses up to 0.1 mg/kg of *cupric sulfate* have been given by mouth, or 1 to 2 mg per day may be added to the solution of nutrients for parenteral administration.

PYRIDOXINE

Harris and associates first described pyridoxine-responsive anemia in 1956. Subsequent reports suggested that the vitamin might improve hematopoiesis in up to 50% of patients with either hereditary or acquired sidero-

blastic anemia. These patients characteristically have impaired hemoglobin synthesis and accumulate iron in the perinuclear mitochondria of erythroid precursor cells, so-called ringed sideroblasts. Hereditary sideroblastic anemia is an X-linked recessive trait with variable penetrance and expression that results from mutations in the erythrocyte form of δ -aminolevulinic synthase. Affected men typically show a dual population of normal red cells and microcytic, hypochromic cells in the circulation. In contrast, idiopathic acquired sideroblastic anemia and the sideroblastic anemias associated with a number of drugs, inflammatory states, neoplastic disorders, and preleukemic syndromes show a variable morphological picture. Moreover, erythrokinetic studies demonstrate a spectrum of abnormalities, from a hypoproliferative defect with little tendency to accumulate iron to marked ineffective erythropoiesis with iron overload of the tissues (Solomon and Hillman, 1979a).

Oral therapy with pyridoxine is of proven benefit in correcting the sideroblastic anemias associated with the antituberculosis drugs *isoniazid* and *pyrazinamide*, which act as vitamin B₆ antagonists. A daily dose of 50 mg of pyridoxine completely corrects the defect without interfering with treatment, and routine supplementation of pyridoxine often is recommended (*see* Chapter 47). In contrast, if pyridoxine is given to counteract the sideroblastic abnormality associated with administration of levodopa, the effectiveness of levodopa in controlling Parkinson's disease is decreased. Pyridoxine therapy does not correct the sideroblastic abnormalities produced by chloramphenicol or lead.

Patients with idiopathic acquired sideroblastic anemia generally fail to respond to oral pyridoxine, and those individuals who appear to have a pyridoxine-responsive anemia require prolonged therapy with large doses of the vitamin, 50 to 500 mg per day. Unfortunately, the early enthusiasm for treatment with pyridoxine was not reinforced by results of later studies (Chillar *et al.*, 1976; Solomon and Hillman, 1979a). Moreover, even when a patient with sideroblastic anemia responds, the improvement is only partial because both the ringed sideroblasts and the red cell defect persist, and the hematocrit rarely returns to normal. Nonetheless, in view of the low toxicity of oral pyridoxine, a therapeutic trial with pyridoxine is appropriate.

As shown in studies of normal subjects, oral pyridoxine in a dosage of 100 mg three times daily produces a maximal increase in red cell pyridoxine kinase and the major pyridoxal phosphate-dependent enzyme glutamic-aspartic aminotransferase (Solomon and Hillman, 1978). For an adequate therapeutic trial, the drug is administered for at least 3 months while the response is monitored by measuring the reticulocyte index and the hemoglobin concentration. The occasional patient who is refractory to oral pyridoxine may respond to parenteral administration of pyridoxal phosphate. However, oral pyridoxine in doses of 200 to 300 mg per day produces intracellular concentrations of pyridoxal phosphate equal to or greater than those generated by therapy with the phosphorylated vitamin (Solomon and Hillman, 1979b).

RIBOFLAVIN

Pure red cell aplasia that responded to the administration of riboflavin was reported in patients with protein depletion and complicating infections. Lane and associates induced riboflavin deficiency in human beings and demonstrated that a hypoproliferative anemia resulted within a month. The spontaneous appearance in human beings of red cell aplasia due to riboflavin deficiency undoubtedly is rare, if it occurs at all. It has been described in combination with infection and protein deficiency, both of which are capable of producing a hypoproliferative anemia. However, it seems reasonable to include riboflavin in the nutritional management of patients with gross, generalized malnutrition.

III. VITAMIN B₁₂, FOLIC ACID, AND THE TREATMENT OF MEGALOBLASTIC ANEMIAS

Vitamin B₁₂ and *folic acid* are dietary essentials. A deficiency of either vitamin impairs DNA synthesis in any cell in which chromosomal replication and division are taking place. Since tissues with the greatest rate of cell turnover show the most dramatic changes, the hematopoietic system is especially sensitive to deficiencies of these vitamins. An early sign of deficiency is megaloblastic anemia. Abnormal macrocytic red blood cells are produced, and the patient becomes severely anemic. Recognized in the 19th century, this pattern of abnormal hematopoiesis, termed *pernicious anemia*, spurred investigations that ultimately led to the discovery of vitamin B₁₂ and folic acid. Even today, the characteristic abnormality in red blood cell morphology is important for diagnosis and as a therapeutic guide following administration of the vitamins.

History. The discovery of vitamin B₁₂ and folic acid is a dramatic story that started more than 180 years ago and includes two Nobel prize-winning discoveries. The first descriptions of what must have been megaloblastic anemias came from the work of Combe and Addison, who published a series of case reports beginning in 1824. It still is common practice to describe megaloblastic anemia as Addisonian pernicious anemia. Although Combe suggested that the disorder might have some relationship to digestion, it was Austin Flint who in 1860 first described the severe gastric atrophy and called attention to its possible relationship to the anemia.

After the observation by Whipple in 1925 that liver is a source of a potent hematopoietic substance for iron-deficient dogs, Minot

and Murphy carried out Nobel Prize-winning experiments that demonstrated the effectiveness of the feeding of liver to reverse pernicious anemia. Soon thereafter, Castle defined the need for both intrinsic factor, a substance secreted by the parietal cells of the gastric mucosa, and extrinsic factor, the vitamin-like material provided by crude liver extracts. Nearly 20 years passed before Rickes and coworkers and Smith and Parker isolated and crystallized vitamin B₁₂; Dorothy Hodgkin received the Nobel Prize for determining its x-ray crystal structure.

As attempts were being made to purify extrinsic factor, Wills and her associates described a macrocytic anemia in women in India that responded to a factor present in crude liver extracts but not in the purified fractions known to be effective in pernicious anemia. This factor, first called Wills' factor and later vitamin M, is now known to be folic acid. The term folic acid was coined by Mitchell and coworkers in 1941, after its isolation from leafy vegetables.

More recent work has shown that neither vitamin B₁₂ nor folic acid as purified from foodstuffs is the active coenzyme for human beings. During extraction, active, labile forms are converted to stable congeners of vitamin B₁₂ and folic acid, *cyanocobalamin* and *pteroylglutamic acid*, respectively. These congeners must then be modified *in vivo* to be effective. While a great deal has been learned about the intracellular metabolic pathways in which these vitamins function as required cofactors, many questions remain. The most important of these is the relationship of vitamin B₁₂ deficiency to the neurological abnormalities that occur with this disorder (Charnarin *et al.*, 1985).

Relationships Between Vitamin B₁₂ and Folic Acid.

The major roles of vitamin B₁₂ and folic acid in intracellular metabolism are summarized in Figure 53-6. Intracellular vitamin B₁₂ is maintained as two active coenzymes: methylcobalamin and deoxyadenosylcobalamin. Deoxyadenosylcobalamin (deoxyadenosyl B₁₂) is a cofactor for the mitochondrial mutase enzyme that catalyzes the isomerization of L-methylmalonyl CoA to succinyl CoA, an important reaction in carbohydrate and lipid metabolism. This reaction has no direct relationship to the metabolic pathways that involve folate. In contrast, methylcobalamin (CH₃B₁₂) supports the methionine synthetase reaction, which is essential for normal metabolism of folate (Weir and Scott, 1983). Methyl groups contributed by methyltetrahydrofolate (CH₃H₄PteGlu₁) are used to form methylcobalamin, which then acts as a methyl group donor for the conversion of homocysteine to methionine. This folate-cobalamin interaction is pivotal for normal synthesis of purines and pyrimidines, and therefore of DNA. The methionine synthetase reaction is largely responsible for the control of the recycling of folate cofactors; the maintenance of intracellular concentrations of folylpolyglutamates; and, through the synthesis of methionine and its product, S-adenosylmethionine, the maintenance of a number of methylation reactions.

Figure 53–6. Interrelationships and metabolic roles of vitamin B_{12} and folic acid. See text for explanation and Figure 53–9 for structures of the various folate coenzymes. FIGLU, formiminoglutamic acid, which arises from the catabolism of histidine; TcII, transcobalamin II; $\text{CH}_3\text{H}_4\text{PteGlu}_1$, methyltetrahydrofolate.

Since methyltetrahydrofolate is the principal folate congener supplied to cells, the transfer of the methyl group to cobalamin is essential for the adequate supply of tetrahydrofolate ($\text{H}_4\text{PteGlu}_1$), the substrate for a number of metabolic steps. Tetrahydrofolate is a precursor for the formation of intracellular folylpolyglutamates; it also acts as the acceptor of a one-carbon unit in the conversion of serine to glycine, with the resultant formation of 5,10-methylenetetrahydrofolate ($5,10\text{-CH}_2\text{H}_4\text{PteGlu}$). The latter derivative donates the methylene group to deoxyuridylyl (dUMP) for the synthesis of thymidylyl (dTMP)—an extremely important reaction in DNA synthesis. In the process, the $5,10\text{-CH}_2\text{H}_4\text{PteGlu}$ is converted to dihydrofolate (H_2PteGlu). The cycle then is completed by the reduction of the H_2PteGlu to H_4PteGlu by dihydrofolate reductase, the step that is blocked by folate antagonists such as methotrexate (see Chapter 51). As shown in Figure 53–6, other pathways also lead to the synthesis of 5,10-methylenetetrahydrofolate. These pathways are important in the metabolism of formiminoglutamic acid (FIGLU) and purines and pyrimidines (see reviews by Weir and Scott, 1983; Chanarin *et al.*, 1985).

In the presence of a deficiency of either vitamin B_{12} or folate, the decreased synthesis of methionine and *S*-adenosylmethionine interferes with protein biosynthesis, a number of methylation reactions, and the synthesis of

polyamines. In addition, the cell responds to the deficiency by redirecting folate metabolic pathways to supply increasing amounts of methyltetrahydrofolate; this tends to preserve essential methylation reactions at the expense of nucleic acid synthesis. With vitamin B_{12} deficiency, methylenetetrahydrofolate reductase activity increases, directing available intracellular folates into the methyltetrahydrofolate pool (not shown in Figure 53–6). The methyltetrahydrofolate then is trapped by the lack of sufficient vitamin B_{12} to accept and transfer methyl groups, and subsequent steps in folate metabolism that require tetrahydrofolate are deprived of substrate. This process provides a common basis for the development of megaloblastic anemia with deficiency of either vitamin B_{12} or folic acid.

The mechanisms responsible for the neurological lesions of vitamin B_{12} deficiency are less well understood (Weir and Scott, 1983). Damage to the myelin sheath is the most obvious lesion in this neuropathy. This observation led to the early suggestion that the deoxyadenosyl B_{12} -dependent methylmalonyl CoA mutase reaction, a step in propionate metabolism, is related to the abnormality. However, other evidence suggests that the deficiency of methionine synthetase and the block of the conversion of methionine to *S*-adenosylmethionine are more likely to be responsible (Scott *et al.*, 1981).

Nitrous oxide (N_2O), used for anesthesia (see Chapter 13), can cause megaloblastic changes in the marrow and a neuropathy that resemble those of vitamin B_{12} deficiency (Chanarin *et al.*, 1985). Studies with N_2O have demonstrated a reduction in methionine synthetase and reduced concentrations of methionine and *S*-adenosylmethionine. The latter is necessary for methylation reactions, including those required for the synthesis of phospholipids and myelin. Significantly, the neuropathy induced with N_2O can be prevented partially by feeding methionine. A neuropathy similar to that occurring with vitamin B_{12} deficiency has been reported in dentists who are exposed to N_2O used as an anesthetic.

VITAMIN B_{12}

Chemistry. The structural formula of vitamin B_{12} is shown in Figure 53–7. The three major portions of the molecule are:

A planar group or corrin nucleus—a porphyrin-like ring structure with four reduced pyrrole rings (A to D in Figure 53–7) linked to a central cobalt atom and extensively substituted with methyl, acetamide, and propionamide residues.

A 5,6-dimethylbenzimidazolyl nucleotide, which links almost at right angles to the corrin nucleus with bonds to the cobalt atom and to the propionate side chain of the C pyrrole ring.

A variable R group—the most important of which are found in the stable compounds cyanocobalamin and *hydroxocobalamin* and the active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin.

The terms *vitamin B_{12}* and *cyanocobalamin* are used interchangeably as generic terms for all of the cobamides active in humans. Preparations of vitamin B_{12} for therapeutic use contain either cyanocobalamin or hydroxocobalamin, since only these derivatives remain active after storage.

Metabolic Functions. The active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin are essential for cell growth and replication. Methylcobalamin is required for the conversion of homocysteine to methionine and its derivative *S*-adenosylmethionine. In addition, when concentrations of vitamin B_{12} are inadequate, folate becomes “trapped” as methyltetrahydrofolate to cause a functional deficiency of other required intracellular forms of folic acid (see Figures 53–6 and 53–7 and discussion above). The hematological abnormalities in vitamin B_{12} -deficient patients result from this process. 5-Deoxyadenosylcobalamin is required for the isomerization of L-methylmalonyl CoA to succinyl CoA (Figure 53–6).

Sources in Nature. Humans depend on exogenous sources of vitamin B_{12} . In nature, the primary sources are certain microorganisms that grow in soil, sewage, water,

or the intestinal lumen of animals that synthesize the vitamin. Vegetable products are free of vitamin B_{12} unless they are contaminated with such microorganisms, so that animals are dependent on synthesis in their own alimentary tract or the ingestion of animal products containing vitamin B_{12} . The daily nutritional requirement of 3 to 5 μg must be obtained from animal by-products in the diet. Despite this, strict vegetarians rarely develop vitamin B_{12} deficiency. Some vitamin B_{12} is available from legumes, which are contaminated with bacteria capable of synthesizing vitamin B_{12} , and vegetarians often fortify their diets with a wide range of vitamins and minerals.

Absorption, Distribution, Elimination, and Daily Requirements. In the presence of gastric acid and pancreatic proteases, dietary vitamin B_{12} is released from

food and salivary binding protein and bound to gastric intrinsic factor. When the vitamin B₁₂-intrinsic factor complex reaches the ileum, it interacts with a receptor on the mucosal cell surface and is actively transported into circulation. Adequate intrinsic factor, bile, and sodium bicarbonate (to provide a suitable pH) all are required for ileal transport of vitamin B₁₂. Vitamin B₁₂ deficiency in adults is rarely the result of a deficient diet *per se*; rather, it usually reflects a defect in one or another aspect of this complex sequence of absorption (Figure 53–8). Achlorhydria and decreased secretion of intrinsic factor by parietal cells secondary to gastric atrophy or gastric surgery is a common cause of vitamin B₁₂ deficiency in adults. Antibodies to parietal cells or intrinsic factor complex also can play a prominent role in producing a deficiency. A number of intestinal diseases can interfere with absorption, including pancreatic disorders (loss of pancreatic protease secretion), bacterial overgrowth, intestinal parasites, sprue, and localized damage to ileal mucosal cells by disease or as a result of surgery.

Once absorbed, vitamin B₁₂ binds to transcobalamin II, a plasma β -globulin, for transport to tissues. Two other transcobalamins (I and III) also are present in plasma; their concentrations are related to the rate of turnover of granulocytes. They may represent intracellular storage proteins that are released with cell death. Vitamin B₁₂ bound to transcobalamin II is rapidly cleared from plasma and preferentially distributed to hepatic parenchymal cells. The liver is a storage depot for other tissues. In normal adults, as much as 90% of the body's stores of vitamin B₁₂, from 1 to 10 mg, is in the liver. Vitamin B₁₂ is stored as the active coenzyme with a turnover rate of 0.5 to 8 μ g per day, depending on the size of the body stores. The recommended daily intake of the vitamin in adults is 2.4 μ g.

Approximately 3 μ g of cobalamins is secreted into bile each day, 50% to 60% of which is not destined for reabsorption. This enterohepatic cycle is important because interference with reabsorption by intestinal disease can progressively deplete hepatic stores of the vitamin. This process may help explain why patients can develop vitamin B₁₂ deficiency within 3 to 4 years of major gastric surgery, even though a daily requirement of 1 to 2 μ g would not be expected to deplete hepatic stores of more than 2 to 3 mg during this time.

The supply of vitamin B₁₂ available for tissues is directly related to the size of the hepatic storage pool and the amount of vitamin B₁₂ bound to transcobalamin II (Figure 53–8). The plasma concentration of vitamin B₁₂ is the best routine measure of B₁₂ deficiency, and normally ranges from 150 to 660 pmol (about 200 to 900 pg/ml). Deficiency should be suspected whenever the con-

Figure 53–8. The absorption and distribution of vitamin B₁₂. Deficiency of vitamin B₁₂ can result from a congenital or acquired defect in any one of the following: (1) inadequate dietary supply; (2) inadequate secretion of intrinsic factor (classical pernicious anemia); (3) ileal disease; (4) congenital absence of transcobalamin II (TcII); or (5) rapid depletion of hepatic stores by interference with reabsorption of vitamin B₁₂ excreted in bile. The utility of measurements of the concentration of vitamin B₁₂ in plasma to estimate supply available to tissues can be compromised by liver disease and (6) the appearance of abnormal amounts of transcobalamins I and III (TcI and TcIII) in plasma. Finally, the formation of methylcobalamin requires (7) normal transport into cells and an adequate supply of folic acid as CH₃H₄PteGlu₁.

centration falls below 150 pmol. The correlation is excellent except when the plasma concentrations of transcobalamin I and III are increased, as occurs with hepatic disease or a myeloproliferative disorder. Inasmuch as the vitamin B₁₂ bound to these transport proteins is relatively unavailable to cells, tissues can become deficient when the concentration of vitamin B₁₂ in plasma is normal or even high. In subjects with congenital absence of transcobalamin II, megaloblastic anemia occurs despite relatively normal plasma concentrations of vitamin B₁₂; the anemia will respond to parenteral doses of vitamin B₁₂ that exceed the renal clearance (Hakami *et al.*, 1971).

Defects in intracellular metabolism of vitamin B₁₂ have been reported in children with methylmalonic aciduria and homocystinuria. Potential mechanisms include an incapacity of cells to transport vitamin B₁₂ or accumulate the vitamin because of a failure to synthesize an intracellular acceptor, a defect in the formation of deoxyadenosylcobalamin, or a congenital lack of methylmalonyl CoA isomerase.

Vitamin B₁₂ Deficiency. Vitamin B₁₂ deficiency is recognized clinically by its impact on the hematopoietic and nervous systems. The sensitivity of the hematopoietic system relates to its high rate of cell turnover. Other tissues with high rates of cell turnover (*e.g.*,

mucosa and cervical epithelium) also have high requirements for the vitamin.

As a result of an inadequate supply of vitamin B₁₂, DNA replication becomes highly abnormal. Once a hematopoietic stem cell is committed to enter a programmed series of cell divisions, the defect in chromosomal replication results in an inability of maturing cells to complete nuclear divisions while cytoplasmic maturation continues at a relatively normal rate. This results in the production of morphologically abnormal cells and death of cells during maturation, a phenomenon referred to as *ineffective hematopoiesis*. These abnormalities are readily identified by examination of the marrow and peripheral blood. Maturation of red cell precursors is highly abnormal (megaloblastic erythropoiesis). Those cells that do leave the marrow also are abnormal, and many cell fragments, poikilocytes, and macrocytes appear in the peripheral blood. The mean red cell volume increases to values greater than 110 fl. Severe deficiency affects all cell lines, and a pronounced pancytopenia results.

The diagnosis of a vitamin B₁₂ deficiency usually can be made using measurements of the serum vitamin B₁₂ and/or serum methylmalonic acid. The latter is somewhat more sensitive and has been used to identify metabolic deficiency in patients with normal serum vitamin B₁₂ levels. As part of the clinical management of a patient with severe megaloblastic anemia, a therapeutic trial using very small doses of the vitamin can be used to confirm the diagnosis. Serial measurements of the reticulocyte count, serum iron, and hematocrit are performed to define the characteristic recovery of normal red cell production. The Schilling test can be used to quantitate the absorption of the vitamin and delineate the mechanism of the disease. By performing the Schilling test with and without added intrinsic factor, it is possible to discriminate between intrinsic factor deficiency by itself and primary ileal cell disease.

Vitamin B₁₂ deficiency can irreversibly damage the nervous system. Progressive swelling of myelinated neurons, demyelination, and neuronal cell death are seen in the spinal column and cerebral cortex. This causes a wide range of neurological signs and symptoms, including paresthesias of the hands and feet, decreased vibration and position senses with resultant unsteadiness, decreased deep tendon reflexes, and in the later stages, confusion, moodiness, loss of memory, and even a loss of central vision. The patient may exhibit delusions, hallucinations, or even overt psychosis. Since the neurological damage can be dissociated from the changes in the hematopoietic system, vitamin B₁₂ deficiency must be

considered in elderly patients with dementia or psychiatric disorders, even if they are not anemic (Lindenbaum *et al.*, 1988).

Vitamin B₁₂ Therapy. Vitamin B₁₂ is available for injection or oral administration; combinations with other vitamins and minerals also can be given orally or parenterally. The choice of a preparation always depends on the cause of the deficiency. Although oral preparations may be used to supplement deficient diets, they are of limited value in the treatment of patients with deficiency of intrinsic factor or ileal disease. Even though small amounts of vitamin B₁₂ may be absorbed by simple diffusion, the oral route of administration cannot be relied upon for effective therapy in the patient with a marked deficiency of vitamin B₁₂ and abnormal hematopoiesis or neurological deficits. Therefore, the preparation of choice for treatment of a vitamin B₁₂-deficiency state is cyanocobalamin, and it should be administered by intramuscular or subcutaneous injection.

Cyanocobalamin injection is safe when given by the intramuscular or deep subcutaneous route, but it should never be given intravenously. There have been rare reports of transitory exanthema and anaphylaxis after injection. If a patient reports a previous sensitivity to injections of vitamin B₁₂, an intradermal skin test should be performed before the full dose is administered.

Cyanocobalamin is administered in doses of 1 to 1000 µg. Tissue uptake, storage, and utilization depend on the availability of transcobalamin II (*see above*). Doses in excess of 100 µg are cleared rapidly from plasma into the urine, and administration of larger amounts of vitamin B₁₂ will not result in greater retention of the vitamin. Administration of 1000 µg is of value in the performance of the Schilling test. After isotopically labeled vitamin B₁₂ is administered orally, the compound that is absorbed can be quantitatively recovered in the urine if 1000 µg of cyanocobalamin is administered intramuscularly. This unlabeled material saturates the transport system and tissue binding sites, so that more than 90% of the labeled and unlabeled vitamin is excreted during the next 24 hours.

A number of multivitamin preparations are marketed either as nutritional supplements or for the treatment of anemia. Many of these contain up to 80 µg of cyanocobalamin without or with intrinsic factor concentrate prepared from the stomachs of hogs or other domestic animals. One oral unit of intrinsic factor is defined as that amount of material that will bind and transport 15 µg of cyanocobalamin. Most multivitamin preparations supplemented with intrinsic factor contain 0.5 oral unit per tablet. While the combination of oral vitamin B₁₂ and intrinsic factor would appear to be ideal for patients with an intrinsic factor deficiency, such preparations are not reliable. With prolonged therapy, some patients become refractory to oral intrinsic factor, perhaps related to production of an intraluminal antibody against the hog protein. Patients taking such preparations must be reevaluated at periodic intervals for recurrence of pernicious anemia.

Hydroxocobalamin given in doses of 100 µg intramuscularly has been reported to have a more sustained effect than cyanocobal-

amin, with a single dose maintaining plasma vitamin B₁₂ concentrations in the normal range for up to 3 months. However, some patients show reductions of the concentration of vitamin B₁₂ in plasma within 30 days, similar to that seen after cyanocobalamin. Furthermore, the administration of hydroxocobalamin has resulted in the formation of antibodies to the transcobalamin II–vitamin B₁₂ complex.

Vitamin B₁₂ has an undeserved reputation as a health tonic and has been used for a number of disease states. Effective use of the vitamin depends on accurate diagnosis and an understanding of the following general principles of therapy:

1. Vitamin B₁₂ should be given prophylactically only when there is a reasonable probability that a deficiency exists or will exist. Dietary deficiency in the strict vegetarian, the predictable malabsorption of vitamin B₁₂ in patients who have had a gastrectomy, and certain diseases of the small intestine constitute such indications. When gastrointestinal function is normal, an oral prophylactic supplement of vitamins and minerals, including vitamin B₁₂, may be indicated. Otherwise, the patient should receive monthly injections of cyanocobalamin.
2. The relative ease of treatment with vitamin B₁₂ should not prevent a full investigation of the etiology of the deficiency. The initial diagnosis usually is suggested by a macrocytic anemia or an unexplained neuropsychiatric disorder. Full understanding of the etiology of vitamin B₁₂ deficiency involves studies of dietary supply, gastrointestinal absorption, and transport.
3. Therapy always should be as specific as possible. While a large number of multivitamin preparations are available, the use of “shotgun” vitamin therapy in the treatment of vitamin B₁₂ deficiency can be dangerous. With such therapy, there is the danger that sufficient folic acid will be given to result in a hematological recovery. This can mask continued vitamin B₁₂ deficiency and permit neurological damage to develop or progress.
4. Although a classical therapeutic trial with small amounts of vitamin B₁₂ can help confirm the diagnosis, acutely ill, elderly patients may not be able to tolerate the delay in the correction of a severe anemia. Such patients require supplemental blood transfusions and immediate therapy with folic acid and vitamin B₁₂ to guarantee rapid recovery.
5. Long-term therapy with vitamin B₁₂ must be evaluated at intervals of 6 to 12 months in patients who are otherwise well. If there is an additional illness or a condition that may increase the requirement for the vitamin (*e.g.*, pregnancy), reassessment should be performed more frequently.

Treatment of the Acutely Ill Patient. The therapeutic approach depends on the severity of the patient’s illness. In uncomplicated pernicious anemia, in which the abnormality is restricted to a mild or moderate anemia without leukopenia, thrombocytopenia, or neurological signs or symptoms, the administration of vitamin B₁₂ alone will suffice. Moreover, therapy may be delayed until other causes of megaloblastic anemia have been excluded and sufficient studies of gastrointestinal function have been performed to reveal the underlying cause of the disease. In this situation, a therapeutic trial with small amounts of parenteral vitamin B₁₂ (1 to 10 μg per day) can confirm the presence of an uncomplicated vitamin B₁₂ deficiency.

In contrast, patients with neurological changes or severe leukopenia or thrombocytopenia associated with infection or bleeding require emergency treatment. The older individual with a severe anemia (hematocrit less than 20%) is likely to have tissue hypoxia, cerebrovascular insufficiency, and congestive heart failure. Effective therapy must not wait for detailed diagnostic tests. Once the megaloblastic erythropoiesis has been confirmed and sufficient blood collected for later measurements of vitamin B₁₂ and folic acid, the patient should receive intramuscular injections of 100 μg of cyanocobalamin and 1 to 5 mg of folic acid. For the next 1 to 2 weeks the patient should receive daily intramuscular injections of 100 μg of cyanocobalamin, together with a daily oral supplement of 1 to 2 mg of folic acid. Because an effective increase in red cell mass will not occur for 10 to 20 days, the patient with a markedly depressed hematocrit and tissue hypoxia also should receive a transfusion of 2 to 3 units of packed red blood cells. If congestive heart failure is present, diuretics can be administered to prevent volume overload.

Patients usually report an increased sense of well-being within the first 24 hours of the initiation of therapy. Objectively, memory and orientation can improve dramatically, although full recovery of mental function may take months, or may never occur. In addition, even before an obvious hematological response is apparent, the patient may report an increase in strength, a better appetite, and reduced soreness of the mouth and tongue.

The first objective hematological change is the disappearance of the megaloblastic morphology of the bone marrow. As the ineffective erythropoiesis is corrected, the concentration of iron in plasma falls dramatically as the metal is used in the formation of hemoglobin. This usually occurs within the first 48 hours. Full correction of precursor maturation in marrow with production of an increased number of reticulocytes begins about the second or third day and peaks 3 to 5 days later. When the anemia is moderate to severe, the maximal reticulocyte index will be between three and five times the normal value (*i.e.*, a reticulocyte count of 20% to 40%). The ability of the marrow to sustain a high rate of production determines the rate of recovery of the hematocrit. Patients with complicating iron deficiency, an infection or other inflammatory state, or renal disease may be unable to correct their anemia. Therefore it is important to monitor the reticulocyte index over the first several weeks. If it does not continue at elevated levels while the hematocrit is less than 35%, plasma concentrations of iron and folic acid should again be determined and the patient reevaluated for an illness that could inhibit the response of the marrow.

The degree and rate of improvement of neurological signs and symptoms depend on the severity and the duration of the abnormalities. Those that have been present for only a few months usually disappear relatively rapidly. When a defect has been present for many months or years, full return to normal function may never occur.

Long-Term Therapy with Vitamin B₁₂. Once begun, vitamin B₁₂ therapy must be maintained for life. This fact must be impressed upon the patient and family, and a system must be established to guarantee continued monthly injections of cyanocobalamin. Intramuscular injection of 100 μg of cyanocobalamin every 4 weeks is sufficient to maintain a normal concentration of vitamin B₁₂ in plasma and an adequate supply for tissues. Patients with severe neurological symptoms and signs may be treated with larger doses of vitamin B₁₂ in the period immediately after the diagnosis. Doses of 100 μg per day or several times per week may be given for several months with the hope of encouraging faster and more complete recovery. It is important to monitor vitamin B₁₂ concentrations in plasma and to obtain peripheral blood counts at intervals of 3 to 6 months to confirm the adequacy of therapy. Since refractoriness to therapy can develop at any time, evaluation must continue throughout the patient's life.

Other Therapeutic Uses of Vitamin B₁₂. Vitamin B₁₂ has been used in the therapy of a number of conditions, including trigeminal neuralgia, multiple sclerosis and other neuropathies, various psychiatric disorders, poor growth or nutrition, and as a "tonic" for patients complaining of tiredness or easy fatigue. There is no evidence for the validity of such therapy in any of these conditions. Maintenance therapy with vitamin B₁₂ has been used with some apparent success in the treatment of children with methylmalonic aciduria.

FOLIC ACID

Chemistry and Metabolic Functions. The structural formula of pteroylglutamic acid (PteGlu) is shown in Figure 53–9. Major portions of the molecule include a pteridine ring linked by a methylene bridge to para-aminobenzoic acid, which is joined by an amide linkage to glutamic acid. While pteroylglutamic acid is the common pharmaceutical form of folic acid, it is neither the principal folate congener in food nor the active coenzyme for intracellular metabolism. After absorption, PteGlu is rapidly reduced at the 5, 6, 7, and 8 positions to tetrahydrofolic acid (H₄PteGlu), which then acts as an acceptor of a number of one-carbon units. These are attached at either the 5 or the 10 position of the pteridine ring or may bridge these atoms to form a new five-membered ring. The most important forms of the coenzyme that are synthesized by these reactions are listed in Figure 53–9. Each plays a specific role in intracellular metabolism, summarized as follows (*see* "Relationships Between Vitamin B₁₂ and Folic Acid," above, as well as Figure 53–6):

Conversion of homocysteine to methionine. This reaction requires CH₃H₄PteGlu as a methyl donor and utilizes vitamin B₁₂ as a cofactor.

Conversion of serine to glycine. This reaction requires tetrahydrofolate as an acceptor of a methylene group from serine and utilizes pyridoxal phosphate as a cofactor. It results in the formation of 5,10-CH₂H₄PteGlu, an essential coenzyme for the synthesis of thymidylate.

Synthesis of thymidylate. 5,10-CH₂H₄PteGlu donates a methylene group and reducing equivalents to deoxyuridylylate for the synthesis of thymidylate—a rate-limiting step in DNA synthesis.

Histidine metabolism. H₄PteGlu also acts as an acceptor of a formimino group in the conversion of formiminoglutamic acid to glutamic acid.

Synthesis of purines. Two steps in the synthesis of purine nucleotides require the participation of derivatives of folic acid. Glycinamide ribonucleotide is formylated by 5,10-CHH₄PteGlu; 5-aminoimidazole-4-carboxamide ribonucleotide is formylated by 10-CHOH₄PteGlu. By these reactions, carbon atoms at positions 8 and 2, respectively, are incorporated into the growing purine ring.

Utilization or generation of formate. This reversible reaction utilizes H₄PteGlu and 10-CHOH₄PteGlu.

Daily Requirements. Many food sources are rich in folates, especially fresh green vegetables, liver, yeast, and some fruits. However, lengthy cooking can destroy up to 90% of the folate content of such food. Generally, a standard United States diet provides 50 to 500 μg of absorbable folate per day, although individuals with high intakes of fresh vegetables and meats will ingest as much as 2 mg per day. In the normal adult, the recommended daily intake is 400 μg, while pregnant or lactating women and patients with high rates of cell turnover (such as patients with a hemolytic anemia) may require 500 to 600 μg or more per day. For the prevention of neural tube defects, a daily intake of at least 400 μg of folate in food or in supplements beginning a month before pregnancy and continued for at least the first trimester is recommended. Folate supplementation also is being considered in patients with elevated levels of plasma homocysteine (*see* below).

Absorption, Distribution, and Elimination. As with vitamin B₁₂, the diagnosis and management of deficiencies of folic acid depend on an understanding of the transport pathways and intracellular metabolism of the vitamin (Figure 53–10). Folates present in food are largely in the form of reduced polyglutamates, and absorption requires transport and the action of a pteroylglutamyl carboxypeptidase associated with mucosal cell membranes. The mucosae of the duodenum and upper part of the jejunum are rich in dihydrofolate reductase and can methylate most or all of the reduced folate that is absorbed. Since most absorption occurs in the proximal portion of the small intestine, it is not unusual for folate deficiency to occur when the jejunum is diseased. Both nontropical and tropical sprue are common causes of folate deficiency and megaloblastic anemia.

Once absorbed, folate is transported rapidly to tissues as CH₃H₄PteGlu. While certain plasma proteins do bind folate derivatives, they have a greater affinity for nonmethylated analogs. The role of such binding proteins in folate homeostasis is not well understood. An increase in binding capacity is detectable in folate deficiency and in certain disease states, such as uremia, cancer, and alcohol-

Figure 53–9. The structures and nomenclature of pteroylglutamic acid (folic acid) and its congeners. X represents additional residues of glutamate; polyglutamates are the storage and active forms of the vitamin. The subscript that designates the number of residues of glutamate is frequently omitted because this number is variable.

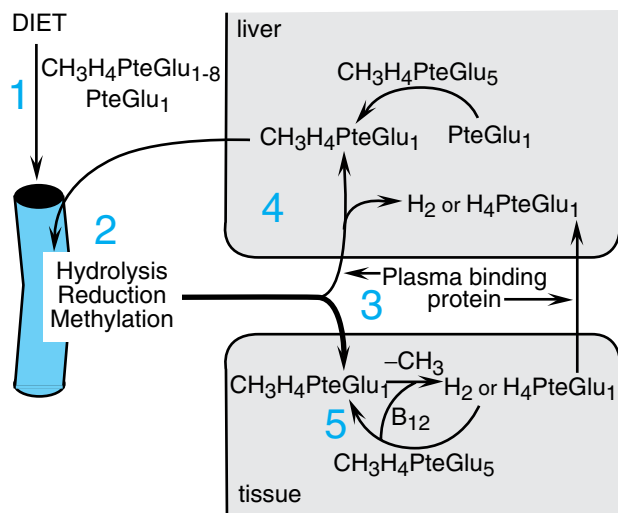

Figure 53–10. Absorption and distribution of folate derivatives. Dietary sources of folate polyglutamates are hydrolyzed to the monoglutamate, reduced, and methylated to CH₃H₄PteGlu₁ during gastrointestinal transport. Folate deficiency commonly results from (1) inadequate dietary supply and (2) small intestinal disease. In patients with uremia, alcoholism, or hepatic disease there may be defects in (3) the concentration of folate binding proteins in plasma and (4) the flow of CH₃H₄PteGlu₁ into bile for reabsorption and transport to tissue (the folate enterohepatic cycle). Finally, vitamin B₁₂ deficiency will (5) “trap” folate as CH₃H₄PteGlu, thereby reducing the availability of H₄PteGlu₁ for its essential roles in purine and pyrimidine synthesis.

ism, but how binding affects transport and tissue supply requires further investigation.

A constant supply of CH₃H₄PteGlu is maintained by food and by an enterohepatic cycle of the vitamin. The liver actively reduces and methylates PteGlu (and H₂ or H₄PteGlu) and then transports the CH₃H₄PteGlu into bile for reabsorption by the gut and subsequent delivery to tissues (Steinberg *et al.*, 1979). This pathway may provide 200 μg or more of folate each day for recirculation to tissues. The importance of the enterohepatic cycle is suggested by animal studies that show a rapid reduction of the plasma folate concentration after either drainage of bile or ingestion of alcohol, which apparently blocks the release of CH₃H₄PteGlu from hepatic parenchymal cells (Hillman *et al.*, 1977).

Following uptake into cells, CH₃H₄PteGlu acts as a methyl donor for the formation of methylcobalamin and as a source of H₄PteGlu and other folate congeners, as described above. Folate is stored within cells as polyglutamates.

Folate Deficiency. Folate deficiency is a common complication of diseases of the small intestine, which interfere with the absorption of folate from food and the recirculation of folate through the enterohepatic cycle. In acute or chronic alcoholism, daily intake of folate in food may be severely restricted, and the enterohepatic cycle of the vitamin may be impaired by toxic effects of

alcohol on hepatic parenchymal cells; this is the most common cause of folate-deficient megaloblastic erythropoiesis. However, it also is the most amenable to therapy, inasmuch as the reinstatement of a normal diet is sufficient to overcome the effect of alcohol. Disease states characterized by a high rate of cell turnover, such as hemolytic anemias, also may be complicated by folate deficiency. Additionally, drugs that inhibit dihydrofolate reductase (e.g., methotrexate and trimethoprim) or that interfere with the absorption and storage of folate in tissues (e.g., certain anticonvulsants and oral contraceptives) can lower the concentration of folate in plasma and may cause a megaloblastic anemia (Stebbins and Bertino, 1976).

Folate deficiency has been implicated in the incidence of neural tube defects, including spina bifida, encephaloceles, and anencephaly. This is true even in the absence of folate-deficient anemia or alcoholism. A less-than-adequate intake of folate also can result in elevations in plasma homocysteine (Green and Miller, 1999). Since even moderate hyperhomocysteinemia is considered an independent risk factor for coronary artery and peripheral vascular disease and for venous thrombosis, the role of folate as a methyl donor in the homocysteine-to-methionine conversion is getting increased attention. Patients who are heterozygous for one or another enzymatic defect and have high normal to moderate elevations of plasma homocysteine may improve with folic acid therapy.

Folate deficiency is recognized by its impact on the hematopoietic system. As with vitamin B₁₂, this fact reflects the increased requirement associated with high rates of cell turnover. The megaloblastic anemia that results from folate deficiency cannot be distinguished from that caused by vitamin B₁₂ deficiency. This finding is to be expected because of the final common pathway of the major intracellular metabolic roles of the two vitamins. At the same time, folate deficiency is rarely if ever associated with neurological abnormalities. Thus the observation of characteristic abnormalities in vibratory and position sense and in motor and sensory pathways is incompatible with an isolated deficiency of folic acid.

After deprivation of folate, megaloblastic anemia develops much more rapidly than it does following interruption of vitamin B₁₂ absorption (e.g., gastric surgery). This observation reflects the fact that body stores of folate are limited. Although the rate of induction of megaloblastic erythropoiesis may vary, a folate-deficiency state may appear in 1 to 4 weeks, depending on the individual's dietary habits and stores of the vitamin.

Folate deficiency is best diagnosed from measurements of folate in plasma and in red cells. However, an empiric trial of folate in cases of suspected deficiency has been proposed as more cost effective (Robinson and Mladenovic, 2001). Indeed, the concentration of folate in plasma is extremely sensitive to changes in dietary intake of the vitamin and the influence of inhibitors of folate metabolism or transport, such as alcohol. Normal folate concentrations in plasma range from 9 to 45 nmol (4 to 20 ng/ml); below 9 nmol is considered folate deficient. The plasma folate concentration rapidly falls to values indicative of deficiency within 24 to 48 hours of steady ingestion of alcohol (Eichner and Hillman, 1971; Eichner and Hillman, 1973). The plasma folate concentration will revert quickly to normal once such ingestion is stopped, even while the marrow is still megaloblastic. Such rapid fluctuations detract from the clinical utility of the plasma folate concentration. The amount of folate in red cells or the adequacy of stores in lymphocytes (as measured by the deoxyuridine suppression test) may be used to diagnose a long-standing deficiency of folic acid. A positive result on either test shows that the deficiency must have existed for a sufficient time to allow the production of a population of cells with deficient folate stores.

Folic acid is marketed as oral tablets containing 0.4, 0.8, and 1 mg pteroylglutamic acid, as an aqueous solution for injection (5 mg/ml), and in combination with other vitamins and minerals.

Folinic acid (leucovorin calcium, citrovorum factor) is the 5-formyl derivative of tetrahydrofolic acid. The principal therapeutic uses of folinic acid are to circumvent the inhibition of dihydrofolate reductase as a part of high-dose methotrexate therapy and to potentiate fluorouracil in the treatment of colorectal cancer (see Chapter 51). It also has been used as an antidote to counteract the toxicity of folate antagonists such as pyrimethamine or trimethoprim. While it can be used to treat any folate-deficient state, folinic acid provides no advantage over folic acid, is more expensive, and therefore is not recommended. A single exception is the megaloblastic anemia associated with congenital dihydrofolate reductase deficiency. Leucovorin should never be used for the treatment of pernicious anemia or other megaloblastic anemias secondary to a deficiency of vitamin B₁₂. Just as is seen with folic acid, its use can result in an apparent response of the hematopoietic system, but neurological damage may occur or progress if already present.

Untoward Effects. There have been rare reports of reactions to parenteral injections of folic acid and leucovorin. If a patient describes a history of a reaction before the drug is given, caution should be exercised. Oral folic acid usually is not toxic. Even with doses as high as 15 mg/day, there have been no substantiated reports of side effects. Folic acid in large amounts may counteract the antiepileptic effect of *phenobarbital*, *phenytoin*, and *primidone*, and increase the frequency of seizures in susceptible children (Reynolds, 1968). While some studies have not supported these contentions, the FDA recommends that oral tablets of folic acid be limited to strengths of 1 mg or less.

General Principles of Therapy. The therapeutic use of folic acid is limited to the prevention and treatment of deficiencies of the vitamin. As with vitamin B₁₂ therapy, effective use of the vitamin depends on accurate diagnosis and an understanding of the mechanisms that are opera-

tive in a specific disease state. The following general principles of therapy should be respected:

1. Prophylactic administration of folic acid should be undertaken for clear indications. Dietary supplementation is necessary when there is a requirement that may not be met by a “normal” diet. The daily ingestion of a multivitamin preparation containing 400 to 500 μg of folic acid has become standard practice before and during pregnancy to reduce the incidence of neural tube defects and for as long as a woman is breastfeeding. In women with a history of a pregnancy complicated by a neural tube defect, an even larger dose of 4 mg a day has been recommended (MRC Vitamin Study Research Group, 1991). Patients on total parenteral nutrition should receive folic acid supplements as part of their fluid regimen because liver folate stores are limited. Adult patients with a disease state characterized by high cell turnover (*e.g.*, hemolytic anemia) generally require larger doses, 1 mg of folic acid given once or twice a day. The 1-mg dose also has been used in the treatment of patients with elevated levels of homocysteine.
2. As with vitamin B₁₂ deficiency, any patient with folate deficiency and a megaloblastic anemia should be evaluated carefully to determine the underlying cause of the deficiency state. This should include evaluation of the effects of medications, the amount of alcohol intake, the patient’s history of travel, and the function of the gastrointestinal tract.
3. Therapy always should be as specific as possible. Multivitamin preparations should be avoided unless there is good reason to suspect deficiency of several vitamins.
4. *The potential danger of mistreating a patient who has vitamin B₁₂ deficiency with folic acid must be kept in mind.* The administration of large doses of folic acid can result in an apparent improvement of the megaloblastic anemia, inasmuch as PteGlu is converted by dihydrofolate reductase to H₄PteGlu; this circumvents the methylfolate “trap.” However, folate therapy does not prevent or alleviate the neurological defects of vitamin B₁₂ deficiency, and these may progress and become irreversible.

