CONTENTS

- Contributors / xi
- Consultants to the Editors / xvii
- Preface / xxi
- Preface to the First Edition / xxiii

SECTION I

GENERAL PRINCIPLES

1

1. Pharmacokinetics and Pharmacodynamics: The Dynamics of Drug Absorption, Distribution, Action, and Elimination / 1
Iain L. O. Buxton
2. Membrane Transporters and Drug Response / 41
Kathleen M. Giacomini and Yuichi Sugiyama
3. Drug Metabolism / 71
Frank J. Gonzalez and Robert H. Tukey
4. Pharmacogenetics / 93
Mary V. Relling and Kathleen M. Giacomini
5. The Science of Drug Therapy / 117
John A. Oates

SECTION II

DRUGS ACTING AT SYNAPTIC AND NEUROEFFECTOR JUNCTIONAL SITES

137

6. Neurotransmission: The Autonomic and Somatic Motor Nervous Systems / 137
Thomas C. Westfall and David P. Westfall
7. Muscarinic Receptor Agonists and Antagonists / 183
Joan Heller Brown and Palmer Taylor
8. Anticholinesterase Agents / 201
Palmer Taylor
9. Agents Acting at the Neuromuscular Junction and Autonomic Ganglia / 217
Palmer Taylor
10. Adrenergic Agonists and Antagonists / 237
Thomas C. Westfall and David P. Westfall

11. 5-Hydroxytryptamine (Serotonin): Receptor Agonists and Antagonists / 297

Elaine Sanders-Bush and Steven E. Mayer

SECTION III

DRUGS ACTING ON THE CENTRAL NERVOUS SYSTEM

317

12. Neurotransmission and the Central Nervous System / 317

Floyd E. Bloom

13. General Anesthetics / 341

Alex S. Evers, C. Michael Crowder, and Jeffrey R. Balse

14. Local Anesthetics / 369

William A. Catterall and Ken Mackie

15. Therapeutic Gases: Oxygen, Carbon Dioxide, Nitric Oxide, and Helium / 387

Brett A. Simon, Eric J. Moody, and Roger A. Johns

16. Hypnotics and Sedatives / 401

Dennis S. Charney, S. John Mihic, and R. Adron Harris

17. Drug Therapy of Depression and Anxiety Disorders / 429

Ross J. Baldessarini

18. Pharmacotherapy of Psychosis and Mania / 461

Ross J. Baldessarini and Frank I. Tarazi

19. Pharmacotherapy of the Epilepsies / 501

James O. McNamara

20. Treatment of Central Nervous System Degenerative Disorders / 527

David G. Standaert and Anne B. Young

21. Opioid Analgesics / 547

Howard B. Gutstein and Huda Akil

22. Ethanol / 591

Michael F. Fleming, S. John Mihic, and R. Adron Harris

23. Drug Addiction and Drug Abuse / 607

Charles P. O'Brien

SECTION IV

AUTACOIDS: DRUG THERAPY OF INFLAMMATION

629

24. Histamine, Bradykinin, and Their Antagonists / 629

Randal A. Skidgel and Ervin G. Erdös

25. Lipid-Derived Autacoids: Eicosanoids and Platelet-Activating Factor / 653*Emer M. Smyth, Anne Burke, and Garret A. FitzGerald***26. Analgesic-Antipyretic Agents; Pharmacotherapy of Gout / 671***Anne Burke, Emer M. Smyth, and Garret A. FitzGerald***27. Pharmacotherapy of Asthma / 717***Bradley J. Undem***SECTION V****DRUGS AFFECTING RENAL AND CARDIOVASCULAR FUNCTION****737****28. Diuretics / 737***Edwin K. Jackson***29. Vasopressin and Other Agents Affecting the Renal Conservation of Water / 771***Edwin K. Jackson***30. Renin and Angiotensin / 789***Edwin K. Jackson***31. Treatment of Myocardial Ischemia / 823***Thomas Michel***32. Therapy of Hypertension / 845***Brian B. Hoffman***33. Pharmacotherapy of Congestive Heart Failure / 869***Thomas P. Rocco and James C. Fang***34. Antiarrhythmic Drugs / 899***Dan M. Roden***35. Drug Therapy for Hypercholesterolemia and Dyslipidemia / 933***Robert W. Mahley and Thomas P. Bersot***SECTION VI****DRUGS AFFECTING GASTROINTESTINAL FUNCTION****967****36. Pharmacotherapy of Gastric Acidity, Peptic Ulcers, and Gastroesophageal Reflux Disease / 967***Willemijntje A. Hoogerwerf and Pankaj Jay Pasricha***37. Treatment of Disorders of Bowel Motility and Water Flux; Antiemetics; Agents Used in Biliary and Pancreatic Disease / 983***Pankaj Jay Pasricha***38. Pharmacotherapy of Inflammatory Bowel Disease / 1009***Joseph H. Sellin and Pankaj Jay Pasricha*