Treatment of the Acutely Ill Patient. As described in detail in the section on vitamin B₁₂, treatment of the patient who is acutely ill with megaloblastic anemia should begin with intramuscular injections of vitamin B₁₂ and folic acid. Inasmuch as the patient requires therapy before the exact cause of the disease has been defined, it is important to avoid the potential problem of a combined deficiency of vitamin B₁₂ and folic acid. When the patient is deficient in both, therapy with only one vitamin will not provide an optimal response. Longstanding nontropical sprue is one example of a disease in which combined deficiency of B₁₂ and folate is common. When

indicated, vitamin B₁₂ (100 μg) and folic acid (1 to 5 mg) should be administered intramuscularly, and the patient should then be maintained on daily oral supplements of 1 to 2 mg of folic acid for the next 1 to 2 weeks.

Oral administration of folate generally is satisfactory for patients who are not acutely ill, regardless of the cause of the deficiency state. Even the patient with tropical or nontropical sprue and a demonstrable defect in absorption of folic acid will respond adequately to such therapy. Abnormalities in the activity of pteroyl- γ -glutamyl carboxypeptidase and the function of mucosal cells will not prevent passive diffusion of sufficient amounts of PteGlu across the mucosal barrier if the dosage is adequate, and continued ingestion of alcohol or other drugs also will not prevent an adequate therapeutic response. The effects of most inhibitors of folate transport or dihydrofolate reductase are overcome easily by administration of pharmacological doses of the vitamin. Folinic acid is the appropriate form of the vitamin for use in chemotherapeutic protocols, including “rescue” from methotrexate (*see* Chapter 51). Perhaps the only situation in which oral administration of folate will be ineffective is when vitamin C is severely deficient. Patients with scurvy may suffer from a megaloblastic anemia despite increased intake of folate and normal or high concentrations of the vitamin in plasma and cells.

The therapeutic response may be monitored by study of the hematopoietic system in a fashion identical to that described for vitamin B₁₂. Within 48 hours of the initiation of appropriate therapy, megaloblastic erythropoiesis disappears, and as efficient erythropoiesis begins, the concentration of iron in plasma falls to normal or below-normal values. The reticulocyte count begins to rise on the second or third day and reaches a peak by the fifth to seventh days; the reticulocyte index reflects the proliferative state of the marrow. Finally, the hematocrit begins to rise during the second week.

It is possible to use the pattern of recovery as the basis for a therapeutic trial. For this purpose, the patient should receive a daily parenteral injection of 50 to 100 μg of folic acid. Administration of doses in excess of 100 μg per day entails the risk of inducing a hematopoietic response in patients who are deficient in vitamin B₁₂, while oral administration of the vitamin may be unreliable because of intestinal malabsorption. A number of other complications also may interfere with the therapeutic trial. The patient with sprue and deficiencies of other vitamins or iron may fail to respond because of these inadequacies. In cases of alcoholism, the presence of hepatic disease, inflammation, or iron deficiency can blunt the proliferative response of the marrow and prevent the correction of the anemia. For these reasons, the therapeutic trial for the evaluation of the patient with a potential deficiency of folic acid has not gained great popularity.

CLINICAL SUMMARY

Several hematopoietic growth factors are available for clinical use. Recombinant erythropoietin routinely is used for patients with the anemia of renal insufficiency, inflammation, and associated with cancer or the therapy of cancer. Longer-acting growth factors that permit less frequent dosing schedules are coming into increased use. One of the first of these is novel erythropoiesis-stimulat-

ing protein (NESP), produced by the insertion of two extra N-linked sialic acid side chains into the erythropoietin molecule. Myeloid growth factors (*e.g.*, GM-CSF and G-CSF) are used to hasten the recovery of granulocytes after myelosuppressive therapy, to help mobilize hematopoietic stem cells into the peripheral blood to allow their harvest for transplantation, and to augment the number of mature leukocytes in the peripheral blood so that they can be used in patients with overwhelming infection. Finally, the development of IL-11 for use in thrombocytopenia and the investigational use of thrombopoietin or mimics of the molecule may provide many of the same therapeutic advances.

BLOOD COAGULATION AND ANTICOAGULANT, THROMBOLYTIC, AND ANTIPLATELET DRUGS

Philip W. Majerus and Douglas M. Tollefsen

The physiological systems that control blood fluidity are both complex and elegant. Blood must remain fluid within the vasculature and yet clot quickly when exposed to nonendothelial surfaces at sites of vascular injury. When intravascular thrombi do occur, a system of fibrinolysis is activated to restore fluidity. In the normal situation, a delicate balance prevents both thrombosis and hemorrhage and allows physiological fibrinolysis without excess pathological fibrinogenolysis. The drugs described in this chapter have very different mechanisms of action, but all alter the balance between procoagulant and anticoagulant reactions. With these drugs, efficacy and toxicity are necessarily intertwined. For example, the desired therapeutic effect of anticoagulation can be offset by the toxic effect of bleeding due to overdosing of anticoagulant. Similarly, overstimulation of fibrinolysis can lead to systemic destruction of fibrinogen and coagulation factors. This chapter reviews the predominant agents for controlling blood fluidity, including (1) the parenteral anticoagulant heparin and its derivatives, which stimulate a natural inhibitor of coagulant proteases; (2) the coumarin anticoagulants, which block multiple steps in the coagulation cascade; (3) fibrinolytic agents, which lyse pathological thrombi; and (4) antiplatelet agents, especially aspirin.

OVERVIEW OF HEMOSTASIS: PLATELET FUNCTION, BLOOD COAGULATION, AND FIBRINOLYSIS

Hemostasis is the cessation of blood loss from a damaged vessel. Platelets first adhere to macromolecules in the subendothelial regions of the injured blood vessel; they

then aggregate to form the primary hemostatic plug. Platelets stimulate local activation of plasma coagulation factors, leading to generation of a fibrin clot that reinforces the platelet aggregate. Later, as wound healing occurs, the platelet aggregate and fibrin clot are degraded. The process of platelet aggregation and blood coagulation are summarized in Figures 54–1 and 54–2. The pathway of clot removal, fibrinolysis, is shown in Figure 54–3, along with sites of action of fibrinolytic agents.

Coagulation involves a series of zymogen activation reactions, as shown in Figure 54–2 (Mann *et al.*, 2003). At each stage, a precursor protein, or *zymogen*, is converted to an active protease by cleavage of one or more peptide bonds in the precursor molecule. The components at each stage include a protease from the preceding stage, a zymogen, a nonenzymatic protein cofactor, Ca^{2+} , and an organizing surface that is provided by a phospholipid emulsion *in vitro* or by platelets *in vivo*. The final protease generated is thrombin (factor IIa).

Conversion of Fibrinogen to Fibrin. Fibrinogen is a 330,000-dalton protein that consists of three pairs of polypeptide chains (designated $A\alpha$, $B\beta$, and γ) covalently linked by disulfide bonds. Thrombin converts fibrinogen to fibrin monomers by cleaving fibrinopeptides A (16 amino acid residues) and B (14 amino acid residues) from the amino-terminal ends of the $A\alpha$ and $B\beta$ chains, respectively. Removal of the fibrinopeptides allows the fibrin monomers to form a gel, which is the end point of *in vitro* assays of coagulation (*see below*). Initially, the fibrin monomers are bound to each other noncovalently. Subsequently, factor XIIIa catalyzes an interchain transglutamination reaction that cross-links adjacent fibrin monomers to enhance the strength of the clot.

Structure of Coagulation Protease Zymogens. The protease zymogens involved in coagulation include factors II (prothrombin), VII, IX, X, XI, XII, and prekallikrein. About 200 amino acid residues at the car-

Figure 54–1. Platelet adhesion and aggregation. GPIa/IIa and GPIb are platelet membrane proteins that bind to collagen and von Willebrand factor (vWF), causing platelets to adhere to the subendothelium of a damaged blood vessel. PAR1 and PAR4 are protease-activated receptors that respond to thrombin (IIa); P2Y₁ and P2Y₁₂ are receptors for ADP (adenosine diphosphate); when stimulated by agonists, these receptors activate the fibrinogen-binding protein GPIIb/IIIa and cyclooxygenase-1 (COX-1) to promote platelet aggregation and secretion. Thromboxane A₂ (TXA₂) is the major product of COX-1 involved in platelet activation. Prostaglandin I₂ (PGI₂), synthesized by endothelial cells, inhibits platelet activation.

Figure 54–2. Major reactions of blood coagulation. Shown are interactions among proteins of the “extrinsic” (tissue factor and factor VII), “intrinsic” (factors IX and VIII), and “common” (factors X, V, and II) coagulation pathways that are important *in vivo*. Boxes enclose the coagulation factor zymogens (indicated by Roman numerals) and the rounded boxes represent the active proteases. TF, tissue factor; activated coagulation factors are followed by the letter “a.” II, prothrombin; IIa, thrombin.

Figure 54–3. Fibrinolysis. Endothelial cells secrete tissue plasminogen activator (t-PA) at sites of injury. t-PA binds to fibrin and cleaves plasminogen to plasmin, resulting in fibrin digestion. Plasminogen activator inhibitors-1 and -2 (PAI-1, PAI-2) inactivate t-PA; α_2 -antiplasmin (α_2 -AP) inactivates plasmin.

boxyl-terminal end of each zymogen are homologous to trypsin and contain the active site of the protease. In addition, 9 to 12 glutamate residues near the amino-terminal ends of factors II, VII, IX, and X are converted to γ -carboxyglutamate (Gla) residues during biosynthesis in the liver. The Gla residues bind Ca^{2+} and are necessary for the coagulant activities of these proteins.

Nonenzymatic Protein Cofactors. Factors V and VIII are homologous 350,000-dalton proteins. Factor VIII circulates in plasma bound to von Willebrand factor, while factor V is present both freely in plasma and as a component of platelets. Thrombin cleaves V and VIII to yield activated factors (Va and VIIIa) that have at least 50 times the coagulant activity of the precursor forms. Factors Va and VIIIa have no intrinsic enzymatic activity but serve as cofactors that increase the proteolytic efficiency of Xa and IXa, respectively. Tissue factor (TF) is a nonenzymatic lipoprotein cofactor that greatly increases the proteolytic efficiency of VIIa. It is present on the surface of cells that do not normally contact plasma (e.g., macrophages and smooth muscle cells) and initiates coagulation outside a broken blood vessel. Monocytes and endothelial cells also may express tissue factor when exposed to a variety of stimuli, such as endotoxin, tumor necrosis factor, and interleukin-1. Thus these cells may be involved in thrombus formation under pathological circumstances. High-molecular-weight kininogen is a plasma protein that serves as the cofactor for XIIa when clotting is initiated *in vitro* in the activated partial thromboplastin time (aPTT) test.

Activation of Prothrombin. Factor Xa cleaves two peptide bonds in prothrombin to form thrombin. Activation of prothrombin by Xa is accelerated by Va, phospholipids, and Ca^{2+} . When these components are all present, prothrombin is activated nearly 20,000 times faster than the rate achieved by Xa and Ca^{2+} alone. The maximal

rate of activation occurs only when prothrombin and Xa both contain Gla residues, and therefore have the ability to bind to phospholipids. Purified platelets can substitute for phospholipids and Va to facilitate activation of prothrombin *in vitro*, provided that the platelets are stimulated to release endogenous platelet factor Va or that factor Va is added exogenously to unstimulated platelets. The surface of platelets that are aggregated at the site of hemostasis concentrates the factors required for prothrombin activation.

Initiation of Coagulation. Coagulation is initiated *in vivo* by the extrinsic pathway. Small amounts of factor VIIa in the plasma bind to subendothelial tissue factor following vascular injury. Tissue factor accelerates activation of factor X by VIIa, phospholipids, and Ca^{2+} about 30,000-fold. VIIa also can activate IX in the presence of tissue factor, providing a convergence between the extrinsic and intrinsic pathways.

Clotting by the intrinsic pathway is initiated *in vitro* when XII, prekallikrein, and high-molecular-weight kininogen interact with kaolin, glass, or another surface to generate small amounts of XIIa. Activation of XI to XIa and IX to IXa follows. IXa then activates X in a reaction that is accelerated by VIIIa, phospholipids, and Ca^{2+} . Activation of factor X by IXa appears to occur by a mechanism similar to that for activation of prothrombin and may also be accelerated by platelets *in vivo*. Activation of factor XII is not required for hemostasis, since patients with deficiency of XII, prekallikrein, or high-molecular-

weight kininogen do not bleed abnormally, even though their aPTT values are prolonged. Factor XI deficiency is associated with a variable and usually mild bleeding disorder. The mechanism for activation of factor XI *in vivo* is not known, although thrombin activates factor XI *in vitro*.

Fibrinolysis and Thrombolysis

The fibrinolytic system dissolves intravascular clots as a result of the action of plasmin, an enzyme that digests fibrin. Plasminogen, an inactive precursor, is converted to plasmin by cleavage of a single peptide bond. Plasmin is a relatively nonspecific protease; it digests fibrin clots and other plasma proteins, including several coagulation factors. Therapy with thrombolytic drugs tends to dissolve both pathological thrombi and fibrin deposits at sites of vascular injury. Therefore, the drugs are toxic, producing hemorrhage as a major side effect.

The fibrinolytic system is regulated such that unwanted fibrin thrombi are removed, while fibrin in wounds persists to maintain hemostasis (Lijnen and Collen, 2001). *Tissue plasminogen activator (t-PA)* is released from endothelial cells in response to various signals, including stasis produced by vascular occlusion. It is rapidly cleared from blood or inhibited by circulating inhibitors, plasminogen activator inhibitor-1 and plasminogen activator inhibitor-2, and thus exerts little effect on circulating plasminogen. t-PA binds to fibrin and converts plasminogen, which also binds to fibrin, to plasmin. Plasminogen and plasmin bind to fibrin at binding sites located near their amino termini that are rich in lysine residues (*see below*). These sites also are required for binding of plasmin to the inhibitor α_2 -antiplasmin. Therefore, fibrin-bound plasmin is protected from inhibition. Any plasmin that escapes this local milieu is rapidly inhibited. Some α_2 -antiplasmin is bound covalently to fibrin and thereby protects fibrin from premature lysis. When plasminogen activators are administered for thrombolytic therapy, massive fibrinolysis is initiated, and the inhibitory controls are overwhelmed. The pathway of fibrinolysis and sites of pharmacologic perturbation are summarized by Figure 54-3.

Coagulation In Vitro. Blood clots in 4 to 8 minutes when placed in a glass tube. Clotting is prevented if a chelating agent such as ethylenediaminetetraacetic acid (EDTA) or citrate is added to bind Ca^{2+} . Recalcified plasma clots in 2 to 4 minutes. The clotting time after recalcification is shortened to 26 to 33 seconds by the addition of negatively charged phospholipids and a particulate substance such as kaolin (aluminum silicate); this is termed

the *activated partial thromboplastin time* (aPTT). Alternatively, recalcified plasma will clot in 12 to 14 seconds after addition of “thromboplastin” (a mixture of tissue factor and phospholipids); this is termed the *prothrombin time* (PT).

Two pathways of coagulation are recognized. An individual with a prolonged aPTT and a normal PT is considered to have a defect in the *intrinsic coagulation pathway*, because all of the components of the aPTT test (except kaolin) are intrinsic to the plasma. A patient with a prolonged PT and a normal aPTT has a defect in the *extrinsic coagulation pathway*, since thromboplastin is extrinsic to the plasma. Prolongation of both the aPTT and the PT suggests a defect in a common pathway.

Natural Anticoagulant Mechanisms. Platelet activation and coagulation normally do not occur within an intact blood vessel (Edelberg *et al.*, 2001). Thrombosis is prevented by several regulatory mechanisms that require a normal vascular endothelium. Prostacyclin (prostaglandin I_2 ; PGL_2), a metabolite of arachidonic acid, is synthesized by endothelial cells and inhibits platelet aggregation and secretion (*see Chapter 25*). Antithrombin is a plasma protein that inhibits coagulation factors of the intrinsic and common pathways (*see below*). Heparan sulfate proteoglycans synthesized by endothelial cells stimulate the activity of antithrombin. Protein C is a plasma zymogen that is homologous to II, VII, IX, and X; its activity depends on the binding of Ca^{2+} to Gla residues within its amino-terminal domain. Activated protein C, in combination with its non-enzymatic Gla-containing cofactor (protein S), degrades cofactors Va and VIIIa and thereby greatly diminishes the rates of activation of prothrombin and factor X (Esmon, 2003). Protein C is activated by thrombin only in the presence of thrombomodulin, an integral membrane protein of endothelial cells. Like antithrombin, protein C appears to exert an anticoagulant effect in the vicinity of intact endothelial cells. Tissue factor pathway inhibitor (TFPI) is found in the lipoprotein fraction of plasma. When bound to factor Xa, TFPI inhibits factor Xa and the factor VIIa-tissue factor complex. By this mechanism, factor Xa may regulate its own production.

PARENTERAL ANTICOAGULANTS

Heparin

Biochemistry. Heparin is a glycosaminoglycan found in the secretory granules of mast cells. It is synthesized from

Figure 54-4. The antithrombin-binding structure of heparin. Sulfate groups required for binding to antithrombin are indicated in blue.

UDP-sugar precursors as a polymer of alternating D-glucuronic acid and *N*-acetyl-D-glucosamine residues (Figure 54-4) (Sugahara and Kitagawa, 2002). About 10 to 15 glycosaminoglycan chains, each containing 200 to 300 monosaccharide units, are attached to a core protein and yield a proteoglycan with a molecular mass of 750,000 to 1,000,000 daltons. The glycosaminoglycan then undergoes a series of modifications, which include the following: *N*-deacetylation and *N*-sulfation of glucosamine residues, epimerization of D-glucuronic acid to L-iduronic acid, *O*-sulfation of iduronic and glucuronic acid residues at the C2 position, and *O*-sulfation of glucosamine residues at the C3 and C6 positions. Each of these modifications is incomplete, yielding a variety of oligosaccharide structures. After the heparin proteoglycan has been transported to the mast cell granule, an endo- β -D-glucuronidase degrades the glycosaminoglycan chains to fragments of 5000 to 30,000 daltons (mean, about 12,000 daltons or 40 monosaccharide units) over a period of hours.

Heparan Sulfate. Heparan sulfate is synthesized from the same repeating disaccharide precursor (D-glucuronic acid linked to *N*-acetyl-D-glucosamine) as is heparin. However, heparan sulfate undergoes less modification of the polymer than does heparin and therefore contains higher proportions of glucuronic acid and *N*-acetylglucosamine and fewer sulfate groups. Heparan sulfate on the surface of vascular endothelial cells or in the subendothelial extracellular matrix interacts with circulating antithrombin (*see below*) to provide a natural antithrombotic mechanism. Patients with malignancies may experience bleeding related to circulating heparan sulfate or related glycosaminoglycans that probably originate from lysis of the tumor cells.

Source. Heparin is commonly extracted from porcine intestinal mucosa or bovine lung, and preparations may contain small amounts of other glycosaminoglycans. Despite the heterogeneity in composition among different commercial preparations of heparin, their biological activities are similar (about 150 USP units/mg). The USP unit is the quantity of heparin that prevents 1 ml of citrated sheep plasma from clotting for 1 hour after the addition of 0.2 ml of 1% CaCl_2 .

Low-molecular-weight heparins (1000 to 10,000 daltons; mean, 4500 daltons, or 15 monosaccharide units) are isolated from standard heparin by gel filtration chromatography, precipitation with

ethanol, or partial depolymerization with nitrous acid and other chemical or enzymatic reagents. Low-molecular-weight heparins differ from standard heparin and from each other in their pharmacokinetic properties and mechanism of action (*see below*). The biological activity of low-molecular-weight heparin is generally measured with a factor Xa inhibition assay, which is mediated by antithrombin (*see below*).

Mechanism of Action. Heparin catalyzes the inhibition of several coagulation proteases by antithrombin, a glycosylated, single-chain polypeptide composed of 432 amino acid residues (Olson and Chuang, 2002). Antithrombin is synthesized in the liver and circulates in plasma at an approximate concentration of 2.6 μM . It inhibits activated coagulation factors of the intrinsic and common pathways, including thrombin, Xa, and IXa; however, it has relatively little activity against factor VIIa. Antithrombin is a “suicide substrate” for these proteases; inhibition occurs when the protease attacks a specific Arg-Ser peptide bond in the reactive site of antithrombin and becomes trapped as a stable 1:1 complex.

Heparin increases the rate of the thrombin-antithrombin reaction at least a thousandfold by serving as a catalytic template to which both the inhibitor and the protease bind. Binding of heparin also induces a conformational change in antithrombin that makes the reactive site more accessible to the protease. Once thrombin has become bound to antithrombin, the heparin molecule is released from the complex. The binding site for antithrombin on heparin is a specific pentasaccharide sequence that contains a 3-O-sulfated glucosamine residue (Figure 54-4). This structure occurs in about 30% of heparin molecules and less abundantly in heparan sulfate. Other glycosaminoglycans (*e.g.*, dermatan sulfate, chondroitin-4-sulfate, and chondroitin-6-sulfate) lack the antithrombin-binding structure and do not stimulate antithrombin. Heparin molecules containing fewer than 18 monosaccharide units (<5400 daltons) also do not catalyze inhibition of thrombin by antithrombin. Molecules of 18 monosaccharides or greater are required to bind thrombin and antithrombin

simultaneously. In contrast, the pentasaccharide shown in Figure 54–4 catalyzes inhibition of factor Xa by antithrombin. In this case, catalysis may occur solely by induction of a conformational change in antithrombin that facilitates reaction with the protease. Low-molecular-weight heparin preparations produce an anticoagulant effect mainly through inhibition of Xa by antithrombin, because the majority of molecules are of insufficient length to catalyze inhibition of thrombin.

When the concentration of heparin in plasma is 0.1 to 1 units/ml, thrombin, factor IXa, and factor Xa are inhibited rapidly (half-lives less than 0.1 second) by antithrombin. This effect prolongs both the aPTT and the thrombin time (*i.e.*, the time required for plasma to clot when exogenous thrombin is added); the PT is affected to a lesser degree. Factor Xa bound to platelets in the prothrombinase complex and thrombin bound to fibrin are both protected from inhibition by antithrombin in the presence of heparin. Thus, heparin may promote inhibition of factor Xa and thrombin only after they have diffused away from these binding sites. Platelet factor 4, released from the α -granules during platelet aggregation, blocks binding of antithrombin to heparin or heparan sulfate and may promote local clot formation at the site of hemostasis.

Miscellaneous Pharmacological Effects. High doses of heparin can interfere with platelet aggregation and thereby prolong bleeding time. It is unclear to what extent the antiplatelet effect of heparin contributes to the hemorrhagic complications of treatment with the drug. Heparin “clears” lipemic plasma *in vivo* by causing the release of lipoprotein lipase into the circulation. Lipoprotein lipase hydrolyzes triglycerides to glycerol and free fatty acids. The clearing of lipemic plasma may occur at concentrations of heparin below those necessary to produce an anticoagulant effect. Rebound hyperlipemia may occur after heparin administration is stopped.

Clinical Use. Heparin is used to initiate treatment of venous thrombosis and pulmonary embolism because of its rapid onset of action (Hirsh *et al.*, 2001). An oral anticoagulant usually is started concurrently, and heparin is continued for at least 4 to 5 days to allow the oral anticoagulant to achieve its full therapeutic effect (*see Clinical Use and Monitoring Anticoagulant Therapy*). Patients who experience recurrent thromboembolism despite adequate oral anticoagulation (*e.g.*, patients with Trousseau’s syndrome) may benefit from long-term heparin administration. Heparin is used in the initial management of patients with unstable angina or acute myocardial infarction, during and after coronary angioplasty or stent placement, and during surgery requiring cardiopulmonary bypass. Heparin also is used to treat selected patients with disseminated intravascular coagulation. Low-dose heparin regimens are effective in preventing venous thromboembolism in certain high-risk patients. Specific recommendations for heparin use have been reviewed (Hirsh *et al.*, 2001).

Low-molecular-weight heparin preparations were first approved for prevention of venous thromboembolism.

They are also effective in the treatment of venous thrombosis, pulmonary embolism, and unstable angina (Hirsh *et al.*, 2001). The principal advantage of low-molecular-weight heparin over standard heparin is a more predictable pharmacokinetic profile, which allows weight-adjusted subcutaneous administration without laboratory monitoring. Thus, therapy of many patients with acute venous thromboembolism can be provided in the outpatient setting. Other advantages of low-molecular-weight heparin include a lower incidence of heparin-induced thrombocytopenia and possibly lower risks of bleeding and osteopenia.

In contrast to warfarin, heparin does not cross the placenta and has not been associated with fetal malformations; therefore it is the drug of choice for anticoagulation during pregnancy. Heparin does not appear to increase the incidence of fetal mortality or prematurity. If possible, the drug should be discontinued 24 hours before delivery to minimize the risk of postpartum bleeding. The safety and efficacy of low-molecular-weight heparin use during pregnancy have not been adequately evaluated.

Absorption and Pharmacokinetics. Heparin is not absorbed through the gastrointestinal mucosa and therefore is given by continuous intravenous infusion or subcutaneous injection. Heparin has an immediate onset of action when given intravenously. In contrast, there is considerable variation in the bioavailability of heparin given subcutaneously, and the onset of action is delayed 1 to 2 hours; low-molecular-weight heparins are absorbed more uniformly.

The half-life of heparin in plasma depends on the dose administered. When doses of 100, 400, or 800 units/kg of heparin are injected intravenously, the half-lives of the anticoagulant activities are approximately 1, 2.5, and 5 hours, respectively (*see Appendix II for pharmacokinetic data*). Heparin appears to be cleared and degraded primarily by the reticuloendothelial system; a small amount of undegraded heparin also appears in the urine. The half-life of heparin may be shortened in patients with pulmonary embolism and prolonged in patients with hepatic cirrhosis or end-stage renal disease. Low-molecular-weight heparins have longer biological half-lives than do standard preparations of the drug.

Administration and Monitoring. Full-dose heparin therapy usually is administered by continuous intravenous infusion. Treatment of venous thromboembolism is initiated with a bolus injection of 5000 units, followed by 1200 to 1600 units per hour delivered by an infusion pump. Therapy routinely is monitored by the aPTT. The therapeutic range for standard heparin is considered to be

that which is equivalent to a plasma heparin level of 0.3 to 0.7 units/ml as determined with an anti-factor Xa assay (Hirsh *et al.*, 2001). The aPTT value that corresponds to this range varies depending on the reagent and instrument used to perform the assay. A clotting time of 1.8 to 2.5 times the normal mean aPTT value generally is assumed to be therapeutic; however, values in this range obtained with some aPTT assays may overestimate the amount of circulating heparin, and therefore be subtherapeutic. The risk of recurrence of thromboembolism is greater in patients who do not achieve a therapeutic level of anticoagulation within the first 24 hours. Initially, the aPTT should be measured and the infusion rate adjusted every 6 hours; dose adjustments may be aided by use of a nomogram (Hirsh *et al.*, 2001). Once a steady dosage schedule has been established, daily monitoring is sufficient.

Very high doses of heparin are required to prevent coagulation during cardiopulmonary bypass. The aPTT is infinitely prolonged over the dosage range used. Another coagulation test, such as the activated clotting time, is employed to monitor therapy in this situation.

Subcutaneous administration of heparin can be used for the long-term management of patients in whom warfarin is contraindicated (*e.g.*, during pregnancy). A total daily dose of about 35,000 units administered as divided doses every 8 to 12 hours usually is sufficient to achieve an aPTT of 1.5 times the control value (measured midway between doses). Monitoring generally is unnecessary once a steady dosage schedule is established.

Low-dose heparin therapy is used prophylactically to prevent deep venous thrombosis and thromboembolism in susceptible patients. (Until recently a suggested regimen for such treatment was 5000 units of heparin given every 8 to 12 hours.) The body of evidence now suggests that this regimen is clinically less effective than giving heparin every 8 hours in hospitalized medical and surgical patients at high risk for venous thromboembolism (Cade, 1982; Gardlund, 1996; Belch *et al.*, 1981). Laboratory monitoring is unnecessary, since this regimen does not prolong the aPTT.

Low-Molecular-Weight Heparin Preparations. *Enoxaparin* (LOVENOX), *dalteparin* (FRAGMIN), *tinzaparin* (INNOHEP, others), *ardeparin* (NORMIFLO), *nadroparin* (FRAXIPARINE, others), and *reviparin* (CLIVARINE) differ considerably in composition, and it cannot be assumed that two preparations that have similar anti-factor Xa activity will produce equivalent antithrombotic effects. The more predictable pharmacokinetic properties of low-molecular-weight heparins, however, permit administration in a fixed or weight-adjusted dosage regimen once or twice daily by

subcutaneous injection. Since they have a minimal effect on tests of clotting *in vitro*, monitoring is not done routinely. Patients with end-stage renal failure may require monitoring with an anti-factor Xa assay because this condition may prolong the half-life of low-molecular-weight heparin. Specific dosage recommendations for various low-molecular-weight heparins may be obtained from the manufacturer's literature. Nadroparin and reviparin are not currently available in the United States.

Synthetic Heparin Derivatives. *Fondaparinux* (ARIXTRA) is a synthetic pentasaccharide based on the structure of the antithrombin binding region of heparin. It mediates inhibition of factor Xa by antithrombin but does not cause thrombin inhibition due to its short polymer length. Fondaparinux is administered by subcutaneous injection, reaches peak plasma levels in 2 hours, and is excreted in the urine with a half-life of 17 to 21 hours. It should not be used in patients with renal failure. Because it does not interact significantly with blood cells or plasma proteins other than antithrombin, fondaparinux can be given once a day at a fixed dose without coagulation monitoring. Fondaparinux appears to be much less likely than heparin or low-molecular-weight heparin to trigger the syndrome of heparin-induced thrombocytopenia (*see* below). Fondaparinux is approved for thromboprophylaxis of patients undergoing hip or knee surgery (Buller *et al.*, 2003) and for the therapy of pulmonary embolism and deep venous thrombosis. *Idraparinux* (undergoing phase III clinical testing as of 2004) is a more highly sulfated derivative of fondaparinux that has a half-life of 5 to 6 days; the lack of a suitable antidote may limit its clinical application.

Heparin Resistance. The dose of heparin required to produce a therapeutic aPTT varies due to differences in the concentrations of heparin-binding proteins in plasma, such as histidine-rich glycoprotein, vitronectin, and platelet factor 4; these proteins competitively inhibit binding of heparin to antithrombin. Occasionally a patient's aPTT will not be prolonged unless very high doses of heparin (>50,000 units per day) are administered. Such patients may have "therapeutic" concentrations of heparin in plasma at the usual dose when values are measured by other tests (*e.g.*, anti-factor Xa activity or protamine sulfate titration). These patients may have very short aPTT values prior to treatment because of the presence of an increased concentration of factor VIII and may not be truly resistant to heparin. Other patients may require large doses of heparin because of accelerated clearance of the drug, as may occur with massive pulmonary embolism. Patients with inherited antithrombin deficiency ordinarily have 40% to 60% of the normal plasma concentration of this inhibitor and respond normally to intravenous heparin. However, acquired antithrombin deficiency (concentration less than 25% of normal) may occur in patients with hepatic cirrhosis, nephrotic syndrome, or disseminated intravascular coagulation; large doses of heparin may not prolong the aPTT in these individuals.

Toxicities. Bleeding. Bleeding is the primary untoward effect of heparin. Major bleeding occurs in 1% to 5% of patients treated with intravenous heparin for venous thromboembolism (Hirsh *et al.*, 2001). The incidence of bleeding is somewhat less in patients treated with low-molecular-weight heparin for this indication. Although the number of bleeding episodes appears to increase with the total daily dose of heparin and with the degree of prolongation of the aPTT, these correlations are weak, and patients can bleed with aPTT values that are within the therapeutic range. Often an underlying cause for bleeding is present, such as recent surgery, trauma, peptic ulcer disease, or platelet dysfunction.

The anticoagulant effect of heparin disappears within hours of discontinuation of the drug. Mild bleeding due to heparin usually can be controlled without the administration of an antagonist. If life-threatening hemorrhage occurs, the effect of heparin can be reversed quickly by the slow intravenous infusion of *protamine sulfate*, a mixture of basic polypeptides isolated from salmon sperm. Protamine binds tightly to heparin and thereby neutralizes its anticoagulant effect. Protamine also interacts with platelets, fibrinogen, and other plasma proteins and may cause an anticoagulant effect of its own. Therefore, one should give the minimal amount of protamine required to neutralize the heparin present in the plasma. This amount is approximately 1 mg of protamine for every 100 units of heparin remaining in the patient; it is given intravenously at a slow rate (up to 50 mg over 10 minutes).

Protamine is used routinely to reverse the anticoagulant effect of heparin following cardiac surgery and other vascular procedures. Anaphylactic reactions occur in about 1% of patients with diabetes mellitus who have received protamine-containing insulin (*NPH insulin* or *protamine zinc insulin*) but are not limited to this group. A less common reaction consisting of pulmonary vasoconstriction, right ventricular dysfunction, systemic hypotension, and transient neutropenia also may occur after protamine administration.

Heparin-Induced Thrombocytopenia. Heparin-induced thrombocytopenia (platelet count <150,000/ml or a 50% decrease from the pretreatment value) occurs in about 0.5% of medical patients 5 to 10 days after initiation of therapy with standard heparin (Warkentin, 2003). The incidence of thrombocytopenia is lower with low-molecular-weight heparin. Thrombotic complications that can be life-threatening or lead to amputation occur in about one-half of the affected heparin-treated patients and may precede the onset of thrombocytopenia. The incidence of heparin-induced thrombocytopenia and thrombosis is

higher in surgical patients. Venous thromboembolism occurs most commonly, but arterial thromboses causing limb ischemia, myocardial infarction, and stroke also occur. Bilateral adrenal hemorrhage, skin lesions at the site of subcutaneous heparin injection, and a variety of systemic reactions may accompany heparin-induced thrombocytopenia. The development of IgG antibodies against complexes of heparin with platelet factor 4 (or, rarely, other chemokines) appears to cause all of these reactions. These complexes activate platelets by binding to Fc γ 1a receptors, which results in platelet aggregation, release of more platelet factor 4, and thrombin generation. The antibodies also may trigger vascular injury by binding to platelet factor 4 attached to heparan sulfate on the endothelium.

Heparin should be discontinued immediately if unexplained thrombocytopenia or any of the clinical manifestations mentioned above occur 5 or more days after beginning heparin therapy, regardless of the dose or route of administration. The onset of heparin-induced thrombocytopenia may occur earlier in patients who have received heparin within the previous 3 to 4 months and have residual circulating antibodies. The diagnosis of heparin-induced thrombocytopenia can be confirmed by a heparin-dependent platelet activation assay or an assay for antibodies that react with heparin/platelet factor 4 complexes. Since thrombotic complications may occur after cessation of therapy, an alternative anticoagulant such as *lepirudin*, *argatroban*, or *danaparoid* (*see below*) should be administered to patients with heparin-induced thrombocytopenia. Low-molecular-weight heparins should be avoided, because these drugs often cross-react with standard heparin in heparin-dependent antibody assays. Warfarin may precipitate venous limb gangrene or multicentric skin necrosis in patients with heparin-induced thrombocytopenia and should not be used until the thrombocytopenia has resolved and the patient is adequately anticoagulated with another agent.

Other Toxicities. Abnormalities of hepatic function tests occur frequently in patients who are receiving heparin intravenously or subcutaneously. Mild elevations of the activities of hepatic transaminases in plasma occur without an increase in bilirubin levels or alkaline phosphatase activity. Osteoporosis resulting in spontaneous vertebral fractures can occur, albeit infrequently, in patients who have received full therapeutic doses of heparin (greater than 20,000 units per day) for extended periods of time (*e.g.*, 3 to 6 months). Heparin can inhibit the synthesis of aldosterone by the adrenal glands and occasionally causes hyperkalemia, even when low doses are given. Allergic reactions to heparin (other than thrombocytopenia) are rare.

Other Parenteral Anticoagulants

Lepirudin. Lepirudin (REFLUDAN) is a recombinant derivative (Leu¹-Thr²-63-desulfohirudin) of hirudin, a direct thrombin inhibitor present in the salivary glands of the medicinal leech. It is a 65-amino-acid polypeptide that binds tightly to both the catalytic site and the extended substrate recognition site (exosite I) of thrombin. Lepirudin is approved in the United States for treatment of patients with heparin-induced thrombocytopenia. It is administered intravenously at a dose adjusted to maintain the aPTT at 1.5 to 2.5 times the median of the laboratory's normal range for aPTT. The drug is excreted by the kidneys and has a half-life of about 1.3 hours. Lepirudin should be used cautiously in patients with renal failure, since it can accumulate and cause bleeding in these patients. Patients may develop antihirudin antibodies that occasionally cause a paradoxical increase in the aPTT; therefore, daily monitoring of the aPTT is recommended. There is no antidote for lepirudin.

Bivalirudin. Bivalirudin (ANGIOMAX) is a synthetic, 20-amino-acid polypeptide that directly inhibits thrombin by a mechanism similar to that of lepirudin. Bivalirudin contains the sequence Phe¹-Pro²-Arg³-Pro⁴, which occupies the catalytic site of thrombin, followed by a polyglycine linker and a hirudin-like sequence that binds to exosite I. Thrombin slowly cleaves the Arg³-Pro⁴ peptide bond and thus regains activity. Bivalirudin is administered intravenously and is used as an alternative to heparin in patients undergoing coronary angioplasty. The half-life of bivalirudin in patients with normal renal function is 25 minutes; dosage reductions are recommended for patients with moderate or severe renal impairment.

Argatroban. Argatroban, a synthetic compound based on the structure of L-arginine, binds reversibly to the catalytic site of thrombin. It is administered intravenously and has an immediate onset of action. Its half-life is 40 to 50 minutes. Argatroban is metabolized by cytochrome P450 enzymes in the liver and is excreted in the bile; therefore dosage reduction is required for patients with hepatic insufficiency. The dosage is adjusted to maintain an aPTT of 1.5 to 3 times the baseline value. Argatroban can be used as an alternative to lepirudin for prophylaxis or treatment of patients with or at risk of developing heparin-induced thrombocytopenia.

Danaparoid. Danaparoid (ORGARAN) is a mixture of nonheparin glycosaminoglycans isolated from porcine intestinal mucosa (84% heparan sulfate, 12% dermatan

sulfate, 4% chondroitin sulfate) with a mean mass of 5500 daltons. Danaparoid is approved in the United States for prophylaxis of deep venous thrombosis. It also is an effective anticoagulant for patients with heparin-induced thrombocytopenia and has a low rate of cross-reactivity with heparin in platelet-activation assays. Danaparoid mainly promotes inhibition of factor Xa by antithrombin, but it does not prolong the PT or aPTT at the recommended dosage. Danaparoid is administered subcutaneously at a fixed dose for prophylactic use and intravenously at a higher, weight-adjusted dose for full anticoagulation. Its half-life is about 24 hours. Patients with renal failure may require monitoring with an anti-factor Xa assay because of a prolonged half-life of the drug. No antidote is available. Danaparoid is no longer available in the United States.

Drotrecogin Alfa. Drotrecogin alfa (XIGRIS) is a recombinant form of human activated protein C that inhibits coagulation by proteolytic inactivation of factors Va and VIIIa. It also has antiinflammatory effects (Esmon, 2003). A 96-hour continuous infusion of drotrecogin alfa decreases mortality in adult patients who are at high risk for death from severe sepsis if given within 48 hours of the onset of organ dysfunction (*e.g.*, shock, hypoxemia, oliguria). The major adverse effect is bleeding.

ORAL ANTICOAGULANTS

Warfarin

History. Following the report of a hemorrhagic disorder in cattle that resulted from the ingestion of spoiled sweet clover silage, Campbell and Link, in 1939, identified the hemorrhagic agent as bishydroxycoumarin (dicoumarol). In 1948, a more potent synthetic congener was introduced as an extremely effective rodenticide; the compound was named *warfarin* as an acronym derived from the name of the patent holder, Wisconsin Alumni Research Foundation. Warfarin's potential as a therapeutic anticoagulant was recognized but not widely accepted, partly due to fear of unacceptable toxicity. However, in 1951, an Army inductee uneventfully survived an attempted suicide with massive doses of a preparation of warfarin intended for rodent control. Since then, these anticoagulants have become a mainstay for prevention of thromboembolic disease.

Chemistry. Numerous anticoagulants have been synthesized as derivatives of 4-hydroxycoumarin and of the related compound, indan-1,3-dione (Figure 54-5). Only the coumarin derivatives are widely used; the 4-hydroxycoumarin residue, with a nonpolar carbon substituent at the 3 position, is the minimal structural requirement for activity. This carbon is asymmetrical in warfarin (and in *phenprocoumon* and *acenocoumarol*). The enantiomers differ in anticoagulant potency, metabolism, elimination, and interactions with other drugs. Commercial preparations of these anticoagulants

Figure 54–5. Structural formulas of the oral anticoagulants. 4-Hydroxycoumarin and indan-1,3-dione are the parent molecules from which the oral anticoagulants are derived. The asymmetrical carbon atoms in the coumarins are shown in blue.

are racemic mixtures. No advantage of administering a single enantiomer has been established.

Mechanism of Action. The oral anticoagulants are antagonists of vitamin K (*see* section on vitamin K, below). Coagulation factors II, VII, IX, and X and the anticoagulant proteins C and S are synthesized mainly in the liver and are biologically inactive unless 9 to 13 of the amino-terminal glutamate residues are carboxylated to form the Ca^{2+} -binding γ -carboxyglutamate (Gla) residues. This reaction of the descarboxy precursor protein requires carbon dioxide, molecular oxygen, and reduced vitamin K, and is catalyzed by γ -glutamyl carboxylase in the rough endoplasmic reticulum (Figure 54–6). Carboxylation is directly coupled to the oxidation of vitamin K to its corresponding epoxide.

Reduced vitamin K must be regenerated from the epoxide for sustained carboxylation and synthesis of biologically competent proteins. The enzyme that catalyzes

this, vitamin K epoxide reductase, is inhibited by therapeutic doses of warfarin. Vitamin K (but not vitamin K epoxide) also can be converted to the corresponding hydroquinone by a second reductase, DT-diaphorase. This enzyme requires high concentrations of vitamin K and is less sensitive to coumarin drugs, which may explain why administration of sufficient vitamin K can counteract even large doses of oral anticoagulants.

Therapeutic doses of warfarin decrease by 30% to 50% the total amount of each vitamin K–dependent coagulation factor made by the liver; in addition, the secreted molecules are undercarboxylated, resulting in diminished biological activity (10% to 40% of normal). Congenital deficiencies of the procoagulant proteins to these levels cause mild bleeding disorders. Oral anticoagulants have no effect on the activity of fully carboxylated molecules in the circulation. Thus, the time required for the activity of each factor in plasma to reach a new steady state after therapy is initiated or adjusted depends on its individual

Figure 54–6. The Vitamin K cycle: γ -glutamyl carboxylation of vitamin K–dependent proteins. The enzyme γ -glutamyl carboxylase couples the oxidation of the reduced hydroquinone form (KH_2) of vitamin K_1 or K_2 , to γ -carboxylation of Glu residues on vitamin K–dependent proteins, generating the epoxide of vitamin K (KO) and γ -carboxyglutamate (Gla) residues in vitamin K–dependent precursor proteins in the endoplasmic reticulum. A 2,3-epoxide reductase regenerates vitamin KH_2 and is the warfarin-sensitive step. The R on the vitamin K molecule represents a 20-carbon phytyl side chain in vitamin K_1 and a 5- to 65-carbon prenyl side chain in vitamin K_2 .

rate of clearance. The approximate half-lives (in hours) are as follows: factor VII, 6; factor IX, 24; factor X, 36; factor II, 50; protein C, 8; and protein S, 30. Because of the long half-lives of some of the coagulation factors, in particular factor II, the full antithrombotic effect of warfarin is not achieved for several days, even though the PT may be prolonged soon after administration due to the more rapid reduction of factors with a shorter half-life, in particular factor VII. There is no obvious selectivity of the effect of warfarin on any particular vitamin K–dependent coagulation factor, although the antithrombotic benefit and the hemorrhagic risk of therapy may be correlated with the functional level of prothrombin, and to a lesser extent, factor X (Zivelin *et al.*, 1993).

Dosage. The usual adult dose of warfarin (COUMADIN) is 5 mg per day for 2 to 4 days, followed by 2 to 10 mg per day as indicated by measurements of the international normalized ratio (INR), a value derived from the patient's PT (see functional definition of INR in section on laboratory monitoring, below). A lower initial dose should be given to

patients with an increased risk of bleeding, including the elderly. Warfarin usually is administered orally; age correlates with increased sensitivity to oral anticoagulants. Warfarin also can be given intravenously without modification of the dose. Intramuscular injection is not recommended because of the risk of hematoma formation.

Absorption. The bioavailability of warfarin is nearly complete when the drug is administered orally, intravenously, or rectally. Bleeding has occurred from repeated skin contact with solutions of warfarin used as a rodenticide. However, different commercial preparations of warfarin tablets vary in their rate of dissolution, and this causes some variation in the rate and extent of absorption. Food in the gastrointestinal tract also can decrease the rate of absorption. Warfarin usually is detectable in plasma within 1 hour of its oral administration, and concentrations peak in 2 to 8 hours.

Distribution. Warfarin is almost completely (99%) bound to plasma proteins, principally albumin, and the drug distributes rapidly into a volume equivalent to the albumin space (0.14 L/kg). Concentrations in fetal plasma approach the maternal values, but active warfarin is not found in milk (unlike other coumarins and indandiones).

Biotransformation and Elimination. Warfarin is a racemic mixture of R (weak) and S (potent) anticoagulant enantiomers. S-warfarin is transformed into inactive metabolites by CYP2C9 and R-warfarin is transformed by CYP1A2, CYP2C19 (minor pathway), and CYP3A4 (minor pathway). The inactive metabolites of warfarin are excreted in urine and stool. The average rate of clearance from plasma is $0.045 \text{ ml/min}^{-1} \cdot \text{kg}^{-1}$. The half-life ranges from 25 to 60 hours, with a mean of about 40 hours; the duration of action of warfarin is 2 to 5 days.

Drug and Other Interactions. The list of drugs and other factors that may affect the action of oral anticoagulants is prodigious and expanding (Hirsh *et al.*, 2003). Any substance or condition is potentially dangerous if it alters (1) the uptake or metabolism of the oral anticoagulant or vitamin K; (2) the synthesis, function, or clearance of any factor or cell involved in hemostasis or fibrinolysis; or (3) the integrity of any epithelial surface. Patients must be educated to report the addition or deletion of any medication, including nonprescription drugs and food supplements. Some of the more commonly described factors that cause a decreased effect of oral anticoagulants include: reduced absorption of drug caused by binding to *cholestyramine* in the gastrointestinal tract; increased volume of distribution and a short half-life secondary to hypoproteinemia, as in nephrotic syndrome; increased metabolic clearance of drug secondary to induction of hepatic enzymes, especially CYP2C9, by barbiturates, *carbamazepine*, or *rifampin*; ingestion of large amounts of vitamin K–rich foods or supplements; and increased levels of coagulation factors during pregnancy. Hence, the PT can be shortened in any of these cases.

Frequently cited interactions that enhance the risk of hemorrhage in patients taking oral anticoagulants include decreased metabolism due to CYP2C9 inhibition by *amiodarone*, azole antifungals, *cimetidine*, *clopidogrel*, *cotrimoxazole*, *disulfiram*, *fluoxetine*, *isoniazid*, *metronidazole*, *sulfapyrazone*, *tolcapone*, or *zafirlukast*, and displacement from protein binding sites caused by loop diuretics or *valproate*. Relative deficiency of vitamin K may result from inad-

quate diet (e.g., postoperative patients on parenteral fluids), especially when coupled with the elimination of intestinal flora by antimicrobial agents. Gut bacteria synthesize vitamin K and thus are an important source of this vitamin. Consequently, antibiotics can cause excessive PT prolongation in patients adequately controlled on warfarin. In addition to an effect on reducing intestinal flora, cephalosporins containing heterocyclic side chains also inhibit steps in the vitamin K cycle. Low concentrations of coagulation factors may result from impaired hepatic function, congestive heart failure, or hypermetabolic states, such as hyperthyroidism; generally, these conditions increase the prolongation of the PT. Serious interactions that do not alter the PT include inhibition of platelet function by agents such as *aspirin* and gastritis or frank ulceration induced by antiinflammatory drugs. Agents may have more than one effect; for example, *clofibrate* increases the rate of turnover of coagulation factors and inhibits platelet function. Elderly patients are more sensitive to oral anticoagulants.

Resistance to Warfarin. Some patients require more than 20 mg per day of warfarin to achieve a therapeutic INR. These patients often have excessive vitamin K intake from the diet or parenteral supplementation. Noncompliance and laboratory error are other causes of apparent warfarin resistance. A few patients with hereditary warfarin resistance have been reported, in whom very high plasma concentrations of warfarin are associated with minimal depression of vitamin K–dependent coagulation factor biosynthesis; mutations in the vitamin K epoxide reductase gene have been identified in some of these patients (Rost *et al.*, 2004).

Sensitivity to Warfarin. Approximately 10% of patients require less than 1.5 mg per day of warfarin to achieve an INR of 2 to 3. These patients are more likely to possess one or two variant alleles of CYP2C9, which is the major enzyme responsible for converting the S-enantiomer warfarin to its inactive metabolites (Daly and King, 2003). In comparison with the wild-type CYP2C9*1 allele, the variant alleles CYP2C9*2 and CYP2C9*3 have been shown to inactivate S-warfarin much less efficiently *in vitro*. The variant alleles are present in 10% to 20% of Caucasians, but in <5% of African-Americans or Asians.

Toxicities. Bleeding. Bleeding is the major toxicity of oral anticoagulant drugs (Hirsh *et al.*, 2003). The risk of bleeding increases with the intensity and duration of anticoagulant therapy, the use of other medications that interfere with hemostasis, and the presence of a potential anatomical source of bleeding. Especially serious episodes involve sites where irreversible damage may result from compression of vital structures (e.g., intracranial, pericardial, nerve sheath, or spinal cord) or from massive internal blood loss that may not be diagnosed rapidly (e.g., gastrointestinal, intraperitoneal, or retroperitoneal). Although the reported incidence of major bleeding episodes varies considerably, it is generally less than 5% per year in patients treated with a target INR of 2 to 3. The risk of intracranial hemorrhage increases dramatically with an INR greater than 4, especially in older patients. In a large outpatient anticoagulation clinic, the most common factors

associated with a transient elevation of the INR (>6) were use of a new medication known to potentiate warfarin (e.g., *acetaminophen*), advanced malignancy, recent diarrheal illness, decreased oral intake, and taking more warfarin than prescribed (Hylek *et al.*, 1998). Patients must be informed of the signs and symptoms of bleeding, and laboratory monitoring should be done at frequent intervals during intercurrent illnesses or any changes of medication or diet.

If the INR is above the therapeutic range but <5 and the patient is not bleeding or in need of a surgical procedure, warfarin can be discontinued temporarily and restarted at a lower dose once the INR is within the therapeutic range (Hirsh *et al.*, 2003). If the INR is ≥ 5 , vitamin K₁ (*phytonadione*, MEPHYTON, AQUAMEPHYTON) can be given orally at a dose of 1 to 2.5 mg (for an INR between 5 and 9) or 3 to 5 mg (for an INR >9). These doses of oral vitamin K₁ generally cause the INR to fall substantially within 24 to 48 hours without rendering the patient resistant to further warfarin therapy. Higher doses may be required if more rapid correction of the INR is necessary. The effect of vitamin K₁ is delayed for at least several hours, because reversal of anticoagulation requires synthesis of fully carboxylated coagulation factors. If immediate hemostatic competence is necessary because of serious bleeding or profound warfarin overdosage (INR >20), adequate concentrations of vitamin K–dependent coagulation factors can be restored by transfusion of fresh frozen plasma (10 to 20 ml per kg), supplemented with 10 mg of vitamin K₁, given by slow intravenous infusion. Transfusion of plasma may need to be repeated, since the transfused factors (particularly factor VII) are cleared from the circulation more rapidly than the residual oral anticoagulant. Vitamin K₁ administered intravenously carries the risk of anaphylactoid reactions, and therefore should be used cautiously. Patients who receive high doses of vitamin K₁ may become unresponsive to warfarin for several days, but heparin can be used if continued anticoagulation is required.

Birth Defects. Administration of warfarin during pregnancy causes birth defects and abortion. A syndrome characterized by nasal hypoplasia and stippled epiphyseal calcifications that resemble chondrodysplasia punctata may result from maternal ingestion of warfarin during the first trimester. Central nervous system abnormalities have been reported following exposure during the second and third trimesters. Fetal or neonatal hemorrhage and intrauterine death may occur, even when maternal PT values are in the therapeutic range. Oral anticoagulants should not be used during pregnancy, but as indicated in the previous section, heparin can be used safely in this circumstance.

Skin Necrosis. Warfarin-induced skin necrosis is a rare complication characterized by the appearance of skin lesions 3 to 10 days after treatment is initiated. The lesions typically are on the extremi-

ties, but adipose tissue, the penis, and the female breast also may be involved. Lesions are characterized by widespread thrombosis of the microvasculature and can spread rapidly, sometimes becoming necrotic and requiring disfiguring débridement or occasionally amputation. Cases have been reported in subjects heterozygous for protein C or protein S deficiency. Since protein C has a shorter half-life than do the other vitamin K–dependent coagulation factors (except factor VII), its functional activity falls more rapidly in response to the initial dose of vitamin K antagonist. It has been proposed that the dermal necrosis is a manifestation of a temporal imbalance between the anticoagulant protein C and one or more of the procoagulant factors and is exaggerated in patients who are partially deficient in protein C or protein S. However, not all patients with heterozygous deficiency of protein C or protein S develop skin necrosis when treated with warfarin, and patients with normal activities of these proteins also can be affected. Morphologically similar lesions can occur in patients with vitamin K deficiency.

Other Toxicities. A reversible, sometimes painful, blue-tinged discoloration of the plantar surfaces and sides of the toes that blanches with pressure and fades with elevation of the legs (purple toe syndrome) may develop 3 to 8 weeks after initiation of therapy with warfarin; cholesterol emboli released from atheromatous plaques have been implicated as the cause. Other infrequent reactions include alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramps, and anorexia.

Warfarin appears to precipitate the syndromes of venous limb gangrene and multicentric skin necrosis that sometimes are associated with heparin-induced thrombocytopenia (Warkentin, 2003). Other anticoagulant agents, such as lepirudin or argatroban, should be used until the heparin-induced thrombocytopenia has resolved (*see* Heparin Toxicities, above).

Clinical Use

Oral anticoagulants are used to prevent the progression or recurrence of acute deep vein thrombosis or pulmonary embolism following an initial course of heparin. They also are effective in preventing venous thromboembolism in patients undergoing orthopedic or gynecological surgery and in preventing systemic embolization in patients with acute myocardial infarction, prosthetic heart valves, or chronic atrial fibrillation. Specific recommendations for oral anticoagulant use for these and other indications have been reviewed (The Sixth American College of Chest Physicians Guidelines for Antithrombotic Therapy for Prevention and Treatment of Thrombosis, 2001).

Prior to initiation of therapy, laboratory tests are used in conjunction with the patient's history and physical examination to uncover hemostatic defects that might make the use of oral anticoagulant drugs more dangerous (congenital coagulation factor deficiency, thrombocytopenia, hepatic or renal insufficiency, vascular abnormalities, *etc.*). Thereafter, the INR calculated from the patient's PT is used to monitor efficacy and compliance. Therapeutic ranges for various clinical indications have been established empirically and reflect dosages that reduce the

morbidity from thromboembolic disease while minimally increasing the risk of serious hemorrhage. For most indications the target INR is 2 to 3. A higher target INR (*e.g.*, 2.5 to 3.5) generally is recommended for patients with mechanical prosthetic heart valves (Hirsh *et al.*, 2003).

For treatment of acute venous thromboembolism, heparin usually is continued for at least 4 to 5 days after oral anticoagulation is begun and until the INR is in the therapeutic range on 2 consecutive days. This overlap allows for adequate depletion of the vitamin K–dependent coagulation factors with long half-lives, especially factor II. Daily INR measurements are indicated at the onset of therapy to guard against excessive anticoagulation in the unusually sensitive patient. The testing interval can be lengthened gradually to weekly and then to monthly for patients on long-term therapy in whom test results have been stable.

Monitoring Anticoagulant Therapy: The INR (International Normalized Ratio). To monitor therapy, a fasting blood sample is usually obtained 8 to 14 hours after the last dose of an oral anticoagulant, and the patient's PT is determined along with that of a sample of normal pooled plasma. Formerly, the results were reported as a simple ratio of the two PT values. However, this ratio can vary widely depending on the thromboplastin reagent and the instrument used to initiate and detect clot formation. The PT is prolonged when the functional levels of fibrinogen, factor V, or the vitamin K–dependent factors II, VII, or X are decreased. Reduced levels of factor IX or proteins C or S have no effect on the PT. PT measurements are converted to INR measurements by the following equation:

$$\text{INR} = \left(\frac{\text{PT}_{\text{pt}}}{\text{PT}_{\text{ref}}} \right)^{\text{ISI}} \quad (54-1)$$

where INR = International Normalized Ratio
ISI = International Sensitivity Index

The ISI value, generally supplied by the manufacturer, indicates the relative sensitivity of the PT determined with a given thromboplastin to decreases in the vitamin K–dependent coagulation factors in comparison with a World Health Organization human thromboplastin standard. Reagents with lower ISI values are more sensitive to the effects of oral anticoagulants (*i.e.*, the PT is prolonged to a greater extent in comparison with that obtained with a less sensitive reagent having a higher ISI). Ideally, the ISI value of each batch of thromboplastin should be confirmed in each clinical laboratory using a set of reference plasmas to control for local variables of sample handling and instrumentation.

The major practical consequence of standardization to the INR has been an appreciation that the commercial thromboplastins from rabbit tissue, used especially in North America, are relatively insensitive. This property led to administration of larger doses of oral anticoagulants than were considered optimal in many of the original clinical trials in which more sensitive human brain thromboplastins generally were used. Thus, the target INR of 2 to 3 corresponds to a PT ratio of 1.2 to 1.5 if rabbit thromboplastin is used or 2 to 3 if human thromboplastin is used.

The INR does not provide a reliable indication of the degree of anticoagulation in patients with the lupus anticoagulant, in whom the PT and other phospholipid-dependent coagulation tests are prolonged at baseline. In these patients, a chromogenic anti-factor Xa assay or the prothrombin-proconvertin-time assay may be used to monitor therapy (Moll and Ortel, 1997).

Other Oral Anticoagulants

Phenprocoumon and Acenocoumarol. These agents are not generally available in the United States but are prescribed in Europe and elsewhere. Phenprocoumon (MARCUMAR) has a longer plasma half-life (5 days) than warfarin, as well as a somewhat slower onset of action and a longer duration of action (7 to 14 days). It is administered in daily maintenance doses of 0.75 to 6 mg. By contrast, acenocoumarol (SINTHROME) has a shorter half-life (10 to 24 hours), a more rapid effect on the PT, and a shorter duration of action (2 days). The maintenance dose is 1 to 8 mg daily.

Indandione Derivatives. *Anisindione* (MIRADON) is available for clinical use in some countries. It is similar to warfarin in its kinetics of action; however, it offers no clear advantages and may have a higher frequency of untoward effects. *Phenindione* (DINDEVAN) still is available in some countries. Serious hypersensitivity reactions, occasionally fatal, can occur within a few weeks of starting therapy with this drug, and its use can no longer be recommended.

Rodenticides. *Bromadiolone*, *brodifacoum*, *diphenadione*, *chlorophacinone*, and *pindone* are long-acting agents (prolongation of the PT may persist for weeks). They are of interest because they sometimes are agents of accidental or intentional poisoning. In this setting, reversal of the coagulopathy can require very large doses of vitamin K (*i.e.*, >100 mg/day) for weeks or months.

Ximelagatran. *Ximelagatran* is a novel drug that is readily absorbed after oral administration and is rapidly metabolized to *melagatran*, a direct thrombin inhibitor. Therefore, its onset of action is much faster than that of warfarin. *Ximelagatran* is administered twice daily at a fixed dose and does not appear to require coagulation monitoring. *Melagatran* is excreted primarily by the kidney; therefore, dosage reduction may be necessary for patients with renal failure. *Ximelagatran* has been used successfully in clinical trials for prevention of venous thromboembolism (Francis *et al.*, 2003; Schulman *et al.*, 2003). *Ximelagatran* causes elevation of hepatic transaminases in about 6% of patients, but this side effect usually

is asymptomatic and often is transient. The drug has not yet been approved for use in the United States.

FIBRINOLYTIC DRUGS

The fibrinolytic pathway is summarized by Figure 54–3. The action of fibrinolytic agents is best understood in conjunction with an understanding of the characteristics of the physiologic components.

Plasminogen. Plasminogen is a single-chain glycoprotein that contains 791 amino acid residues; it is converted to an active protease by cleavage at arginine 560. High-affinity binding sites mediate the binding of plasminogen (or plasmin) to carboxyl-terminal lysine residues in partially degraded fibrin; this enhances fibrinolysis. A plasma carboxypeptidase termed *thrombin-activatable fibrinolysis inhibitor* (TAFI) can remove these lysine residues and thereby attenuate fibrinolysis. The lysine binding sites are in the amino-terminal “kringle” domain of plasminogen between amino acids 80 and 165, and they also promote formation of complexes of plasmin with α_2 -antiplasmin, the major physiological plasmin inhibitor. Plasminogen concentrations in human plasma average 2 μM . A degraded form of plasminogen termed *lys-plasminogen* binds to fibrin much more rapidly than does intact plasminogen.

α_2 -Antiplasmin. α_2 -Antiplasmin is a glycoprotein of 452 amino acid residues. It forms a stable complex with plasmin, thereby inactivating it. Plasma concentrations of α_2 -antiplasmin (1 μM) are sufficient to inhibit about 50% of potential plasmin. When massive activation of plasminogen occurs, the inhibitor is depleted, and free plasmin causes a “systemic lytic state,” in which hemostasis is impaired. In this state, fibrinogen is destroyed and fibrinogen degradation products impair formation of fibrin and therefore increase bleeding from wounds. α_2 -Antiplasmin inactivates plasmin nearly instantaneously, as long as the lysine binding sites on plasmin are unoccupied by fibrin or other antagonists, such as *aminocaproic acid* (*see below*).

Streptokinase. *Streptokinase* (STREPTASE) is a 47,000-dalton protein produced by β -hemolytic streptococci. It has no intrinsic enzymatic activity, but it forms a stable, noncovalent 1:1 complex with plasminogen. This produces a conformational change that exposes the active site on plasminogen that cleaves arginine 560 on free plasminogen to form free plasmin. Streptokinase is rarely used clinically for fibrinolysis since the advent of newer agents.

Tissue Plasminogen Activator (t-PA). t-PA is a serine protease that contains 527 amino acid residues. It is a poor plasminogen activator in the absence of fibrin (Lijnen and Collen, 2001). t-PA binds to fibrin *via* lysine binding sites at its amino terminus and activates bound plasminogen several hundredfold more rapidly than it

activates plasminogen in the circulation. The lysine binding sites on t-PA are in a “finger” domain that is homologous to similar sites on fibronectin. Under physiological conditions (t-PA concentrations of 5 to 10 ng/ml), the specificity of t-PA for fibrin limits systemic formation of plasmin and induction of a systemic lytic state. During therapeutic infusions of t-PA, however, concentrations rise to 300 to 3000 ng/ml. Clearance of t-PA primarily occurs by hepatic metabolism, and its half-life is 5 to 10 minutes. t-PA is effective in lysing thrombi during treatment of acute myocardial infarction. t-PA (*alteplase*, ACTIVASE) is produced by recombinant DNA technology. The currently recommended (“accelerated”) regimen for coronary thrombolysis is a 15-mg intravenous bolus, followed by 0.75 mg/kg of body weight over 30 minutes (not to exceed 50 mg) and 0.5 mg/kg (up to 35 mg accumulated dose) over the following hour. Recombinant mutant variants of t-PA now are available (*reteplase*, RETAVASE and *tenekteplase*, TNKASE). They differ from native t-PA by having increased plasma half-lives that allow convenient bolus dosing (2 doses of 15 milligrams given 30 minutes apart). They also are relatively resistant to inhibition by plasma activator inhibitor-1. Despite these apparent advantages, these agents are similar to t-PA in efficacy and toxicity (GUSTO III Investigators, 1997).

Hemorrhagic Toxicity of Thrombolytic Therapy. The major toxicity of all thrombolytic agents is hemorrhage, which results from two factors: (1) the lysis of fibrin in “physiological thrombi” at sites of vascular injury; and (2) a systemic lytic state that results from systemic formation of plasmin, which produces fibrinogenolysis and destruction of other coagulation factors (especially factors V and VIII). The actual toxicity of streptokinase and t-PA is difficult to assess. In early clinical trials, many bleeding episodes resulted from the extensive invasive monitoring of therapy that was required by the protocol. Many studies to evaluate thrombolysis involved concurrent systemic heparinization, which also contributes to bleeding complications. Analysis of more recent clinical trials suggests that heparin confers no benefit in patients receiving fibrinolytic therapy plus aspirin (Collins *et al.*, 1997; Zijlstra *et al.*, 1999).

The contraindications to fibrinolytic therapy are listed in Table 54–1. Patients with these conditions should not receive such treatment, and invasive procedures (*e.g.*, cardiac catheterization and arterial blood gases) should be avoided. If heparin is used concurrently with either streptokinase or t-PA, serious hemorrhage will occur in 2% to 4% of patients. Intracranial hemorrhage is by far the most serious problem. Hemorrhagic stroke occurs with all regimens and is more common when heparin is used. In several large

Table 54–1
Contraindications to Thrombolytic Therapy

1. Surgery within 10 days, including organ biopsy, puncture of noncompressible vessels, serious trauma, cardiopulmonary resuscitation
2. Serious gastrointestinal bleeding within 3 months
3. History of hypertension (diastolic pressure >110 mm Hg)
4. Active bleeding or hemorrhagic disorder
5. Previous cerebrovascular accident or active intracranial process
6. Aortic dissection
7. Acute pericarditis

studies, t-PA was associated with an excess of hemorrhagic strokes of about 0.3% of treated patients. Based on the data of three large trials involving almost 100,000 patients, the efficacies of t-PA and streptokinase in treating myocardial infarction are essentially identical. Both agents reduce death and reinfarction by about 30% in regimens containing aspirin (Zijlstra *et al.*, 1999). Recent studies suggest that angioplasty with or without stent placement, when feasible, is superior to thrombolytic therapy, although direct comparisons using otherwise identical regimens have not been performed (Armstrong *et al.*, 2003; Andersen *et al.*, 2003).

Inhibition of Fibrinolysis

Aminocaproic Acid. Aminocaproic acid (AMICAR) is a lysine analog that competes for lysine binding sites on plasminogen and plasmin, thus blocking the interaction of plasmin with fibrin. Aminocaproic acid is thereby a potent inhibitor of fibrinolysis and can reverse states that are associated with excessive fibrinolysis. The main problem with its use is that thrombi that form during treatment with the drug are not lysed. For example, in patients with hematuria, ureteral obstruction by clots may lead to renal failure after treatment with aminocaproic acid. Aminocaproic acid has been used to reduce bleeding after prostatic surgery or after tooth extractions in hemophiliacs. Use of aminocaproic acid to treat a variety of other bleeding disorders has been unsuccessful, either because of limited benefit or because of thrombosis (*e.g.*, after subarachnoid hemorrhage). Aminocaproic acid is absorbed rapidly after oral administration, and 50% is excreted unchanged in the urine within 12 hours. For intravenous use, a loading dose of 4 to 5 g is given over 1 hour, followed by an infusion of 1 g per hour until bleeding is controlled. No more than 30 g should be given in a 24-hour period. Rarely, the drug causes myopathy and muscle necrosis.

ANTIPLATELET DRUGS

Platelets provide the initial hemostatic plug at sites of vascular injury. They also participate in pathological throm-

boses that lead to myocardial infarction, stroke, and peripheral vascular thromboses. Potent inhibitors of platelet function have been developed in recent years. These drugs act by discrete mechanisms, and thus in combination their effects are additive or even synergistic. Their availability has led to a revolution in cardiovascular medicine, whereby angioplasty and vascular stenting of lesions now is feasible with low rates of restenosis and thrombosis when effective platelet inhibition is employed.

Aspirin. Processes including thrombosis, inflammation, wound healing, and allergy are modulated by oxygenated metabolites of arachidonate and related polyunsaturated fatty acids that are collectively termed *eicosanoids*. Interference with the synthesis of eicosanoids is the basis for the effects of many therapeutic agents, including analgesics, antiinflammatory drugs, and antithrombotic agents (see Chapters 25 and 26).

In platelets, the major cyclooxygenase product is thromboxane A_2 , a labile inducer of platelet aggregation and a potent vasoconstrictor. Aspirin blocks production of thromboxane A_2 by acetylating a serine residue near the active site of platelet cyclooxygenase (COX-1), the enzyme that produces the cyclic endoperoxide precursor of thromboxane A_2 . Since platelets do not synthesize new proteins, the action of aspirin on platelet cyclooxygenase is permanent, lasting for the life of the platelet (7 to 10 days). Thus, repeated doses of aspirin produce a cumulative effect on platelet function. Complete inactivation of platelet COX-1 is achieved when 160 mg of aspirin is taken daily. Therefore, aspirin is maximally effective as an antithrombotic agent at doses much lower than those required for other actions of the drug. Numerous trials indicate that aspirin, when used as an antithrombotic drug, is maximally effective at doses of 50 to 320 mg per day (Antithrombotic Trialists' Collaboration, 2002; Patrono *et al.*, 2004). Higher doses do not improve efficacy; moreover, they potentially are less efficacious because of inhibition of prostacyclin production, which can be largely spared by using lower doses of aspirin. Higher doses also increase toxicity, especially bleeding.

Other NSAIDs that are reversible inhibitors of COX-1 have not been shown to have antithrombotic efficacy and in fact may even interfere with low-dose aspirin regimens.

Dipyridamole. *Dipyridamole* (PERSANTINE) is a vasodilator that, in combination with warfarin, inhibits embolization from prosthetic heart valves. Dipyridamole has little or no benefit as an antithrombotic drug. In trials in which a regimen of dipyridamole plus aspirin was compared with aspirin alone, dipyridamole provided no additional beneficial effect (Antithrombotic Trialists' Collaboration, 2002). A single study suggests that dipyridamole plus aspirin reduces strokes in patients with prior strokes or transient ischemic attack (Diener *et al.*, 1996). A formulation containing 200 mg of dipyridamole, in an extended-release form, and 25 mg of aspirin (AGGRENEX) is available. Dipyridamole interferes with platelet function by increasing the cellular concentration of adenosine 3',5'-monophosphate (cyclic AMP). This effect is mediated by inhibition of cyclic nucleotide phosphodiesterase and/or by blockade of uptake of adenosine, which acts at adenosine A_2 receptors to stimulate platelet adenylyl cyclase. The only current recommended use of dipyridamole is in combination with warfarin for postoperative primary prophylaxis of thromboemboli in patients with prosthetic heart valves.

Ticlopidine. Purinergic receptors respond to extracellular nucleotides as agonists. Platelets contain two purinergic receptors, $P2Y_1$ and $P2Y_{12}$; both are GPCRs for ADP. The ADP-activated platelet $P2Y_1$ receptor couples to the G_q -PLC-IP $_3$ -Ca $^{2+}$ pathway and induces a shape change and aggregation. The $P2Y_{12}$ receptor couples to G_i and, when activated by ADP, inhibits adenylyl cyclase, resulting in lower levels of cyclic AMP and thereby less cyclic AMP-dependent inhibition of platelet activation. Based on pharmacological studies, it appears that both receptors must be stimulated to result in platelet activation (Jin and Kunapuli, 1998), and inhibition of either receptor is sufficient to block platelet activation. *Ticlopidine* (TICLID) is a thienopyridine (Figure 54–7) that inhibits the $P2Y_{12}$ receptor. Ticlopidine is a prodrug that requires conversion to the active thiol metabolite by a hepatic cytochrome P450 enzyme (Savi *et al.*, 2000). It is rapidly absorbed and highly bioavailable. It permanently inhibits the $P2Y_{12}$ receptor by forming a disulfide bridge between the thiol on the drug and a free cysteine residue in the extracellular region of the receptor and thus has a prolonged effect. Like aspirin it has a short half-life with a long duration of action, which has been termed “hit-and-run pharmacology” (Hollopeter *et al.*, 2001). Maximal inhibition of platelet aggregation is not seen until 8 to 11 days after starting therapy. Thus, “loading doses” of 500 mg sometimes are given to achieve a more rapid onset of action. The usual dose is 250 mg twice per day. Inhibition of platelet aggregation persists for a few days after the drug is stopped.

Adverse Effects. The most common side effects are nausea, vomiting, and diarrhea. The most serious is severe neutropenia (absolute neutrophil count [ANC] $<1500/\mu\text{L}$), which occurred in 2.4% of stroke patients given the drug during premarketing clinical trials. Fatal agranulocytosis with thrombopenia has occurred within the first 3 months of therapy; therefore, frequent blood counts should be obtained during the first few months of therapy, with immediate dis-

Figure 54–7. Structure of ticlopidine and clopidogrel.

continuation of therapy should cell counts decline. Platelet counts also should be monitored, as thrombocytopenia has been reported. Rare cases of thrombotic thrombocytopenic purpura-hemolytic uremic syndrome (TTP-HUS) have been associated with ticlopidine with a reported incidence of 1 in 1600 to 4800 patients when the drug is used after cardiac stenting; the mortality associated with these cases is reported to be as high as 18% to 57% (Bennett *et al.*, 1998; Bennett *et al.*, 1999). Remission of TTP has been reported when the drug is stopped (Quinn and Fitzgerald, 1999).

Therapeutic Uses. Ticlopidine has been shown to prevent cerebrovascular events in secondary prevention of stroke and is at least as good as aspirin in this regard (Patrono *et al.*, 1998). It also reduces cardiac events in patients with unstable angina; however, its only FDA-approved indication is to reduce the risk of thrombotic stroke in patients who have experienced stroke precursors, and in patients who have had a completed thrombotic stroke. Since ticlopidine has a mechanism of action distinct from that of aspirin, combining the drugs might be expected to provide additive or even synergistic effects. This appears to be the case, and the combination has been used in patients undergoing angioplasty and stenting for coronary artery disease, with a very low frequency of stent thrombosis occurring over a short, 30-day follow-up (<1%) (Leon *et al.*, 1998). As ticlopidine is associated with life-threatening blood dyscrasias and a relatively high rate of TTP, it is generally reserved for patients who are intolerant or allergic to aspirin or who have failed aspirin therapy.

Clopidogrel. The thienopyridine clopidogrel (PLAVIX) is closely related to ticlopidine (Figure 54–7) and appears to have a slightly more favorable toxicity profile with less frequent thrombocytopenia and leukopenia, although thrombotic thrombocytopenic purpura has been reported (Bennett *et al.*, 2000). Clopidogrel is a prodrug with a slow onset of action. The usual dose is 75 mg per day with or without an initial loading dose of 300 mg. The drug is equivalent to aspirin in the secondary prevention of stroke, and in combination with aspirin it appears to be as effective as ticlopidine and aspirin. It is used with aspirin after angioplasty and should be continued for at least 1 year (Steinhubl *et al.*, 2002). In one study, the combination of clopidogrel and aspirin clearly was superior to aspirin alone; this finding suggests that the actions of the two drugs are synergistic, as might be expected from their distinct mechanisms of action (Yusuf *et al.*, 2001). The FDA-approved indications for clopidogrel are to reduce the rate of stroke, MI, and death in patients with recent myocardial infarction or stroke, established peripheral arterial disease, or acute coronary syndrome.

Glycoprotein IIb/IIIa Inhibitors. Glycoprotein IIb/IIIa is a platelet-surface integrin which, by the integrin nomenclature, is designated $\alpha_{IIb}\beta_3$. This dimeric glycoprotein is a receptor for fibrinogen and von Willebrand factor, which anchor platelets to foreign surfaces and to each other, thereby mediating aggregation. The integrin heterodimer/receptor is activated by platelet agonists such as thrombin, collagen,

or thromboxane A_2 to develop binding sites for its ligands, which do not bind to resting platelets. Inhibition of binding to this receptor blocks platelet aggregation induced by any agonist. Thus, inhibitors of this receptor are potent antiplatelet agents that act by a mechanism distinct from that of aspirin or the thienopyridine platelet inhibitors. Three agents are approved for use at present, with others under development.

Abciximab. Abciximab (REOPRO) is the Fab fragment of a humanized monoclonal antibody directed against the $\alpha_{IIb}\beta_3$ receptor. It also binds to the vitronectin receptor on platelets, vascular endothelial cells, and smooth muscle cells. The antibody is used in conjunction with percutaneous angioplasty for coronary thromboses, and when used in conjunction with aspirin and heparin, has been shown to be quite effective in preventing restenosis, recurrent myocardial infarction, and death. The reduction in total events is about 50% in various large trials (Scarborough *et al.*, 1999). The unbound antibody is cleared from the circulation with a half-life of about 30 minutes, but antibody remains bound to the $\alpha_{IIb}\beta_3$ receptor and inhibits platelet aggregation as measured *in vitro* for 18 to 24 hours after infusion is stopped. It is given as a 0.25-mg/kg bolus followed by 0.125 $\mu\text{g}/\text{kg}$ per minute for 12 hours or longer.

Adverse Effects. The major side effect of abciximab is bleeding, and the contraindications to its use are similar to those for fibrinolytic agents listed in Table 54–1. The frequency of major hemorrhage in clinical trials varies from 1% to 10%, depending on the intensity of anticoagulation with heparin. Thrombocytopenia of less than 50,000 μL is seen in about 2% of patients and may be due to development of neo-epitopes induced by bound antibody. Since the duration of action is long, if major bleeding or emergent surgery occurs, platelet transfusions can reverse the aggregation defect, because free antibody concentrations fall rapidly after cessation of infusion. Readministration of antibody has been performed in a small number of patients without evidence of decreased efficacy or allergic reactions. The expense of the antibody limits its use.

Eptifibatide. Eptifibatide (INTEGRILIN) is a cyclic peptide inhibitor of the fibrinogen binding site on $\alpha_{IIb}\beta_3$. It blocks platelet aggregation *in vitro* after intravenous infusion into patients. Eptifibatide is given as a bolus of 180 $\mu\text{g}/\text{kg}$ followed by 2 $\mu\text{g}/\text{kg}$ per minute for up to 96 hours. It is used to treat acute coronary syndrome and for angioplastic coronary interventions. In the latter case, myocardial infarction and death have been reduced by about 20%. Although the drug has not been compared directly to abciximab, it appears that its benefit is somewhat less than that obtained with the antibody, perhaps because eptifibatide is specific for $\alpha_{IIb}\beta_3$ and does not react with the vitronectin receptor. The duration of action of the drug is relatively short and platelet aggregation is restored within 6 to 12 hours after

cessation of infusion. Eptifibatid generally is administered in conjunction with aspirin and heparin.

Adverse Effects. The major side effect is bleeding, as is the case with abciximab. The frequency of major bleeding in trials was about 10%, compared with about 9% in a placebo group, which included heparin. Thrombocytopenia has been seen in 0.5% to 1% of patients.

Tirofiban. *Tirofiban* (AGGRASTAT) is a nonpeptide, small-molecule inhibitor of $\alpha_{IIb}\beta_3$ that appears to have a similar mechanism of action as eptifibatid. Tirofiban has a short duration of action and has efficacy in non-Q-wave myocardial infarction and unstable angina. Reductions in death and myocardial infarction have been about 20% compared to placebo, results similar to those with eptifibatid. Side effects also are similar to those of eptifibatid. The agent is specific to $\alpha_{IIb}\beta_3$ and does not react with the vitronectin receptor. Meta-analysis of trials using $\alpha_{IIb}\beta_3$ inhibitors suggests that their value in antiplatelet therapy after acute myocardial infarction is limited (Boersma *et al.*, 2002). Tirofiban is administered intravenously at an initial rate of 0.4 $\mu\text{g}/\text{kg}$ per minute for 30 minutes, and then continued at 0.1 mg/kg per minute for 12 to 24 hours after angioplasty or atherectomy. It is used in conjunction with heparin.

THE ROLE OF VITAMIN K

Vitamin K is essential in both mammals and in photosynthetic organisms. In certain photosynthetic bacteria, vitamin K is a cofactor in the photosynthetic electron-transport system; in green plants, vitamin K_1 is a component of photosystem I, the membrane-bound macromolecular light-sensitive complex. Green plants are a nutritional source of vitamin K for humans, in whom vitamin K is an essential cofactor in the γ -carboxylation of multiple glutamate (Glu) residues of several clotting factors and anticoagulant proteins. The vitamin K-dependent formation of γ -carboxy-glutamate (Gla) residues permits the appropriate interactions of clotting factors, Ca^{2+} , and membrane phospholipids and modulator proteins (Figures 54-1, 54-2, and 54-3). Oral anticoagulant drugs (coumadin derivatives, Figure 54-5) block Gla formation and thereby inhibit clotting; excess vitamin K_1 can reverse the effects of these oral anticoagulants.

History. In 1929, Dam observed that chickens fed inadequate diets developed a deficiency disease characterized by spontaneous bleeding and reduced prothrombin in the blood. Subsequently, Dam and coworkers (1935, 1936) found that the condition could be alleviated rapidly by feeding an unidentified fat-soluble substance, named *vitamin K* (*Koagulation* vitamin) by Dam. Independently, Almquist

and Stokstad (1935) performed similar work. Quick and coworkers (1935) observed a coagulation defect in jaundiced individuals that was due to a decrease in the plasma concentration of prothrombin. In the same year, Hawkins and Whipple reported that animals with biliary fistulas were likely to develop excessive bleeding. Subsequently, Hawkins and Brinkhous (1936) showed that this, too, was due to a deficiency in prothrombin and that the condition could be relieved by the feeding of bile salts. The culmination of these studies came with the demonstration by Butt and coworkers (1938) and Warner and associates (1938) that combination therapy with vitamin K and bile salts was effective in the treatment of the hemorrhagic diathesis of jaundice. Thus, the relationship between vitamin K, adequate hepatic function, and the physiological mechanisms operating in the normal clotting of blood was established.

Chemistry and Occurrence. Vitamin K activity is associated with at least two distinct natural substances, designated as vitamin K_1 and vitamin K_2 . Vitamin K_1 , or *phylloquinone* (*phytonadione*), is 2-methyl-3-phytyl-1,4-naphthoquinone; it is found in plants and is the only natural vitamin K available for therapeutic use. Vitamin K_2 is actually a series of compounds (the *menaquinones*) in which the phetyl side chain of phylloquinone has been replaced by a side chain built up of 2 to 13 prenyl units. Considerable synthesis of menaquinones occurs in gram-positive bacteria; indeed, intestinal flora synthesize the large amounts of vitamin K contained in human and animal feces (Bentley and Meganathan, 1982). In animals, menaquinone-4 can be synthesized from the vitamin precursor *menadione* (2-methyl-1,4-naphthoquinone), or vitamin K_3 . Depending on the bioassay system used, menadione is at least as active on a molar basis as phylloquinone. The structures of phylloquinone and the menaquinone series are:

Physiological Functions and Pharmacological Actions. In normal animals and humans, phylloquinone and menaquinones are virtually devoid of pharmacodynamic activity. However, in subjects deficient in vitamin K, the vitamin performs its normal physiological function: to promote the biosynthesis of the γ -carboxy-glutamate (Gla) forms of factors II (prothrombin), VII, IX, and X, anticoagulant proteins C and S, protein Z (a cofactor to the inhibitor of Xa), the bone Gla protein osteocalcin, matrix Gla protein, growth arrest-specific protein 6 (Gas6), and four transmembrane monospans of unknown function (Brown *et al.*, 2000; Broze, 2001; Kulman *et al.*, 2001).

Figure 54–6 summarizes the coupling of the vitamin K cycle with glutamate carboxylation. Vitamin K, as KH_2 , the reduced vitamin K hydroquinone, is an essential cofactor for γ -glutamyl carboxylase (Rishavy *et al.*, 2004). Using KH_2 , O_2 , CO_2 , and the glutamate-containing substrate, the enzyme forms a γ -carboxy-glutamyl protein (Gla protein) and concomitantly, the 2,3-epoxide of vitamin K. A coumarin-sensitive 2,3-epoxide reductase regenerates KH_2 . The γ -glutamyl carboxylase and epoxide reductase are integral membrane proteins of the endoplasmic reticulum and seem to function as a multicomponent system that may include the chaperone protein, calumenin, which reportedly inhibits γ -carboxylation (Wajih *et al.*, 2004). Two natural mutations in γ -glutamyl carboxylase lead to bleeding disorders (Mutucumarana *et al.*, 2003). With respect to proteins affecting blood coagulation, these reactions occur in the liver, but γ -carboxylation of glutamate also occurs in lung, bone, and other cell types. Vitamin K epoxide reductase recently has been cloned (Rost *et al.*, 2004; Li *et al.*, 2004).

The γ -carboxylation reaction is aided by the grouping of glutamate residues in a *Gla domain* (about 45 residues in clotting factors) near the amino terminus of the nascent substrate protein; the reaction is guided by an adjacent propeptide (18 to 28 amino acids) that interacts with the carboxylase. In the case of the vitamin K–dependent clotting proteins, the Gla domain is about 45 residues long, and 9 to 13 glutamates are γ -carboxylated in the primary sequence of the Gla domain, C-terminal to the propeptide. The $\text{Glu} \rightarrow \text{Gla}$ conversion enables the factors to interact well with Ca^{2+} and thence with phospholipids of platelet membranes, positioning the factors in the proper conformations for interacting with their substrates and modulators. In the absence of vitamin K (or in the presence of a coumarin derivative), newly synthesized vitamin K–dependent clotting factors lack Gla residues and are inactive because the molecular conformations needed for their interactions are not achieved.

Human Requirements. The human requirement for vitamin K has not been defined precisely. In patients made vitamin K–deficient by a starvation diet and antibiotic therapy for 3 to 4 weeks, the minimum daily requirement is estimated to be 0.03 $\mu\text{g}/\text{kg}$ of body weight (Frick, 1967) and possibly as high as 1 $\mu\text{g}/\text{kg}$, which is approximately the recommended intake for adults (70 $\mu\text{g}/\text{day}$).

Symptoms of Deficiency. The chief clinical manifestation of vitamin K deficiency is an increased tendency to bleed (*see* discussion of hypoprothrombinemia in section on oral anticoagulants, above). Ecchymoses, epistaxis, hematuria, gastrointestinal bleeding, and postoperative hemorrhage are common; intracranial hemorrhage may occur. Hemoptysis is uncommon. The discovery of a vitamin K–dependent protein in bone suggests that the fetal bone abnormalities associated with the administration of oral anticoagulants during the first trimester of pregnancy (“fetal warfarin syndrome”) may be related to a deficiency of the vitamin.

Considerable evidence indicates a role for vitamin K in adult skeletal maintenance and osteoporosis. Low concentrations of the vitamin are associated with deficits in bone mineral density and fractures; vitamin K supplementation increases the carboxylation state of osteocalcin and also improves bone mineral density, but the relationship of these two effects is unclear (Feskanich *et al.*, 1999). Bone mineral density in adults is not changed by therapeutic use of oral anticoagulants (Rosen *et al.*, 1993), but new bone formation may be affected.