SECTION VII

CHEMOTHERAPY OF PARASITIC INFECTIONS 1021

39. Chemotherapy of Protozoal Infections: Malaria / 1021
Theresa A. Shapiro and Daniel E. Goldberg
40. Chemotherapy of Protozoal Infections: Amebiasis, Giardiasis, Trichomoniasis, Trypanosomiasis, Leishmaniasis, and Other Protozoal Infections / 1049
Margaret A. Phillips and Samuel L. Stanley, Jr.
41. Chemotherapy of Helminth Infections / 1073
Alex Loukas and Peter J. Hotez

SECTION VIII

CHEMOTHERAPY OF MICROBIAL DISEASES 1095

42. General Considerations of Antimicrobial Therapy / 1095
Henry F. Chambers
43. Sulfonamides, Trimethoprim-Sulfamethoxazole, Quinolones, and Agents for Urinary Tract Infections / 1111
William A. Petri, Jr.
44. Penicillins, Cephalosporins, and Other β -Lactam Antibiotics / 1127
William A. Petri, Jr.
45. Aminoglycosides / 1155
Henry F. Chambers
46. Protein Synthesis Inhibitors and Miscellaneous Antibacterial Agents / 1173
Henry F. Chambers
47. Chemotherapy of Tuberculosis, *Mycobacterium avium* Complex Disease, and Leprosy / 1203
William A. Petri, Jr.
48. Antifungal Agents / 1225
John E. Bennett
49. Antiviral Agents (Nonretroviral) / 1243
Frederick C. Hayden
50. Antiretroviral Agents and Treatment of HIV Infection / 1273
Charles Flexner

SECTION IX**CHEMOTHERAPY OF NEOPLASTIC DISEASES 1315****51. Antineoplastic Agents / 1315**

Bruce A. Chabner, Philip C. Amrein, Brian Druker, M. Dror Michaelson, Constantine S. Mitsiades, Paul E. Goss, David P. Ryan, Sumant Ramachandra, Paul G. Richardson, Jeffrey G. Supko, and Wyndham H. Wilson

SECTION X**IMMUNOMODULATORS 1405****52. Immunosuppressants, Tolerogens, and Immunostimulants / 1405**

Alan M. Krensky, Flavio Vincenti, and William M. Bennett

SECTION XI**DRUGS ACTING ON THE BLOOD AND THE BLOOD-FORMING ORGANS 1433****53. Hematopoietic Agents: Growth Factors, Minerals, and Vitamins / 1433**

Kenneth Kaushansky and Thomas J. Kipps

54. Blood Coagulation and Anticoagulant, Thrombolytic, and Antiplatelet Drugs / 1467

Philip W. Majerus and Douglas M. Tollefsen

SECTION XII**HORMONES AND HORMONE ANTAGONISTS 1489****55. Pituitary Hormones and Their Hypothalamic Releasing Factors / 1489**

Keith L. Parker and Bernard P. Schimmer

56. Thyroid and Antithyroid Drugs / 1511

Alan P. Farwell and Lewis E. Braverman

57. Estrogens and Progestins / 1541

David S. Loose and George M. Stancel

58. Androgens / 1573

Peter J. Snyder

59. Adrenocorticotrophic Hormone; Adrenocortical Steroids and Their Synthetic Analogs; Inhibitors of the Synthesis and Actions of Adrenocortical Hormones / 1587

Bernard P. Schimmer and Keith L. Parker

60. Insulin, Oral Hypoglycemic Agents, and the Pharmacology of the Endocrine Pancreas / 1613
Stephen N. Davis
61. Agents Affecting Mineral Ion Homeostasis and Bone Turnover / 1647
Peter A. Friedman

SECTION XIII

DERMATOLOGY 1679

62. Dermatological Pharmacology / 1679
Lindy P. Fox, Hans F. Merk, and David R. Bickers

SECTION XIV

OPHTHALMOLOGY 1707

63. Ocular Pharmacology / 1707
Jeffrey D. Henderer and Christopher J. Rapuano

SECTION XV

TOXICOLOGY 1739

64. Principles of Toxicology and Treatment of Poisoning / 1739
Curtis D. Klaassen
65. Heavy Metals and Heavy-Metal Antagonists / 1753
Curtis D. Klaassen

APPENDICES

- I. Principles of Prescription Order Writing and Patient Compliance / 1777
Iain L. O. Buxton
- II. Design and Optimization of Dosage Regimens; Pharmacokinetic Data / 1787
Kenneth E. Thummel, Danny D. Shen, Nina Isoherranen, and Helen E. Smith

Index / 1889

CONTRIBUTORS

Huda Akil, MD

Co-Director, Mental Health Research Institute;
University of Michigan
Ann Arbor, Michigan

Philip C. Amrein, MD

Assistant Professor of Medicine, Harvard Medical School;
Physician, Massachusetts General Hospital
Boston, Massachusetts

Ross J. Baldessarini, MD

Professor of Psychiatry (Neuroscience)
Harvard Medical School
Boston, Massachusetts;
Director, Neuropharmacology Laboratory & Psychopharmacology
Program
McLean Division of Massachusetts General Hospital
Belmont, Massachusetts