Toxicity. Phylloquinone and the menaquinones are nontoxic to animals, even when given at 500 times the RDA. However, menadione

and its derivatives (synthetic forms of vitamin K) have been implicated in producing hemolytic anemia and kernicterus in neonates, especially in premature infants (Diploma and Ritchie, 1997). For this reason menadione should not be used as a therapeutic form of vitamin K.

Absorption, Fate, and Excretion. The mechanism of intestinal absorption of compounds with vitamin K activity varies with their solubility. In the presence of bile salts, phylloquinone and the menaquinones are adequately absorbed from the intestine, almost entirely by way of the lymph. Phylloquinone is absorbed by an energy-dependent, saturable process in proximal portions of the small intestine; menaquinones are absorbed by diffusion in the distal portions of the small intestine and in the colon. Following absorption, phylloquinone is incorporated into chylomicrons in close association with triglycerides and lipoproteins. In a large survey, plasma phylloquinone and triglyceride concentration were well correlated (Sadowski *et al.*, 1989). The extremely low phylloquinone levels in newborns may be partly related to very low plasma lipoprotein concentrations at birth and may lead to an underestimation of vitamin K tissue stores. After absorption, phylloquinone and menaquinones are concentrated in the liver, but the concentration of phylloquinone declines rapidly. Menaquinones, produced in the lower bowel, are less biologically active than phylloquinone due to their long side chain. Very little vitamin K accumulates in other tissues.

Phylloquinone is metabolized rapidly to more polar metabolites, which are excreted in the bile and urine. The major urinary metabolites result from shortening of the side chain to five or seven carbon atoms, yielding carboxylic acids that are conjugated with glucuronate prior to excretion.

Apparently, there is only modest storage of vitamin K in the body. Under circumstances in which lack of bile interferes with absorption of vitamin K, hypoprothrombinemia develops slowly over a period of several weeks.

Therapeutic Uses. Vitamin K is used therapeutically to correct the bleeding tendency or hemorrhage associated with its deficiency. Vitamin K deficiency can result from inadequate intake, absorption, or utilization of the vitamin, or as a consequence of the action of a vitamin K antagonist.

Phylloquinone (AQUAMEPHYTON, KONAKION, MEPHYTON) is available as tablets and in a dispersion with buffered polysorbate and propylene glycol (KONAKION) or polyoxyethylated fatty acid derivatives and dextrose (AQUAMEPHYTON). KONAKION is administered only intramuscularly. AQUAMEPHYTON may be given by any parenteral route; however, subcutaneous or intramuscular injection is preferred because severe reactions resembling anaphylaxis have followed its intravenous administration.

Inadequate Intake. After infancy, hypoprothrombinemia due to dietary deficiency of vitamin K is extremely rare: The vitamin is present in many foods and also is synthesized by intestinal bacteria. Occasionally, the use of a broad-spectrum antibiotic may itself produce a hypoprothrombinemia that responds readily to small doses of vitamin K and reestablishment of normal bowel flora. Hypoprothrombinemia can occur in patients receiving prolonged intravenous alimentation. It is recommended to give 1 mg of phylloquinone per week (the equivalent of about 150 μg per day) to patients on total parenteral nutrition.

Hypoprothrombinemia of the Newborn. Healthy newborn infants show decreased plasma concentrations of vitamin K–dependent clotting factors for a few days after birth, the time required to obtain an adequate dietary intake of the vitamin and to establish a normal

intestinal flora. In premature infants and in infants with hemorrhagic disease of the newborn, the concentrations of clotting factors are particularly depressed. The degree to which these changes reflect true vitamin K deficiency is controversial. Measurements of non- γ -carboxylated prothrombin suggests that vitamin K deficiency occurs in about 3% of live births (Shapiro *et al.*, 1986).

Hemorrhagic disease of the newborn has been associated with breast-feeding; human milk has low concentrations of vitamin K (Haroon *et al.*, 1982). In addition, the intestinal flora of breast-fed infants may lack microorganisms that synthesize the vitamin (Keenan *et al.*, 1971). Commercial infant formulas are supplemented with vitamin K.

In the neonate with hemorrhagic disease of the newborn, the administration of vitamin K raises the concentration of these clotting factors to the level normal for the newborn infant and controls the bleeding tendency within about 6 hours. The routine administration of 1 mg phyloquinone intramuscularly at birth is required by law in the United States. This dose may have to be increased or repeated if the mother has received anticoagulant or anticonvulsant drug therapy or if the infant develops bleeding tendencies. Alternatively, some clinicians treat mothers who are receiving anticonvulsants with oral vitamin K prior to delivery (20 mg per day for 2 weeks) (Vert and Deblay, 1928).

Inadequate Absorption. Vitamin K is poorly absorbed in the absence of bile. Thus, hypoprothrombinemia may be associated with either intrahepatic or extrahepatic biliary obstruction or a severe defect in the intestinal absorption of fat from other causes.

Biliary Obstruction or Fistula. Bleeding that accompanies obstructive jaundice or biliary fistula responds promptly to the administration of vitamin K. Oral phyloquinone administered with bile salts is both safe and effective and should be used in the care of the jaundiced patient, both preoperatively and postoperatively. In the absence of significant hepatocellular disease, the prothrombin activity of the blood rapidly returns to normal. If oral administration is not feasible, a parenteral preparation should be used. The usual dose is 10 mg of vitamin K per day.

The treatment of a patient during hemorrhage requires transfusion of fresh blood or reconstituted fresh plasma. Vitamin K also should be given. If biliary obstruction has caused hepatic injury, the response to vitamin K may be poor.

Malabsorption Syndromes. Among the disorders that result in inadequate absorption of vitamin K from the intestinal tract are: cystic fibrosis, sprue, Crohn's disease and enterocolitis, ulcerative colitis, dysentery, and extensive resection of bowel. Since drugs that greatly reduce the bacterial population of the bowel are used frequently in many of these disorders, the availability of the vitamin may be further reduced. Moreover, dietary restrictions also may limit the availability of the vitamin. For immediate correction of the deficiency, parenteral therapy should be used.

Inadequate Utilization. Hepatocellular disease may be accompanied or followed by hypoprothrombinemia. Hepatocellular damage also may be secondary to long-lasting biliary obstruction. In these conditions, the damaged parenchymal cells may not be able to produce the vitamin K-dependent clotting factors, even if excess vitamin is available. However, if an inadequate secretion of bile salts is contributing to the syndrome, some benefit may be obtained from the parenteral administration of 10 mg of phyloquinone daily. Paradoxically, the administration of large doses of vitamin K or its analogs in an attempt to correct the hypoprothrombinemia associated with severe hepatitis or cirrhosis actually may result in a further depression of the concentration of prothrombin. The mechanism for this action is unknown.

Drug-Induced Hypoprothrombinemia. Anticoagulant drugs such as warfarin and its congeners act as competitive antagonists of vitamin K and interfere with the hepatic biosynthesis of Gla-containing clotting factors. The treatment of bleeding caused by oral anticoagulants is discussed above. Vitamin K may be of help in combating the bleeding and hypoprothrombinemia that follow the bite of the tropical American pit viper or other species whose venom destroys or inactivates prothrombin.

CLINICAL SUMMARY

A variety of anticoagulant, thrombolytic, and antiplatelet agents are available and are among the most widely used drugs. Heparin and its low-molecular-weight derivatives are commonly used to treat venous thromboembolism, unstable angina, and acute myocardial infarction; these agents are also used to prevent thrombosis during and after coronary angioplasty, during surgery requiring cardiopulmonary bypass, and in certain other high-risk patients. The major toxicities of heparin are bleeding and the syndrome of heparin-induced thrombocytopenia, which often precipitates venous or arterial thrombosis. Direct thrombin inhibitors, such as lepirudin or argatroban, are indicated for patients with heparin-induced thrombocytopenia. Warfarin and other vitamin K antagonists are used to prevent the progression or recurrence of acute venous thromboembolism following an initial course of heparin. They also decrease the incidence of systemic embolization in patients with prosthetic heart valves or after acute myocardial infarction. Warfarin causes major bleeding in a significant number of patients and produces fetal abnormalities when given during pregnancy. Fibrinolytic agents, such as t-PA or streptokinase, reduce the mortality of acute myocardial infarction and are used in situations in which angioplasty is not readily available. Antiplatelet agents, including aspirin, ticlopidine, clopidogrel, and glycoprotein IIb/IIIa inhibitors, are often used to prevent restenosis and thrombosis following coronary angioplasty and in the secondary prophylaxis of myocardial infarction and stroke. Bleeding is the major toxicity of the antiplatelet agents, but thrombocytopenia and neutropenia can also occur. New agents, such as the oral direct thrombin inhibitor ximelagatran, may prove to be more effective, less toxic, and easier to use than currently available drugs.

SECTION XII

Hormones and Hormone Antagonists

CHAPTER

55

PITUITARY HORMONES AND THEIR HYPOTHALAMIC RELEASING HORMONES

Keith L. Parker and Bernard P. Schimmer

The peptide hormones of the anterior pituitary are essential for the regulation of growth and development, reproduction, responses to stress, and intermediary metabolism. Their synthesis and secretion are controlled by hypothalamic hormones and by hormones from the peripheral endocrine organs. A large number of disease states, as well as a diverse group of drugs, also affect their secretion. The complex interactions among the hypothalamus, pituitary, and peripheral endocrine glands provide elegant examples of integrated feedback regulation. Clinically, an improved understanding of the mechanisms that underlie these interactions provides the rationale for diagnosing and treating endocrine disorders and for predicting certain side effects of drugs that affect the endocrine system. Moreover, the elucidation of the structures of the anterior pituitary hormones and hypothalamic-releasing hormones makes it possible to produce synthetic peptide agonists and antagonists that have important diagnostic and therapeutic applications.

The anterior pituitary hormones can be classified into three different groups based on their structural features (Table 55–1). *Growth hormone* (GH) and *prolactin* (PRL) belong to the somatotrophic family of hormones, which in humans also includes placental lactogen. The glycoprotein hormones—*thyroid-stimulating hormone* (TSH, also called thyrotropin), *luteinizing hormone* (LH), and *follicle-stimulating hormone* (FSH)—share a common α -sub-

unit but have different β -subunits that determine their distinct biological activities. In humans, the glycoprotein hormone family also includes *human chorionic gonadotropin* (hCG). *Corticotropin* (adrenocorticotrophic hormone; ACTH) and *α -melanocyte-stimulating hormone* (α -MSH) are part of a family of peptides derived from *pro-opiomelanocortin* (POMC) by proteolytic processing (see Chapter 59).

The synthesis and release of anterior pituitary hormones are influenced by the central nervous system. Their secretion is positively regulated by a group of peptides referred to as *hypothalamic releasing hormones*, which are released from hypothalamic neurons in the region of the median eminence and reach the anterior pituitary through the hypothalamic-adenohypophyseal portal system (Figure 55–1). The hypothalamic releasing hormones include *growth hormone-releasing hormone* (GHRH), *gonadotropin-releasing hormone* (GnRH), *thyrotropin-releasing hormone* (TRH), and *corticotropin-releasing hormone* (CRH). *Somatostatin* (SST), another hypothalamic peptide, negatively regulates pituitary secretion of growth hormone and thyrotropin. The catecholamine *dopamine* inhibits the secretion of prolactin by lactotropes.

The posterior pituitary gland, also known as the neurohypophysis, contains the endings of nerve axons arising from distinct populations of neurons in the supraoptic and

Table 55–1*Properties of the Protein Hormones of the Human Adenohypophysis and Placenta*

HORMONE	MOLECULAR MASS, DALTONS	PEPTIDE CHAINS	AMINO ACID RESIDUES	CHROMOSOMAL LOCATION	COMMENTS
<i>Somatotropic hormones</i>					
Growth hormone (GH)	22,000	1	191	17q22-24

Follicle-stimulating hormone (FSH)	32,600	2	α -92 β -111	6q12.q21 11p13	
Human chorionic gonadotropin (hCG)	38,600	2	α -92 β -145	6q12.q21 19q13.3	
Thyroid-stimulating hormone (TSH)	28,000	2	α -92 β -118	6q12.q21 1p13	
<i>POMC-derived hormones*</i>					
Corticotropin (ACTH)	4500	1	39	2p22.3	These peptides are derived by proteolytic processing of the common precursor, pro-opiomelanocortin (POMC)
α -Melanocyte-stimulating hormone (α -MSH)	1650	1	13		

*See Chapter 59 for further discussion of POMC-derived peptides, including ACTH and α -MSH.

paraventricular nuclei that synthesize either *arginine vasopressin* or *oxytocin* (Figure 55–1). Arginine vasopressin plays an important role in water homeostasis (see Chapter 29); oxytocin plays important roles in labor and parturition and in milk let-down, as discussed below.

GROWTH HORMONE

The gene encoding human growth hormone (GH) resides on the long arm of chromosome 17 (17q22), which also contains three different variants of placental lactogen and a GH variant expressed in the syncytiotrophoblast (chorionic somatotropin). Secreted GH is a heterogeneous mixture of peptides; the principal 22,000-dalton form is a single polypeptide chain of 191 amino acids that has two disulfide bonds and is not glycosylated. Alternative splicing deletes residues 32 to 46 of the larger form to produce a smaller form (~20,000 daltons) with equal bioactivity that makes up 5% to 10% of circulating GH. Additional GH species, differing in size or charge, are found in

serum, but their physiological significance is unclear. In the circulation, approximately 45% of the 22,000-dalton and 25% of the 20,000-dalton GH are bound by a 55,000-dalton binding protein that contains the extracellular domain of the GH receptor and apparently arises from proteolytic cleavage. A second protein unrelated to the GH receptor also binds approximately 5% to 10% of circulating GH with lower affinity. Bound GH is cleared more slowly and has a biological half-life approximately 10 times that of unbound GH, suggesting that the binding protein may provide a GH reservoir that dampens acute fluctuations in GH levels associated with its pulsatile secretion. Alternatively, the binding protein may decrease GH bioactivity by preventing it from binding to its receptor in target tissues. Obesity and estrogen treatment increase circulating levels of GH binding proteins, and thus may affect the clinical response to exogenous GH.

Regulation of Growth Hormone Secretion

Growth hormone, the most abundant anterior pituitary hormone, is synthesized and secreted by somatotropes.

Figure 55–1. Organization of the anterior and posterior pituitary gland. Hypothalamic neurons in the supraoptic (SON) and paraventricular (PVN) nuclei synthesize arginine vasopressin (AVP) or oxytocin (OXY). Most of their axons project directly to the posterior pituitary, from which AVP and OXY are secreted into the systemic circulation to regulate their target tissues. Neurons that regulate the anterior lobe cluster in the mediobasal hypothalamus, including the PVN and the arcuate (ARC) nuclei. They secrete hypothalamic releasing hormones, which reach the anterior pituitary *via* the hypothalamic-adenohypophyseal portal system and stimulate distinct populations of pituitary cells. These cells, in turn, secrete the trophic hormones, which regulate endocrine organs and other tissues.

The somatotropes account for about 40% of hormone-secreting cells of the anterior pituitary and cluster at the lateral wings of the gland. Daily GH secretion varies throughout life; secretion is high in children, reaches maximal levels at puberty, and then decreases in an age-related manner in adulthood. GH is secreted in discrete but irregular pulses. Between these pulses, circulating GH falls to levels that are undetectable with most current assays. The amplitude of secretory pulses is maximal at night, and the most consistent period of GH secretion is shortly after the onset of deep sleep.

The regulation of GH secretion, as illustrated in Figure 55–2, incorporates many of the features of the classic negative feedback systems seen in other endocrine axes.

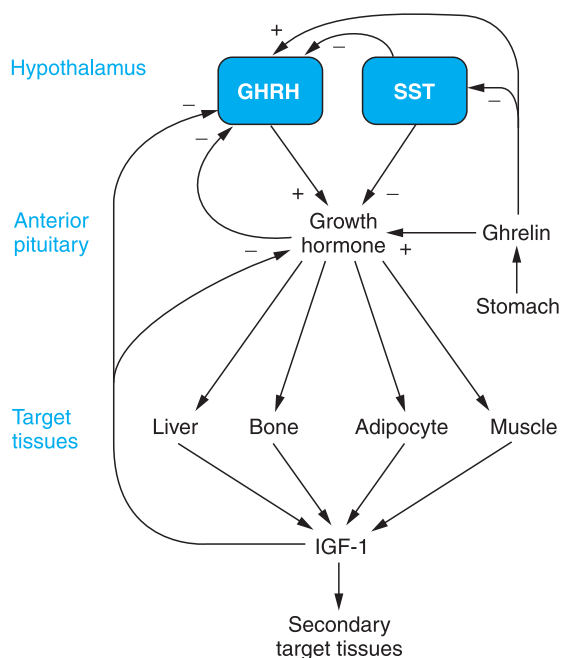

Figure 55–2. Secretion and actions of growth hormone. Two hypothalamic factors, growth hormone-releasing hormone (GHRH) and somatostatin (SST), act on the somatotropes in the anterior pituitary to regulate growth hormone secretion. SST also inhibits GHRH release. Growth hormone exerts direct effects on target tissues and indirect effects mediated by stimulating the release of insulin-like growth factor-1 (IGF-1). The gastric peptide ghrelin enhances growth hormone release, directly by actions at the anterior pituitary and indirectly by multiple actions on the hypothalamus. IGF-1 feeds back at the anterior pituitary to inhibit growth hormone secretion and also to inhibit further GHRH release by the hypothalamus.

GHRH, produced by hypothalamic neurons found predominantly in the arcuate nucleus, stimulates GH secretion by binding to a specific G protein–coupled receptor on somatotropes that resembles most closely the receptors for secretin, vasoactive intestinal polypeptide, pituitary adenylyl cyclase–activating peptide, glucagon, glucagon-like peptide 1, calcitonin, and parathyroid hormone. Upon binding GHRH, the GHRH receptor couples to G_s to elevate intracellular cyclic AMP and Ca^{2+} concentrations and thereby stimulates GH synthesis and secretion. Loss-of-function mutations of the GHRH receptor cause a rare form of dwarfism in human beings, thereby demonstrating the essential role of the GHRH receptor in normal GH secretion.

Typical of other endocrine systems, GH and its predominant peripheral effector, insulin-like growth factor-1 (IGF-1), act in negative feedback loops to suppress GH

secretion. The negative effect of IGF-1 is predominantly through direct effects on the anterior pituitary gland. In contrast, the negative feedback action of GH is mediated in part by SST, which is synthesized by more widely distributed neurons, as well as by neuroendocrine cells in the gastrointestinal tract and pancreas.

Somatostatin is synthesized as a 92-amino-acid precursor and processed by proteolytic cleavage to generate two predominant forms: SST-14 and SST-28. The somatostatins exert their effects by binding to and activating a family of five related G protein-coupled receptors that signal through G_i to inhibit cyclic AMP accumulation and to activate K^+ channels and phosphotyrosine phosphatases. Each of the SST receptor subtypes (abbreviated SSTR or sstr) binds SST with nanomolar affinity; whereas receptor types 1 to 4 (SSTR1–4) bind the two SSTs with approximately equal affinity, type 5 (SSTR5) has a ten- to fifteenfold greater selectivity for somatostatin-28. SSTR2 and SSTR5 are the most important for regulation of GH secretion. SST exerts direct effects on somatotropes in the pituitary and indirect effects mediated *via* GHRH neurons in the arcuate nucleus. As discussed below, SST analogs play a key role in the therapy of syndromes of GH excess such as acromegaly.

Appreciation of a third regulator of GH secretion has emerged from the development of peptide and nonpeptide compounds, called GH secretagogues, that stimulate GH secretion. These secretagogues act primarily through a distinct G protein-coupled receptor, called the GH secretagogue receptor. Although GH secretagogues directly stimulate GH release by isolated somatotropes, their major action on GH secretion apparently is through actions on the GHRH neurons in the arcuate nucleus. The endogenous ligand for the GH secretagogue receptor is ghrelin, a 28-amino-acid peptide with an octanoylated serine at residue 3. Ghrelin is synthesized predominantly in endocrine cells in the fundus of the stomach, but also is produced at lower levels at a number of other sites. Both fasting and hypoglycemia stimulate circulating ghrelin levels. In human beings and experimental animals, ghrelin stimulates appetite and increases food intake, apparently by central actions on NPY and agouti-related peptide neurons in the hypothalamus. Thus ghrelin and its receptor play complex roles to integrate the gastrointestinal tract, the hypothalamus, and the anterior pituitary (Yoshihara *et al.*, 2002).

Several neurotransmitters, drugs, metabolites, and other stimuli modulate the release of GHRH and/or SST and thereby affect GH secretion. Dopamine, 5-hydroxytryptamine, and α_2 adrenergic receptor agonists stimulate GH release, as do hypoglycemia, exercise, stress, emotional excitement, and ingestion of protein-rich meals. In contrast, β adrenergic receptor agonists, free fatty acids, insulin-like growth factor-1 (IGF-1, *see* below), and GH itself inhibit release, as does the administration of glucose to normal subjects in an oral glucose tolerance test.

These observations form the basis for provocative tests to assess the ability of the pituitary to secrete GH. Provocative stimuli include arginine, glucagon, insulin-induced hypoglycemia, clonidine, and the dopamine precursor levodopa; these agents all increase circulating GH levels in normal subjects within 45 to 90 minutes. At present, insulin-induced hypoglycemia is preferred by some authorities, whereas the FDA recommends two independent tests of GH deficiency to establish the diagnosis. When excess GH secretion is suspected (*see* below), the failure of an oral glucose load to suppress GH is diagnostically useful. Finally, as described below, GH secretion in response to GHRH can be used to distinguish pituitary disease from hypothalamic disease.

Molecular and Cellular Bases of Growth Hormone Action

All of the effects of GH result from its interactions with the GH receptor, as evidenced by the severe phenotype of rare patients with homozygous mutations of the GH receptor gene (the Laron syndrome of GH-resistant dwarfism). The GH receptor is a widely distributed cell-surface receptor that belongs to the Class I cytokine receptor superfamily and thus shares structural similarity with the receptors for prolactin, erythropoietin, granulocyte-macrophage colony-stimulating factor, and several of the interleukins. Like other members of the cytokine receptor family, the GH receptor contains an extracellular domain that binds GH, a single membrane-spanning region, and an intracellular domain that mediates signal transduction. Receptor activation results from the binding of a single GH molecule to two identical receptor molecules, forming a ligand-occupied receptor dimer that presumably brings the intracellular domains of the receptor into close proximity to activate cytosolic components critical for cell signaling.

The mature human GH receptor contains 620 amino acids, ~250 of which are extracellular, 24 of which are transmembrane, and ~350 of which are cytoplasmic. The GH receptor exists as a dimer and forms a ternary complex with one molecule of GH. The formation of the GH-GH receptor ternary complex is initiated by high-affinity interaction of GH with one monomer of the GH receptor dimer (mediated by GH site 1), followed by a second interaction of GH with the GH receptor (mediated by GH site 2); these interactions induce a conformational change that activates downstream signaling. Guided by structure-function analyses, GH analogs have been engineered with a disrupted site 2; these analogs bind the receptor and induce its internalization but cannot induce a conformational change or stimulate downstream events in the signal transduction pathway. One such analog, *pegvisomant*, behaves as a GH antagonist and is used for the treatment of acromegaly (Kopchick *et al.*, 2002; *see* below).

Figure 55–3. Mechanisms of growth hormone and prolactin action and of GH receptor antagonism. **A.** The binding of GH to two molecules of the growth hormone receptor (GHR) induces autophosphorylation of JAK2. JAK2 then phosphorylates cytoplasmic proteins that activate downstream signaling pathways, including signal transducer and activator of transcription (Stat)5 and mediators upstream of mitogen-activated protein kinase (MAPK), which ultimately modulate gene expression. The structurally related prolactin receptor also is a ligand-activated homodimer that recruits the JAK-Stat signaling pathway (*see text* for further details). The GHR also activates the insulin receptor substrate-1 (IRS-1), which may mediate the increased expression of glucose transporters on the plasma membrane. The diagram does not reflect the localization of the intracellular molecules, which presumably exist in multicomponent signaling complexes. **B.** Pegvisomant, a recombinant pegylated variant of human GH, contains mutations that increase the affinity for the GHR but do not activate downstream signaling by the GHR. It thus interferes with GH signaling in target tissues. JAK2, Janus kinase 2; IRS-1, insulin receptor substrate-1; PI3K, phosphatidylinositol-3 kinase; STAT, signal transducer and activator of transcription; MAPK, mitogen-activated protein kinase; SHC, Src homology containing.

The ligand-occupied receptor dimer does not have inherent tyrosine kinase activity, but rather provides docking sites for two molecules of Jak2, a cytoplasmic tyrosine kinase of the Janus kinase family. The juxtaposition of two Jak2 molecules leads to *trans*-phosphorylation and autoactivation of Jak2, with consequent tyrosine phosphorylation of cytoplasmic proteins that mediate downstream signaling events (Herrington and Carter-Su, 2001). These include Stat proteins (signal transducers and activators of transcription), Shc (an adapter protein that regulates the Ras/MAP kinase signaling pathway), and IRS-1 and IRS-2 (insulin-receptor substrate proteins that activate the PI3 kinase regulatory pathway) (Figure 55–3).

Physiological Effects of Growth Hormone

The most striking physiological effect of GH—and the basis for its name—is the stimulation of the longitudinal growth of bones. GH also increases bone mineral density after longitudinal growth ceases and epiphyses

have closed. These effects of GH involve the differentiation of prechondrocytes to chondrocytes and stimulation of osteoclast and osteoblast proliferation. Other effects of GH include the stimulation of myoblast differentiation (in experimental animals) and increased muscle mass (in human subjects with growth hormone deficiency), increased glomerular filtration rate, and stimulation of preadipocyte differentiation into adipocytes. GH has potent anti-insulin actions in both the liver and peripheral sites (*e.g.*, adipocytes and muscle) that decrease glucose utilization and increase lipolysis. Finally, GH has been implicated in the development and function of the immune system.

GH acts directly on adipocytes to increase lipolysis and on hepatocytes to stimulate gluconeogenesis, but its anabolic and growth-promoting effects are mediated indirectly through the induction of insulin-like growth factor-1 (IGF-1). Although most circulating IGF-1 is made in the liver, IGF-1 produced locally in many tissues is critical for growth, as revealed by normal growth in mice that

have a hepatocyte-specific inactivation of IGF-1. Circulating IGF-1 is associated with a family of binding proteins that serve as transport proteins, which also may mediate certain aspects of IGF-1 signaling (Firth and Baxter, 2002). The essential role of IGF-1 in GH signaling is evidenced by a patient with loss-of-function mutations in both alleles of the *IGF1* gene whose severe intrauterine and postnatal growth retardation was unresponsive to GH but responsive to recombinant human IGF-1 (Comacho-Hubner *et al.*, 1999) and by the association of mutations in the IGF-1 receptor with intrauterine growth retardation (Abuzzahab *et al.*, 2003).

After its synthesis and release, IGF-1 interacts with receptors on the cell surface that mediate its biological activities. The type 1 IGF receptor is closely related to the insulin receptor, consisting of a hetero-tetramer with intrinsic tyrosine kinase activity. This receptor is present in essentially all tissues and binds IGF-1 and the related growth factor, IGF-2, with high affinity; insulin also can activate the type 1 IGF receptor, but with an affinity approximately two orders of magnitude less than that of the IGFs. The signal transduction pathway for the insulin receptor is described in detail in Chapter 60.

Clinical Disorders of Growth Hormone

Although the manifestations vary depending on the age of onset, GH deficiency and excess are associated with defined diseases that form an important part of endocrine practice.

Diagnosis of Growth Hormone Deficiency. Clinically, children with GH deficiency present with short stature, delayed bone age, and a low age-adjusted growth velocity. Most commonly, these children have an isolated deficiency of GH without other documented pathology (*e.g.*, idiopathic, isolated GH deficiency) and are presumed to have a hypothalamic defect. *Because GH secretion is episodic, random sampling of serum GH is insufficient to diagnose GH deficiency.* Tests that provide an estimate of integrated GH levels over time (*e.g.*, IGF-1 and IGF-binding protein 3 levels) are more useful, although provocative tests usually are required. After excluding other causes of poor growth, the diagnosis of GH deficiency should be entertained in patients with height more than 2 to 2.5 standard deviations below normal, delayed bone age, a decreased growth velocity, and a predicted adult height substantially below the mean parental height (Vance and Mauras, 1999). In this setting, a serum GH level of less than 10 ng/ml following provocative testing (*e.g.*, insulin-induced hypoglycemia, arginine, levodopa, or glucagon) indicates GH deficiency; a stimulated value of less than 5 ng/ml reflects severe deficiency.

In adults, overt GH deficiency almost always results from pituitary disease due either to a functioning or nonfunctioning pituitary adenoma or secondary to surgery or radiotherapy for a pituitary or suprasellar mass. Almost all patients with multiple deficits in other pituitary hormones also will have deficient GH secretion, and some experts incorporate the number of other pituitary deficiencies into a diagnostic algorithm for diagnosing GH deficiency (Molitch, 2002b). Others will accept a serum IGF-1 level below the age- and

sex-adjusted normal value as indicative of GH deficiency in a patient with known pituitary disease. Finally, some experts require an inadequate GH response to provocative testing, with either insulin-induced hypoglycemia or a combination of arginine and GHRH, as the preferred stimulus for GH secretion. The risk of false-positive provocative tests (*i.e.*, a subnormal GH response) is increased in obese subjects.

Indications for Growth Hormone Treatment. GH deficiency in children is a well-accepted cause of short stature, and replacement therapy has been used for more than 30 years to treat children with severe GH deficiency. With the advent of essentially unlimited supplies of recombinant GH, therapy has been extended to children with other conditions associated with short stature despite adequate GH production, including Turner's syndrome, Prader-Willi syndrome (in the absence of morbid obesity or obstructive sleep apnea), chronic renal insufficiency, children born small for gestational age, and children with idiopathic short stature (*i.e.*, more than 2.25 standard deviations below mean height for age and sex but normal laboratory indices of growth hormone levels).

In adults, GH deficiency is associated with a defined endocrinopathy that includes increased mortality from cardiovascular causes, probably secondary to deleterious changes in fat distribution, increases in circulating lipids, and increased inflammation; decreased muscle mass and exercise capacity; decreased bone density; and impaired psychosocial function (Cummings and Merriam, 2003). With the ready availability of recombinant human GH, attention also has shifted to the proper role of GH therapy in GH-deficient adults. While this is an area of ongoing debate, the consensus is that at least the most severely affected GH-deficient adults may benefit from GH replacement therapy. The FDA also has approved GH therapy for AIDS-associated wasting and for malabsorption associated with the short bowel syndrome. The latter indication is based on GH action to stimulate adaptation of gastrointestinal epithelial cells; in this setting, GH is administered once daily for 4 weeks.

Based on controlled clinical trials showing increased mortality, GH should not be used in patients with acute critical illness due to complications after open heart or abdominal surgery, multiple accidental trauma, or acute respiratory failure. GH also should not be used in patients who have any evidence of neoplasia, and antitumor therapy should be completed before initiation of GH therapy.

Treatment of Growth Hormone Deficiency. Humans do not respond to GH from nonprimate species. GH for therapeutic use formerly was purified from human cadav-

er pituitaries and thus was available in very limited quantities and carried the risk of Creutzfeldt-Jakob disease. The production of human GH by recombinant DNA technology not only increased availability of the hormone, but also eliminated the risk of disease transmission associated with the pituitary-derived hormone.

GH is used for replacement therapy in GH-deficient children, whether the deficiency is congenital or acquired (Vance and Mauras, 1999). By convention, *somatropin* refers to the many GH preparations whose sequences match that of native GH (SEROSTIM, GENOTROPIN, HUMATROPE, NUTROPIN, NORDITROPIN, SAIZEN), while *somatrem* refers to a derivative of GH with an additional methionine at the amino terminus (PROTROPIN). Although the microbial systems used to express the recombinant hormone subtly affect the structures of these preparations, they all have similar biological actions and potencies. To mimic the normal pattern of secretion, they typically are administered to GH-deficient children in a dose of 40 $\mu\text{g}/\text{kg}$ per day subcutaneously in the evening; although the circulating half-life of GH is only 20 minutes, its biological half-life is in the range of 9 to 17 hours, and once-daily administration is sufficient. Higher daily doses (e.g., 50 $\mu\text{g}/\text{kg}$) are employed for patients with Turner's syndrome, who have partial GH resistance. In children with overt GH deficiency, measurements of serum IGF-1 levels are used to monitor initial response and compliance; long-term response is monitored by close evaluation of height, sometimes in conjunction with measurements of serum IGF-1 levels. Although the most pronounced increase in growth velocity occurs within the first 2 years of therapy, GH is continued until the epiphyses are fused, and also may be extended into the transition period from childhood to adulthood (Quigley, 2003).

Newer GH formulations are supplied in prefilled syringes, which may be more convenient for the patient, or in non-needle injection systems. The FDA also has approved an encapsulated form of somatropin (NUTROPIN DEPOT) that is injected intramuscularly either monthly (1.5 mg/kg body weight) or every 2 weeks (0.75 mg/kg body weight). The depot formulation was associated with local reactions at the site of injection, and the manufacturer has announced a decision to discontinue commercialization of this product. The relative advantages of any specific formulations over others in clinical use have not been definitively established.

In addition to GH, *sermorelin acetate* (GEREF), a synthetic form of human GHRH, is FDA approved for treatment of GH deficiency (Anonymous, 1999). Sermorelin is a peptide of 29 amino acids that corresponds in sequence to the first 29 amino acids of human GHRH (a 44-amino-acid peptide) and has full biological activi-

ty. Sermorelin generally is well tolerated and is less expensive than somatropin, but at recommended doses (30 $\mu\text{g}/\text{kg}$ per day given subcutaneously) it has been less effective than GH in clinical trials. Moreover, this agent will not work in patients whose GH deficiency results from defects in the anterior pituitary. Therefore, a GH response (>2 ng/ml) to a test dose of sermorelin should be documented before initiating therapy, and patients must be monitored frequently to ascertain continued growth on therapy. Sermorelin also has been employed diagnostically to distinguish between pituitary and hypothalamic disease, although its clinical utility for this purpose is not fully established.

In view of the increased appreciation of the effects of GH on bone density and the manifestations of GH deficiency in adults, some experts continue therapy into adulthood for children with GH deficiency. However, many patients who clearly were GH deficient in childhood, especially those with idiopathic, isolated GH deficiency, respond normally to provocative tests as adults. Thus it is essential to confirm GH deficiency after optimal growth has been achieved so as to identify patients who will benefit from continuing GH treatment.

Growth impairment also may be associated with elevated GH levels and GH resistance, most frequently secondary to mutations in the GH receptor (Laron dwarfism). These patients can be treated effectively with recombinant human IGF-1 (IGEF), which is administered subcutaneously either once or twice daily in doses ranging from 40 to 120 $\mu\text{g}/\text{kg}$ (Comacho-Hubner *et al.*, 1999). Although this therapy clearly is beneficial in promoting growth, the optimal regimen remains to be established, and novel approaches to modulate the IGF-1 pathway are under investigation (Torrado and Carrascosa, 2003).

For adults, the FDA recommends a starting dose of 3 to 4 $\mu\text{g}/\text{kg}$, given once daily by subcutaneous injection, with a maximum dose of 25 $\mu\text{g}/\text{kg}$ in patients ≤ 35 years old and 12.5 $\mu\text{g}/\text{kg}$ in older patients. Other experts recommend a starting dose of 150 to 300 $\mu\text{g}/\text{day}$ regardless of body weight. Clinical response is monitored by serum IGF-1 levels, which should be restored to the mid-normal range adjusted for age and sex. Either an elevated serum IGF-1 or persistent side effects are grounds for decreasing the dose; conversely, the dose can be increased if serum IGF-1 has not reached the normal range after 2 months of GH therapy. Because estrogen increases the levels of GH binding proteins, women taking oral—but not transdermal—estrogen often require larger GH doses to achieve the target IGF-1 level. In clinical trials in the setting of AIDS-related wasting, considerably higher doses (e.g., 100 $\mu\text{g}/\text{kg}$) have been used.

Based on the known age-related decline in GH levels, the use of GH therapy to ameliorate or even reverse the consequences of aging has been widely promoted. Many of the studies supporting this use were not placebo-controlled and involved small numbers of subjects. Moreover, at least one well-designed trial showed no improvement in strength or aerobic performance with GH therapy in elderly subjects. In violation of regulations and standard medical practice, some athletes also use injectable GH preparations as anabolic agents to enhance performance. In addition to the parenteral GH preparations, oral preparations containing “stacked” amino acids that reportedly stimulate GH release have been marketed as nutritional supplements. Despite the absence of validation in controlled trials, these formulations are part of multibillion dollar anti-aging and performance-enhancing programs.

Side Effects of GH Therapy. In children, GH therapy is associated with remarkably few side effects. Rarely, generally within the first 8 weeks of therapy, patients develop intracranial hypertension, with papilledema, visual changes, headache, nausea, and/or vomiting. Because of this, fundoscopic examination is recommended at the initiation of therapy and at periodic intervals thereafter. Leukemia has been reported in some children receiving GH therapy; a causal relationship has not been established, and conditions associated with GH deficiency (*e.g.*, Down’s syndrome, cranial irradiation for CNS tumors) probably explain the apparent increased incidence of leukemia. Despite this, the consensus is that GH should not be administered in the first year after treatment of pediatric tumors, including leukemia, or during the first 2 years after therapy for medulloblastomas or ependymomas. An increased incidence of type 2 diabetes mellitus has been reported. Finally, too-rapid growth may be associated with slipped epiphyses or scoliosis.

In adults, side effects associated with the initiation of GH therapy include peripheral edema, carpal tunnel syndrome, arthralgia, and myalgia. These symptoms, which occur most frequently in patients who are older or more obese, generally respond to a decrease in dose. Although there are potential concerns about impaired glucose tolerance secondary to anti-insulin actions of GH, this generally has not been a major problem with clinical use at the recommended doses. In fact, changes in visceral fat composition associated with GH replacement may improve insulin sensitivity in some patients.

Syndromes of GH Excess

GH excess causes distinct clinical syndromes depending on the age of the patient. If the epiphyses are unfused, GH excess causes increased longitudinal growth, resulting in gigantism. In adults, GH excess causes acromegaly. The symptoms and signs of acromegaly (*e.g.*, arthropathy, carpal tunnel syndrome, generalized visceromegaly, macroglossia, hypertension, glucose intolerance, headache, lethargy, excess perspiration, and sleep apnea) progress slowly, and

diagnosis often is delayed. Life expectancy is shortened in these patients; mortality is increased at least twofold relative to age-matched controls due to increased death from cardiovascular disease, upper airway obstruction, and gastrointestinal malignancies.

Diagnosis of GH Excess. While the diagnosis of acromegaly should be suspected in patients with the appropriate symptoms and signs, confirmation requires the demonstration of increased circulating GH or IGF-1. The gold standard diagnostic test for acromegaly is the oral glucose tolerance test. While normal subjects suppress their GH level to <1 ng/ml in response to a 75-g glucose challenge (the absolute value may vary depending on the sensitivity of the assay), patients with acromegaly either fail to suppress or show a paradoxical increase in GH level.

Treatment options in acromegaly include transsphenoidal surgery, radiation, and drugs that inhibit GH secretion or action. Pituitary surgery traditionally has been viewed as the treatment of choice. In patients with microadenomas (*i.e.*, tumors <1 cm in diameter), skilled neurosurgeons can achieve cure rates of 60% to 90%; however, the long-term success rate for patients with macroadenomas (*i.e.*, tumors ≥1 cm in diameter) typically is less than 50%. In addition, there is increasing appreciation that acromegalic patients previously considered cured by pituitary surgery actually have persistent GH excess, with its attendant complications, and that pituitary irradiation may be associated with significant long-term complications. Thus, more attention has been given to the pharmacological management of acromegaly, either as a primary treatment modality or for the treatment of persistent GH excess after transsphenoidal surgery.

Somatostatin Analogs. The development of analogs of SST (Figure 55–4) revolutionized the medical treatment of acromegaly. Based on structure-function studies of SST and its derivatives, the amino acid residues in positions 7 to 10 [FWKT] are the major determinants of biological activity. Residues W⁸ and K⁹ appear to be essential, whereas conservative substitutions at F⁷ and T¹⁰ are permissible. Active SST analogs retain this core segment constrained in a cyclic structure—formed either by a disulfide bond or amide linkage that stabilizes the optimal conformation (Weckbecker *et al.*, 2003). The endogenous peptides, SST-14 and SST-28, do not show specificity for SSTR subtypes except for SSTR5, for which SST-28 shows some preference. Some of the somatostatin analogs exhibit greater selectivity. For example, the octapeptides *octreotide*, *lanreotide*, and *vapreotide* and the hexapeptide *seglitide* all bind to the SSTR subtypes with the following order of selectivity: SSTR2 > SSTR5 > SSTR3 >> SSTR1 and SSTR4. The octapeptide analog BIM23268 exhibits modest selectivity for SSTR5, and the undecapeptide CH275 appears to bind preferentially to SSTR1 and SSTR4. More recently, small nonpeptide agonists that exhibit high selectivity for SSTR subtypes have been isolated from combinatorial chemical libraries; these compounds may lead to a new class of highly selective, orally active somatostatin mimetics (Weckbecker *et al.*, 2003).

Somatostatin-28 (Prosomatostatin):

Ser-Ala-Asn-Ser-Asn-Pro-Ala-Met-Ala-Pro-Arg-Glu-Arg-Lys-Ala-Gly-Cys-Lys-Asn-Phe-Phe-Trp-Lys-Thr-Phe-Thr-Ser-Cys

Somatostatin-14:

Ala-Gly-Cys-Lys-Asn-Phe-Phe-Trp-Lys-Thr-Phe-Thr-Ser-Cys

Octreotide: D-Phe-Cys-Phe-D-Trp-Lys-Thr-Cys-Thr-ol

Lanreotide: D-Nal-Cys-Tyr-D-Trp-Lys-Val-Cys-Thr-NH₂

Seglitide: N-Methyl-Ala-Tyr-D-Trp-Lys-Val-Phe

Vapreotide: D-Phe-Cys-Tyr-D-Trp-Lys-Val-Cys-Trp-NH₂

Figure 55–4. Structures of the somatostatins and clinically available analogs. The amino acid sequences of SST-28 and SST-14 are shown. Residues that play key roles in receptor binding, as discussed in the text, are shown in blue. Also shown are the structures of the synthetic somatostatin analogs, octreotide, lanreotide, seglitide, and vapreotide. *Abbreviation:* D-Nal, 3-(2-naphthyl)-D-alanyl.

Currently, the most widely used somatostatin analog is octreotide (SANDOSTATIN), an 8-amino-acid synthetic derivative of somatostatin that has a longer half-life and binds preferentially to SSTR-2 and SSTR-5 receptors. Typically, octreotide (100 µg) is administered subcutaneously three times daily; bioactivity is virtually 100%, peak effects are seen within 30 minutes, serum half-life is approximately 90 minutes, and duration of action is approximately 12 hours. The goal of treatment is to decrease GH levels to less than 2 ng/ml after an oral glucose tolerance test and to bring IGF-1 levels to within the normal range for age and gender. Depending on the biochemical response, higher or lower octreotide doses may be used in individual patients.

In addition to its effect on GH secretion, octreotide can decrease tumor size—although tumor growth generally resumes after octreotide treatment is stopped. Octreotide also has significant inhibitory effects on thyrotropin secretion, and it is the treatment of choice for patients who have thyrotrope adenomas that oversecrete TSH and who are not good candidates for surgery. The use of octreotide in gastrointestinal disorders is discussed in Chapter 37.

Gastrointestinal side effects—including diarrhea, nausea, and abdominal pain—occur in up to 50% of patients receiving octreotide. In most patients, these symptoms diminish over time and do not require cessation of therapy. Approximately 25% of patients receiving octreotide develop gallstones, presumably due to decreased gallblad-

der contraction and gastrointestinal transit time. In the absence of symptoms, gallstones are not a contraindication to continued use of octreotide. Compared to somatostatin, octreotide reduces insulin secretion to a lesser extent and only infrequently affects glycemic control.

The need to inject octreotide three times daily poses a significant obstacle to patient compliance. A long-acting, slow-release form (SANDOSTATIN LAR) is a more convenient alternative that can be administered intramuscularly once every 4 weeks; the recommended dose is 20 or 30 mg (McKeage *et al.*, 2003). The long-acting preparation is at least as effective as the regular formulation and is used in patients who have responded favorably to a trial of the shorter-acting formulation of octreotide. Like the shorter-acting formulation, the longer-acting formulation of octreotide generally is well tolerated and has a similar incidence of side effects (predominantly gastrointestinal and/or discomfort at the injection site) that do not require cessation of therapy.

Lanreotide (SOMATULINE LA) is another long-acting octapeptide analog of somatostatin that causes prolonged suppression of GH secretion when administered in a 30-mg dose intramuscularly. Although its efficacy appears comparable to that of the long-acting formulation of octreotide, its duration of action is shorter; thus it must be administered either at 10- or 14-day intervals. A 60-mg formulation of lanreotide (SOMATULINE AUTOGEL) has recently been introduced that reduces the required dosing frequency to once every 4 weeks; current results are com-

parable to those with the slow-release octreotide formulation, as are the incidence and severity of side effects. Lanreotide has not been approved by the FDA for use in the United States.

Somatostatin blocks not only GH secretion, but also the secretion of other hormones, growth factors, and cytokines. Thus, octreotide and the delayed-release somatostatin analogs have been used to treat symptoms associated with metastatic carcinoid tumors (*e.g.*, flushing and diarrhea) and adenomas secreting vasoactive intestinal peptide (*e.g.*, watery diarrhea). Octreotide also is used for treatment of acute variceal bleeding, for perioperative prophylaxis in pancreatic surgery, and for TSH-secreting adenomas in patients who are not candidates for surgery. Novel uses under evaluation currently include the treatment of eye diseases associated with excessive proliferation and inflammation (*e.g.*, Graves' orbitopathy and diabetic retinopathy), diabetic nephropathy, and various systemic diseases associated with inflammation (*e.g.*, rheumatoid arthritis, inflammatory bowel disease, and psoriasis). Finally, modified forms of octreotide labeled with indium or technetium have been used for diagnostic imaging of neuroendocrine tumors such as pituitary adenomas and carcinoids; modified forms labeled with β emitters such as ^{90}Y have been used in selective destruction of SSTR-2-positive tumors.

Dopamine-Receptor Agonists. The dopamine-receptor agonists are described in more detail below in the section dealing with treatment of prolactin excess. Although dopamine-receptor agonists normally stimulate GH secretion, they paradoxically decrease GH secretion in some patients with acromegaly. The best responses have been seen in patients whose tumors secrete both GH and prolactin. The long-acting dopamine-receptor agonist *cabergoline* (DOSTINEX) may lower GH and IGF-1 levels into the target range and thus may be of value in patients who are unwilling to undergo treatment with drugs administered by injection. Doses used in treating acromegaly typically are considerably higher than those employed in prolactinomas.

Growth Hormone Antagonists. Pegvisomant (SOMAVERT) is a GH antagonist that is FDA approved for the treatment of acromegaly. Pegvisomant binds to the GH receptor but does not activate Jak-Stat signaling or stimulate IGF-1 secretion (Figure 55-3). Pegvisomant is administered subcutaneously as a 40-mg loading dose under physician supervision, followed by self-administration of 10 mg/day. Based on serum IGF-1 levels, the dose is titrated at 4- to 6-week intervals to a maximum of 40 mg/day. Liver function should be monitored in all patients, and pegvisomant should not be used in patients with elevated levels of liver transaminases. Because there are concerns that loss of negative feedback by GH and IGF-1 may increase the growth of GH-secreting adenomas, careful follow-up by pituitary MRI is mandatory. Pegvisomant differs structurally from native GH and induces the formation of specific antibodies in ~15% of patients despite the covalent coupling to lysine residues of 4 to 5 molecules of a polyethylene glycol polymer per modified GH molecule. Nevertheless, the development of tachyphylaxis due to these antibodies has not been reported.

In clinical trials, pegvisomant at higher doses significantly decreased serum IGF-1 to normal age- and sex-adjusted levels in >90% of patients, and significantly improved clinical parameters such as ring size, soft-tissue swelling, excessive perspiration, and fatigue. Thus, while its ultimate role in the management of acro-

megaly remains to be determined, pegvisomant is an exciting new pharmacologic agent, particularly for those acromegalic patients who do not respond to somatostatin analogs.

PROLACTIN

As a member of the somatotropin family, prolactin is related structurally to GH and placental lactogen (Table 55-1). Human prolactin is a 23,000-dalton protein of 199 amino acids with three intramolecular disulfide bonds. It is synthesized by lactotropes in the anterior pituitary gland, and a portion of secreted prolactin is glycosylated at a single asparagine residue. In circulation, dimeric and polymeric forms of prolactin also are found, as are degradation products of 16,000 and 18,000 daltons; the biological significance of these different forms is not known.

Secretion

Prolactin synthesis and secretion in the fetal pituitary start in the fifth week of gestation. Serum prolactin levels decline shortly after birth. Whereas serum prolactin levels remain low throughout life in normal males, they are elevated somewhat in normal cycling females. Prolactin levels rise markedly during pregnancy, reach a maximum at term, and decline thereafter unless the mother breast-feeds the child. Suckling or breast manipulation in nursing mothers stimulates circulating prolactin levels, which can rise ten- to one hundredfold within 30 minutes of stimulation. This response is transmitted from the breast to the hypothalamus *via* the spinal cord and the median forebrain bundle, and is distinct from milk let-down, which is mediated by oxytocin release by the posterior pituitary gland. The precise mechanism for suckling-induced prolactin secretion is not known but involves both decreased secretion of dopamine by tuberoinfundibular neurons and possibly increased release of factors that stimulate prolactin secretion (*see* below). The suckling response becomes less pronounced after several months of breast-feeding, and prolactin concentrations eventually decline to prepregnancy levels.

Prolactin detected in maternal and fetal blood originates from maternal and fetal pituitaries, respectively. Prolactin also is synthesized by decidual cells near the end of the luteal phase of the menstrual cycle and early in pregnancy; the latter source is responsible for the very high levels of prolactin in amniotic fluid during the first trimester.

Many of the physiological factors that influence prolactin secretion are similar to those that affect GH secre-

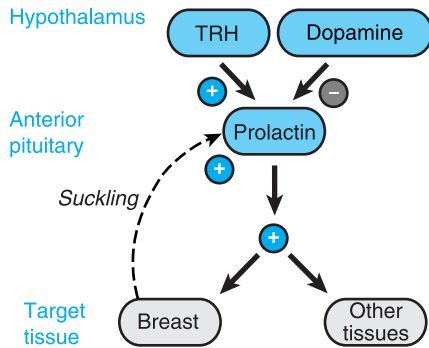

Figure 55–5. Prolactin secretion and actions. Prolactin is the only anterior pituitary hormone for which a unique stimulatory releasing factor has not been identified. Thyrotropin-releasing hormone (TRH), however, can stimulate prolactin release and dopamine can inhibit it. Prolactin affects lactation and reproductive functions but it also has varied effects on many other tissues. Prolactin is not under feedback control by peripheral hormones, but its secretion is induced by suckling (*see* text for further details).

tion. Thus, sleep, stress, hypoglycemia, exercise, and estrogen increase the secretion of both hormones.

Like other anterior pituitary hormones, prolactin is secreted in a pulsatile manner. Prolactin is unique among the anterior pituitary hormones in that hypothalamic regulation of its secretion is predominantly inhibitory. The major regulator of prolactin secretion is dopamine, which is released by tuberoinfundibular neurons and interacts with the D_2 receptor on lactotropes to inhibit prolactin secretion (Figure 55–5). A number of putative prolactin-releasing factors have been described, including thyrotropin-releasing hormone (TRH), vasoactive intestinal peptide, prolactin-releasing peptide, and pituitary adenylyl cyclase-activating peptide (PACAP), but their physiological roles are unclear. Under certain pathophysiological conditions, such as severe primary hypothyroidism, persistently elevated levels of TRH can induce hyperprolactinemia and galactorrhea.

Molecular and Cellular Bases of Prolactin Action

The effects of prolactin result from interactions with specific receptors that are widely distributed among a variety of cell types within many tissues (Goffin *et al.*, 2002). The prolactin receptor is encoded by a single gene on chromosome 5. Alternative splicing of this gene gives rise to multiple forms of the receptor, including a short form of 310 amino acids, a long form of 610 amino acids, and an intermediate form of 412 amino acids. In addition, sol-

uble forms that correspond to the extracellular domain of the receptor are found in the circulation. The membrane-bound prolactin receptor is related structurally to receptors for GH and several cytokines and uses similar signaling mechanisms. Like the GH receptor, the prolactin receptor lacks intrinsic tyrosine kinase activity; prolactin induces a conformational change leading to recruitment and activation of Jak kinases (Figure 55–3). The activated Jak2 kinase, in turn, induces phosphorylation, dimerization, and nuclear translocation of the transcription factor Stat5. Unlike human GH and placental lactogen, which bind to the prolactin receptor and are lactogenic, prolactin binds specifically to the prolactin receptor and has no somatotropic (GH-like) activity.

Physiological Effects of Prolactin

A number of hormones—including estrogens, progesterone, placental lactogen, and GH—stimulate development of the breast and prepare it for lactation. Prolactin, acting *via* prolactin receptors, plays an important role in inducing growth and differentiation of the ductal and lobuloalveolar epithelium and is essential for lactation. Target genes by which prolactin induces mammary development include those encoding milk proteins (*e.g.*, caseins), genes important for intracellular structure (*e.g.*, keratins), genes important for cell-cell communication (*e.g.*, amphiregulin and Wnt4), and components of the extracellular matrix (*e.g.*, laminin and collagen).

Prolactin receptors are present in many other sites, including the hypothalamus, liver, testes, ovaries, prostate, and immune system, prompting the hypothesis that prolactin plays multiple roles outside the breast. The physiological effects of prolactin at these sites, however, remain poorly characterized. For example, a considerable body of evidence suggests that prolactin can stimulate immune function *via* effects on multiple cell types; however, knockout mice lacking either prolactin or its receptor exhibit neither immunodeficiency nor autoimmune disease. Some have therefore proposed that prolactin modulates immune function during stress rather than under normal circumstances.

Agents Used to Treat Syndromes of Prolactin Excess

Prolactin has no therapeutic uses. Hyperprolactinemia is a relatively common endocrine abnormality that can result from hypothalamic or pituitary diseases that interfere with the delivery of inhibitory dopaminergic signals, from renal failure, from primary hypothyroidism associated

with increased TRH levels, or from treatment with dopamine-receptor antagonists. Most often, hyperprolactinemia is caused by prolactin-secreting pituitary adenomas—either microadenomas or macroadenomas. Manifestations of prolactin excess in women include galactorrhea, amenorrhea, and infertility. In men, hyperprolactinemia causes loss of libido, impotence, and infertility.

The therapeutic options for patients with prolactinomas include transsphenoidal surgery, radiation, and treatment with dopamine-receptor agonists that suppress prolactin production *via* activation of D₂ dopamine receptors. Inasmuch as initial surgical cure rates are only 50% to 70% with microadenomas and 30% with macroadenomas, most patients with prolactinomas ultimately require drug therapy. Thus, dopamine-receptor agonists have become the initial treatment of choice for many patients (Molitch, 2002a). These agents generally decrease both prolactin secretion and the size of the adenoma, thereby improving the endocrine abnormalities, as well as the neurological symptoms caused directly by the adenoma (including visual field deficits).

Bromocriptine. *Bromocriptine* (PARLODEL) is the dopamine-receptor agonist against which newer agents are compared. Bromocriptine is a semisynthetic ergot alkaloid that interacts with D₂ dopamine receptors to inhibit spontaneous and TRH-induced release of prolactin; to a lesser extent, it also activates D₁ dopamine receptors. Bromocriptine normalizes serum prolactin levels in 70% to 80% of patients with prolactinomas and decreases tumor size in more than 50% of patients, including those with macroadenomas. It is worth noting that bromocriptine does not cure the underlying adenoma, and hyperprolactinemia and tumor growth typically recur upon cessation of therapy.

Frequent side effects of bromocriptine include nausea and vomiting, headache, and postural hypotension—particularly on initial use. Less-frequent side effects include nasal congestion, digital vasospasm, and CNS effects such as psychosis, hallucinations, nightmares, or insomnia. These side effects can be diminished by starting at a low dose (1.25 mg) administered at bedtime with a snack. After 1 week, a morning dose of 1.25 mg can be added. If clinical symptoms persist or serum prolactin levels remain elevated, the dose can be increased gradually, every 3 to 7 days, to 5 mg twice per day or 2.5 mg three times a day as tolerated. Patients often develop tolerance to the side effects of bromocriptine. Those who do not respond to bromocriptine or who develop intractable side effects may respond to a different dopamine agonist. Although a high fraction of the oral dose of bromocriptine is absorbed, only 7% of the dose reaches the systemic circulation because of a high extraction rate and extensive first-pass metabolism in the liver. Furthermore, bromocriptine has a relatively short elimination half-life (between 2 and 8 hours). To avoid the need for frequent dosing, a slow-release oral form is available outside the United States. Bromocriptine may be administered intravaginally (2.5 mg once daily), reportedly with fewer gastrointestinal side effects. At higher concentrations, bromocriptine is used in the management of acromegaly, as noted above, and at still higher concentrations is used in the management of Parkinson's disease. A parenteral long-acting form

of bromocriptine incorporated into biodegradable microspheres (PARLODEL-LAR) has been developed, but is not available in the United States. In clinical trials, this product has produced results that are comparable to those with oral bromocriptine.

Pergolide. *Pergolide* (PERMAX), an ergot derivative approved by the FDA for treatment of Parkinson's disease, also is used "off label" to treat hyperprolactinemia. If the cost of therapy is the key consideration, pergolide is the least expensive dopamine-receptor agonist currently available. It induces many of the same side effects as does bromocriptine, but it can be given once a day, starting at 0.025 mg at bedtime and increased gradually to a maximum daily dose of 0.5 mg.

Cabergoline. Cabergoline (DOSTINEX) is an ergot derivative with a longer half-life (approximately 65 hours), higher affinity, and greater selectivity for the D₂ receptor (approximately four times more potent) than bromocriptine. It has been approved by the FDA for the treatment of hyperprolactinemia and likely will play an increasing role in the treatment of this syndrome. Compared to bromocriptine, cabergoline has a much lower tendency to induce nausea, although it still may cause hypotension and dizziness. In some clinical trials, cabergoline has been more effective than bromocriptine in decreasing serum prolactin in patients with hyperprolactinemia, although this may reflect improved adherence to therapy due to decreased side effects. Therapy is initiated at a dose of 0.25 mg twice a week or 0.5 mg once a week. If the serum prolactin remains elevated, the dose can be increased to a maximum of 1.5 to 2 mg two or three times a week as tolerated; however, the dose should not be increased more often than once every 4 weeks.

Quinagolide. *Quinagolide* (NORPROLAC) is a nonergot D₂ dopamine agonist with a half-life of 22 hours. Quinagolide is administered once daily at doses of 0.1 to 0.5 mg/day. It is not approved by the FDA but has been used extensively in Europe.

Patients with prolactinomas who wish to become pregnant comprise a special subset of hyperprolactinemic patients. In this setting, drug safety during pregnancy is an important consideration. Bromocriptine, cabergoline, and quinagolide all relieve the inhibitory effect of prolactin on ovulation and permit most patients with prolactinomas to become pregnant without apparent detrimental effects on pregnancy or fetal development. However, experience with cabergoline and quinagolide is less extensive than that with bromocriptine. Therefore, bromocriptine is recommended as the first-line treatment in this setting; this opinion may change as experience with cabergoline or quinagolide increases.

GONADOTROPIN-RELEASING HORMONE AND GONADOTROPIC HORMONES

Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) were named initially based on their actions on the ovary; appreciation of their roles in male reproductive function came later. These pituitary hormones, together with the related placental hormone human chorionic gonadotropin (hCG), are collectively referred to as the gonadotropic hormones because of their actions on the gonads (Table 55–1).

Figure 55–6. The hypothalamic-pituitary-gonadal axis. A single hypothalamic releasing factor, gonadotropin-releasing hormone (GnRH), controls the synthesis and release of both gonadotropins (LH and FSH) in males and females. Gonadal steroid hormones (androgens, estrogens, and progesterone) cause feedback inhibition at the level of the pituitary and the hypothalamus. The preovulatory surge of estrogen also can exert a stimulatory effect at the level of the pituitary and the hypothalamus. Inhibins, polypeptide hormones produced by the gonads, specifically inhibit FSH secretion by the pituitary.

The regulation of gonadotropin secretion is described in detail in Chapters 57 and 58. LH and FSH are synthesized and secreted by gonadotropes, which make up approximately 20% of the hormone-secreting cells in the anterior pituitary. hCG, which is produced only in primates and horses, is synthesized by syncytiotrophoblast cells of the placenta. Pituitary gonadotropin production is stimulated by GnRH and is further regulated by feedback effects of the gonadal hormones (Figure 55–6; *see also* Figure 57–2).

Regulation of Release of GnRH. GnRH is a decapeptide with blocked amino and carboxyl termini (Table 55–2) that is derived by proteolytic cleavage of a 92-amino-acid precursor peptide. GnRH release is intermittent and is governed by a neural pulse generator in the mediobasal hypothalamus, primarily in the arcuate nucleus, that controls the frequency and amplitude of GnRH release. The GnRH

pulse generator is active late in fetal life and for approximately one year after birth, but decreases considerably thereafter, presumably secondarily to CNS inhibition. Shortly before puberty, CNS inhibition decreases and the amplitude and frequency of GnRH pulses increase, particularly during sleep. As puberty progresses, the GnRH pulses increase further in amplitude and frequency until the normal adult pattern is established. The intermittent release of GnRH is crucial for the proper synthesis and release of the gonadotropins; the continuous administration of GnRH leads to desensitization and down-regulation of GnRH receptors on pituitary gonadotropes. This down-regulation forms the basis for the clinical use of long-acting GnRH analogs to suppress gonadotropin secretion (*see below*).

Molecular and Cellular Bases of GnRH Action.

GnRH signals through a specific G protein–coupled receptor on gonadotropes that activates $G_{q/11}$ and stimulates the PLC- IP_3 - Ca^{2+} pathway (*see* Chapter 1) resulting in increased synthesis and secretion of LH and FSH. Although cyclic AMP is not the major mediator of GnRH action, binding of GnRH to its receptor also increases adenylyl cyclase activity. GnRH receptors also are present in the ovary and testis, where their physiological significance remains to be determined.

Other Regulators of Gonadotropin Production.

Gonadal steroids regulate gonadotropin production at the level of the pituitary and the hypothalamus, but effects on the hypothalamus predominate. The feedback effects of gonadal steroids are sex-, dosage-, and time-dependent. In women, low levels of estradiol and progesterone inhibit gonadotropin production, largely through opioid action on the neural pulse generator that controls GnRH secretion. Higher and more sustained levels of estradiol have positive feedback effects that ultimately result in the gonadotropin surge that precedes ovulation. In men, testosterone inhibits gonadotropin production, in part through direct actions and in part *via* its conversion to estradiol.

Gonadotropin production also is regulated by the *inhibins*, which are members of the bone morphogenetic protein family of secreted signaling proteins. Inhibins are made by granulosa cells in the ovary and Sertoli cells in the testis in response to the gonadotropins and local growth factors. They act directly in the pituitary to inhibit FSH secretion without affecting that of LH.

Molecular and Cellular Bases of Gonadotropin Action

The gonadotropins (LH, FSH, and hCG), together with TSH, constitute the glycoprotein family of pituitary hor-

mones. Each hormone is a glycosylated heterodimer containing a common α -subunit and a distinct β -subunit that confers specificity of action. Among the β -subunits of this family, that of hCG is most different because it contains a carboxy-terminal extension of 30 amino acids and extra carbohydrate residues. The carbohydrate residues on the gonadotropins play a role in signal transduction at the gonadotropin receptors and also influence the rates of clearance of the gonadotropins from the circulation and thus their serum half-lives; the longer half-life of hCG has some clinical relevance for its use in assisted reproduction technologies (*see below*).

The actions of LH and hCG are mediated by the LH receptor, while those of FSH are mediated by the FSH receptor. Both of these G protein-coupled receptors have large, glycosylated extracellular domains that contribute to their affinity and specificity for their ligands. The FSH and LH receptors couple to G_s to activate the adenylyl cyclase-cyclic AMP pathway. At higher ligand concentrations, the agonist-occupied gonadotropin receptors also activate protein kinase C and Ca^{2+} signaling pathways *via* G_q -mediated effects on $PLC\beta$. Since most, if not all, of the actions of the gonadotropins can be mimicked by cyclic AMP analogs, the precise physiological role of Ca^{2+} and protein kinase C in gonadotropin action remains to be determined.

Physiological Effects of Gonadotropins

In men, LH acts on testicular Leydig cells to stimulate the *de novo* synthesis of androgens, primarily testosterone, from cholesterol. Testosterone is required for gametogenesis within the seminiferous tubules and for maintenance of libido and secondary sexual characteristics (*see Chapter 58*). FSH acts on the Sertoli cells to stimulate the production of proteins and nutrients required for sperm maturation, thereby indirectly supporting germ cell maturation.

In women, the actions of FSH and LH are more complicated. FSH stimulates the growth of developing ovarian follicles and induces the expression of LH receptors on theca and granulosa cells. FSH also regulates the activity of aromatase in granulosa cells, thereby stimulating the production of 17β -estradiol. LH acts on the theca cells to stimulate the *de novo* synthesis of androstenedione, the major precursor of ovarian 17β -estradiol in premenopausal women (*see Figure 57–1*). LH also is required for the rupture of the dominant follicle during ovulation and for the synthesis of progesterone by the corpus luteum.

Mutations in genes encoding the gonadotropin subunits or their cognate receptors impair sexual development and reproduction

(Achermann and Jameson, 1999). Women with mutations in either $FSH\beta$ or its receptor present clinically with primary amenorrhea, infertility, and the absence of breast development. Histologically, the ovarian follicles fail to mature and corpora lutea are missing. In men, mutations of $FSH\beta$ or the FSH receptor are associated with decreased testes size and oligospermia, although several subjects have been fertile.

An inactivating mutation of $LH\beta$ has been reported in a 46-year-old XY subject with Leydig cell hypoplasia, lack of spontaneous puberty, and infertility. The external genitalia were masculinized, suggesting that androgen production *in utero* was driven by hCG. In contrast, apparently complete loss-of-function mutations of the LH receptor cause phenotypes ranging from male hypogonadism to male-to-female sex reversal of the external genitalia and failure to initiate puberty. Presumably, the loss of the LH receptor leads to a combined loss of responsiveness to both hCG and LH signaling *in utero*, which prevents virilization of the external genitalia. Women with homozygous inactivating mutations of the LH receptor present with primary amenorrhea or oligomenorrhea and infertility and have cystic ovaries on histological examination.

Mutations that constitutively activate the LH receptor cause an autosomal dominant syndrome of precocious puberty in males, a condition called testotoxicosis. The excessive production of testosterone before true puberty commences induces virilization in an LH-independent manner. A subset of these LH receptor mutations that also activate the phosphoinositide pathway has been associated with familial testicular tumors.

CLINICAL USES OF GnRH

As illustrated in Table 55–2, a number of clinically useful GnRH analogs have been synthesized. These include synthetic GnRH (gonadorelin) and GnRH analogs that contain substitutions at position 6 that protect against proteolysis and substitutions at the C-terminus that improve receptor-binding affinity. The analogs exhibit enhanced potency and a prolonged duration of action compared to GnRH, which has a half-life of approximately 2 to 4 minutes.

Pure GnRH antagonists have been developed that do not cause the initial increase in gonadotropin secretion seen when long-acting GnRH agonists are used to down-regulate gonadotropin secretion. The antagonists used currently elicit fewer of the manifestations of local and systemic release of histamine that hampered the development of earlier compounds for clinical use.

Diagnostic Use of GnRH. Synthetic GnRH (*gonadorelin hydrochloride*; FACTREL) is marketed for diagnostic purposes to differentiate between pituitary and hypothalamic defects in patients with hypogonadotropic hypogonadism. After a blood sample is obtained for the baseline LH value, a single 100- μ g dose of GnRH is administered subcutaneously or intravenously and serum LH levels are measured over the next 2 hours (at 15, 30, 45, 60, and 120 minutes after injection). A normal LH response to >10 mIU/ml indicates the presence of functional pituitary gonadotropes and prior exposure to GnRH.

Inasmuch as the long-term absence of GnRH can result in a decreased responsiveness of otherwise normal gonadotropes, the absence of a response does not always indicate intrinsic pituitary disease. Thus, some experts advocate use of multiple doses of GnRH in an effort to restore responsiveness of the gonadotropes. GnRH-stimulation testing also is used to determine whether a subject with precocious puberty has central (*i.e.*, GnRH-dependent) or peripheral (*i.e.*, GnRH-independent) precocious puberty. A GnRH-induced rise in plasma LH to greater than 10 mIU/ml in boys or 7 mIU/ml in girls is indicative of true precocious puberty rather than a GnRH-independent process. Due to intermittent problems with gonadorelin availability, some experts have employed GnRH agonists off-label as the stimulating agent for diagnostic assessment.

Therapeutic Uses of GnRH

Management of Infertility. Until recently, synthetic GnRH (*gonadorelin acetate*, LUTREPULSE) was used to treat patients with reproductive disorders secondary to disordered secretion of GnRH or GnRH deficiency. In women, it was administered either intravenously or subcutaneously by a pump in pulses that promoted a physiological cycle, with a starting dose of 2.5 μg per pulse every 120 minutes. If necessary, the dose was increased to 10 to 20 μg per pulse until ovulation was induced. Advantages over gonadotropin therapy (*see below*) included a lower risk of multiple pregnancies and a decreased need to monitor plasma estrogen levels or follicle size by ovarian ultrasonography. Side effects generally were minimal; the most common was local irritation due to the infusion device. In women, normal cycling levels of ovarian steroids could be achieved, leading to ovulation and menstruation. Because of its complexity, this regimen was previously available only in specialized centers of reproductive endocrinology. Production was discontinued by the United States manufacturer in 2003 and GnRH is no longer available.

Two GnRH antagonists, *ganirelix* (ANTAGON) and *cetrotorelix* (CETROTIDE) (Table 55–2), have been used to suppress the LH surge and thus prevent premature follicular luteinization in ovarian-stimulation protocols that are part of assisted reproduction techniques. The GnRH antagonist is given either in the follicular phase (termed the “short protocol”) or in the midluteal phase (termed the “long protocol”)—in conjunction with gonadotropins—to induce follicular maturation (*see below*). Ovulation is then induced with hCG or LH. Because they lack the initial stimulation of gonadotropin secretion seen with GnRH agonists, the GnRH antagonists provide a more rapid effect and are likely to become the preferred drugs in this setting.

Suppression of Gonadotropin Secretion. As noted above, long-acting GnRH analogs eventually desensitize GnRH signaling pathways, markedly inhibiting gonado-

tropin secretion and decreasing the production of gonadal steroids. This pharmacological castration is useful in disorders that respond to reductions in gonadal steroids. A clear indication for this therapy is in children with gonadotropin-dependent precocious puberty, whose premature sexual maturation can be arrested with minimal side effects by chronic administration of a GnRH agonist.

Long-acting GnRH agonists are used for palliative therapy of hormonally responsive tumors (*e.g.*, prostate or breast cancer), generally in conjunction with agents that block steroid biosynthesis or action to avoid transient increases in hormone levels (*see Chapter 51*). Because it does not transiently increase sex steroid production, an extended-release form of the GnRH antagonist *abarelix* (PLENAXIS) also is marketed for use in prostate cancer patients in whom serious adverse consequences might accompany any stimulus to tumor growth (*e.g.*, in patients with spinal cord metastases where increased tumor growth could lead to paralysis). The GnRH agonists also are used to suppress steroid-responsive conditions such as endometriosis, uterine leiomyomas, and acute intermittent porphyria. Depot preparations of *goserelin* (ZOLADEX), *leuprolide* (LUPRON DEPOT, ELEGARD) or *triptorelin* (TRELSTAR LA), which can be administered subcutaneously or intramuscularly monthly or every 3 months, can be used in these settings and may be particularly useful for pharmacological castration in disorders such as paraphilia, for which strict patient compliance is problematic.

The long-acting agonists generally are well tolerated, and side effects are those that would be predicted to occur when gonadal steroidogenesis is inhibited (*e.g.*, hot flashes, vaginal dryness and atrophy, decreased bone density). Because of these effects, therapy in non-life-threatening diseases such as endometriosis or uterine leiomyomas generally is limited to 6 months unless add-back therapy with estrogens and/or progestins is incorporated into the regimen. In addition to these predicted effects, *abarelix* has been associated with a significant incidence of hypersensitivity reactions, and its therapeutic role remains to be defined. For safety reasons, *abarelix* distribution is limited to physicians who are enrolled in the manufacturer’s prescribing program.

Clinical Uses of Gonadotropins

The gonadotropins are used increasingly in the arena of reproductive endocrinology. As a result, a number of formulations are available for clinical use.

Diagnostic Uses of Gonadotropins

Diagnosis of Pregnancy. Significant amounts of hCG are present in the maternal bloodstream and urine during

pregnancy and can be detected immunologically with antisera specific for its unique β -subunit. This provides the basis for commercial pregnancy kits that qualitatively assay for the presence or absence of hCG in the urine. These kits offer a rapid, noninvasive means of detecting pregnancy within a few days after a woman's first missed menstrual period and are widely available without a prescription.

Quantitative measurements of plasma hCG concentration are made by immunoassay. These assays typically are used to assess whether or not pregnancy is proceeding normally or to help detect the presence of an ectopic pregnancy, hydatidiform mole, or choriocarcinoma. They also are employed to follow the therapeutic response of malignancies, such as germ cell tumors, that secrete hCG.

Timing of Ovulation. Ovulation occurs approximately 36 hours after the onset of the LH surge (10 to 12 hours after the peak of LH). Therefore, urinary concentrations of LH can be used to predict the time of ovulation. Kits are available over the counter that use LH-specific antibodies to provide a semiquantitative assessment of LH levels in urine. Urine LH levels are measured every 12 to 24 hours, beginning on day 10 to 12 of the menstrual cycle (assuming a 28-day cycle), to detect the rise in LH and thus estimate the time of ovulation. Such estimates facilitate the timing of sexual intercourse to achieve pregnancy.

Differential Diagnosis of Diseases of Male and Female Reproduction. Measurements of plasma LH and FSH levels, as determined by quantitative β -subunit-specific immunoassays, are useful in the diagnosis of several reproductive disorders. Low or undetectable levels of LH and FSH are indicative of hypogonadotropic hypogonadism and suggest hypothalamic or pituitary disease, whereas high levels of gonadotropins suggest primary gonadal diseases. Therefore, in cases of amenorrhea in women or delayed puberty in men and women, measurements of plasma gonadotropins can be used to distinguish between gonadal failure and hypothalamic-pituitary failure.

The FSH level on day 3 of the menstrual cycle is useful in assessing relative fertility. An FSH level of ≥ 10 mIU/ml is associated with reduced fertility, even if a woman is menstruating normally, and predicts a lower likelihood of success in assisted reproduction techniques such as *in vitro* fertilization.

The administration of hCG also is used to stimulate testosterone production and thus to assess Leydig cell function in men suspected of having Leydig cell failure (for example, in delayed puberty). Serum testosterone levels are assayed after multiple injections of hCG. A diminished testosterone response to hCG indicates Leydig

cell failure; a normal testosterone response suggests a hypothalamic-pituitary disorder.

Therapeutic Uses of Gonadotropins

Gonadotropins are purified from human urine or prepared using recombinant DNA technology. Several preparations of urinary gonadotropins have been developed. *Chorionic gonadotropin* (PREGNYL, NOVAREL, PROFASI, others), which mimics the action of LH, is obtained from the urine of pregnant women. Urine from postmenopausal women is the source of *menotropins* (PERGONAL, REPRONEX), which contain roughly equal amounts of FSH and LH, as well as a number of other urinary proteins. Because of their relatively low purity, menotropins are administered intramuscularly to decrease the incidence of hypersensitivity reactions. *Urofollitropin* (uFSH; BRAVELLE) is a highly purified FSH prepared by immunoconcentration with monoclonal antibodies and pure enough to be administered subcutaneously.

Recombinant preparations of gonadotropins are assuming an increasing role in clinical practice. Recombinant FSH (rFSH) is prepared by expressing cDNAs encoding the α and β subunits of FSH in a mammalian cell line, yielding products whose glycosylation pattern mimics that of FSH produced by gonadotropes. The two rFSH preparations that are available (*follitropin α* [GONAL-F] and *follitropin β* [PUREGON, FOLLISTIM]) differ slightly in their carbohydrate structures; both exhibit less inter-batch variability than do preparations purified from urine and can be administered subcutaneously, since they are considerably purer. The recombinant preparations are more expensive than the naturally derived hormones, and their relative advantages (*i.e.*, efficacy, lower frequency of side effects such as ovarian hyperstimulation) have not been definitively established despite much debate in the published literature.

Recombinant forms of hCG (choriogonadotropin alfa; OVIDREL) and LH (LUVERIS, LHADI) also have been developed and are being investigated for the treatment of infertility. Providing that their cost-benefit ratios are favorable, it is likely that these recombinant gonadotropin preparations will have an increasing role in the future, possibly replacing the urinary preparations entirely. In addition, recombinant technology is likely to lead to improved forms of gonadotropins with increased half-lives or higher clinical efficacy.

Female Infertility. Infertility affects approximately 10% of couples of reproductive age. Gonadotropins are used in

the treatment of infertility, either for the induction of ovulation or in conjunction with assisted reproduction technologies (Huirne *et al.*, 2004). The administration of gonadotropins in these settings should be limited to physicians experienced in the treatment of infertility or endocrine disorders. Although most clearly indicated for ovulation induction in anovulatory women with hypogonadotropic hypogonadism secondary to hypothalamic or pituitary dysfunction, gonadotropins also are used to induce ovulation in women with the polycystic ovary syndrome who do not respond to clomiphene citrate (*see* Chapter 57). Gonadotropins also are used in women who are infertile despite normal ovulation, although therapy with clomiphene citrate typically is attempted first.

The goal of ovulation induction in anovulatory women is to induce the formation and ovulation of a single dominant follicle. A typical therapeutic regimen is to administer 75 IU of FSH daily in a “low-dose, step-up protocol.” This dose is given daily until cycle day 6 or 7, after which transvaginal ultrasound is used to assess the number and size of developing follicles. Scans typically are performed every 2 to 3 days and focus on identifying intermediate follicles. Although the criteria used at different centers vary, the finding of a follicle larger than 18 mm in diameter indicates that follicular development has progressed adequately. If three or more follicles >16 mm are present, gonadotropin therapy generally is stopped and pregnancy prevented by barrier contraception to decrease the likelihood of multiple pregnancies or the ovarian hyperstimulation syndrome (OHSS; *see* below). Measurements of serum estradiol levels also may be helpful. The target estradiol range is from 500 to 1500 pg/ml, with lower levels indicating inadequate gonadotropin stimulation and higher values portending an increased risk of OHSS. If laboratory assessment indicates impaired ovarian response, the dose of FSH can be increased in increments of 37.5 IU daily to a maximum range of 225 to 450 IU/day.

To complete follicular maturation and induce ovulation, hCG (5000 to 10,000 IU) is given one day after the last dose of FSH. Despite the precautions outlined above, gonadotropin-induced ovulation results in multiple births in up to 10% to 20% of cases, due to the nonphysiological development of more than one preovulatory follicle and the release of more than one ovum.

Gonadotropin induction also is used for ovarian stimulation in conjunction with *in vitro* fertilization (IVF) and intracytoplasmic sperm injection (ICSI). In this setting, larger doses of FSH (typically 225 IU/day) are administered to induce the maturation of multiple follicles, thus permitting the retrieval of multiple oocytes for IVF and intrauterine transfer. In the most common “long protocol,” FSH is administered in conjunction with a GnRH analog to prevent premature ovulation. Thereafter, hCG is given to induce final oocyte development (with typical doses of 5000 to 10,000 IU of urine-derived product or 250 μ g of recombinant hCG), and then the mature eggs are retrieved from the preovulatory follicles at 32 to 36 hours after hCG administration. The ova are retrieved transvaginally under ultrasound guidance, fertilized *in vitro* with sperm (IVF) or by sperm injection (ICSI), and then transferred to the uterus (IVF) or less frequently to the fallopian tubes (gamete intrafallopian transfer). With these approaches, the increased risk of multiple births is related to the number of embryos that are transferred to the woman,

and there is a trend towards decreasing the number of embryos transferred to diminish this risk.

Aside from the risk of multiple births and its attendant complications, the major side effect of gonadotropin treatment is OHSS, which is believed to result from increased ovarian secretion of substances that increase vascular permeability and is characterized by rapid accumulation of fluid in the peritoneal cavity, thorax, and even the pericardium. Signs and symptoms include abdominal pain and/or distention, nausea and vomiting, diarrhea, marked ovarian enlargement, dyspnea, and oliguria. OHSS can lead to hypovolemia, electrolyte abnormalities, abnormal fluid accumulation (*e.g.*, ascites, pleural effusions, and hemoperitoneum), acute respiratory distress syndrome, thromboembolic events, and hepatic dysfunction. If there is clinical suspicion that OHSS is developing, or if routine laboratory investigation reveals the presence of more than 2 follicles greater than 17 mm or an estrogen level of >1500 pg/ml, then hCG should be withheld. Clinical data suggest that ovulation induction with either a GnRH agonist or recombinant LH, whose half-life is considerably shorter than that of hCG, may diminish the incidence of OHSS.

Apart from OHSS, there is debate about the potential deleterious effects of gonadotropins. Some studies have suggested that gonadotropins are associated with an increased risk of ovarian cancer, but this conclusion is controversial. Similarly, although there is emerging evidence that IVF itself may be associated with abnormal imprinting that increases the risk of developmental syndromes such as Angelman and Beckwith-Wiedemann syndromes (Gosden *et al.*, 2003), there is no evidence that the gonadotropins themselves increase the rate of congenital abnormalities in babies born from stimulated oocytes.

Male Infertility. In men with impaired fertility secondary to gonadotropin deficiency, gonadotropins can establish or restore fertility. Due to expense and to the occasional development of resistance to gonadotropins with prolonged use, standard treatment is to induce sexual development with androgens, reserving gonadotropins until fertility is desired.

Treatment typically is initiated with hCG (1500 to 2000 IU intramuscularly or subcutaneously) three times per week until clinical parameters and the plasma testosterone level indicate full induction of steroidogenesis. Thereafter, the dose of hCG is reduced to 2000 IU twice a week or 1000 IU three times a week, and menotropins (FSH + LH) or recombinant FSH is injected three times a week (typical doses for menotropins range from 75 to 150 IU or 37.5 IU for rFSH) to fully induce spermatogenesis. The most common side effect of gonadotropin therapy is gynecomastia, which occurs in up to one-third of patients and presumably reflects increased production of estrogens due to the induction of aromatase. Maturation of the prepubertal testes typically requires treatment for more than 6 months, and optimal spermatogenesis in some patients may require treatment for up to 2 years. Once spermatogenesis has been initiated by this combined therapy or in patients who develop hypogonadotropic hypogonadism after sexual maturation, ongoing treatment with hCG alone usually is sufficient to support sperm production. As discussed in the section entitled “Female Infertility,” regimens employing recombinant LH, FSH, and hCG very likely will play increasing clinical roles.

Cryptorchidism. Cryptorchidism, the failure of one or both testes to descend into the scrotum, affects up to 3% of full-term male infants and becomes less prevalent with advancing postnatal age. Cryptorchid testes have defective spermatogenesis and are at increased risk for developing germ cell tumors. Hence, the current approach is to reposition the testes as early as possible, typically at 1 year of age but definitely before 2 years of age. The local actions of androgens stimulate descent of the testes; thus, hCG can be used to induce testicular descent if the cryptorchidism is not secondary to anatomical blockage. Therapy usually consists of injections of hCG (3000 IU/m² body surface area) intramuscularly every other day for 6 doses. If this does not induce testicular descent, orchiopexy should be performed.

OXYTOCIN

The structures of the neurohypophyseal hormones oxytocin and arginine vasopressin (also called antidiuretic hormone, or ADH) and the physiology and pharmacology of vasopressin are presented in Chapter 29. The following discussion emphasizes the physiology of oxytocin and its use in pregnancy.

Biosynthesis of Oxytocin

Oxytocin is a cyclic nonapeptide that differs from vasopressin by only two amino acids. It is synthesized as a larger precursor molecule in cell bodies of the paraventricular nucleus, and to a lesser extent, the supraoptic nucleus in the hypothalamus. The precursor is rapidly converted by proteolysis to the active hormone and its neurophysin, packaged into secretory granules as an oxytocin-neurophysin complex, and secreted from nerve endings that terminate primarily in the posterior pituitary gland (neurohypophysis). In addition, oxytocinergic neurons that regulate the autonomic nervous system project to regions of the hypothalamus, brainstem, and spinal cord. Other sites of oxytocin synthesis include the luteal cells of the ovary, the endometrium, and the placenta.

Stimuli for oxytocin secretion include sensory stimuli arising from dilation of the cervix and vagina and from suckling at the breast. Increases in circulating oxytocin in women in labor are difficult to detect, partly because of the pulsatile nature of oxytocin secretion and partly because of the activity of circulating oxytocinase. Nevertheless, increased oxytocin in maternal circulation is detected in the second stage of labor, likely triggered by sustained distension of the uterine cervix and vagina. Estradiol stimulates

oxytocin secretion, whereas the ovarian polypeptide relaxin inhibits release. The inhibitory effect of relaxin appears to be the net result of a direct stimulatory effect on oxytocin-producing cells and an inhibitory action mediated indirectly by endogenous opioids. Other factors that primarily affect vasopressin secretion also have some impact on oxytocin release (*e.g.*, ethanol inhibits release, while pain, dehydration, hemorrhage, and hypovolemia stimulate release). Although peripheral actions of oxytocin appear to play no significant role in the response to dehydration, hemorrhage, or hypovolemia, oxytocin may participate in the central regulation of blood pressure. As described below, pharmacological doses of oxytocin can inhibit free water clearance by the kidney through activity similar to that of arginine vasopressin at vasopressin V₂ receptors, occasionally causing water intoxication if administered with large volumes of hypotonic fluid.

Physiological Roles of Oxytocin

Uterus. The human uterus has a very low level of motor activity during the first two trimesters of pregnancy. During the third trimester, spontaneous motor activity increases progressively until the sharp rise that constitutes the initiation of labor. Oxytocin stimulates the frequency and force of uterine contractions. Uterine responsiveness to oxytocin roughly parallels this increase in spontaneous activity and is highly dependent on estrogen, which increases the expression of the oxytocin receptors. Progesterone antagonizes the stimulant effect of oxytocin *in vitro*, and a decline in progesterone receptor signaling in late pregnancy may contribute to the normal initiation of human parturition. Because of difficulties associated with the measurement of oxytocin levels (*see* above) and because loss of pituitary oxytocin apparently does not compromise labor and delivery, the physiological role of oxytocin in pregnancy has been highly debated. Exogenous oxytocin can initiate or enhance rhythmic contractions at any time, but a considerably higher dose is required in early pregnancy. An eightfold increase in uterine sensitivity to oxytocin occurs in the last half of pregnancy, mostly in the last 9 weeks, accompanied by a thirtyfold increase in oxytocin receptor number between early pregnancy and early labor. The finding that the oxytocin antagonist *atosiban* (TRACTOCILE) is effective in suppressing preterm labor (*see* below) further supports the physiological importance of oxytocin in this setting.

Breast. Oxytocin plays an important physiological role in milk ejection. Stimulation of the breast through suckling or mechanical manipulation induces oxytocin secretion, causing contraction of the myoepithelium that surrounds alveolar channels in the mammary gland. This action forces milk from the alveolar channels into large collecting sinuses, where it is available to the suckling infant.