Jeffrey R. Balse, MD, PhD

Associate Vice Chancellor for Research
The James Tayloe Gwathmey Professor of Anesthesiology and
Pharmacology
Vanderbilt University Medical Center
Nashville, Tennessee

William M. Bennett, MD

Medical Director, Transplant Services
Legacy Transplant Services
Portland, Oregon

John E. Bennett, MD

Head, Clinical Mycology Section
Laboratory of Clinical Infectious Diseases, NIAID
National Institutes of Health
Bethesda, Maryland

Thomas P. Bersot, MD, PhD

Professor of Medicine
University of California, San Francisco;
Associate Investigator
Gladstone Institute of Cardiovascular Disease
San Francisco, California

David R. Bickers, MD

Carl Truman Nelson Professor/Chair
Department of Dermatology
Columbia University Medical Center
New York, New York

Floyd E. Bloom, MD

Professor Emeritus
Department of Neuropharmacology
The Scripps Research Institute
La Jolla, California

Lewis E. Braverman, MD

Chief, Section of Endocrinology, Diabetes,
and Nutrition
Boston Medical Center
Professor of Medicine
Boston University School of Medicine
Boston Massachusetts

Joan Heller Brown, PhD

Chair and Professor of Pharmacology
Department of Pharmacology
University of California, San Diego
La Jolla, California

Anne Burke, MB, BCh, BAO

Assistant Professor of Medicine
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Iain L. O. Buxton, DPH

Professor of Pharmacology
University of Nevada School of Medicine
Reno, Nevada

William A. Catterall, PhD

Professor and Chair
Department of Pharmacology
University of Washington
Seattle, Washington

Bruce A. Chabner, MD

Professor of Medicine, Harvard Medical School
Clinical Director, Massachusetts General Hospital Cancer Center
Boston, Massachusetts

Henry F. Chambers, MD

Professor of Medicine, University of California, San Francisco
Chief, Division of Infectious Diseases
San Francisco General Hospital
San Francisco, California

Dennis S. Charney, MD

Dean of Research
Anne and Joel Ehrenkranz Professor
Departments of Psychiatry, Neuroscience, and Pharmacology &
Biological Chemistry
Mount Sinai School of Medicine
New York, New York

C. Michael Crowder, MD, PhD

Associate Professor of Anesthesiology and Molecular Biology/
Pharmacology
Washington University School of Medicine
St. Louis, Missouri

Stephen N. Davis, MD

Chief, Division of Diabetes, Endocrinology & Metabolism;
Rudolph Kampmeier Professor of Medicine,
Professor of Molecular Physiology & Biophysics
Vanderbilt University Medical Center
Nashville, Tennessee

Brian Druker, MD

Investigator, Howard Hughes Medical Institute
JELD-WEN Chair of Leukemia Research
Oregon Health & Science University Cancer Institute
Portland, Oregon

Ervin G. Erdős, MD

Professor of Pharmacology and Anesthesiology
University of Illinois at Chicago College of Medicine
Chicago, Illinois

Alex S. Evers, MD

Henry E. Mallinckrodt Professor and Head of Anesthesiology
Professor of Internal Medicine and Molecular Biology and
Pharmacology
Washington University School of Medicine
Anesthesiologist-in-Chief
Barnes-Jewish Hospital
St. Louis, Missouri

James C. Fang, MD

Medical Director of Heart Transplantation and Circulatory
Assistance
Brigham and Women's Hospital
Associate Professor of Medicine
Harvard Medical School
Boston, Massachusetts

Alan P. Farwell, MD

Associate Professor of Medicine
Division of Endocrinology
University of Massachusetts Medical School
Worcester, Massachusetts

Garret A. FitzGerald, MD

Chair, Department of Pharmacology
Director, Institute for Translational Medicine and Therapeutics
University of Pennsylvania
Philadelphia, Pennsylvania

Michael F. Fleming, MD, MPH

Professor of Family Medicine
University of Wisconsin
Madison, Wisconsin

Charles Flexner, MD

Associate Professor of Medicine, Pharmacology and Molecular
Sciences, and International Health
Johns Hopkins University
Baltimore, Maryland

Lindy P. Fox, MD

Instructor in Dermatology
Department of Dermatology
Yale University School of Medicine
New Haven, Connecticut

Peter A. Friedman, PhD

Professor of Pharmacology
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Kathleen M. Giacomini, PhD

Professor and Chair, Department of Biopharmaceutical
Sciences
School of Pharmacy
University of California, San Francisco
San Francisco, California

Daniel E. Goldberg, MD, PhD

Professor of Medicine and Molecular Microbiology
Washington University School of Medicine
Investigator, Howard Hughes Medical Institute
St. Louis, Missouri

Frank J. Gonzalez, PhD

Chief, Laboratory of Metabolism
Center for Cancer Research
National Cancer Institute
Bethesda, Maryland

Paul E. Goss, MD, PhD, FRCPC, FRCP (UK)