Mechanism of Action

Oxytocin acts *via* specific G protein–coupled receptors closely related to the V_{1a} and V_2 vasopressin receptors. In the human myometrium, these receptors couple to G_q and G_{11} , activating the $PLC\beta$ - IP_3 - Ca^{2+} pathway and enhancing activation of voltage-sensitive Ca^{2+} channels. Oxytocin also increases local prostaglandin production, which further stimulates uterine contractions.

Clinical Use of Oxytocin

Induction of Labor. Uterine-stimulating agents are used most frequently to induce or augment labor in selected pregnant women. Indications for induction of labor include situations in which the risk of continued pregnancy to the mother or fetus is considered to be greater than the risks of delivery or of pharmacological induction. Such circumstances include premature rupture of the membranes, isoimmunization, fetal growth restriction, and uteroplacental insufficiency (as in diabetes, preeclampsia, or eclampsia). Before labor is induced, it is essential to verify that the fetal lungs are sufficiently mature (*i.e.*, the lecithin-sphingomyelin ratio in amniotic fluid is >2) and to exclude potential contraindications (*e.g.*, abnormal fetal position, evidence of fetal distress, placental abnormalities, or previous uterine surgery that predisposes the uterus to rupture during labor).

Oxytocin (PITOCIN, SYNTOCINON) is the drug of choice for labor induction. It is administered by intravenous infusion of a diluted solution (typically 10 mIU/mL), preferably by means of an infusion pump. Although there is continuing debate concerning the optimal dose to induce labor, some physicians use a protocol involving an initial dose of 1 mIU/minute, with dose increases of no greater than 1 mIU/minute every 30 to 40 minutes. Other authorities advocate a more aggressive approach, with starting doses of 6 mIU/minute and increases of up to 2 mIU/minute at 20-minute intervals. Some published trials have suggested that the higher-dose regimens result in a lower rate of cesarean sections. If doses of 40 mIU/minute fail to initiate satisfactory uterine contractions, higher rates of infusion are unlikely to be successful. As labor progresses, the dose of oxytocin required to maintain good uterine contractions may decrease.

During labor induction, a physician must be immediately available, and the mother and fetus should be monitored continuously to determine fetal and maternal heart rates, maternal blood pressure, and the strength of uterine contractions. If uterine hyperstimulation occurs, as evidenced by too-frequent contractions or the development

of uterine tetany, the oxytocin should be discontinued immediately. The half-life of intravenous oxytocin is short (~3 minutes); thus the hyperstimulatory effects of oxytocin should resolve within several minutes after the infusion is stopped. Because of its structural similarity to vasopressin, oxytocin at higher doses has antidiuretic effects and infusions of ≥ 20 mIU/minute decrease free water clearance by the kidney. Particularly if hypotonic fluids (*e.g.*, dextrose in water) are infused too liberally, water intoxication may result in convulsions, coma, and even death. Vasodilating actions of oxytocin also have been noted, particularly at high doses, which may provoke hypotension and reflex tachycardia. Deep anesthesia may exaggerate the hypotensive effect of oxytocin by preventing the reflex tachycardia.

Augmentation of Labor. Because the resulting uterine hyperstimulation often is too forceful and sustained to be compatible with the safety of the mother and fetus, oxytocin generally should not be used to augment labor that is progressing normally. To augment hypotonic contractions in dysfunctional labor, it rarely is necessary to exceed an infusion rate of 10 mIU/minute, and doses of >20 mIU/minute rarely are effective when lower concentrations fail. Potential complications of overstimulation include trauma of the mother or fetus due to forced passage through an incompletely dilated cervix, uterine rupture, and compromised fetal oxygenation due to decreased uterine perfusion. In the setting of dysfunctional labor, as seen most frequently in nulliparous women, oxytocin can be used to advantage by experienced obstetricians to facilitate labor progression. Oxytocin usually is effective when there is a prolonged latent phase of cervical dilation and when, in the absence of cephalopelvic disproportion, there is an arrest of dilation or descent. Epidural anesthesia can impair the reflex stimulation of endogenous oxytocin during the second stage of labor; in this setting, the cautious administration of oxytocin may facilitate labor progression.

Third Stage of Labor and Puerperium. Postpartum hemorrhage is a significant problem in developed nations and is of even greater importance in underdeveloped countries. After delivery of the fetus or after therapeutic abortion, a firm, contracted uterus greatly reduces the incidence and extent of hemorrhage. Oxytocin (10 IU/minute intramuscularly) often is given immediately after delivery to help maintain uterine contractions and tone. Alternatively, 20 IU of oxytocin is diluted in 1 L of intravenous solution and infused at a rate of 10 ml/minute until the uterus is contracted. Then the infusion rate is reduced to 1 to 2 ml/minute until the mother is ready for transfer

to the postpartum unit. If this is ineffective, ergot alkaloids such as *ergonovine maleate* (ERGOTRATE) or its methyl analog *methylergonovine maleate* (METHERGINE) or the prostaglandin analog *misoprostol* may be used in normotensive patients. The ergot alkaloids are discussed in more detail in Chapter 11; prostaglandins are discussed in Chapter 25.

Oxytocin Challenge Test. In patients whose pregnancy holds increased risk for maternal or fetal complications (*e.g.*, maternal diabetes mellitus or hypertension), an oxytocin challenge test can be used to assess fetal well-being. Oxytocin is infused intravenously, initially at a rate of 0.5 mIU/minute; this rate is increased slowly until 3 uterine contractions occur in 10 minutes. Concurrent monitoring of the fetal heart rate indicates whether or not the uterine contractions are associated with changes in fetal heart rate known to be associated with fetal distress. The outcome of the oxytocin challenge test is helpful in determining the presence of adequate placental reserve for continuation of high-risk pregnancies.

Oxytocin-Receptor Antagonists

Peptide analogs that competitively inhibit the interaction of oxytocin with its membrane receptor have been developed, and one such antagonist, atosiban, has been introduced in a number of countries for the treatment of preterm labor. In clinical trials, atosiban decreased the frequency of uterine contractions and increased the number of women who remained undelivered, with at least comparable efficacy to β adrenergic agonists but with a lower incidence of side effects (Tsatsaris *et al.*, 2004). To date, however, studies have not demonstrated a significant improvement in infant outcome. Establishing the relative roles of atosiban and other oxytocin receptor antagonists under development *versus* agents such as calcium channel blockers in premature labor remains an area of active investigation.

CLINICAL SUMMARY

We continue to make advances in the pharmacotherapy of certain endocrine and reproductive disorders. In children, the indications for growth hormone therapy have been expanded beyond patients with classic, unequivocal growth hormone deficiency, and the drug increasingly is used in conditions such as Turner's syndrome, chronic renal failure, cystic fibrosis, and other conditions associated with short stature, including idiopathic short stature. Although it remains controversial, growth hormone also is used increasingly to treat adults with growth hormone deficiency, with proposed benefits that include increased muscle mass, decreased adiposity, increased bone mineral density, and improved subjective well-being. Adverse effects occur more commonly in adults, and the dose should be adjusted so that the serum IGF-1 level is in the mid-normal range.

Pharmacotherapy also plays an important role in the treatment of functional tumors that produce growth hor-

none (acromegaly) or prolactin (prolactinomas). For acromegaly, sustained-release preparations of somatostatin analogs normalize growth hormone and IGF-1 levels in approximately 65% of patients. Pegvisomant, a growth hormone receptor antagonist, is even more effective, normalizing these parameters in up to 90% of patients. For prolactinomas, dopamine receptor antagonists remain the mainstay of treatment; cabergoline is preferred by many patients because of its lower incidence of side effects relative to other agents.

Another important use of the pituitary hormones is in reproductive medicine. Both GnRH receptor agonists and GnRH receptor antagonists can be used to down-regulate gonadotropin levels and block endogenous production of sex steroids. Indications include interruption of precocious puberty, therapy of cancers whose growth is stimulated by sex steroids (*e.g.*, breast, prostate), and suppression of endogenous gonadotropins in assisted reproduction technologies. Gonadotropins are frequently used in assisted reproduction technologies to stimulate follicular maturation and to induce ovulation. Although debate continues about relative efficacy and cost-benefit factors of these alternative therapies, recombinant gonadotropins largely are replacing gonadotropins purified from human urine in clinical use.

Oxytocin is used to induce labor or to augment its progression. After delivery, oxytocin also can be used to increase uterine tone and diminish postpartum hemorrhage. In contrast, the oxytocin receptor antagonist, atosiban, can be used to suppress uterine contractions in the setting of premature labor; its precise role relative to other drugs is still under evaluation.

THYROID AND ANTITHYROID DRUGS

Alan P. Farwell and Lewis E. Braverman

Thyroid hormones, the only known iodine-containing compounds with biological activity, have two important functions. In developing animals and human beings, they are crucial determinants of normal development, especially in the central nervous system (CNS). In the adult, thyroid hormones act to maintain metabolic homeostasis, affecting the function of virtually all organ systems. To meet these requirements, the thyroid gland contains large stores of preformed hormone. Metabolism of the thyroid hormones occurs primarily in the liver, although local metabolism also occurs in target tissues such as the brain. Serum concentrations of thyroid hormones are precisely regulated by the pituitary hormone, thyrotropin, in a classic negative-feedback system. The predominant actions of thyroid hormone are mediated *via* binding to nuclear thyroid hormone receptors (TRs) and modulating transcription of specific genes. In this regard, thyroid hormones share a common mechanism of action with steroid hormones, vitamin D, and retinoids, whose receptors make up a superfamily of nuclear receptors (*see* Chapter 1). As with steroid hormones, it has become clear that thyroid hormones also have diverse nongenomic actions (Yen and Chin, 2005).

Disorders of the thyroid are common. They consist of two general presentations: changes in the size or shape of the gland or changes in secretion of hormones from the gland. Thyroid nodules and goiter in the euthyroid patient are the most common endocrinopathies and can be caused by benign and malignant tumors. Overt hyper- and hypothyroidism often exhibit dramatic clinical manifestations; however, more subtle presentations require the use of biochemical tests of thyroid function. Screening of the newborn population for congenital hypothyroidism, followed by the institution of appropriate thyroid hormone replacement therapy, has dramatically decreased the incidence of mental retardation and cretinism in the United

States. Congenital hypothyroidism due to iodine deficiency remains the major preventable cause of mental retardation worldwide, although much progress has been made to eradicate iodine deficiency.

Effective treatment of most thyroid disorders is readily available. Treatment of the hypothyroid patient is straightforward and consists of hormone replacement. There are more options for treatment of the hyperthyroid patient, including the use of antithyroid drugs to decrease hormone synthesis and secretion and destruction of the gland by the administration of radioactive iodine or by surgical removal. Treatment of thyroid disorders in general is extremely satisfying, as most patients can be either cured or have their diseases controlled (Braverman and Utiger, 2005).

THYROID

The thyroid gland is the source of two fundamentally different types of hormones. The iodothyronine hormones include *thyroxine* (T_4) and *3,5,3'-triiodothyronine* (T_3); they are essential for normal growth and development and play an important role in energy metabolism. The other known secretory product of the thyroid, calcitonin, is produced by the parafollicular (C-) cells and is discussed in Chapter 61.

History. The thyroid gland was described by Galen and was named “glandulae thyroidea” by Wharton in 1656. For two centuries thereafter, various clinicians offered opinions about the gland’s function (Harington, 1935): that the viscous fluid within the follicles lubricated the trachea and that the gland was larger in women, to serve a cosmetic function in giving grace to the contour of the neck (Wharton); that the liberal blood supply of the gland provided a vascular shunt for the brain; that the larger size of the gland in women was “necessary to guard the female system from the influence of the

more numerous causes of irritation and vexation of mind to which they are exposed than the male sex" (Rush), a view opposed by Hofrichter, who pointed out, "If it were indeed true that the thyroid contains more blood at some times than at others, this effect would be visible to the naked eye; in this case women would certainly have long ceased to go about with bare necks, for husbands would have learned to recognize the swelling of this gland as a danger signal of threatening trouble from their better halves." Reading this, one cannot but wonder at how future scientists will look upon some of the biomedical opinions of our own age.

The thyroid was first recognized as an organ of importance when enlargement was observed to be associated with changes in the eyes and the heart in the condition we now call *hyperthyroidism*. This condition, the manifestations of which can be as striking as any in medicine, escaped description until Parry saw his first case in 1786. Parry's account, published in 1825, was followed in 1835 and 1840 by those of Graves and Basedow, whose names became applied to the disorder. In 1874, Gull associated atrophy of the gland with the symptoms now known to be characteristic of *hypothyroidism*, also known in adults as *Gull's disease*. The term *myxedema* was applied to the clinical syndrome in 1878 by Ord in the belief that the characteristic thickening of the subcutaneous tissues was due to excessive formation of mucus.

Extirpation experiments to elucidate the function of the thyroid were at first misinterpreted because of the simultaneous removal of the parathyroids. However, Gley's research on the parathyroid glands in the late 19th century allowed the functional differentiation of these two endocrine glands. Only after calcitonin was discovered in 1961 was it realized that the thyroid also plays a role in the regulation of Ca^{2+} . In 1891, Murray first treated a case of hypothyroidism by injecting an extract of the thyroid gland; in 1892, Howitz, Mackenzie, and Fox independently discovered that thyroid tissue was fully effective when given by mouth.

Magnus-Levy discovered the effect of the thyroid on metabolic rate in 1895; he found that Gull's disease was characterized by a low rate of metabolism and that the administration of thyroid to hypothyroid or normal individuals increased oxygen consumption.

Chemistry of Thyroid Hormones. The principal hormones of the thyroid gland are the iodine-containing amino acid derivatives of thyronine—(T_4 and T_3 ; Figure 56–1). Thyroxine was isolated and crystallized from a hydrolysate of thyroid by Kendall in 1915; he found that the crystalline product exerted the same physiological effects as the extract from which it was obtained. Eleven years later, Harington elucidated the structural formula of thyroxine, and in 1927 Harington and Barger synthesized the hormone.

Following the isolation and the chemical identification of thyroxine, it was generally believed that all the hormonal activity of thyroid tissue could be accounted for by its content of thyroxine. However, careful studies revealed that crude thyroid preparations possessed greater calorogenic activity than could be accounted for by their thyroxine content. The enigma was resolved with the detection, isolation, and synthesis of triiodothyronine by Gross and Pitt-Rivers (1952). Triiodothyronine is qualitatively similar to thyroxine in its biological action but is much more potent on a molar basis.

Structure–Activity Relationships. The stereochemical nature of the thyroid hormones plays an important role in defining hormone activity. Myriad structural analogs of thyroxine have been synthesized to define the structure–activity relationship, to detect antagonists of thyroid hormones, and to find compounds exhibiting a desirable activity while not showing unwanted effects. The only significant success has

been the partial separation of the cholesterol-lowering action of thyroxine analogs from their calorogenic or cardiac effects. For example, introduction of specific arylmethyl groups at the 3' position of triiodothyronine results in analogs that are liver-selective, cardiac-sparing thyromimetics (Leeson *et al.*, 1989). The D isomer of thyroxine was once used to lower the concentration of cholesterol in plasma, but cardiac side effects resulted in discontinuation of the clinical uses of this hormone. 3,5,3'-triiodothyroacetic acid (triac) has less thyromimetic activity in the heart than in other thyroid hormone-responsive tissues (Liang *et al.*, 1997). GC-1, a new thyromimetic, offers preferential binding to the β isoform of the thyroid hormone receptor (TR β), which should result in specific metabolic effects in different target tissues (Yoshihara *et al.*, 2003).

The structural requirements for a significant degree of thyroid hormone activity have been defined (Cody, 2005; Baxter *et al.*, 2004). The 3'-monosubstituted compounds are more active than the 3',5'-disubstituted molecules. Thus, triiodothyronine is five times more potent than thyroxine, while 3'-isopropyl-3,5-diiodothyronine has seven times the activity.

Figure 56–2. Structural formula of 3,5-diiodothyronine, drawn to show the conformation in which the planes of the aromatic rings are perpendicular to each other. (Adapted from Jorgensen, 1964. See also Cody, 2005.)

Although the chemical nature of the 3, 5, 3', and 5' substituents is important, their effects on the conformation of the molecule are even more so. In thyronine, the two rings are angulated at about 120° at the ether oxygen and are free to rotate on their axes. As depicted schematically in Figure 56–2, the 3,5 iodines restrict rotation of the two rings, which tend to take up positions perpendicular to one another. While not potent, even halogen-free derivatives possess some activity if they have the proper conformation. In general, the affinity of iodothyronines for the TRs parallels their biological potency (Yen and Chin, 2005), but additional factors can affect therapeutic potency, including affinity for plasma proteins, rate of metabolism, and rate of entry into cell nuclei. There are, for instance, T₄ transporters resembling the monocarboxylate transporter MCT8.

Recent structure–activity correlations indicate that certain plant flavonoids that are long-standing folk remedies can exhibit antithyroid properties, including inhibition of the enzyme that catalyzes 5'-(outer, or tyrosyl ring) deiodination of T₄ (type I iodothyronine 5'-deiodinase) (Cody, 2005). These compounds are also potent competitors of thyroxine binding to transthyretin. Computer graphic modeling suggests that the best structural homology between thyroid hormones and flavonoids involves their respective phenolic rings.

Biosynthesis of Thyroid Hormones. The synthesis of the thyroid hormones is unique, complex, and seemingly grossly inefficient. The thyroid hormones are synthesized and stored as amino acid residues of thyroglobulin, a protein constituting the vast majority of the thyroid follicular colloid. The thyroid gland is unique in storing great quantities of potential hormone in this way, and extracellular thyroglobulin can represent a large portion of the thyroid mass. Thyroglobulin is a complex glycoprotein made up of two apparently identical subunits, each of 330,000 daltons. Interestingly, molecular cloning has revealed that thyroglobulin belongs to a superfamily of serine hydrolases, including acetylcholinesterase (see Chapter 7).

The major steps in the synthesis, storage, release, and interconversion of thyroid hormones are the following: (1) uptake of iodide ion (I⁻) by the gland; (2) oxidation of iodide and the iodination of tyrosyl groups of thyroglobulin; (3) coupling of iodotyrosine residues by ether linkage

Figure 56–3. Major pathways of thyroid hormone biosynthesis and release. Abbreviations: Tg, thyroglobulin; DIT, diiodotyrosine; MIT, monoiodotyrosine; TPO, thyroid peroxidase; HOI, hypoiodous acid; EOI, enzyme-linked species; PTU, propylthiouracil; MMI, methimazole; ECF, extracellular fluid. (Adapted from Taurog, 2000, with permission.)

to generate the iodothyronines; (4) resorption of the thyroglobulin colloid from the lumen into the cell; (5) proteolysis of thyroglobulin and the release of thyroxine and triiodothyronine into the blood; (6) recycling of the iodine within the thyroid cell via de-iodination of mono- and diiodotyrosines and reuse of the I⁻; and (7) conversion of thyroxine (T₄) to triiodothyronine (T₃) in peripheral tissues as well as in the thyroid. These processes are summarized in Figure 56–3 and described in the correspondingly labeled sections below.

1. Uptake of Iodide. Iodine ingested in the diet reaches the circulation in the form of iodide. Under normal circumstances, its concentration in the blood is very low (0.2 to 0.4 μg/dl; about 15 to 30 nM), but the thyroid efficient-

ly and actively transports the ion *via* a specific, membrane-bound protein, termed the sodium-iodide symporter (NIS) (Dohan *et al.*, 2003). As a result, the ratio of thyroid to plasma iodide concentration is usually between 20 and 50 and can far exceed 100 when the gland is stimulated. The iodide transport mechanism is inhibited by a number of ions such as thiocyanate and perchlorate (Figure 56–3). Thyrotropin (thyroid-stimulating hormone [TSH]; *see* below) stimulates the NIS, which is controlled by an autoregulatory mechanism. Thus, decreased stores of thyroid iodine enhance iodide uptake, and the administration of iodide can reverse this situation by decreasing NIS protein expression (Eng *et al.*, 1999).

The NIS is more easily studied when further metabolism of I^- is inhibited by antithyroid drugs. Thus, the NIS has been identified in many other tissues, including the salivary glands, gastric mucosa, midportion of the small intestine, choroid plexus, skin, mammary gland, and perhaps the placenta, all of which maintain a concentration of iodide greater than that of the blood (Carrasco, 2005). Iodide accumulation by the placenta and mammary gland may provide adequate supplies for the fetus and infant; no obvious purpose is served by the accumulation of iodide at the other sites.

2. Oxidation and Iodination. Consistent with the conditions generally necessary for halogenation of aromatic rings, the iodination of tyrosine residues requires the iodinating species to be in a higher state of oxidation than is the anion. The exact nature of the iodinating species was uncertain for many years. However, Magnusson and coworkers (1984) have provided convincing evidence that it is hypoiodate, either as hypoiodous acid or as an enzyme-linked species.

The oxidation of iodide to its active form is accomplished by thyroid peroxidase, a heme-containing enzyme that utilizes hydrogen peroxide (H_2O_2) as the oxidant (Arvan, 2005). The peroxidase is membrane-bound and appears to be concentrated at or near the apical surface of the thyroid cell. The reaction results in the formation of monoiodotyrosyl and diiodotyrosyl residues in thyroglobulin just prior to its extracellular storage in the lumen of the thyroid follicle. The formation of the H_2O_2 that serves as a substrate for the peroxidase probably occurs near its site of utilization and is stimulated by a rise in cytosolic Ca^{2+} (Takasu *et al.*, 1987). The TSH receptor is notably promiscuous in its coupling, stimulating members of four G protein families including G_q , which couples to the PLC- IP_3 - Ca^{2+} pathway (Laugwitz *et al.*, 1996); thus, a Ca^{2+} -dependent effect on H_2O_2 production may be a means by which TSH stimulates the organification of iodide in thyroid cells.

3. Formation of Thyroxine and Triiodothyronine from Iodotyrosines. The remaining synthetic step is the coupling of two diiodotyrosyl residues to form thyroxine or of monoiodotyrosyl and diiodotyrosyl residues to form triiodothyronine. These oxidative reactions apparently are catalyzed by the same peroxidase discussed above. The mechanism involves the enzymatic transfer of groups, perhaps as iodotyrosyl free radicals or positively charged ions, within thyroglobulin. Although many other proteins can serve as substrates for the peroxidase, none is as efficient as thyroglobulin in yielding thyroxine. The conformation of the protein is thus presumed to facilitate this coupling reaction. Thyroxine formation primarily occurs near the amino terminus of the protein, while most of the triiodotyrosine is synthesized near the carboxy terminus (Dunn and Dunn, 2000). The relative rates of synthetic activity at the various sites depend on the concentration of TSH and the availability of iodide. This may account, at least in part, for the long-known relationship between the proportion of thyroxine and triiodothyronine formed in the thyroid and the availability of iodide or the relative quantities of the two iodotyrosines. For example, when there is a deficiency of iodine in rat thyroid, the ratio of thyroxine to triiodothyronine decreases from 4:1 to 1:3 (Greer *et al.*, 1968). Because triiodothyronine is the transcriptionally active iodothyronine and contains only three-fourths as much iodine, a decrease in the quantity of available iodine need have little impact on the effective amount of thyroid hormone elaborated by the gland. Although a decrease in the availability of iodide and the associated increase in the proportion of monoiodotyrosine favor the formation of triiodothyronine over thyroxine, a deficiency in diiodotyrosine ultimately can impair the formation of both compounds. In addition to the coupling reaction, intrathyroidal and secreted T_3 is generated by the 5'-deiodination of thyroxine.

4. Resorption; 5. Proteolysis of Colloid; 6. Secretion of Thyroid Hormones. Since T_4 and T_3 are synthesized and stored within thyroglobulin, proteolysis is an important part of the secretory process. This process is initiated by endocytosis of colloid from the follicular lumen at the apical surface of the cell, with the participation of a thyroglobulin receptor, megalin. This “ingested” thyroglobulin appears as intracellular colloid droplets, which apparently fuse with lysosomes containing the requisite proteolytic enzymes. It is generally believed that thyroglobulin must be completely broken down into its constituent amino acids for the hormones to be released. As the molecular mass of thyroglobulin is 660,000 daltons, and the protein is made up of about 300 carbohydrate residues and 5500 amino acid residues, only two to five of which are thyrox-

Figure 56-4. Pathways of iodothyronine deiodination.

ine, this is an extravagant process. TSH appears to enhance the degradation of thyroglobulin by increasing the activity of several thiol endopeptidases of the lysosomes. The endopeptidases selectively cleave thyroglobulin, yielding hormone-containing intermediates that subsequently are processed by exopeptidases (Dunn and Dunn, 2000). The liberated hormones then exit the cell, presumably at its basal membrane. When thyroglobulin is hydrolyzed, monoiodotyrosine and diiodotyrosine also are liberated but usually do not leave the thyroid. Instead, they are selectively metabolized; the iodine, liberated in the form of iodide, is reincorporated into protein. Normally, all this iodide is reused; however, when proteolysis is activated intensely by TSH, some of the iodide reaches the circulation, at times accompanied by trace amounts of the iodotyrosines.

7. Conversion of Thyroxine to Triiodothyronine in Peripheral Tissues. The normal daily production of thyroxine is estimated to range between 70 and 90 μg , while that of triiodothyronine is between 15 and 30 μg . Although triiodothyronine is secreted by the thyroid, metabolism of thyroxine by sequential monodeiodination in the peripheral tissues accounts for about 80% of circulating triiodothyronine (Figure 56-4). Removal of the 5', or outer ring, iodine leads to the formation of

triiodothyronine and is the “activating” metabolic pathway. The major nonthyroidal site of conversion of T₄ to T₃ is the liver. Thus, when thyroxine is given to hypothyroid patients in doses that produce normal plasma concentrations of thyroxine, the plasma concentration of T₃ also normalizes (Braverman *et al.*, 1970). Most peripheral target tissues utilize T₃ that is derived from the circulating hormone. Notable exceptions are the brain and pituitary, where local generation of T₃ is the major source of intracellular hormone. Removal of the iodine on position 5 of the inner ring produces the metabolically inactive 3,3',5'-triiodothyronine (reverse T₃, rT₃; Figure 56-1). Under normal conditions, about 41% of T₄ is converted to T₃, about 38% is converted to reverse T₃, and about 21% is metabolized *via* other pathways, such as conjugation in the liver and excretion in the bile. Normal circulating concentrations of T₄ in plasma range from 4.5 to 11 $\mu\text{g}/\text{dl}$, while those of T₃ are about one hundredfold less (60 to 180 ng/dl).

The enzymes that convert thyroxine to triiodothyronine are iodothyronine 5'-deiodinases, which exist as two distinct isozymes that are differentially expressed and regulated in peripheral tissues (Figure 56-5). Type I 5'-deiodinase (D1) is found in the liver, kidney, and thyroid and generates circulating T₃ that is utilized by most peripheral target tissues. Although 5'-deiodination is the major

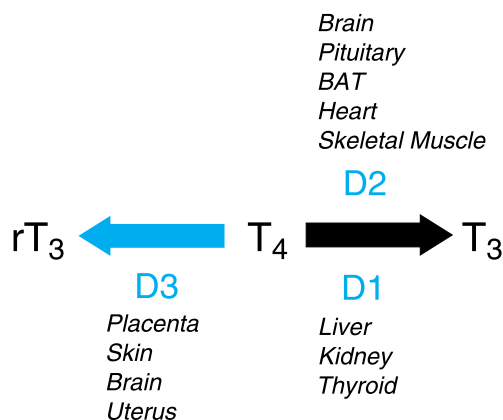

Figure 56–5. Deiodinase isozymes. Abbreviations: D1, type I iodothyronine 5′-deiodinase; D2, type II iodothyronine 5′-deiodinase; D3, type III iodothyronine 5-deiodinase; BAT, brown adipose tissue.

function of this isozyme, D1 also catalyzes 5-deiodination. D1 is inhibited by a variety of factors (Table 56–1), including the antithyroid drug *propylthiouracil* (see below). The decreased plasma triiodothyronine concentrations observed in nonthyroidal illnesses result from inhibition of D1 (Farwell and Dubord-Tomasetti, 1999) and decreased entrance of thyroxine into cells. D1 is up-regulated in hyperthyroidism and down-regulated in hypothyroidism. The cloning of D1 identified the enzyme as a selenoprotein that contains a selenocysteine at the active site. Type II 5′-deiodinase (D2), also a selenoprotein, is distributed in the brain, pituitary, skeletal and cardiac muscle, and in the rat, in brown fat. It primarily supplies intracellular triiodothyronine to these tissues (Visser *et al.*, 1982). D2 has a much lower K_m for thyroxine than does D1 (nM vs. μ M K_m values), and its activity is unaffected by propylthiouracil. D2 is dynamically regulated by its substrate, thyroxine, such that elevated levels of the enzyme are found in hypothyroidism and suppressed levels are found in hyperthyroidism. Thus, D2 appears to autoregulate the intracellular supply of triiodothyronine in the brain and pituitary. A D2-like selenoprotein DNA has been cloned from frog skin and from mammalian sources; however, some controversy still exists on the exact biochemical nature of D2. Inner ring- or 5-deiodination, a main inactivating pathway for T_3 , is catalyzed by type III deiodinase (D3), which is found in placenta, skin, uterus, and brain. The three deiodinases comprise a family of selenoproteins encoded by different genes (Bianco and Larsen, 2005).

Transport of Thyroid Hormones in the Blood. Iodine in the circulation is normally present in several forms, with 95% as organic iodine and approximately 5% as iodide. Most organic iodine is thyroxine (90% to 95%), while triiodothyronine represents a relatively minor fraction (about 5%). The thyroid hormones are transported in the blood in strong but noncovalent association with certain plasma proteins (Benvenega, 2005).

Thyroxine-binding globulin (TBG) is the major carrier of thyroid hormones. It is an acidic glycoprotein with a molecular mass of approximately 63,000 daltons that

Table 56–1

Conditions and Factors That Inhibit Type I 5′-Deiodinase Activity

Acute and chronic illness
Caloric deprivation (especially carbohydrate)
Malnutrition
Glucocorticoids
β Adrenergic receptor antagonists (<i>e.g.</i> , propranolol in high doses)
Oral cholecystographic agents (<i>e.g.</i> , iopanoic acid, sodium ipodate)
Amiodarone
Propylthiouracil
Fatty acids
Fetal/neonatal period
Selenium deficiency

binds one molecule of T_4 per molecule of protein with a very high affinity (the equilibration association constant, K_a , is approximately $10^{10} M^{-1}$). T_3 is bound less avidly. Thyroxine, but not triiodothyronine, also is bound by transthyretin (thyroxine-binding prealbumin), a retinol-binding protein. This protein is present in higher concentration than is TBG and primarily binds thyroxine with an equilibrium association constant near $10^7 M^{-1}$. Transthyretin has four apparently identical subunits but only a single high-affinity binding site. Albumin also can bind thyroxine when the more avid carriers are saturated but it is difficult to estimate its quantitative or physiological importance except in *familial dysalbuminemic hyperthyroxinemia*. This syndrome is an autosomal dominant disorder characterized by the increased affinity of albumin for thyroxine due to a point mutation in the albumin gene. Thyroxine binds also to the apolipoproteins of the high density lipoproteins, HDL₂ and HDL₃, the significance of which is unclear (Benvenega *et al.*, 1992).

Binding of thyroid hormones to plasma proteins protects the hormones from metabolism and excretion, resulting in their long half-lives in the circulation. The free (unbound) hormone is a small percentage (about 0.03% of thyroxine and about 0.3% of triiodothyronine) of the total hormone in plasma. The differential binding affinities for serum proteins also are reflected in the ten- to one hundredfold differences in circulating hormone concentrations and half-lives of T_4 and T_3 .

Essential to understanding the regulation of thyroid function is the “free hormone” concept: only the unbound hormone has metabolic activity. Thus, because of the high degree of binding of thyroid hormones to plasma proteins,

Table 56–2

Factors That Alter Binding of Thyroxine to Thyroxine-Binding Globulin

INCREASE BINDING	DECREASE BINDING
<i>Drugs</i>	
Estrogens	Glucocorticoids

HIV infection	
Inheritance	

changes in either the concentrations of these proteins or the binding affinity of the hormones for the proteins has major effects on the total serum hormone levels. Certain drugs and a variety of pathological and physiological conditions, such as the changes in circulating concentrations of estrogens during pregnancy or during the administration of oral estrogens, can alter both the binding of thyroid hormones to plasma proteins and the amounts of these proteins (Table 56–2). However, since the pituitary responds to and regulates circulating free hormone levels, minimal changes in free hormone concentrations are seen. Therefore laboratory tests that measure only total hormone levels can be misleading. Appropriate tests of thyroid function are discussed later in this chapter.

Degradation and Excretion (Figure 56–6). Thyroxine is eliminated slowly from the body, with a half-life of 6 to 8 days. In hyperthyroidism, the half-life is shortened to 3 or 4 days, whereas in hypothyroidism it may be 9 to 10 days. These changes presumably reflect altered rates of metabolism of the hormone. In conditions associated with increased binding to TBG, such as pregnancy, clearance is retarded. The increase in TBG is due to the estrogen-induced increase in the sialic acid content of the synthesized TBG, resulting in decreased TBG clearance. The opposite effect is observed

Figure 56–6. Pathways of metabolism of thyroxine (T₄) and triiodothyronine (T₃). Abbreviations: DIT, diiodotyrosine; MIT, monoiodotyrosine; T₄S, T₄ sulfate; T₄G, T₄ glucuronide; T₃S, T₃ sulfate; T₃G, T₃ glucuronide; T₄K, T₄ pyruvic acid; T₃K, T₃ pyruvic acid; Tetrac, tetraiodothyroacetic acid; Triac, triiodothyroacetic acid.

when there is reduced protein binding of thyroid hormones or when binding to protein is inhibited by certain drugs (Table 56–2). T₃, which is less avidly bound to protein, has a half-life of approximately 1 day.

The liver is the major site of non-deiodinative degradation of thyroid hormones; T₄ and T₃ are conjugated with glucuronic and sulfuric acids through the phenolic hydroxyl group and excreted in the bile. Some thyroid hormone is liberated by hydrolysis of the conjugates in the intestine and reabsorbed. A portion of the conjugated material reaches the colon unchanged, where it is hydrolyzed and eliminated in feces as the free compounds.

As discussed above, the major route of metabolism of T₄ is deiodination to either T₃ or reverse T₃. Triiodothyronine and reverse T₃ are deiodinated to three different diiodothyronines, which are further deiodinated to two monoiodothyronines (Figure 56–4), inactive metabolites that are normal constituents of human plasma. Additional metabolites (monoiodotyrosine and diiodotyrosine) in which the diphenyl ether linkage is cleaved have been detected both *in vitro* and *in vivo*.

Regulation of Thyroid Function. Cellular changes occur in the anterior pituitary in association with endemic goiter or following thyroidectomy. The classical observations of Cushing in 1912 and of Simmonds two years later estab-

lished that ablation or disease of the pituitary causes thyroid hypoplasia (Simmonds, 1914). It eventually was determined that thyrotropes of the anterior pituitary secrete *thyrotropin*, or TSH. TSH is a glycoprotein hormone with α and β subunits analogous to those of the gonadotropins. Its structure is discussed with those of other glycoprotein hormones in Chapter 55. Although there was evidence that thyroid hormone or its lack causes cellular changes in the pituitary, the control of secretion of TSH by the negative-feedback action of thyroid hormone was not appreciated fully until its central role in the pathogenesis of goiter was elucidated in the early 1940s. TSH is secreted in a pulsatile manner and circadian pattern, its levels in the circulation being highest during sleep at night. TSH secretion is precisely controlled by the hypothalamic peptide *thyrotropin-releasing hormone* (TRH) and by the concentration of free thyroid hormones in the circulation. Extra thyroid hormone inhibits transcription of both the TRH gene (Wilber and Xu, 1998) and the genes encoding the α and β subunit of thyrotropin, which suppresses the secretion of TSH and causes the thyroid to become inactive and regress. Any decrease in the normal rate of thyroid hormone secretion by the thyroid evokes an enhanced secretion of TSH in an attempt to stimulate the thyroid to secrete more hormone. Additional mechanisms of the effect of thyroid hormone on TSH secretion appear to be a reduction in TRH secretion by the hypothalamus and a reduction in the number of TRH receptors on pituitary cells. Figure 56–7 summarizes the regulation of thyroid hormone secretion.

Thyrotropin-Releasing Hormone (TRH). TRH stimulates the release of preformed TSH from secretory granules and also stimulates the subsequent synthesis of both α and β subunits of TSH. Somatostatin, dopamine, and pharmacological doses of glucocorticoids inhibit TRH-stimulated TSH secretion.

TRH is a tripeptide with both terminal amino and carboxyl groups blocked (L-pyroglutamyl-L-histidyl-L-proline amide). The mature hormone is derived from a precursor protein that contains six copies of the tripeptide flanked by dibasic residues. TRH is synthesized by the hypothalamus and released into the hypophyseal-portal circulation, where it interacts with TRH receptors on thyrotropes. The binding of TRH to its receptor, a GPCR, stimulates the G_q -PLC-IP₃-Ca²⁺ pathway and activates protein kinase C, ultimately stimulating the synthesis and release of TSH by the thyrotropes.

TRH also has been localized in the CNS in the cerebral cortex, circumventricular structures, neurohypophysis, pineal gland, and spinal cord. These findings, as well as its localization in nerve endings, suggest that TRH may

Figure 56–7. Regulation of thyroid hormone secretion.

Myriad neural inputs influence hypothalamic secretion of thyrotropin-releasing hormone (TRH). TRH stimulates release of thyrotropin (TSH, thyroid-stimulating hormone) from the anterior pituitary; TSH stimulates the synthesis and release of the thyroid hormones T₃ and T₄. T₃ and T₄ feed back to inhibit the synthesis and release of TRH and TSH. Somatostatin (SST) can inhibit TRH action, as can dopamine and high concentrations of glucocorticoids. Low levels of I⁻ are required for thyroxine synthesis, but high levels inhibit thyroxine synthesis and release.

act as a neurotransmitter or neuromodulator outside of the hypothalamus. Administration of TRH to animals produces CNS-mediated effects on behavior, thermoregulation, autonomic tone, and cardiovascular function, including increases in blood pressure and heart rate. TRH also has been identified in pancreatic islets, heart, testis, and parts of the gastrointestinal tract. Its physiological role in these sites is not known. TRH has been administered both intravenously and intrathecally as a therapeutic agent in refractory depression (Marangell *et al.*, 1997). TRH is no longer available in the United States.

Actions of TSH on the Thyroid. When TSH is given to experimental animals, the first measurable effect on thyroid hormone metabolism is increased secretion, which is detectable within minutes. All phases of hormone synthesis and release are eventually stimulated: iodide uptake and organification, hormone synthesis, endocytosis, and proteolysis of colloid. There is increased vascularity of the gland and hypertrophy and hyperplasia of thyroid cells.

These effects follow the binding of TSH to its receptor on the plasma membrane of thyroid cells. The TSH receptor is a GPCR that is structurally similar to the receptors for luteinizing hormone and follicle-stimulating hormone (*see* Chapter 55) (Vassart *et al.*, 2004). These

receptors share significant amino acid homology and have large extracellular domains that are involved in hormone binding.

Binding of TSH to its receptor stimulates the G_s -adenylyl cyclase–cyclic AMP pathway. Higher concentrations of TSH activate the G_q -PLC pathway. Both the adenylyl cyclase and the phospholipase C signaling pathways appear to mediate effects of TSH on thyroid function in human beings (Vassart, 2005).

Multiple mutations of the TSH receptor result in clinical thyroid dysfunction (Tonacchera *et al.*, 1996b). Germ-line mutations can present as congenital, nonautoimmune hypothyroidism (Kopp *et al.*, 1995) or as autosomal dominant toxic thyroid hyperplasia (Tonacchera *et al.*, 1996a). Germ-line mutations of the TSH receptor can cause gestational hyperthyroidism due to a hypersensitivity of the receptor to HCG (Rodien *et al.*, 1998). Somatic mutations that result in constitutive activation of the receptor are associated with hyperfunctioning thyroid adenomas (Paschke *et al.*, 1994). Finally, resistance to TSH has been described, both in families with mutant TSH receptors (Sunthornthepvarakul *et al.*, 1995) and in those with no apparent mutations in either the TSH receptor or in TSH itself (Xie *et al.*, 1997).

Relation of Iodine to Thyroid Function. Normal thyroid function obviously requires an adequate intake of iodine; without it, normal amounts of hormone cannot be made, TSH is secreted in excess, and the thyroid becomes hyperplastic and hypertrophies. The enlarged and stimulated thyroid becomes remarkably efficient at extracting the residual traces of iodide from the blood, developing an iodine gradient that may be ten times normal; in mild-to-moderate iodine deficiency, the thyroid usually succeeds in producing sufficient hormone and preferentially secreting T_3 . In more severe iodine deficiency, adult hypothyroidism and cretinism may occur.

In some areas of the world, simple or nontoxic goiter is prevalent because of insufficient dietary iodine (Dunn and Delange, 2005). Regions of iodine deficiency exist in Central and South America, Africa, Europe, Southeast Asia, and China. The daily requirement for iodine in adults is 1 to 2 $\mu\text{g}/\text{kg}$ body weight. In the United States, recommended daily allowances for iodine range from 40 to 120 μg for children, 150 μg for adults, 220 μg for pregnancy, and 270 μg for lactation (Food and Nutrition Board, 2001). Vegetables, meat, and poultry contain minimal amounts of iodine, whereas dairy products and fish are relatively high in iodine content (Table 56–3) (Braverman, 2003). Potable water usually contains negligible amounts of iodine.

Table 56–3

Iodine Content in Some Foodstuffs in the United States (1982–1989)

FOOD	IODINE/SERVING, μg
Ready-to-eat cereals	87
Dairy-based desserts	70
Fish	57
Milk	56
Dairy products	49
Eggs	27
Bread	27
Beans, peas, tubers	17
Meat	16
Poultry	15

SOURCE: Adapted from Braverman *et al.*, 1994.

Iodine has been used empirically for the treatment of iodine-deficiency goiter for 150 years; however, its modern use evolved from extensive studies using iodine to prevent goiter in schoolchildren in Akron, Ohio, where endemic iodine-deficiency goiter was prevalent. The success of these experiments led to the adoption of iodine prophylaxis and therapy in many regions throughout the world where iodine-deficiency goiter was endemic.

The most practical method for providing small supplements of iodine for large segments of the population is the addition of iodide or iodate to table salt; iodate is now preferred. In some countries, the use of iodized salt is required by law; in others, including the United States, the use is optional. In the United States, iodized salt provides 100 μg of iodine per gram. However, while the United States population remains iodine-sufficient, iodine intake has steadily decreased over the last 20 years, a trend that needs to be monitored (Hollowell *et al.*, 1998). Other vehicles for supplying iodine to large populations who are iodine-deficient include oral or intramuscular injection of iodized oil (Elnagar *et al.*, 1995), iodized drinking water supplies, iodized irrigation systems, and iodized animal feed.

Actions of Thyroid Hormones. Although the precise biochemical mechanisms by which thyroid hormones exert their developmental and tissue-specific effects are the subject of ongoing investigation, most actions of thyroid hormones seem to be mediated by nuclear receptors (for review, *see* Yen, 2001; Yen and Chin, 2005). Triiodothyronine binds to high-affinity nuclear receptors, which then bind to specific DNA sequences (thyroid hormone response elements, TREs) in the promoter/regulatory

Figure 56–8. Thyroid hormone receptor isoforms. The percentage of amino acid identity in the DNA binding region is indicated. Identical patterns in the hypervariable and ligand binding regions indicate 100% homology. Three thyroid hormone receptor (TR) isoforms bind thyroid hormone (TRβ₁, TRβ₂, and TRα₁); c-erb A α₂ does not.

ry regions of target genes. In this fashion, triiodothyronine modulates gene transcription, and ultimately, protein synthesis. In general, the unliganded T₃ receptor is bound to thyroid response elements in the basal state. Typically, this represses gene transcription, although there are some examples of constitutive gene activation. Binding by T₃ may activate gene transcription by releasing the repression; the T₃-receptor complex also may have direct activation or repressive actions. T₄ also binds to these receptors, but with a much lower affinity than T₃. Despite its capacity to bind to nuclear receptors, thyroxine has not been shown to alter gene transcription. Thus, it is likely that T₄ serves principally as a “prohormone,” with essentially all transcriptional actions of thyroid hormone caused by T₃.

Nuclear thyroid hormone receptors are the cellular homologs of an avian retroviral oncoprotein, denoted c-erb A. There is considerable homology between the thyroid hormone receptors and the steroid hormone receptors, which make up a gene superfamily that includes the retinoic acid and vitamin D receptors (see Chapters 1 and 61). The thyroid hormone receptors (TRs) are derived from two genes, c-erb A α (TRα) and c-erb A β (TRβ), with multiple isoforms identified (Figure 56–8) (Lazar, 1993). TRα₁ and TRβ₁ are found in virtually all tissues that respond to thyroid hormone; the other isoforms exhibit a more restricted distribution. For example, TRβ₂ is expressed solely in the anterior pituitary. c-erb A α₂, an isoform that binds to the TRE but does not bind T₃, is the most abundant isoform in the brain (Strait *et al.*, 1990). Another level of complexity in the regulation of thyroid hormone action at the transcriptional level was added with the identification of co-activators (Takeshita *et al.*, 1996) and co-repressors (Chen and Evans, 1995; Hörlein *et al.*, 1995) that are associated with the T₃-receptor complex and mediate hormone action (Lee and Yen, 1999). Resistance to thyroid hormone has been described in patients with mutations in the TRβ gene (Brucker-Davis *et al.*, 1995; Adams *et al.*, 1994) and in patients with defective co-activators (Weiss *et al.*, 1996).

Further insight into the mechanisms of thyroid hormone action emerged from transgenic mice lacking one or more of the thyroid hormone receptor isoforms. These knockout mice have abnormali-

ties in the auditory system, the thyroid-pituitary axis, the heart, the skeletal system, and the small intestine (Forrest *et al.*, 1996; Forrest *et al.*, 1990; Fraichard *et al.*, 1997; Wikström *et al.*, 1998). Despite the well-documented roles of thyroid hormone during brain development (Oppenheimer and Schwartz, 1997), knockout mice devoid of all known thyroid hormone receptors had few, if any, obvious abnormalities in brain development (Göthe *et al.*, 1999; Gauthier *et al.*, 2001). Since the overall deficits observed in the absence of TRs are markedly less than what one would expect if the T₃-binding thyroid hormone receptors were the sole mediator(s) of thyroid hormone action, the unliganded TRs may participate in this developmental program and the action of T₃ on target genes during brain development may be to relieve gene repression, rather than to activate gene expression (Hashimoto *et al.*, 2001; Flamant and Samarut, 2003). As noted above, the most abundant thyroid hormone receptor isoform in the brain throughout development is c-erb A α₂ (Strait *et al.*, 1990), which is obligatorily unliganded since it cannot bind T₃; this form continues to be expressed in most knockout mice due to the strategy used for thyroid hormone receptor gene deletion.

In addition to nuclear receptor-mediated actions, there are several well-characterized, nongenomic actions of thyroid hormones, including those occurring at the level of the plasma membrane and on the cellular cyto-architecture (Bassett *et al.*, 2003). In addition, there are thyroid hormone binding sites on mitochondria (Sterling, 1989). In several of these processes, thyroxine is the hormone that produces the response. Previously, the overall contribution of nongenomic actions to the general mechanism of thyroid hormone action was considered to be minor. However, at least in some species, this concept may need to be reassessed in light of the paucity of abnormalities in knockout mice, especially during brain development.

Growth and Development. Thyroid hormones seem to exert most of their effects through control of DNA transcription, and ultimately protein synthesis, profoundly influencing normal growth and development. Perhaps the most dramatic example is the tadpole, which is almost magically transformed into a frog by triiodothyronine. Not only does the animal grow limbs, lungs, and other terrestrial accoutrements, but T₃ also stimulates the synthesis of a host of enzymes, and in a gambit that plastic surgeons

must envy, so influences the tail that it is digested away and used to build new tissue elsewhere.

Thyroid hormone plays a critical role in brain development (Bernal *et al.*, 2003; Koibuchi *et al.*, 2003). The appearance of functional, chromatin-bound thyroid hormone receptors coincides with neurogenesis in the brain (Strait *et al.*, 1990). The absence of thyroid hormone during the period of active neurogenesis (up to 6 months postpartum) leads to irreversible mental retardation (cretinism) and is accompanied by multiple morphological alterations in the brain. These severe morphological alterations result from disturbed neuronal migration, deranged axonal projections, and decreased synaptogenesis. Thyroid hormone supplementation during the first 2 weeks of life prevents the development of these disturbed morphological changes.

Myelin basic protein, a major component of myelin, is regulated by thyroid hormone during development (Farsetti *et al.*, 1991), and decreased expression of myelin basic protein in the hypothyroid brain impairs myelination. The appearance of laminin, an extracellular matrix protein that provides key guidance signals to migrating neurons, is delayed and the content is diminished in the developing cerebellum of the hypothyroid rat (Farwell and Dubord-Tomasetti, 1999). Altered expression of laminin likely alters neuronal migration and leads to the morphological abnormalities observed in the cretinous brain. Several other brain-specific genes reportedly are developmentally regulated by thyroid hormone (Bernal *et al.*, 2003). A common characteristic of many of these proteins is that their expression appears to be merely delayed in the hypothyroid animal; normal levels are eventually achieved in the adult.

The actions of thyroid hormones on protein synthesis and enzymatic activity are certainly not limited to the brain, and a large number of tissues are affected by the administration of thyroid hormone or by its deficiency. The extensive defects in growth and development in cretins vividly illustrate the pervasive effects of thyroid hormones in normal individuals.

Cretinism is usually classified as endemic or sporadic. *Endemic cretinism* occurs in regions of endemic goiter and usually is caused by extreme iodine deficiency. Goiter may or may not be present. *Sporadic cretinism* is a consequence of failure of the thyroid to develop normally or the result of a defect in the synthesis of thyroid hormone. Goiter is present if a synthetic defect is at fault.

While detectable at birth, cretinism often is not recognized until 3 to 5 months of age. When untreated, the condition eventually leads to such gross changes as to be unmistakable: The child is dwarfed, with short extremities, mentally retarded, inactive, uncomplaining, and listless. The face is puffy and expressionless, and the enlarged tongue may protrude through the thickened lips of the half-opened mouth. The skin may have a yellowish hue and feel doughy, and dry, and cool to the touch. The heart rate is slow, the body temperature may be low, closure of the fontanels is delayed, and the teeth erupt late. Appetite is poor, feeding is slow and interrupted by choking, constipation is frequent, and there may be an umbilical hernia.

For treatment to be fully effective, the diagnosis must be made long before these changes are obvious. In regions of endemic cretinism due to iodine deficiency, iodine replacement is best instituted prior to pregnancy. However, iodine replacement given to pregnant women up to the end of the second trimester has been shown to enhance the neurological and psychological development of the children (Cao *et al.*, 1994). Screening of newborn infants for deficient thyroid function is carried out in the United States and in most industrialized countries. Concentrations of TSH and thyroxine are measured in blood from the umbilical cord or from a heel stick. The incidence of congenital dysfunction of the thyroid is about 1 per 4000 births.

Calorigenic Effects. A characteristic response of homeothermic animals to thyroid hormone is increased O_2 consumption. Most peripheral tissues contribute to this response; heart, skeletal muscle, liver, and kidney are stimulated markedly by thyroid hormone. Indeed, 30% to 40% of the thyroid hormone–dependent increase in O_2 consumption can be attributed to stimulation of cardiac contractility. Several organs, including brain, gonads, and spleen, are unresponsive to the calorigenic effects of thyroid hormone. The mechanism of the calorigenic effect of thyroid hormone has been elusive (Silva, 2003). It once was erroneously believed that thyroid hormone uncoupled mitochondrial oxidative phosphorylation. Thyroid hormone–dependent lipogenesis may constitute a quantitatively important energy sink, and studies in rats have demonstrated that about 4% of the increased caloric expenditure induced by thyroid hormone is accounted for by lipogenesis. The observation that T_3 stimulates lipolysis provides a link between lipogenesis and thermogenesis. Further, thyroid hormone induces expression of several lipogenic enzymes, including malic enzyme and fatty acid synthase. Although the entire picture is not clear, there appears to be an integrated program by which thyroid hormone regulates the set-point of energy expenditure and maintains the metabolic machinery necessary to sustain it. Indeed, even small changes in L-thyroxine replacement doses may significantly alter the set-point for resting energy expenditure in the hypothyroid patient (al-Adsani *et al.*, 1997).

Cardiovascular Effects. Thyroid hormone influences cardiac function by direct and indirect actions; changes in the cardiovascular system are prominent clinical consequences in thyroid dysfunctional states. In hyperthyroidism, there is tachycardia, increased stroke volume, increased cardiac index, cardiac hypertrophy, decreased peripheral vascular resistance, and increased pulse pressure. In hypothyroidism, there is bradycardia, decreased cardiac index, pericardial effusion, increased peripheral vascular resistance, decreased pulse pressure, and elevation of mean arterial pressure (Klein, 2005a; Klein, 2005b).

Thyroid hormones directly regulate myocardial gene expression. T_3 regulates genes encoding the isoforms of the sarcomeric myosin heavy chains by increasing the expression of the α gene and decreasing the expression of the β gene. A TRE has been located in the 5-flanking region of the α myosin heavy chain gene. T_3 also upregulates the gene encoding the sarcoplasmic reticulum Ca^{2+} -ATPase, which plays a critical role in myocardial contraction (Rohrer and Dillman, 1988). Regulation of these two genes results in altered contractility observed in hyper- and hypothyroidism. Indeed, stress echocardiography in hyperthyroid patients revealed abnormalities in cardiac contractility that reverted to normal when euthyroidism was restored (Kahaly *et al.*, 1999). Similarly, left ventricular diastolic dysfunction in hypothyroidism was reversed with L-thyroxine replacement therapy (Biondi *et al.*, 1999).

Observations in transgenic mice have provided insight into the action of thyroid hormone on heart rate. Previously, alterations in the sensitivity of the cardiac myocyte to catecholamines (enhanced in hyperthyroidism and depressed in hypothyroidism) were considered an indirect effect of thyroid hormone, possibly due to changes in expression of myocardial β adrenergic receptors. This is the basis for the use of β adrenergic receptor antagonists in relieving some of the cardiac manifestations in hyperthyroidism. However, basal heart rate is decreased in mice lacking the $TR\alpha_1$ gene (Johansson *et al.*, 1998) and increased in mice lacking $TR\beta$ (Johansson *et al.*, 1999), suggesting a more direct role for thyroid hormone in cardiac pacemaking. Finally, T_3 leads to peripheral hemodynamic effects that alter the chronotropic and inotropic state of the myocardium. Interestingly, T_3 appears to have a direct, nongenomic vasodilating effect on vascular smooth muscle (Park *et al.*, 1997; Ojamaa *et al.*, 1996).

Metabolic Effects. Thyroid hormones stimulate metabolism of cholesterol to bile acids, and hypercholesterolemia is a characteristic feature of hypothyroid states. Thyroid hormones increase the specific binding of low-density lipoprotein (LDL) by liver cells (Salter *et al.*, 1988), and the concentration of hepatic receptors for LDL is decreased in hypothyroidism. The number of LDL receptors on the surface of hepatocytes is a strong determinant of the plasma cholesterol concentration (*see* Chapter 35).

Thyroid hormones enhance the lipolytic responses of fat cells to other hormones (*e.g.*, catecholamines) and elevated plasma free fatty acid concentrations are seen in hyperthyroidism. In contrast to other lipolytic hormones, thyroid hormones do not directly increase the accumulation of cyclic AMP. They may, however, regulate the capacity of other hormones to enhance cyclic AMP accumulation by decreasing the activity of a microsomal phosphodiesterase that hydrolyzes cyclic AMP. There also is evidence that thyroid hormones act to maintain normal coupling of the β adrenergic receptor to the catalytic subunit of adenylyl cyclase in fat cells. Fat cells from hypothyroid rats have increased concentrations of G proteins that inhibit adenylyl cyclase. This could account for both the decreased response to lipolytic hormones and the increased sensitivity to inhibitory regulators (*e.g.*, adenosine) that are found in hypothyroidism (Ros *et al.*, 1988).

Thyrotoxicosis is an insulin-resistant state (Gottlieb and Braverman, 1994). Postreceptor defects in the liver and peripheral tissues, manifested by depleted glycogen stores and enhanced gluconeogenesis, lead to insulin insensitivity. In addition, there is increased absorption of glucose from the gut. Compensatory increases in insulin secretion result in order to maintain euglycemia. This may precipitate clinical diabetes in previously undiagnosed patients and increase insulin requirements of diabetic patients already on insulin. Conversely, hypothyroidism results in decreased absorption of glu-

cose from the gut, decreased insulin secretion, and a reduced rate of peripheral glucose uptake; however, glucose utilization by the brain is unaffected. Insulin requirements are decreased in the hypothyroid patient with diabetes.

Thyroid Hyperfunction. Thyrotoxicosis is a condition caused by elevated concentrations of circulating free thyroid hormones. Various disorders of different etiologies can result in this syndrome. The term *hyperthyroidism* is restricted to those conditions in which thyroid hormone production and release are increased due to gland hyperfunction. Iodine uptake by the thyroid gland is increased, as determined by the measurement of the percent uptake of ^{123}I or ^{131}I in a 24-hour radioactive iodine uptake (RAIU) test. In contrast, thyroid inflammation or destruction resulting in excess "leak" of thyroid hormones or excess exogenous thyroid hormone intake results in a low 24-hour RAIU. The term *subclinical hyperthyroidism* is defined as few if any symptoms with a low serum TSH and normal concentrations of T_4 and T_3 .

Graves' disease, or toxic diffuse goiter, is the most common cause of high RAIU thyrotoxicosis. It accounts for 60% to 90% of cases, depending upon age and geographic region. Graves' disease is an autoimmune disorder characterized by hyperthyroidism, diffuse goiter, and IgG antibodies that bind to and activate the TSH receptor. This is a relatively common disorder, with an incidence of 0.02% to 0.4% in the United States. Endemic areas of iodine deficiency have a lower incidence of autoimmune thyroid disease. As with most types of thyroid dysfunction, women are affected more than men, with a ratio ranging from 5:1 to 7:1. Graves' disease is more common between the ages of 20 and 50, but may occur at any age. Major histocompatibility alleles (HLA) B_8 and DR_3 are associated with Graves' disease in Caucasians. Graves' disease is commonly associated with other autoimmune diseases. The characteristic exophthalmos associated with Graves' disease is an infiltrative ophthalmopathy and is considered an autoimmune-mediated inflammation of the periorbital connective tissue and extraocular muscles. This disorder is clinically evident with various degrees of severity in about 50% of patients with Graves' disease, but it is present on radiological studies, such as ultrasound or CT scan, in almost all patients. The pathogenesis of Graves' ophthalmopathy, including the role of the TSH receptor present in retro-orbital tissues, and the management of this disorder, are reviewed by Rapoport and McLachlan (2000).

Toxic multinodular/multinodular goiter accounts for 10% to 40% of cases of hyperthyroidism and is more common in older patients. Infiltrative ophthalmopathy is absent.

A low RAIU is seen in the destructive thyroiditides and in thyrotoxicosis resulting from exogenous thyroid hormone ingestion. Low RAIU thyrotoxicosis caused by subacute (painful) and silent (painless or lymphocytic) thyroiditis represents about 5% to 20% of all cases. Silent thyroiditis occurs in 7% to 10% of postpartum women in the United States (Lazarus, 2005). Other causes of thyrotoxicosis are much less common.

Most of the signs and symptoms of thyrotoxicosis stem from the excessive production of heat and from increased motor activity and increased activity of the sympathetic nervous system. The skin is

flushed, warm, and moist; the muscles are weak and tremulous; the heart rate is rapid, the heartbeat is forceful, and the arterial pulses are prominent and bounding. Increased expenditure of energy gives rise to increased appetite, and if intake is insufficient, to loss of weight. There also may be insomnia, difficulty in remaining still, anxiety and apprehension, intolerance to heat, and increased frequency of bowel movements. Angina, arrhythmias, and heart failure may be present in older patients. Some individuals may show extensive muscular wasting as a result of thyroid myopathy. Patients with long-standing undiagnosed or undertreated thyrotoxicosis may develop osteoporosis due to increased bone turnover (Sheppard, 2005a; Sheppard, 2005b).

The most severe form of hyperthyroidism is thyroid storm, which is discussed below, under therapeutic uses of antithyroid drugs.

Thyroid Hypofunction. Hypothyroidism, known as myxedema when severe, is the most common disorder of thyroid function. Worldwide, hypothyroidism results most often from iodine deficiency. In nonendemic areas where iodine is sufficient, chronic autoimmune thyroiditis (Hashimoto's thyroiditis) accounts for the majority of cases. This disorder is characterized by high levels of circulating antibodies directed against thyroid peroxidase, and less commonly, thyroglobulin. In addition, blocking antibodies directed at the TSH receptor may be present, exacerbating the hypothyroidism (Botero and Brown, 1998). Finally, thyroid destruction may result from apoptotic cell death due to the interaction of Fas with the Fas ligand in the thyrocytes (Giordano *et al.*, 1997). Failure of the thyroid to produce sufficient thyroid hormone is the most common cause of hypothyroidism and is referred to as *primary hypothyroidism*. *Central hypothyroidism* occurs much less often and results from diminished stimulation of the thyroid by TSH because of pituitary failure (*secondary hypothyroidism*) or hypothalamic failure (*tertiary hypothyroidism*). Hypothyroidism present at birth (*congenital hypothyroidism*) is the most common preventable cause of mental retardation in the world. Diagnosis and early intervention with thyroid hormone replacement prevent the development of cretinism, as discussed above.

Nongoitrous hypothyroidism is associated with degeneration and atrophy of the thyroid gland. The same condition follows surgical removal of the thyroid or its destruction by radioactive iodine. Since it also may occur years after antithyroid drug therapy for Graves' disease, some have speculated that hypothyroidism can be the end stage of this disorder ("burnt-out" Graves' disease). *Goitrous hypothyroidism* occurs in Hashimoto's thyroiditis or when there is a severe defect in synthesis of thyroid hormone. When the disease is mild, it may be subtle in its presentation. By the time it has become severe, however, all of the signs are overt. The appearance of the patient is pathognomonic. The face is quite expressionless, puffy, and pallid. The skin is cold and dry, the scalp is scaly, and the hair is coarse, brittle, and sparse. The fingernails are thickened and brittle, the subcutaneous tissue appears to be thickened, and there may

be true edema. The voice is husky and low-pitched, speech is slow, hearing is often faulty, mentation is impaired, and depression may be present. The appetite is poor, gastrointestinal activity is diminished, and constipation is common. Atony of the bladder is rare and suggests that the function of other smooth muscles may be impaired. The voluntary muscles are weak and the relaxation phase of the deep-tendon reflexes is delayed. The heart can be dilated, and there is frequently a pericardial effusion, although this is rarely clinically significant. There also may be pleural effusions and ascites. Anemia, most commonly normochromic and normocytic, is often present, although menstrual irregularity with menorrhagia may result in iron deficiency anemia. Hyperlipidemia often is present in hypothyroid patients. Patients are lethargic and tend to sleep a lot and often complain of cold intolerance.

Thyroid Function Tests. The development of radioimmunoassays, and more recently, chemiluminescent and enzyme-linked immunoassays for T_4 , T_3 , and TSH have greatly improved the laboratory diagnosis of thyroid disorders (Demers and Spencer, 2003). However, measurement of the total hormone concentration in plasma may not give an accurate picture of the activity of the thyroid gland. The total hormone concentration changes with alterations in either the amount of TBG in plasma or the binding affinity of TBG for hormones. Although equilibrium dialysis of undiluted serum and radioimmunoassay for free thyroxine in the dialysate represent the gold standard for determining free thyroxine concentrations, this assay is typically not available in routine clinical laboratories. The free thyroxine index is an estimation of the free thyroxine concentration and is calculated by multiplying the total thyroxine concentration by the thyroid hormone binding ratio, which estimates the degree of saturation of TBG. Additional assays commonly in use for estimating the free T_4 and free T_3 concentrations employ labeled analogs of these iodothyronines in chemiluminescence and enzyme-linked immunoassays. These assays correlate well with free T_4 concentrations measured by the more cumbersome equilibrium dialysis method and are easily adaptable to routine clinical laboratory use. However, the analog assays may be affected by a wide variety of nonthyroidal disease states, including acute illness, and by certain drugs to a greater degree than are the free T_4 index and free T_4 determined by equilibrium dialysis.

Serum measurements of TSH have been available since 1965. In individuals whose pituitary function and TSH secretion are normal, serum measurement of TSH is the thyroid function test of choice (Danese *et al.*, 1996; Helfand and Redfern, 1998), because pituitary secretion of TSH is sensitively regulated in response to circulating concentrations of thyroid hormones.

The first "sensitive" TSH assay was developed in 1985, utilizing a dual-antibody approach. Application of this method resulted in the expansion of the assay detection limit below the normal range. Thus, any assay of this type is referred to as a *sensitive TSH assay* (Demers and Spencer, 2003). A major use of the sensitive TSH assay is to differentiate between normal and thyrotoxic patients, who should exhibit suppressed TSH values. Indeed, the sensitive TSH assay has replaced evaluation of the response of TSH to injection of synthetic TRH (TRH stimulation test) in the thyrotoxic patient. While the serum TSH assay is extremely useful in determining the euthyroid state and titrating the replacement dose of thyroid hormone in patients with primary hypothyroidism, abnormal serum TSH concentrations may not always indicate thyroid dysfunction. In such patients, assessment of the circulating thyroid hormone levels will further determine whether or not thyroid dysfunction is truly

present. Synthetic preparations of TRH (*protirelin*, THYREL) are no longer available in the United States for the evaluation of pituitary or hypothalamic failure as a cause of secondary hypothyroidism.

Recombinant human TSH (*thyrotropin alfa*, THYROGEN) is now available as an injectable preparation to test the ability of thyroid tissue, both normal and malignant, to take up radioactive iodine and release thyroglobulin (Haugen *et al.*, 1999). This preparation replaces *bovine TSH* (THYTROPAR), which was associated with a high incidence of side effects, including anaphylaxis.

Therapeutic Uses of Thyroid Hormone. The major indications for the therapeutic use of thyroid hormone are for hormone replacement therapy in patients with hypothyroidism or cretinism and for TSH suppression therapy in patients with thyroid cancer (Mazzaferri and Kloos, 2001), and occasionally those with nontoxic goiter. While the consensus has been that thyroid hormone therapy is not indicated for treatment of the “low T₄ syndrome” (“sick euthyroid syndrome”) that results from nonthyroidal illness (Brent and Hershman, 1986; Farwell, 2003), this concept has been challenged with the suggestion that severely ill patients may benefit by treatment with T₃ (DeGroot, 1999). However, there is no published evidence supporting this recommendation, which remains a minority opinion. For example, T₃ treatment does not decrease mortality in the sick euthyroid syndrome that occurs in patients undergoing coronary artery bypass surgery (Klempner *et al.*, 1995).

The synthetic preparations of the sodium salts of the natural isomers of the thyroid hormones are available and widely used for thyroid hormone therapy. *Levothyroxine sodium* (L-T₄, SYNTHROID, LEVOXYL, LEVOTHROID, UNITHROID, others) is available in tablets and as a lyophilized powder for injection. L-thyroxine has a narrow therapeutic index, and the FDA has recently altered its recommendations for approval of the various L-thyroxine preparations to assure biological equivalence. *Liothyronine sodium* (L-T₃) is the salt of triiodothyronine and is available in tablets (CYTOMEL) and in an injectable form (TRIOSTAT). A mixture of thyroxine and triiodothyronine is marketed as *liotrix* (THYROLAR). Desiccated thyroid preparations, derived from whole animal thyroids, contain both T₃ and T₄ and have highly variable biologic activity, making these preparations much less desirable.

Thyroid Hormone Replacement Therapy. Thyroxine (levothyroxine sodium) is the hormone of choice for thyroid hormone replacement therapy because of its consistent potency and prolonged duration of action. The absorption of thyroxine occurs in the small intestine and is variable and incomplete, with 50% to 80% of the dose absorbed. Absorption is slightly increased when the hormone is taken on an empty stomach. In addition, certain drugs may interfere with absorption of levothyroxine in the gut, including *sucralfate*, *cholestyramine resin*, *iron and calcium supplements*, *aluminum hydroxide*, and certain soy products. Enhanced biliary excretion of levothyroxine occurs during the administration of drugs that induce hepatic CYPs, such as *phenytoin*, *carbamazepine*, and *rifampin*. This enhanced excretion may necessitate an increase in the dose of orally administered levothyroxine. Triiodothyronine (liothyronine sodium)

may be used occasionally when a quicker onset of action is desired, *e.g.*, in the rare presentation of myxedema coma or for preparing a patient for ¹³¹I therapy for treatment of thyroid cancer. It is less desirable for chronic replacement therapy because of the requirement for more frequent dosing, higher cost, and transient elevations of serum T₃ concentrations above the normal range. Combination therapy with levothyroxine and liothyronine has been suggested for use in hypothyroid patients that remain symptomatic on levothyroxine alone and have serum TSH concentrations in the normal range (Bunevicius *et al.*, 1999). However, three recent studies have not confirmed these findings (Sawka *et al.*, 2003; Walsh *et al.*, 2003; Clyde *et al.*, 2003). Furthermore, this combination may lead to transient elevations of circulating T₃ concentrations in contrast to the steady levels of T₃ during levothyroxine administration due to conversion of T₄ to T₃ in peripheral tissues.

The average daily adult replacement dose of levothyroxine sodium in a 68-kg person is 112 µg as a single dose, while that of liothyronine sodium is 50 to 75 µg in divided doses. Institution of therapy in healthy younger individuals can begin at full replacement doses. Because of the prolonged half-life of thyroxine (7 days), new steady-state concentrations of the hormone will not be achieved until 5 half-lives have elapsed, or at least 5 weeks after a change in dose. Thus, re-evaluation with determination of serum TSH concentration should not be performed at intervals less than 6 to 8 weeks. The goal of thyroxine replacement therapy is to achieve a TSH value in the normal range, since overreplacement of thyroxine, suppressing TSH values to the subnormal range, may induce osteoporosis and cause cardiac dysfunction (Surks *et al.*, 2004). In noncompliant young patients, the cumulative weekly doses of levothyroxine may be given as a single weekly dose, which is safe, effective, and well tolerated (Grebe *et al.*, 1997). In individuals over the age of 60, institution of therapy at a lower daily dose of levothyroxine sodium (25 to 50 µg per day) is indicated to avoid exacerbation of underlying and undiagnosed cardiac disease. Death due to arrhythmias has been reported during the initiation of thyroid hormone replacement therapy in hypothyroid patients. The dose can be increased at a rate of 25 µg per day every few months until the TSH is normalized. For individuals with pre-existing cardiac disease, an initial dose of 12.5 µg per day, with increases of 12.5 to 25 µg per day every 6 to 8 weeks, is indicated. Daily doses of thyroxine may be interrupted periodically because of intercurrent medical or surgical illnesses that prohibit taking medications by mouth. Because of the 7-day half-life of T₄, a lapse of several days of hormone replacement is unlikely to have any significant metabolic consequences. However, if more prolonged interruption in oral therapy is necessary, levothyroxine may be given parenterally at a dose 25% to 50% less than the patient's daily oral requirements.

Subclinical hypothyroidism is a clinical state with few if any symptoms, characterized by elevated serum TSH concentrations (for review, *see* Surks *et al.*, 2004). Population screening has shown that subclinical hypothyroidism is very common, with a prevalence of up to 15% in some populations and up to 25% in the elderly. The decision to use levothyroxine therapy in these patients to normalize the serum TSH must be made on an individual basis, as treatment may not be appropriate for all patients. Patients with subclinical hypothyroidism who may benefit from levothyroxine therapy include those with goiter, autoimmune thyroid disease, hypercholesterolemia, cognitive dysfunction, or pregnancy (*see* below), and those patients who have symptoms of hypothyroidism.

The dose of levothyroxine in the hypothyroid patient who becomes pregnant often needs to be increased, perhaps due to the

increased serum concentrations of TBG induced by estrogen and a small transplacental passage of levothyroxine from mother to fetus (Glinioer, 2005). In addition, pregnancy may “unmask” hypothyroidism in patients with pre-existing autoimmune thyroid disease or in those who reside in a region of iodine deficiency (Glinioer *et al.*, 1994). Overt hypothyroidism during pregnancy is associated with fetal distress (Wasserstrum and Anaia, 1995) and impaired psychoneural development in the progeny (Man *et al.*, 1991). In addition, studies have suggested that subclinical hypothyroidism during pregnancy is associated with mildly impaired psychomotor development in the children (Haddow *et al.*, 1999; Pop *et al.*, 1999). These findings strongly suggest that any degree of hypothyroidism, as judged by an elevated serum TSH, should be treated during pregnancy. Thus, serum TSH values should be determined in the first trimester in all patients with pre-existing hypothyroidism, as well as in those at high risk for developing hypothyroidism. Therapy with levothyroxine should be administered to keep the serum TSH in the normal range. Any adjustment of the levothyroxine dose should be re-evaluated in 4 to 6 weeks to determine if further adjustments are necessary.

Comparative Responses to Thyroid Preparations. There is no significant difference in the qualitative response of the patient with myxedema to triiodothyronine, thyroxine, or desiccated thyroid. However, there are obvious quantitative differences. Following the subcutaneous administration of a large experimental dose of T_3 , a metabolic response can be detected within 4 to 6 hours, at which time the skin becomes detectably warmer and the pulse rate and temperature increase. With this dose, a 40% decrease in metabolic rate can be restored to normal in 24 hours. The maximal response occurs in 2 days or less, and the effects subside with a half-life of about 8 days. The same single dose of T_4 exerts much less effect. However, if thyroxine is given in approximately 4 times the dose of triiodothyronine, a comparable elevation in metabolic rate can be achieved. The peak effect of a single dose is evident in about 9 days, and this declines to half the maximum in 11 to 15 days. In both cases the effects outlast the presence of detectable amounts of hormone; these disappear from the blood with mean half-lives of approximately 1 day for T_3 and 7 days for T_4 .

Myxedema Coma. Myxedema coma is a rare syndrome that represents the extreme expression of severe, long-standing hypothyroidism (Emerson, 2003; Farwell, 2004). It is a medical emergency, and even with early diagnosis and treatment, the mortality rate can be as high as 60%. Myxedema coma occurs most often in elderly patients during the winter months. Common precipitating factors include pulmonary infections, cerebrovascular accidents, and congestive heart failure. The clinical course of lethargy proceeding to stupor and then coma is often hastened by drugs, especially sedatives, narcotics, antidepressants, and tranquilizers. Indeed, many cases of myxedema coma have occurred in hypothyroid patients who have been hospitalized for other medical problems.

Cardinal features of myxedema coma are: (1) hypothermia, which may be profound; (2) respiratory depression; and (3) unconsciousness. Other clinical features include bradycardia, macroglossia, delayed reflexes, and dry, rough skin. Dilutional hyponatremia is common and may be severe. Elevated plasma creatine kinase (CK) and lactate dehydrogenase (LDH) concentrations, acidosis, and anemia are common findings. Lumbar puncture reveals increased opening pressure and high protein content. Hypothyroidism is confirmed by measuring serum free thyroxine index and TSH values. Ultimately, myxedema coma is a clinical diagnosis.

The mainstay of therapy is supportive care, with ventilatory support, rewarming with blankets, correction of hyponatremia, and

treatment of the precipitating incident. Because of a 5% to 10% incidence of coexisting decreased adrenal reserve in patients with myxedema coma, intravenous steroids are indicated before initiating thyroxine therapy (*see* Chapter 59). Parenteral administration of thyroid hormone is necessary due to uncertain absorption through the gut. With intravenous preparations of both levothyroxine and liothyronine now available, a reasonable approach is an initial intravenous loading dose of 200 to 300 μg of levothyroxine with a second dose of 100 μg given 24 hours later. Alternatively, a bolus of 500 μg levothyroxine given orally (by mouth or *via* nasogastric tube) may be administered to patients <50 years old without cardiac complications (Yamamoto *et al.*, 1999). Some clinicians recommend adding liothyronine (at a dose of 10 μg intravenously every 8 hours) with the initial dose of levothyroxine, until the patient is stable and conscious. The dose of thyroid hormone should be adjusted on the basis of hemodynamic stability, the presence of coexisting cardiac disease, and the degree of electrolyte imbalance. Studies suggest that overaggressive treatment with either levothyroxine (>500 μg per day) or liothyronine (>75 μg) may be associated with an increased mortality rate (Yamamoto *et al.*, 1999).

Treatment of Cretinism. Success in the treatment of cretinism depends upon the age at which therapy is started. Because of this, newborn screening for congenital hypothyroidism is routine in the United States, Canada, and many other countries around the world. In cases that do not come to the attention of physicians until retardation of development is clinically obvious, the detrimental effects of thyroid hormone deficiency on mental development will be irreversible. If, on the other hand, therapy is instituted within the first few weeks of life, normal physical and mental development is almost always achieved (Rovet, 2003; Rovet and Daneman, 2003). Prognosis also depends on the severity of the hypothyroidism at birth and may be worse for babies with thyroid agenesis. The most critical need for thyroid hormone is during the period of myelination of the central nervous system that occurs about the time of birth. To rapidly normalize the serum thyroxine concentration in the congenitally hypothyroid infant, an initial daily dose of levothyroxine of 10 to 15 $\mu\text{g}/\text{kg}$ is recommended (Brown, 2005). This dose will increase the total serum thyroxine concentration to the upper half of the normal range in most infants within 1 to 2 weeks. Individual levothyroxine doses are adjusted at 4- to 6-week intervals during the first 6 months, at 2-month intervals during the 6- to 18-month period, and at 3- to 6-month intervals thereafter to maintain serum thyroxine concentrations in the 10- to 16- $\mu\text{g}/\text{dl}$ range and serum TSH values in the normal range. The free thyroxine levels should be kept in the upper normal or elevated range. Assessments that are important guides for appropriate hormone replacement include physical growth, motor development, bone maturation, and developmental progress. Management of premature infants with hypothyroxinemia due to the sick euthyroid syndrome (~50% of those born at less than 30 weeks of gestation) remains a therapeutic dilemma. Despite impaired psychomotor development in these patients (Reuss *et al.*, 1996; Den Ouden *et al.*, 1996), levothyroxine therapy has not been shown to be beneficial and may be deleterious if overreplacement is administered (Den Ouden *et al.*, 1996).

Nodular Thyroid Disease. Nodular thyroid disease is the most common endocrinopathy. The prevalence of clinically apparent nodules is 4% to 7% in the United States, with the frequency increasing throughout adult life. When ultrasound and autopsy data are included, the prevalence of thyroid nodules approaches 50% by age 60. As with other forms of thyroid disease, nodules are more frequent in women. Nodules have been estimated to develop at a rate of 0.1% per year. In

individuals exposed to ionizing radiation, the rate of nodule development is 20 times higher. While the presence of a nodule raises the question of a malignancy, only 8% to 10% of patients with thyroid nodules have thyroid cancer. About 22,000 new cases of thyroid cancer are diagnosed annually, with about 1000 deaths from the disease per year. However, many more people have clinically silent thyroid cancer, as up to 35% of thyroids removed at autopsy or at surgery harbor a small (<1 cm) occult papillary cancer.

The evaluation of the patient with nodular thyroid disease includes a careful physical examination, biochemical analysis of thyroid function, and assessment of the malignant potential of the nodule. If the serum TSH is normal, the most efficacious diagnostic procedure is a fine-needle aspiration biopsy. Other diagnostic measures that may be useful in the evaluation of the nodule include radioisotope scanning and ultrasound.

TSH suppressive therapy with levothyroxine is an option for the patient diagnosed with a benign solitary nodule and a normal serum TSH. The rationale behind levothyroxine therapy is that the benign nodule will either stop growing or decrease in size after TSH stimulation of the thyroid gland has been suppressed. The success rate of such therapy varies widely (Papini *et al.*, 1998; Zelmanovitz *et al.*, 1998; Gharib and Mazzaferri, 1998). Identification of those patients who are most likely to benefit from thyroid hormone therapy can be achieved through measurement of the serum TSH concentration and radioisotope scanning. Suppression therapy will be of no value if thyroid nodule autonomy exists, as evidenced by a subnormal TSH value and all, or almost all, isotope uptake in the nodule. Functioning nodules are the most likely to respond to suppression therapy. However, once TSH concentrations are suppressed, a repeat radioisotope scan (suppression scan) should be obtained. If significant uptake persists on a suppression scan, the nodule is nonsuppressible and levothyroxine therapy should be discontinued. Suppression therapy needs to be considered carefully in older patients or in those with coronary artery disease; in general, such therapy should be avoided in these patients. Hypofunctioning nodules are much less likely to respond to suppression therapy. However, a 6- to 12-month trial of levothyroxine suppression is reasonable (Hermus and Huysmans, 1998). If levothyroxine is administered, therapy should be continued for as long as the nodule is decreasing in size. Once the size of a nodule remains stable for a 6- to 12-month period, therapy may be discontinued and the nodule observed for recurrent growth. Any nodule that grows while on suppression therapy should be rebiopsied and/or surgically excised.

Thyroid Cancer. Surgery is the primary treatment for all forms of thyroid cancer, followed by levothyroxine suppression therapy (Mazzaferri and Kloos, 2001). In most patients, RAI ablation follows surgery (*see below*).

ANTITHYROID DRUGS AND OTHER THYROID INHIBITORS

A large number of compounds are capable of interfering, directly or indirectly, with the synthesis, release, or action of thyroid hormones (Table 56-4). Several are of great clinical value for the temporary or extended control of hyperthyroid states. The major inhibitors may be classified into four categories: (1) antithyroid drugs,

Table 56-4
Antithyroid Compounds

PROCESS AFFECTED	EXAMPLES OF INHIBITORS
Active transport of iodide	Complex anions: perchlorate, fluoborate, pertechnetate, thiocyanate
Iodination of thyroglobulin	Thionamides: propylthiouracil, methimazole, carbimazole Thiocyanate Aniline derivatives; sulfonamides Iodide
Coupling reaction	Thionamides Sulfonamides ?All other inhibitors of iodination
Hormone release	Lithium salts Iodide
Iodotyrosine deiodination	Nitrotyrosines
Peripheral iodothyronine deiodination	Thiouracil derivatives Oral cholecystographic agents Amiodarone
Hormone excretion/inactivation	Inducers of hepatic drug-metabolizing enzymes: phenobarbital, rifampin, carbamazepine, phenytoin
Hormone action	Thyroxine analogs Amiodarone ?Phenytoin Binding in gut: cholestyramine

SOURCE: Adapted from Meier, 2005.

which interfere directly with the synthesis of thyroid hormones; (2) ionic inhibitors, which block the iodide transport mechanism; (3) high concentrations of iodine itself, which decrease release of thyroid hormones from the gland and also may decrease hormone synthesis; and (4) radioactive iodine, which damages the gland with ionizing radiation. Adjuvant therapy with drugs that have no specific effects on thyroid gland hormonogenesis is useful in controlling the peripheral manifesta-

tions of thyrotoxicosis. These drugs include inhibitors of the peripheral deiodination of thyroxine to the active hormone, triiodothyronine; β adrenergic receptor antagonists; and Ca^{2+} channel blockers. The antithyroid drugs have been reviewed by Cooper (2003). Adrenergic receptor antagonists are discussed more fully in Chapter 10 and Ca^{2+} channel blockers in Chapters 31 and 34.

Antithyroid Drugs

The antithyroid drugs that have clinical utility are the thioureylenes, which belong to the family of thionamides. Propylthiouracil may be considered as the prototype.

History. Studies on the mechanism of the development of goiter began with the observation that rabbits fed a diet composed largely of cabbage often developed goiters. This result was probably due to the presence of precursors of the thiocyanate ion in cabbage leaves (see below). Later, two pure compounds were shown to produce goiter: sulfaguanidine and phenylthiourea.

Investigation of the effects of thiourea derivatives revealed that rats became hypothyroid despite hyperplastic changes in their thyroid glands that were characteristic of intense thyrotropic stimulation. After treatment was begun, no new hormone was made, and the goitrogen had no visible effect upon the thyroid gland following hypophysectomy or the administration of thyroid hormone. This suggested to Astwood that the goiter was a compensatory change resulting from the induced state of hypothyroidism and that the primary action of the compounds was to inhibit the formation of thyroid hormone. The therapeutic possibilities of such agents in hyperthyroidism were evident, and the substances so used became known as *antithyroid drugs*.

Structure–Activity Relationship. The two goitrogens found in the early 1940s proved to be prototypes of two different classes of antithyroid drugs. These two, with one later addition, made up three general categories into which the majority of the agents can be assigned: (1) *thioureylenes* include all the compounds currently used clinically (Figure 56–9); (2) *aniline derivatives*, of which the sulfonamides make up the largest number, embrace a few substances that have been found to inhibit thyroid hormone synthesis; and (3) *polyhydric phenols*, such as resorcinol, which have caused goiter in human beings when applied to the abraded skin. A few other compounds, mentioned briefly below, do not fit into any of these categories.

Thiourea and its simpler aliphatic derivatives and heterocyclic compounds containing a thioureylene group make up the majority of the known antithyroid agents that are effective in human beings. Although most of them incorporate the entire thioureylene group, in some a nitrogen atom is replaced by oxygen or sulfur so that only the thioamide group is common to all. Among the heterocyclic compounds, active representatives are the sulfur derivatives of *imidazole*, *oxazole*, *hydantoin*, *thiazole*, *thiadiazole*, *uracil*, and *barbituric acid*.

Figure 56–9. Antithyroid drugs of the thiamide type.

L-5-Vinyl-2-thioxazolidone (goitrogen) is responsible for the goiter that results from consuming turnips or the seeds or green parts of cruciferous plants. These plants are eaten by cows, and the compound is found in cow's milk in areas of endemic goiter in Finland; it is about as active as propylthiouracil in humans.

As the result of industrial exposure, toxicological studies, or clinical trials for various purposes, several other compounds have been noted to possess antithyroid activity (DeRosa *et al.*, 1998). *Thiopental* and oral hypoglycemic drugs of the sulfonylurea class have weak antithyroid action in experimental animals. This is not significant at usual doses in humans. However, antithyroid effects in human beings have been observed from *dimercaprol*, *aminogluthimide*, and *lithium salts*. Polychlorinated biphenyls bear a striking structural resemblance to the thyroid hormones and may function as either agonists or antagonists of thyroid hormone action (DeRosa *et al.*, 1998; Zoeller *et al.*, 2000; Gauger *et al.*, 2004). *Amiodarone*, the iodine-rich drug used in the management of cardiac arrhythmias, has complex effects on thyroid function (Harjai and Licata, 1997). In areas of iodine sufficiency, amiodarone-induced hypothyroidism due to the excess iodine is not uncommon, whereas in iodine-deficient regions, amiodarone-induced thyrotoxicosis predominates, whether because of the excess iodine or the thyroiditis induced by the drug. Amiodarone and its major metabolite, desethylamiodarone, are potent inhibitors of iodothyronine deiodination, resulting in decreased conversion of thyroxine to triiodothyronine. In addition, desethylamiodarone decreases binding of triiodothyronine to its nuclear receptors. Recommendations have been made as to screening methods to identify chemicals that may alter thyroid hormone action or homeostasis (DeVito *et al.*, 1999).

Mechanism of Action. The mechanism of action of the thioureylene drugs has been thoroughly discussed by Taurog (2000). Antithyroid drugs inhibit the formation of thyroid hormones by interfering with the incorporation of iodine into tyrosyl residues of thyroglobulin; they also inhibit the coupling of these iodotyrosyl residues to form iodothyronines. This implies that they interfere with the oxidation of iodide ion and iodotyrosyl groups. Taurog (2000) proposed that the drugs inhibit the peroxidase enzyme, thereby preventing oxidation of iodide or iodotyrosyl groups to the required active state. The antithyroid drugs bind to and inactivate the peroxidase only when the heme of the enzyme is in the oxidized state. Over a period of time, the inhibition of hormone synthesis results in the depletion of stores of iodinated thyroglobulin as the protein is hydrolyzed and the hormones are released into the circulation. Only when the preformed hormone is deplet-

ed and the concentrations of circulating thyroid hormones begin to decline do clinical effects become noticeable.