Professor of Medicine, Harvard Medical School;
Director of Breast Cancer Research, MGH Cancer Center;
Co-Director of the Breast Cancer Disease Program, DF/HCC;
Avon Foundation Senior Scholar
Boston, Massachusetts

Howard B. Gutstein, MD

Associate Professor of Anesthesiology and Molecular Genetics
MD Anderson Cancer Center
Houston, Texas

R. Adron Harris, PhD

Director, Waggoner Center for Alcohol and Addiction
Research
University of Texas, Austin
Austin, Texas

Frederick G. Hayden, MD

Richardson Professor of Clinical Virology
Professor of Internal Medicine and Pathology
University of Virginia School of Medicine
Charlottesville, Virginia

Jeffrey D. Henderer, MD

Assistant Professor of Ophthalmology
Thomas Jefferson University School of Medicine and
Assistant Surgeon
Wills Eye Hospital
Philadelphia, Pennsylvania

Brian B. Hoffman, MD

Professor of Medicine
Harvard Medical School;
Chief of Medicine
VA Boston Health Care System
Boston, Massachusetts

Willemijntje A. Hoogerwerf, MD

Assistant Professor of Medicine
University of Texas Medical Branch
Galveston, Texas

Peter J. Hotez, MD, PhD

Professor and Chair, Department of Microbiology, Immunology
and Tropical Medicine
The George Washington University
Washington, DC

Nina Isoherranen, PhD

Acting Assistant Professor
Department of Pharmaceutics
University of Washington
Seattle, Washington

Edwin K. Jackson, PhD

Professor of Pharmacology
Associate Director, Center for Clinical Pharmacology
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Roger A. Johns, MD, MHS

Professor of Anesthesiology & Critical Care Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland

Kenneth Kaushansky, MD

Helen M. Ranney Professor and Chair
Department of Medicine
University of California, San Diego
San Diego, California

Thomas J. Kipps, MD, PhD

Professor of Medicine
Deputy Director of Research, Moores Cancer Center
University of California, San Diego
La Jolla, California

Curtis D. Klaassen, PhD

University Distinguished Professor and Chair
Department of Pharmacology, Toxicology & Therapeutics
University of Kansas Medical Center
Kansas City, Kansas

Alan M. Krensky, MD

Shelagh Galligan Professor of Pediatrics
Chief, Division of Immunology and Transplantation
Biology
Associate Dean for Children's Health
Stanford University School of Medicine
Stanford, California

David S. Loose, PhD

Associate Professor & Director
Department of Integrative Biology and Pharmacology
University of Texas - Houston Medical School
Houston, Texas

Alex Loukas, PhD

Senior Research Fellow
Queensland Institute of Medical Research
Australia

Ken Mackie, MD

Professor of Anesthesiology
Adjunct Professor of Physiology & Biophysics
University of Washington
Seattle, Washington

Robert W. Mahley, MD, PhD

President, The J. David Gladstone Institutes
 Director, Gladstone Institute of Cardiovascular Disease
 Senior Investigator, Gladstone Institute of Neurological Disease
 San Francisco, California

Philip W. Majerus, MD

Professor of Medicine;
 Co-Chairman, Division of Hematology
 Washington University School of Medicine
 St. Louis, Missouri

Steven E. Mayer, MD

Emeritus Professor of Pharmacology
 University of California, San Diego
 La Jolla, California

James O. McNamara, MD

Carl R. Deane Professor and Chair
 Department of Neurobiology
 Professor of Medicine (Neurology)
 Director, Center for Translational Neuroscience
 Duke University Medical Center
 Durham, North Carolina

Hans F. Merk, MD

Professor of Dermatology & Allergology
 University Hospital - RWTH Aachen
 Aachen, Germany

M. Dror Michaelson, MD

Instructor in Medicine
 Harvard Medical School;
 Physician, Massachusetts General Hospital
 Boston, Massachusetts

Thomas Michel, MD, PhD

Professor of Medicine, Harvard Medical School
 Chief of Cardiology, VA Boston Healthcare System
 Senior Physician, Brigham & Women's Hospital
 Boston, Massachusetts

S. John Mihic, PhD

Associate Professor
 Section of Neurobiology and Waggoner Center for Alcohol &
 Addiction Research
 University of Texas at Austin
 Austin, Texas

Constantine S. Mitsiades, MD, PhD

Instructor in Medicine
 Department of Medical Oncology
 Dana Farber Cancer Institute
 Department of Medicine
 Harvard Medical School
 Boston, Massachusetts

Eric J. Moody, MD

Associate Professor
 Department of Anesthesiology and Critical Care Medicine
 Johns Hopkins University
 Baltimore, Maryland

John A. Oates, MD

Professor of Medicine and Pharmacology
 Vanderbilt University School of Medicine
 Nashville, Tennessee

Charles P. O'Brien, MD, PhD

Professor of Psychiatry
 University of Pennsylvania
 Philadelphia, Pennsylvania

Keith L. Parker, MD, PhD

Professor of Internal Medicine & Pharmacology
 Wilson Distinguished Professor of Biomedical Research
 Chief, Division of Endocrinology & Metabolism
 University of Texas Southwestern Medical Center
 Dallas, Texas

Pankaj Jay Pasricha, MD

Chief, Division of Gastroenterology and Hepatology
 Bassel and Frances Blanton Distinguished Professor of Internal
 Medicine
 Professor of Neuroscience & Cell Biology and Biomedical
 Engineering
 University of Texas Medical Branch
 Galveston, Texas

William A. Petri, Jr., MD, PhD

Wade Hampton Frost Professor of Epidemiology
 Professor of Medicine, Microbiology, and Pathology
 Chief, Division of Infectious Diseases and International Health
 University of Virginia Health System
 Charlottesville, Virginia

Margaret A. Phillips, PhD

Professor of Pharmacology
 University of Texas Southwestern Medical Center
 Dallas, Texas

Sumant Ramachandra, MD, PhD

Vice President, Global Development-Oncology
 Schering-Plough
 Kenilworth, New Jersey

Christopher J. Rapuano, MD

Co-Director and Attending Surgeon, Cornea Service
 Co-Director, Refractive Surgery Department
 Wills Eye Hospital
 Professor, Jefferson Medical College of Thomas Jefferson
 University
 Philadelphia, Pennsylvania

Mary V. Relling, PharmD

Chair, Pharmaceutical Sciences
St. Jude Children's Research Hospital
Professor, University of Tennessee Colleges of Pharmacy and
Medicine
Memphis, Tennessee

Paul G. Richardson, MD

Clinical Director, Jerome Lipper Multiple Myeloma Center;
Assistant Professor in Medicine, Harvard Medical School
Boston, Massachusetts

Thomas P. Rocco, MD

Director, Clinical Cardiology
VA Boston Health Care System
West Roxbury, Massachusetts
Assistant Professor of Medicine
Harvard Medical School
Boston, Massachusetts

Dan M. Roden, MD, CM

Director, Oates Institute for Experimental Therapeutics
William Stokes Professor of Experimental Therapeutics
Vanderbilt University Medical Center
Nashville, Tennessee

David P. Ryan, MD

Clinical Director, Tucker Gosnell Center for Gastrointestinal
Cancers
Massachusetts General Hospital
Assistant Professor of Medicine, Harvard Medical School
Boston, Massachusetts

Elaine Sanders-Bush, PhD

Professor of Pharmacology and Psychiatry
Vanderbilt University School of Medicine
Nashville, Tennessee

Bernard P. Schimmer, PhD

Professor of Medical Research and Pharmacology
Banting & Best Department of Medical Research
University of Toronto
Toronto, Ontario, Canada

Joseph H. Sellin, MD

Professor of Medicine
Director, C²CREATE
Inflammatory Bowel Disease Center
Division of Gastroenterology
University of Texas Medical Branch
Galveston, Texas

Theresa A. Shapiro, MD, PhD

Wellcome Professor and Director
Division of Clinical Pharmacology
Departments of Medicine and Pharmacology and Molecular
Sciences
Johns Hopkins University School of Medicine
Baltimore, Maryland

Danny D. Shen, PhD

Professor & Chair, Department of Pharmacy
University of Washington
Seattle, Washington

Brett A. Simon, MD, PhD

Associate Professor of Anesthesiology/Critical Care Medicine and
Medicine
Vice Chair for Faculty Development
Chief, Division of Adult Anesthesia
Department of Anesthesiology and Critical Care Medicine
Johns Hopkins University
Baltimore, Maryland

Randal A. Skidgel, PhD

Professor of Pharmacology
University of Illinois at Chicago College of Medicine
Chicago, Illinois

Helen E. Smith, RPh, PhD

Clinical Pharmacist/Research Associate
University of Washington
Seattle, Washington

Emer M. Smyth, PhD

Research Assistant Professor of Pharmacology
University of Pennsylvania
Philadelphia, Pennsylvania

Peter J. Snyder, MD

Professor of Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

George M. Stancel, PhD

Dean, Graduate School of Biomedical Sciences
University of Texas Health Science Center at Houston and
M.D. Anderson Cancer Center
Houston, Texas

David G. Standaert, MD, PhD

Associate Professor of Neurology
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts

Samuel L. Stanley, Jr., MD

Professor of Medicine and Molecular Microbiology
Director, Midwest Regional Center of Excellence for
Biodefense and Emerging Infectious Diseases Research
Washington University School of Medicine
St. Louis, Missouri

Yuichi Sugiyama, PhD

Professor and Chair
Department of Molecular Pharmacokinetics
Graduate School of Pharmaceutical Sciences
University of Tokyo
Tokyo, Japan

Jeffrey G. Supko, PhD

Director, Clinical Pharmacology Laboratory
Massachusetts General Hospital Cancer Center
Associate Professor of Medicine
Harvard Medical School
Boston, Massachusetts