There is some evidence that the coupling reaction may be more sensitive to an antithyroid drug, such as propylthiouracil, than is the iodination reaction (Taurog, 2000). This may explain why patients with hyperthyroidism respond well to doses of the drug that only partially suppress organification.

When Graves' disease is treated with antithyroid drugs, the concentration of thyroid-stimulating immunoglobulins in the circulation often decreases, prompting some to propose that these agents act as immunosuppressants. Perchlorate, which acts by an entirely different mechanism, also decreases thyroid-stimulating immunoglobulins, suggesting that improvement in hyperthyroidism may itself favorably affect the abnormal humoral immune state.

In addition to blocking hormone synthesis, propylthiouracil partially inhibits the peripheral deiodination of T_4 to T_3 . *Methimazole* does not have this effect; although the quantitative significance of this inhibition has not been established, it provides a rationale for the choice of propylthiouracil over other antithyroid drugs in the treatment of severe hyperthyroid states or of thyroid storm, where a decreased rate of $T_4 \rightarrow T_3$ conversion would be beneficial.

Absorption, Metabolism, and Excretion. The antithyroid compounds currently used in the United States are propylthiouracil (6-*n*-propylthiouracil) and methimazole (1-methyl-2-mercaptoimidazole; TAPAZOLE). In Great Britain and Europe, *carbimazole* (NEO-MERCAZOLE), a carboxy derivative of methimazole, is available, and its antithyroid action is due to its conversion to methimazole after absorption. Some pharmacological properties of propylthiouracil and methimazole are shown in Table 56-5. Measurements of the course of organification of radioactive iodine by the thyroid show that absorption of effective amounts of propylthiouracil follows within 20 to 30 minutes of an oral dose and that the duration of action of the compounds used clinically is brief. The effect of a dose of 100 mg of propylthiouracil begins to wane in 2 to 3 hours, and even a 500-mg dose is completely inhibitory for only 6 to 8 hours. As little as 0.5 mg of methimazole similarly decreases the organification of radioactive iodine in the thyroid gland, but a single dose of 10 to 25 mg is needed to extend the inhibition to 24 hours.

The half-life of propylthiouracil in plasma is about 75 minutes, whereas that of methimazole is 4 to 6 hours. The drugs are concentrated in the thyroid, and methimazole, derived from the metabolism of carbimazole, accumulates after carbimazole is administered. Drugs and metabolites appear largely in the urine.

Table 56-5

Selected Pharmacokinetic Features of Antithyroid Drugs

	PROPYLTHIOURACIL	METHIMAZOLE
Plasma protein binding	~75%	Nil
Plasma half-life	75 minutes	~4–6 hours
Volume of distribution	~20 liters	~40 liters
Concentrated in thyroid	Yes	Yes
Metabolism of drug during illness		
Severe liver disease	Normal	Decreased
Severe kidney disease	Normal	Normal
Dosing frequency	1 to 4 times daily	Once or twice daily
Transplacental passage	Low	Low
Levels in breast milk	Low	Low

Propylthiouracil and methimazole cross the placenta equally (Mortimer *et al.*, 1997) and also can be found in milk. The use of these drugs during pregnancy is discussed below.

Untoward Reactions. The incidence of side effects from propylthiouracil and methimazole as currently used is relatively low. The overall incidence as compiled from published cases by early investigators was 3% for propylthiouracil and 7% for methimazole, with 0.44% and 0.12% of cases, respectively, developing the most serious reaction, agranulocytosis. The development of agranulocytosis with methimazole is probably dose-related, but no such relationship exists with propylthiouracil. Further observations have found little, if any, difference in side effects between these two agents and suggest that an incidence of agranulocytosis of approximately 1 in 500 is a maximal figure. Agranulocytosis usually occurs during the first few weeks or months of therapy but may occur later. Because agranulocytosis can develop rapidly, periodic white cell counts usually are of little help. Patients should immediately report the development of sore throat or fever, which usually heralds the onset of this reaction. Agranulocytosis is reversible upon discontinuation of the

offending drug, and the administration of recombinant human granulocyte colony-stimulating factor may hasten recovery (Magner and Snyder, 1994). Mild granulocytopenia, if noted, may be due to thyrotoxicosis or may be the first sign of this dangerous drug reaction. Caution and frequent leukocyte counts are then required.

The most common reaction is a mild, occasionally purpuric, urticarial papular rash. It often subsides spontaneously without interrupting treatment, but it sometimes calls for the administration of an antihistamine, corticosteroids, or changing to another drug (cross-sensitivity to propylthiouracil and methimazole is uncommon). Other less frequent complications are pain and stiffness in the joints, paresthesias, headache, nausea, skin pigmentation, and loss of hair. Drug fever, hepatitis, and nephritis are rare, although abnormal liver function tests are not infrequent with higher doses of propylthiouracil. While vasculitis was previously thought to be a rare complication, antineutrophilic cytoplasmic antibodies (ANCA) have been reported to occur in about 50% of patients receiving propylthiouracil and rarely with methimazole (Sera *et al.*, 2000; Sato *et al.*, 2000).

Therapeutic Uses. The antithyroid drugs are used in the treatment of hyperthyroidism in the following three ways: (1) as definitive treatment, to control the disorder in anticipation of a spontaneous remission in Graves' disease; (2) in conjunction with radioactive iodine, to hasten recovery while awaiting the effects of radiation; and (3) to control the disorder in preparation for surgical treatment.

The usual starting dose for propylthiouracil is 100 mg every 8 hours or 150 mg every 12 hours. When doses larger than 300 mg daily are needed, further subdivision of the time of administration to every 4 to 6 hours is occasionally helpful. Methimazole is effective when given as a single daily dose because of its relatively long plasma and intrathyroidal half-life, as well as its long duration of action. Failures of response to daily treatment with 300 to 400 mg of propylthiouracil or 30 to 40 mg of methimazole are most commonly due to noncompliance. Delayed responses also are noted in patients with very large goiters or those in whom iodine in any form has been given beforehand. Once euthyroidism is achieved, usually within 12 weeks, the dose of antithyroid drug can be reduced, but not stopped, lest an enhanced recurrence of Graves' disease occur (*see* Remissions, below).

Response to Treatment. The thyrotoxic state usually improves within 3 to 6 weeks after the initiation of antithyroid drugs. The clinical response is related to the dose of antithyroid drug, the size of the goiter, and pretreatment serum T₃ concentrations. The rate of response is determined by the quantity of stored hormone, the rate of turnover of hormone in the thyroid, the half-life of the hormone in the periphery, and the completeness of the block in synthesis imposed by the dosage given. When large doses are continued, and sometimes with the usual dose, hypothyroidism may develop as a result of overtreatment. The earliest signs of hypothyroidism call for a reduction in dose; if they have advanced to the point of discomfort, thyroid hormone in full replacement doses can be given to hasten recovery; then the lower maintenance dose of antithyroid drug

discussed above is instituted for continued therapy. Despite initial suggestions to the contrary, there is no benefit of combination levothyroxine and methimazole therapy on either remission rates (Rittmaster *et al.*, 1998) or on changes in serum concentrations of thyroid-stimulating immunoglobulins (Rittmaster *et al.*, 1996).

After treatment is initiated, patients should be examined and thyroid function tests (serum free thyroxine index and total triiodothyronine concentrations) measured every 2 to 4 months. Once euthyroidism is established, follow-up every 4 to 6 months is reasonable.

Control of the hyperthyroidism usually is associated with a decrease in goiter size, but if the thyroid enlarges, hypothyroidism probably has been induced. When this occurs, the dose of the antithyroid drug should be significantly decreased and/or levothyroxine can be added once hypothyroidism is confirmed by laboratory testing.

Remissions. The antithyroid drugs have been used in many patients to control the hyperthyroidism of Graves' disease until a remission occurs. Early investigators reported that 50% of patients so treated for 1 year remained well without further therapy for long periods, perhaps indefinitely. More recent reports have indicated that a much smaller percentage of patients sustain remissions after such treatment (Maugendre *et al.*, 1999; Benker *et al.*, 1998). Increased dietary iodine has been implicated in the latter, less favorable rates.

Unfortunately, there is no way of predicting before treatment is begun which patients will eventually achieve a lasting remission and who will relapse. It is clear that a favorable outcome is unlikely when the disorder is of long standing, the thyroid is quite large, or various forms of treatment have failed. To complicate the issue further, remission and eventual hypothyroidism may represent the natural history of Graves' disease.

During treatment, a positive sign that a remission may have taken place is reduced size of the goiter. The persistence of goiter often indicates failure, unless the patient becomes hypothyroid. Another favorable indication is continued freedom from all signs of hyperthyroidism when the maintenance dose is small. Finally, a decrease in thyroid-stimulating immunoglobulins, suppression of ¹²⁵I thyroid uptake when thyroxine or triiodothyronine is given, and a normal serum TSH response to TRH may be helpful in predicting a remission in some patients, although these tests are not routinely performed.

The Therapeutic Choice. Because antithyroid drug therapy, radioactive iodine, and subtotal thyroidectomy all are effective treatments for Graves' disease, there is no worldwide consensus among endocrinologists as to the best approach to therapy. Prolonged drug therapy of Graves' disease in anticipation of a remission is most successful in patients with small goiters or mild hyperthyroidism. Those with large goiters or severe disease usually require definitive therapy with either surgery or radioactive iodine (¹³¹I). Radioactive iodine remains the treatment of choice of many endocrinologists in the United States. Many investigators consider coexisting ophthalmopathy to be a relative contraindication for radioactive iodine therapy, since worsening of ophthalmopathy has been reported after radioactive iodine (Bartelena *et al.*, 1998a), although this remains controversial. Others suggest that development of hypothyroidism, regardless of the treatment, is the strongest risk factor for progression of ophthalmopathy (Manso *et al.*, 1998). Smoking may also be a risk factor for worsening ophthalmopathy (Bartelena *et al.*, 1998b). In older patients, depleting the thyroid gland of preformed hormone by treatment with antithyroid drugs is advisable prior to therapy with radioactive iodine, thus preventing a severe exacerbation of the hyperthyroid state during the subsequent

development of radiation thyroiditis. Subtotal thyroidectomy is advocated for Graves' disease in young patients with large goiters, children who are allergic to antithyroid drugs, pregnant women (usually in the second trimester) who are allergic to antithyroid drugs, and patients who prefer surgery over antithyroid drugs or radioactive iodine. Radioactive iodine or surgery is indicated for definitive therapy in toxic nodular goiter, since remissions following antithyroid drug therapy do not occur.

Thyrotoxicosis in Pregnancy. Thyrotoxicosis occurs in about 0.2% of pregnancies and is caused most frequently by Graves' disease. Antithyroid drugs are the treatment of choice; radioactive iodine is clearly contraindicated. Historically, propylthiouracil has been preferred over methimazole because transplacental passage was thought to be lower; however, as noted above, both propylthiouracil and methimazole cross the placenta equally (Mortimer, 1997). Current data suggest that either may be used safely in the pregnant patient (Momotani *et al.*, 1997; Mortimer *et al.*, 1997). Recent reports from Scandinavia, where carbimazole is used more frequently than propylthiouracil, have suggested that carbimazole administration is rarely associated with congenital gut abnormalities (Barwell *et al.*, 2002; Diav-Citrin and Ornoy, 2002). The antithyroid drug dosage should be minimized in order to keep the serum free thyroxine index in the upper half of the normal range or slightly elevated. As pregnancy progresses, Graves' disease often improves, and it is not uncommon for patients either to be on very low doses or off antithyroid drugs completely by the end of pregnancy. Therefore the antithyroid drug dose should be reduced, and maternal thyroid function should be frequently monitored in order to decrease chances of fetal hypothyroidism. Relapse or worsening of Graves' disease is common after delivery, and patients should be monitored closely. Propylthiouracil is the drug of choice in nursing women, since very small amounts of the drug appear in breast milk and do not appear to affect thyroid function in the suckling baby. However, doses of methimazole up to 20 mg daily in nursing mothers have been shown to have no effect on thyroid function in the baby (Azizi *et al.*, 2003).

Adjuvant Therapy. Several drugs that have no intrinsic antithyroid activity are useful in the symptomatic treatment of thyrotoxicosis. β Adrenergic receptor antagonists (see Chapter 10) are effective in antagonizing the sympathetic/adrenergic effects of thyrotoxicosis, thereby reducing the tachycardia, tremor, and stare, and relieving palpitations, anxiety, and tension. Either *propranolol*, 20 to 40 mg four times daily, or *atenolol*, 50 to 100 mg daily, is usually given initially. Propranolol or *esmolol* can be given intravenously if needed. Propranolol, in addition to its β adrenergic receptor antagonist action, has weak inhibitory effects on peripheral $T_4 \rightarrow T_3$ conversion. *Calcium channel blockers* (*diltiazem*, 60 to 120 mg four times daily) can be used to control tachycardia and decrease the incidence of supraventricular tachyarrhythmias (see Chapter 34). These drugs should be discontinued once the patient is euthyroid.

Other drugs that are useful in the rapid treatment of the severely thyrotoxic patient are agents that inhibit the peripheral conversion of thyroxine to triiodothyronine. *Dexamethasone* (0.5 to 1 mg two to four times daily) and the iodinated radiological contrast agents *iopanoic acid* (TELEPAQUE, 500 to 1000 mg once daily) and *sodium ipodate* (ORAGRAFIN, 500 to 1000 mg once daily) are effective in preoperative preparation. Neither iopanoic acid nor sodium ipodate is available in the United States. Cholestyramine has been used in severely toxic patients to bind thyroid hormones in the gut and thus block the enterohepatic circulation of the iodothyronines (Mercado *et al.*, 1996).

Preoperative Preparation. To reduce operative morbidity and mortality, patients must be rendered euthyroid prior to subtotal thyroidectomy as definitive treatment for hyperthyroidism. It is possible to bring virtually 100% of patients to a euthyroid state; the operative mortality in these patients in the hands of an experienced thyroid surgeon is extremely low. Prior treatment with antithyroid drugs usually is successful in rendering the patient euthyroid for surgery. Iodide is added to the regimen for 7 to 10 days prior to surgery to decrease the vascularity of the gland, making it less friable and decreasing the difficulties for the surgeon. In the patient who is either allergic to antithyroid drugs or is noncompliant, a euthyroid state usually can be achieved by treatment with iopanoic acid, dexamethasone, and propranolol for 5 to 7 days prior to surgery. All of these drugs should be discontinued after surgery.

Thyroid Storm. Thyroid storm is an uncommon but life-threatening complication of thyrotoxicosis in which a severe form of the disease is usually precipitated by an intercurrent medical problem (Safaran *et al.*, 2003; Farwell, 2004). It occurs in untreated or partially treated thyrotoxic patients. Precipitating factors associated with thyrotoxic crisis include infections, stress, trauma, thyroidal or nonthyroidal surgery, diabetic ketoacidosis, labor, heart disease, and rarely, radioactive iodine treatment.

Clinical features are similar to those of thyrotoxicosis, but more exaggerated. Cardinal features include fever (temperature usually over 38.5°C) and tachycardia out of proportion to the fever. Nausea, vomiting, diarrhea, agitation, and confusion are frequent presentations. Coma and death may ensue in up to 20% of patients. Thyroid function abnormalities are similar to those found in uncomplicated hyperthyroidism. Therefore thyroid storm is primarily a clinical diagnosis.

Treatment includes supportive measures such as intravenous fluids, antipyretics, cooling blankets, and sedation. Antithyroid drugs are given in large doses. Propylthiouracil is preferred over methimazole because it also impairs peripheral conversion of $T_4 \rightarrow T_3$. The recommended initial dose of propylthiouracil is 200 to 400 mg every 4 hours. Propylthiouracil and methimazole can be administered by nasogastric tube or rectally if necessary. Neither of these preparations is available for parenteral administration in the United States.

Oral iodides are used after the first dose of an antithyroid drug has been administered (see below). The agents mentioned above as adjuvant therapies of thyrotoxicosis may be usefully applied. Dexamethasone (0.5 to 1 mg intravenously every 6 hours) is recommended both as an inhibitor of conversion of thyroxine to triiodothyronine and as supportive therapy of possible relative adrenal insufficiency. Finally, *treatment of the underlying precipitating illness is essential.*

Ionic Inhibitors

The term *ionic inhibitors* designates substances that interfere with the concentration of iodide by the thyroid gland. The effective agents are anions that resemble iodide: They are all monovalent, hydrated anions of a size similar to that of iodide. The most studied example, *thiocyanate*, differs from the others qualitatively; it is not concentrated by the thyroid gland, but in large amounts may inhibit the organification of iodine. Thiocyanate is produced following the enzymatic hydrolysis of certain plant glycosides. Thus, certain foods (*e.g.*, cabbage) and cigarette smoking result in an increased concentration of thiocyanate in the blood and urine, as does the administration of *sodium nitroprusside*. Indeed, cigarette smoking has been reported to worsen both subclinical hypothyroidism (Müller *et al.*, 1995) and Graves' ophthalmopathy (Bartelena *et al.*,

1998b). Dietary precursors of thiocyanate may be a contributing factor in endemic goiter in certain parts of the world, especially in Central Africa, where the intake of iodine is very low.

Among other anions, *perchlorate* (ClO_4^-) is ten times as active as thiocyanate (Wolff, 1998). Perchlorate blocks the entrance of iodide into the thyroid by competitively inhibiting the NIS (Carrasco, 2005). Although perchlorate can be used to control hyperthyroidism, it has caused fatal aplastic anemia when given in excessive amounts (2 to 3 g daily). Over the past few years, however, perchlorate in doses of 750 mg daily has been used in the treatment of Graves' disease and amiodarone-iodine-induced thyrotoxicosis. Perchlorate can be used to "discharge" inorganic iodide from the thyroid gland in a diagnostic test of iodide organification. Other ions, selected on the basis of their size, also have been found to be active; *fluoborate* (BF_4^-) is as effective as perchlorate.

Over the past few years, concern has been raised in several western states over the potential antithyroid effects of trace amounts of perchlorate contaminating the drinking water. Ammonium perchlorate is an essential oxidizer in the production of rocket fuel, and water supplies have been contaminated with perchlorate derived from these sites. However, the minute amounts detected in drinking water are far below the levels (e.g., 500 μg daily for 2 weeks) that had no effect on thyroid ^{123}I uptake and thyroid function tests in normal volunteers (Greer *et al.*, 2002). Perchlorate levels in drinking water are almost always below 10 $\mu\text{g}/\text{L}$ or 20 μg perchlorate daily, assuming a maximum intake of 2 L. Epidemiological studies around Redlands, California, where perchlorate has been detected in the water supply, have not found any increase in thyroid cancer (Morgan and Cassady, 2002) or elevations in neonatal serum TSH values (Kelsh *et al.*, 2003). However, one study from Arizona has reported an increase in neonatal serum TSH values in neonates in Yuma City (perchlorate found in the water supply) compared to Flagstaff (perchlorate not found) (Brechner *et al.*, 2000). The latter report has been refuted when socioeconomic factors, altitude, time of neonatal sampling, and length of stay in the hospital are accounted for by comparing neonatal serum TSH values in Yuma City with a nearby city in Yuma County where perchlorate is not detected in the water supply (Lamm, 2003). The Environmental Protection Agency and a National Academy of Sciences Committee are currently determining an allowable concentration of perchlorate in drinking water that unequivocally does not affect thyroid function.

Lithium has a multitude of effects on thyroid function; its principal effect is decreased secretion of thyroxine and triiodothyronine (Takami, 1994), which can cause overt hypothyroidism in some patients taking lithium for the treatment of mania (see Chapter 18).

Iodide

Iodide is the oldest remedy for disorders of the thyroid gland. Before the antithyroid drugs were used, it was the only substance available for control of the signs and symptoms of hyperthyroidism. Its use in this way is indeed paradoxical, and the explanation for this paradox is still incomplete.

Mechanism of Action. High concentrations of iodide appear to influence almost all important aspects of iodine metabolism by the thyroid gland (Roti and Vagenakis, 2005). The capacity of iodide to limit its own transport

has been mentioned above. Acute inhibition of the synthesis of iodotyrosines and iodothyronines by iodide also is well known (the *Wolff-Chaikoff effect*). This transient, 2-day inhibition is observed only above critical concentrations of intracellular rather than extracellular concentrations of iodide. With time, "escape" from this inhibition is associated with an adaptive decrease in iodide transport and a lowered intracellular iodide concentration, most likely due to a decrease in NIS mRNA and protein (Eng *et al.*, 1999). The mechanism of the acute Wolff-Chaikoff effect remains elusive and has been postulated to be due to the generation of organic iodo-compounds within the thyroid (Pisarev and Gärtner, 2000).

An important clinical effect of high $[\text{I}^-]_{\text{plasma}}$ is inhibition of the release of thyroid hormone. This action is rapid and efficacious in severe thyrotoxicosis. The effect is exerted directly on the thyroid gland and can be demonstrated in the euthyroid subject as well as in the hyperthyroid patient. Studies in a cultured thyroid cell line suggest that some of the inhibitory effects of iodide on thyrocyte proliferation may be mediated by actions of iodide on crucial regulatory points in the cell cycle (Smerdely *et al.*, 1993).

In euthyroid individuals, the administration of doses of iodide from 1.5 to 150 mg daily results in small decreases in plasma thyroxine and triiodothyronine concentrations and small compensatory increases in serum TSH values, with all values remaining in the normal range. However, euthyroid patients with a history of a wide variety of underlying thyroid disorders may develop iodine-induced hypothyroidism when exposed to large amounts of iodine present in many commonly prescribed drugs (Table 56-6), and these patients do not escape from the acute Wolff-Chaikoff effect (Roti *et al.*, 1997). Among the disorders that predispose patients to iodine-induced hypothyroidism are treated Graves' disease, Hashimoto's thyroiditis, postpartum lymphocytic thyroiditis, subacute painful thyroiditis, and lobectomy for benign nodules. The most commonly prescribed iodine-containing drugs are certain expectorants, topical antiseptics, and radiological contrast agents.

Response to Iodide in Hyperthyroidism. The response to iodides in patients with hyperthyroidism is often striking and rapid. The effect usually is discernible within 24 hours, and the basal metabolic rate may fall at a rate comparable to that following thyroidectomy. This provides evidence that the release of hormone into the circulation is rapidly blocked. Furthermore, thyroid hormone synthesis also is mildly decreased. In the thyroid gland vascularity is reduced, the gland becomes much firmer, the cells become smaller, colloid reaccumulates in the follicles, and the quantity of bound iodine increases, as though an excessive stimulus to the gland has been removed or antagonized. The maximal effect is attained after 10 to 15 days of continuous therapy, when the signs and symptoms of hyperthyroidism may have greatly improved.

Table 56–6
Commonly Used Iodine-Containing Drugs

DRUGS	IODINE CONTENT
Oral or local	
Amiodarone	75 mg/tablet
Calcium iodide (e.g., CALCID-RINE SYRUP)	26 mg/ml
Iodoquinol (diiodohydroxyquin)	134–416 mg/tablet
Echothiophate iodide ophthalmic solution	5–41 μ g/drop
Hydriodic acid syrup	13–15 mg/ml
Iodochlorhydroxyquin	104 mg/tablet
Iodine-containing vitamins	0.15 mg/tablet
Idoxuridine ophthalmic solution	18 μ g/drop
Kelp/seaweed	0.15 mg/tablet
Lugol's solution	6.3 mg/drop
PONARIS nasal emollient	5 mg/0.8 ml
Saturated solution of potassium iodide (SSKI)	38 mg/drop
Topical antiseptics	
Iodoquinol (diiodohydroxyquin) cream	6 mg/g
Iodine tincture	40 mg/ml
Iodochlorhydroxyquin cream	12 mg/g
Iodoform gauze	4.8 mg/100 mg gauze
Povidone–iodine	10 mg/ml
Radiology contrast agents	
Diatrizoate meglumine sodium	370 mg/ml
Propylidone	340 mg/ml
Iopanoic acid	333 mg/tablet
Ipodate	308 mg/capsule
Iothalamate	480 mg/ml
Metrizamide	483 mg/ml before dilution
Iohexol	463 mg/ml

SOURCE: Adapted from Roti *et al.*, 1997.

Unfortunately, iodide therapy usually does not completely control the manifestations of hyperthyroidism, and after a variable period of time, the beneficial effect disappears. With continued treatment, the hyperthyroidism may return in its initial intensity or may become even more severe than it was at first.

Therapeutic Uses. The uses of iodide in the treatment of hyperthyroidism are in the preoperative period in preparation for thyroidecto-

my, and in conjunction with antithyroid drugs and propranolol, in the treatment of thyrotoxic crisis. Prior to surgery, iodide is sometimes employed alone, but more frequently it is used after the hyperthyroidism has been controlled by an antithyroid drug. It is then given for 7 to 10 days immediately preceding the operation. Optimal control of hyperthyroidism is achieved if antithyroid drugs are first given alone. If iodine also is given from the beginning, variable responses are observed; sometimes the effect of iodide predominates, storage of hormone is promoted, and prolonged antithyroid treatment is required before the hyperthyroidism is controlled. These clinical observations may be explained by the capacity of iodide to prevent the inactivation of thyroid peroxidase by antithyroid drugs (Taurog, 2000).

Another use of iodide is to protect the thyroid from radioactive iodine fallout following a nuclear accident. Because the uptake of radioactive iodine is inversely proportional to the serum concentration of stable iodine, the administration of 30 to 100 mg of iodide daily will markedly decrease the thyroid uptake of radioisotopes of iodine. Following the Chernobyl nuclear reactor accident in 1986, approximately 10 million children and adults in Poland were given stable iodide to block the thyroid exposure to radioactive iodine from the atmosphere and from dairy products from cows that ate contaminated grass (Nauman and Wolff, 1993). This prevented the occurrence of radiation-induced thyroid cancer, as observed in children residing near Chernobyl.

The dosage or form in which iodide is administered bears little relationship to the response achieved in hyperthyroidism, provided that not less than the minimal effective amount is given; this dosage is 6 mg of iodide per day in most, but not all, patients. *Strong iodine solution* (Lugol's solution) is widely used and consists of 5% iodine and 10% potassium iodide, which yields a dose of 6.3 mg of iodine per drop. The iodine is reduced to iodide in the intestine before absorption. *Saturated solution of potassium iodide* (SSKI) also is available, containing 38 mg per drop. Typical doses include 3 to 5 drops of Lugol's solution or 1 to 3 drops of SSKI three times a day. These doses have been determined empirically and are far in excess of that needed.

Untoward Reactions. Occasional individuals show marked sensitivity to iodide or to organic preparations that contain iodine when they are administered intravenously. The onset of an acute reaction may occur immediately or several hours after administration. Angioedema is the outstanding symptom, and laryngeal edema may lead to suffocation. Multiple cutaneous hemorrhages may be present. Also, manifestations of the serum-sickness type of hypersensitivity—such as fever, arthralgia, lymph node enlargement, and eosinophilia—may appear. Thrombotic thrombocytopenic purpura and fatal periarteritis nodosa attributed to hypersensitivity to iodide also have been described.

The severity of symptoms of chronic intoxication with iodide (*iodism*) is related to the dose. The symptoms start with an unpleasant brassy taste and burning in the mouth and throat as well as soreness of the teeth and gums. Increased salivation is noted. Coryza, sneezing, and irritation of the eyes with swelling of the eyelids are commonly observed. Mild iodism simulates a “head cold.” The patient often complains of a severe headache that originates in the frontal sinuses. Irritation of the mucous glands of the respiratory tract causes a productive cough. Excess transudation into the bronchial tree may lead to pulmonary edema. In addition, the parotid and submaxillary glands may become enlarged and tender, and the syndrome may be mistaken for mumps parotitis. There also may be

inflammation of the pharynx, larynx, and tonsils. Skin lesions are common and vary in type and intensity. They usually are mildly acneform and distributed in the seborrheic areas. Rarely, severe and sometimes fatal eruptions (ioderma) may occur after the prolonged use of iodides. The lesions are bizarre; they resemble those caused by bromism, a rare problem, and as a rule involute quickly when iodide is withdrawn. Symptoms of gastric irritation are common, and diarrhea, which is sometimes bloody, may occur. Fever is occasionally observed, and anorexia and depression may be present.

Fortunately, the symptoms of iodism disappear spontaneously within a few days after stopping the administration of iodide. The renal excretion of I⁻ can be increased by procedures that promote Cl⁻ excretion (e.g., osmotic diuresis, chloruretic diuretics, and salt loading). These procedures may be useful when the symptoms of iodism are severe.

Radioactive Iodine

Chemical and Physical Properties. Although iodine has several radioactive isotopes, greatest use has been made of ¹³¹I. It has a half-life of 8 days; therefore, more than 99% of its radiation is expended within 56 days. Its radioactive emissions include both γ rays and β particles. The short-lived radionuclide of iodine, ¹²³I, is primarily a γ -emitter with a half-life of only 13 hours. This permits a relatively brief exposure to radiation during thyroid scans.

Effects on the Thyroid Gland. The chemical behavior of the radioactive isotopes of iodine is identical to that of the stable isotope, ¹²⁷I. ¹³¹I is rapidly and efficiently trapped by the thyroid, incorporated into the iodoamino acids, and deposited in the colloid of the follicles, from which it is slowly liberated. Thus, the destructive β particles originate within the follicle and act almost exclusively upon the parenchymal cells of the thyroid, with little or no damage to surrounding tissue. The γ radiation passes through the tissue and can be quantified by external detection. The effects of the radiation depend on the dosage. When small tracer doses of ¹³¹I are administered, thyroid function is not disturbed. However, when large amounts of radioactive iodine gain access to the gland, the characteristic cytotoxic actions of ionizing radiation are observed. Pyknosis and necrosis of the follicular cells are followed by disappearance of colloid and fibrosis of the gland. With properly selected doses of ¹³¹I, it is possible to destroy the thyroid gland completely without detectable injury to adjacent tissues. After smaller doses, some of the follicles, usually in the periphery of the gland, retain their function.

Therapeutic Uses. Radioactive iodine finds its widest use in the treatment of hyperthyroidism and in the diagnosis of disorders of thyroid function. *Sodium iodide* ¹³¹I (IODOTOPE THERAPEUTIC) is available as a solution or in capsules containing essentially carrier-

free ¹³¹I suitable for oral administration. Sodium iodide ¹²³I is available for scanning procedures. Discussion here is limited to the uses of ¹³¹I.

Hyperthyroidism. Radioactive iodine is highly useful in the treatment of hyperthyroidism; in many circumstances it is regarded as the therapeutic procedure of choice for this condition (Leslie *et al.*, 2003). The use of stable iodide as treatment for hyperthyroidism, however, may preclude treatment and certain imaging studies with radioactive iodine for weeks after the iodide has been discontinued.

Dosage and Technique. ¹³¹I, 7000 to 10,000 rads per gram of thyroid tissue, is administered orally. The effective dose for a given patient depends primarily upon the size of the thyroid, the iodine uptake of the gland, and the rate of release of radioactive iodine from the gland subsequent to the nuclide's deposition in the colloid. Comparison studies have shown little advantage of a standard individualized dose, based on gland weight and radioactive iodine uptake, over a fixed dose (Jarløv *et al.*, 1995; de Bruin *et al.*, 1994; Leslie *et al.*, 2003). For these reasons, the optimal dose of ¹³¹I, expressed in terms of microcuries taken up per gram of thyroid tissue, varies in different laboratories from 80 to 150 μ Ci. The usual total dose is 4 to 15 mCi. The incidence of hypothyroidism in the early years after doses on the lower side is reduced; however, many patients with late hypothyroidism may go undetected. Therefore, the ultimate incidence of hypothyroidism is probably no less than with the larger doses. In addition, relapse of the hyperthyroid state, or initial failure to alleviate the hyperthyroid state, is increased in patients receiving lower doses of ¹³¹I. Thus, many endocrinologists recommend initial treatment with thyroid ablative doses of ¹³¹I, with subsequent treatment for hypothyroidism. There also is evidence that pretreatment with propylthiouracil reduces the therapeutic efficacy of ¹³¹I, necessitating a higher dose for a desired effect (Imseis *et al.*, 1998; Tuttle *et al.*, 1995). Methimazole appears not to share this effect of propylthiouracil (Imseis *et al.*, 1998).

Course of Disease. The course of hyperthyroidism in a patient who has received an optimal dose of ¹³¹I is characterized by progressive recovery. Beginning a few weeks after treatment, the symptoms of hyperthyroidism gradually abate over a period of 2 to 3 months. If therapy has been inadequate, the necessity for further treatment is apparent within 6 to 12 months. It is not uncommon, however, for the serum TSH to remain low for several months after ¹³¹I therapy, especially if the patient was not rendered euthyroid prior to receiving the radioactive iodine (Uy *et al.*, 1995). Occasionally, this delayed recovery of the hypothalamic-pituitary-thyroid axis results in a picture of central hypothyroidism, with low circulating thyroid hormones. Thus, assessing radioactive iodine failure based on TSH concentrations alone may be misleading and should always be accompanied by determination of free T₄ and serum T₃ concentrations. Furthermore, transient hypothyroidism, lasting up to 6 months, may occur in up to 50% of patients receiving a dose of ¹³¹I calculated to result in euthyroidism (Aizawa *et al.*, 1997). This is less of a problem if the patient receives a higher, ablative dose of ¹³¹I, since hypothyroidism occurs far more frequently and persists.

Depending to some extent upon the dosage schedule adopted, one-half to two-thirds of patients are cured by a single dose, one-third to one-fifth require two doses, and the remainder require three or more doses before the disorder is controlled. Patients treated with larger doses of ¹³¹I almost always develop hypothyroidism within a few months.

β Adrenergic antagonists, antithyroid drugs, or both, or stable iodide, can be used to hasten the control of hyperthyroidism while awaiting the full effects of the radioactive iodine. However, the anti-

thyroid drugs should be withheld for a few days before and after the therapeutic dose of ^{131}I .

Advantages. The advantages of radioactive iodine in the treatment of Graves' disease are many. No death as a direct result of the use of the isotope has been reported. There have been reports of increased mortality from cardiovascular and cerebrovascular disease in the first year after radioactive iodine therapy (Franklyn *et al.*, 1998); however, there is no evidence that the increased mortality was related to the radioactive iodine itself, and long-term follow-up of radioactive iodine therapy for Graves' disease has demonstrated no increase in overall cancer mortality in patients treated with ^{131}I (Ron *et al.*, 1998). In the nonpregnant patient, no tissue other than the thyroid is exposed to sufficient ionizing radiation to be detectably altered. Nevertheless, continuing concern about potential effects of radiation on germ cells prompts some endocrinologists to advocate antithyroid drugs or surgery in younger patients who are acceptable operative risks. Hypoparathyroidism is a small risk of surgery. With radioactive iodine treatment, the patient is spared the risks and discomfort of surgery. The cost is low, hospitalization is not required in the United States, and patients can indulge in their customary activities during the entire procedure.

Disadvantages. The chief disadvantage of the use of radioactive iodine is the high incidence of delayed hypothyroidism that is induced. Even when elaborate procedures are used to estimate iodine uptake and gland size, a certain percentage of patients will be overtreated. A distressing feature of this complication is its rising prevalence with the passage of time; the longer the interval after treatment, the higher the incidence. Several analyses of groups of patients treated 10 or more years previously suggest that the eventual rate may exceed 80%. However, it now appears that the incidence of hypothyroidism also increases progressively after subtotal thyroidectomy or after antithyroid drug therapy, and such failure of glandular function is probably part of the natural progression of Graves' disease, no matter what the therapy.

Although it is often said that hypothyroidism is not a serious complication because it can be treated so easily with thyroid hormone, its onset may be insidious and overlooked for some time. Also, once diagnosed, it is difficult to ensure that patients who need the hormone actually take it. Since the health risks of untreated subclinical hypothyroidism are becoming increasingly evident (Surks *et al.*, 2004), hypothyroidism, either subclinical or overt, requires long-term follow-up to ensure that optimal replacement therapy is provided.

Another disadvantage of radioactive iodine therapy is the long period of time that is sometimes required before the hyperthyroidism is controlled. When a single dose is effective, the response is most satisfactory; however, when multiple doses are needed, it may be many months or a year or more before the patient is well. This disadvantage can be largely overcome if the initial dose is sufficiently large. Other disadvantages include possible worsening of ophthalmopathy after treatment, although this is controversial (DeGroot *et al.*, 1995). Although extremely rare, thyroid storm has occurred after therapy with ^{131}I , usually in patients who did not receive pretreatment with antithyroid drugs. Finally, salivary gland dysfunction may be seen, especially after the higher doses used for the treatment of thyroid cancer (*see below*) (Caglar *et al.*, 2002).

Indications. The clearest indication for this form of treatment is hyperthyroidism in older patients and in those with heart disease. Radioactive iodine also is the best form of treatment when Graves' disease has persisted or recurred after subtotal thyroidectomy and when prolonged treatment with antithyroid drugs has not led to

remission. Finally, radioactive iodine is indicated in patients with toxic nodular goiter, since the disease does not go into spontaneous remission. The risk of inducing hypothyroidism is less in nodular goiter than in Graves' disease, perhaps because of the normal progression of the latter and the preservation of nonautonomous thyroid tissue in the former. Usually, larger doses of radioactive iodine are required in the treatment of toxic nodular goiter than in the treatment of Graves' disease. Radioactive iodine has been used to decrease the size of large, nontoxic, multinodular goiters that are causing compressive symptoms in patients who are otherwise poor operative risks. While surgery remains the treatment of choice for the young patient with compressive multinodular goiters, radioactive iodine therapy may benefit elderly patients, especially those with cardiopulmonary disease.

Contraindications. The main contraindication for the use of ^{131}I therapy is pregnancy. After the first trimester, the fetal thyroid will concentrate the isotope and thus suffer damage; even during the first trimester, radioactive iodine is best avoided because there may be adverse effects of radiation on fetal tissues. The risk of causing neoplastic changes in the thyroid gland has been an ongoing concern since radioactive iodine was first introduced, and only small numbers of children have been treated in this way. Indeed, many clinics have declined to treat younger patients for fear of causing cancer and have reserved radioactive iodine for patients over some arbitrary age, such as 25 or 30 years. Since experience with ^{131}I is now vast, these age limits are lower than they were in the past. The most recent report by the Cooperative Thyrotoxicosis Therapy Follow-up Study Group shows no increase in total cancer mortality following ^{131}I treatment for Graves' disease (Ron *et al.*, 1998). Furthermore, there was no increase in the occurrence of leukemia following large-dose ^{131}I therapy for thyroid cancer, although there was an increase in colorectal cancers in this population (de Vathaire *et al.*, 1997). These data strongly suggest that laxatives be given to all patients receiving ^{131}I therapy for treatment of thyroid cancer to decrease the risk of future digestive tract malignancies. Transient abnormalities in testicular function have been reported following ^{131}I therapy for treatment of thyroid cancer, but no long-term effects on fertility in either men or women have been demonstrated (Pacini *et al.*, 1994b; Dottorini *et al.*, 1995).

Thyroid Carcinoma. While most well-differentiated thyroid carcinomas accumulate very little iodine, stimulation of iodine uptake with TSH often is used effectively to treat metastases. Follicular carcinomas, which account for 10% to 15% of thyroid malignancies, are especially amenable to this treatment. Currently, endogenous TSH stimulation is evoked by withdrawal of thyroid hormone replacement therapy in patients previously treated with near-total thyroidectomy with or without radioactive ablation of residual thyroid tissue. Total body ^{131}I scanning and measurement of serum thyroglobulin when the patient is hypothyroid (TSH >35 milliunits/L) should be performed to identify metastatic disease or residual thyroid bed tissue. Depending upon the residual uptake or the presence of metastatic disease, an ablative dose of ^{131}I ranging from 30 to 150 mCi is administered, and a repeat total body scan is obtained 1 week later. The precise amount of ^{131}I needed to treat residual tissue and metastases is controversial. *Recombinant human TSH* (THYROGEN) is now available to test the ability of thyroid tissue, both normal and malignant, to take up radioactive iodine and to secrete thyroglobulin (Haugen *et al.*, 1999). The major advantage to the use of this medication is that patients do not have to stop their suppressive levothyroxine therapy and become clinically hypothyroid for the presence of persistent or metastatic disease to be assessed. While recombi-

nant human TSH is not yet approved for treatment prior to therapeutic administration of ^{131}I , trials are ongoing to assess this therapeutic indication (Robbins *et al.*, 2002; Robbins and Robbins, 2003).

TSH-suppressive therapy with levothyroxine is indicated in all patients after treatment for thyroid cancer. The goal of therapy usually is to keep serum TSH levels in the subnormal range (Burmeister *et al.*, 1992). Follow-up evaluation every 6 months is reasonable, along with determination of serum thyroglobulin concentrations. A rise in serum thyroglobulin concentration is often the first indication of recurrent disease. Prognosis in patients with thyroid cancer depends upon the pathology and size of the tumor and is generally worse in the elderly. Overall, the vast majority of patients with thyroid cancer will not die of their disease. Papillary cancer is not aggressive; the 10-year survival rate exceeds 40%. Follicular cancer is more aggressive and can metastasize *via* the bloodstream. Still, prognosis is fair and long-term survival is common. Even in patients with metastatic, differentiated thyroid cancer, ^{131}I therapy is very effective and may be even curative (Pacini *et al.*, 1994a). Anaplastic cancer is the exception, as it is highly malignant with survival usually less than 1 year. Medullary thyroid carcinomas do not accumulate I⁻ and cannot usually be treated with ^{131}I .

Diagnostic Uses. Measurement of the thyroïdal accumulation of a tracer dose is helpful in the differential diagnosis of thyrotoxicosis and nodular goiter. The response of the thyroid to TSH-suppressive doses of thyroid hormone can be evaluated in this way. Following the administration of a tracer dose, the pattern of localization in the thyroid gland can be depicted by a special scanning apparatus, and this technique is sometimes useful in defining thyroid nodules as functional (“hot”) or nonfunctional (“cold”) and in finding ectopic thyroid tissue and occasionally metastatic thyroid tumors.

CLINICAL SUMMARY

Replacement therapy for hypothyroidism typically uses oral L-thyroxine given once daily, with the goal of restoring the serum TSH concentrations to the mid-normal or low-normal range. This usually is possible and most patients are treated successfully. Based on the prolonged half-life of thyroxine, at least 6 to 8 weeks are required before a new steady-state level is reached following initiation of therapy or adjustment of dose. Special cases of hypothyroidism include patients following surgical resection of differentiated thyroid carcinoma and pregnancy. In the former setting, the goal is to suppress the TSH level to below normal, thereby removing the potential effect of TSH to stimulate proliferation of the cancer cells. In pregnant patients, the standard replacement dose generally must be increased due to higher levels of TBG and small amounts of thyroxine crossing the placenta to reach the fetus. Realizing the effects of even relatively mild hypothyroidism on neurological development of the fetus, it is especially important to carefully monitor thyroid function tests during pregnancy.

Options available for treating hyperthyroid patients include antithyroid drugs (*e.g.*, propylthiouracil and methimazole), radioactive iodine ablation, and surgery. The preferred therapy differs among endocrinologists and regions. Special circumstances such as the presence of coexisting ophthalmopathy in patients with Graves’ disease also may influence the choice of therapy; radioactive iodine may aggravate the ophthalmopathy. Although younger patients with hyperthyroidism often can be treated effectively with radioactive iodine, medical therapy with antithyroid drugs to reduce the levels of thyroid hormone may be preferred. In younger patients with very large goiters, thyroidectomy is a viable alternative. In older patients or those with cardiac disease, radioactive iodine usually is recommended after the patient has been rendered euthyroid with antithyroid medication. Recombinant human TSH is available for stimulation of radioactive iodine uptake and release of thyroglobulin in patients with thyroid cancer after thyroidectomy. It essentially has replaced induced hypothyroidism after thyroid hormone withdrawal for most patients who are having a total body scan and serum thyroglobulin measurement to determine the presence of residual tissue.