Frank I. Tarazi, PhD, MSc

Associate Professor of Psychiatry and Neuroscience
Harvard Medical School;
Director, Psychiatric Neuroscience Laboratory
Mailman Research Center
McLean Division of Massachusetts General Hospital
Belmont, Massachusetts

Palmer Taylor, PhD

Sandra and Monroe Trout Professor of Pharmacology
Dean, Skaggs School of Pharmacy and Pharmaceutical Sciences
Associate Vice Chancellor, Health Sciences
University of California, San Diego
La Jolla, California

Kenneth E. Thummel, MD

Professor of Pharmaceutics
Associate Dean for Research and New Initiatives
University of Washington, School of Pharmacy
Seattle, Washington

Douglas M. Tollefsen, MD, PhD

Professor of Medicine
Washington University Medical School
St. Louis, Missouri

Robert H. Tukey, PhD

Professor of Chemistry & Biochemistry and Pharmacology
University of California, San Diego
La Jolla, California

Bradley J. Udem, PhD

Professor of Medicine
Johns Hopkins Asthma and Allergy Center
Baltimore, Maryland

Flavio Vincenti, MD

Professor of Clinical Medicine
University of California, San Francisco
San Francisco, California

Thomas C. Westfall, PhD

William Beaumont Professor and Chairman
Department of Pharmacological and Physiological Science
Saint Louis University School of Medicine
St. Louis, Missouri

David P. Westfall, PhD

Dean, College of Science
University of Nevada, Reno;
Foundation Professor of Pharmacology
University of Nevada School of Medicine
Reno, Nevada

Wyndham H. Wilson, MD, PhD

Senior Investigator and Chief, Lymphoma Section
Experimental Transplantation and Immunology Branch
National Cancer Institute
Bethesda, Maryland

Anne B. Young, MD, PhD

Julieanne Dom Professor of Neurology
Harvard Medical School
Cambridge, Massachusetts

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

PREFACE

Upon learning that I was assuming the editorship of this book, a senior colleague warned, “Be careful. Don’t tamper lightly with the bible.” This reputation of “G & G” as the “bible of pharmacology” is a tribute to the ideals and writing of the original authors, Alfred Gilman and Louis Goodman. In 1941, they set forth the principles that have guided this book through ten prior editions and that the associate editors and I have continued to use: to correlate pharmacology with related medical sciences, to re-interpret the actions and uses of drugs in light of advances in medicine and the basic biomedical sciences, to emphasize the applications of pharmacodynamics to therapeutics, and to create a book that will be useful to students of pharmacology and physicians alike.

As with all editions since the second, expert scholars have written the individual chapters, a number of which are new to this edition. We have emphasized basic principles, adding chapters on drug transporters and drug metabolism; the material covered in these chapters explains many prominent drug-drug interactions and adverse drug responses. We have also added a chapter on the emerging field of pharmacogenetics, looking toward the individualization of therapy and an understanding of how our genetic make-up influences our responses to drugs. A chapter entitled “The Science of Drug Therapy” describes how basic principles of pharmacology apply to the care of the individual patient. Most other chapters have been extensively revised; a few have been condensed or eliminated.

Assembling a multi-author pharmacology book challenges contributors and editors in different ways. Among the apparently irresistible and understandable temptations in writing a chapter are the desire to cover everything, the urge to explain G-protein coupled signaling, and the inclination to describe in detail the history of the field in which one is an expert, citing all relevant papers from Claude Bernard to the present. These hazards, plus the continuing advance of knowledge, produce considerable pressure to increase the length of the book. As an anti-

dote, the associate editors and I have worked to eliminate repetition and extraneous text. We have pressed contributors hard, using the communicative rapidity and ease of e-mail to interact with them, to clarify and condense, and to re-write while adhering to the principles of the original authors and retaining the completeness for which the book is known. We have tried to standardize the organization of chapters; thus, students should easily find the physiology and basic pharmacology set forth in regular type in each chapter, and the clinician and expert will find details in extract type under identifiable headings. We have also tried to improve the clarity of tables and figures to provide summaries of concepts and large amounts of information. Although this 11th edition is slightly shorter than its predecessor, we believe that it is every bit as thorough.

Many deserve thanks for their contributions to the preparation of this edition. Professors Keith Parker (UT Southwestern) and John Lazo (U. Pittsburgh) have lent their considerable energy and expertise as associate editors. Professor Nelda Murri (U. Washington) has read each chapter with her keen pharmacist’s eye. Two Nashville novelists played essential roles: Lynne Hutchison again served ably as managing editor, coordinating the activities of contributors, editors, and word processors; and, for the second time, Chris Bell checked references and assembled the master copy. Each chapter has been read by an expert in addition to the editors, and the editors thank those readers. We also express our appreciation to former contributors, who will, no doubt, recognize some of their best words from previous editions. We are grateful to our editors at McGraw-Hill, Janet Foltin and James Shanahan, who have shepherded the edited text into print, and to our wives, whose support and forbearance are gifts beyond reckoning.

Lastly, I would like to pay tribute to my friend, Alfred G. Gilman. As a teacher, mentor, researcher, editor of several editions of this book, Nobel laureate, chair of a distinguished pharmacology department, and now dean of a medical school, he has enriched every aspect of our field.

PREFACE TO THE FIRST EDITION

Three objectives have guided the writing of this book—the correlation of pharmacology with related medical sciences, the reinterpretation of the actions and uses of drugs from the viewpoint of important advances in medicine, and the placing of emphasis on the applications of pharmacodynamics to therapeutics.

Although pharmacology is a basic medical science in its own right, it borrows freely from and contributes generously to the subject matter and technics of many medical disciplines, clinical as well as preclinical. Therefore, the correlation of strictly pharmacological information with medicine as a whole is essential for a proper presentation of pharmacology to students and physicians. Furthermore, the reinterpretation of the actions and uses of well-established therapeutic agents in the light of recent advances in the medical sciences is as important a function of a modern textbook of pharmacology as is the description of new drugs. In many instances these new interpretations necessitate radical departures from accepted but outworn concepts of the actions of drugs. Lastly, the emphasis throughout the book, as indicated in its title, has been clinical. This is mandatory because medical students must be taught pharmacology from the standpoint

of the actions and uses of drugs in the prevention and treatment of disease. To the student, pharmacological data per se are valueless unless he/she is able to apply this information in the practice of medicine. This book has also been written for the practicing physician, to whom it offers an opportunity to keep abreast of recent advances in therapeutics and to acquire the basic principles necessary for the rational use of drugs in his/her daily practice.

The criteria for the selection of bibliographic references require comment. It is obviously unwise, if not impossible, to document every fact included in the text. Preference has therefore been given to articles of a review nature, to the literature on new drugs, and to original contributions in controversial fields. In most instances, only the more recent investigations have been cited. In order to encourage free use of the bibliography, references are chiefly to the available literature in the English language.

The authors are greatly indebted to their many colleagues at the Yale University School of Medicine for their generous help and criticism. In particular they are deeply grateful to Professor Henry Gray Barbour, whose constant encouragement and advice have been invaluable.

SECTION I

General Principles

CHAPTER 1

PHARMACOKINETICS AND PHARMACODYNAMICS

The Dynamics of Drug Absorption, Distribution, Action, and Elimination

Iain L. O. Buxton

Numerous factors in addition to a known pharmacological action in a specific tissue at a particular receptor contribute to successful drug therapy. When a drug enters the body, the body begins immediately to work on the drug: absorption, distribution, metabolism (biotransformation), and elimination. These are the processes of *pharmacokinetics*. The drug also acts on the body, an interaction to which the concept of a drug receptor is key, since the receptor is responsible for the selectivity of drug action and for the quantitative relationship between drug and effect. The mechanisms of drug action are the processes of *pharmacodynamics*. The time course of therapeutic drug action in the body can be understood in terms of pharmacokinetics and pharmacodynamics (Figure 1–1).

I. PHARMACOKINETICS: THE DYNAMICS OF DRUG ABSORPTION, DISTRIBUTION, METABOLISM, AND ELIMINATION

PHYSICOCHEMICAL FACTORS IN TRANSFER OF DRUGS ACROSS MEMBRANES

The absorption, distribution, metabolism, and excretion of a drug all involve its passage across cell membranes. Mechanisms by which drugs cross membranes and the

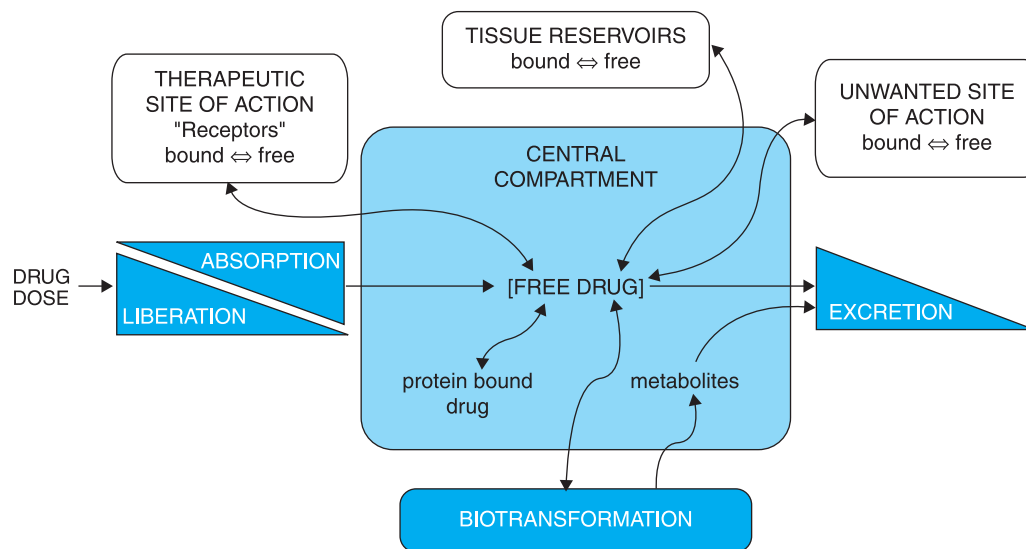

Figure 1–1. The interrelationship of the absorption, distribution, binding, metabolism, and excretion of a drug and its concentration at its sites of action. Possible distribution and binding of metabolites in relation to their potential actions at receptors are not depicted.

physicochemical properties of molecules and membranes that influence this transfer are critical to understanding the disposition of drugs in the human body. The characteristics of a drug that predict its movement and availability at sites of action are its molecular size and shape, degree of ionization, relative lipid solubility of its ionized and nonionized forms, and its binding to serum and tissue proteins.

In most cases, a drug must traverse the plasma membranes of many cells to reach its site of action. Although barriers to drug movement may be a single layer of cells (intestinal epithelium) or several layers of cells and associated extracellular protein (skin), the plasma membrane represents the common barrier to drug distribution.

Cell Membranes. The plasma membrane consists of a bilayer of amphipathic lipids with their hydrocarbon chains oriented inward to the center of the bilayer to form a continuous hydrophobic phase and their hydrophilic heads oriented outward. Individual lipid molecules in the bilayer vary according to the particular membrane and can move laterally and organize themselves with cholesterol (*e.g.*, sphingolipids), endowing the membrane with fluidity, flexibility, organization, high electrical resistance, and relative impermeability to highly polar molecules. Membrane proteins embedded in the bilayer serve as receptors, ion channels, or transporters to transduce electrical or chemical signaling pathways and provide selective targets for drug actions. These proteins may be associated with caveolin and sequestered within caveolae, they may be excluded from caveolae, or they may be organized in signaling domains rich in cholesterol and sphingolipid not containing caveolin.

Cell membranes are relatively permeable to water either by diffusion or by flow resulting from hydrostatic or osmotic differences across the membrane, and bulk flow of water can carry with it drug molecules. However, proteins with drug molecules bound to them are too large and polar for this type of transport to occur; thus, transmembrane movement generally is limited to unbound drug. Paracellular transport through intercellular gaps is sufficiently large that passage across most capillaries is limited by blood flow and not by other factors (*see below*). As described later, this type of transport is an important factor in filtration across glomerular membranes in the kidney. Important exceptions exist in such capillary diffusion, however, because “tight” intercellular junctions are present in specific tissues, and paracellular transport in them is limited. Capillaries of the central nervous system (CNS) and a variety of epithelial tissues have tight junctions (*see below*). Bulk flow of water can carry with it small water-soluble substances, but bulk-flow transport is limited when the molecular mass of the solute exceeds 100 to 200 daltons. Accordingly, most large lipophilic drugs must pass through the cell membrane itself.

Passive Membrane Transport. Drugs cross membranes either by passive processes or by mechanisms involving the active participation of components of the membrane. In passive transport, the drug molecule usually penetrates by diffusion along a concentration gradient by virtue of its solubility in the lipid bilayer. Such transfer is directly proportional to the magnitude of the concentration gradient across the membrane, to the lipid–water partition coefficient of the drug, and to the membrane surface area exposed to the drug. The greater the partition coefficient, the higher is the concentration of drug in the membrane, and the faster is its diffusion. After a steady state is attained, the concentration of the unbound drug is the same on both sides of the membrane if the drug is a nonelectrolyte. For ionic compounds, the steady-state concentrations depend on the electrochemical gradient for the ion and on differences in pH across the membrane, which may influence the state of ionization of the molecule disparately on either side of the membrane.

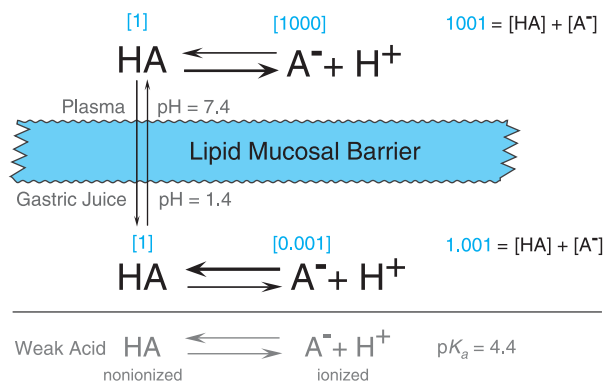

Figure 1–2. Influence of pH on the distribution of a weak acid between plasma and gastric juice separated by a lipid barrier.

Weak Electrolytes and Influence of pH. Most drugs are weak acids or bases that are present in solution as both the nonionized and ionized species. The nonionized molecules usually are more lipid-soluble and can diffuse readily across the cell membrane. In contrast, the ionized molecules usually are unable to penetrate the lipid membrane because of their low lipid solubility.

Therefore, the transmembrane distribution of a weak electrolyte is determined by its pK_a and the pH gradient across the membrane. The pK_a is the pH at which half the drug (weak electrolyte) is in its ionized form. To illustrate the effect of pH on distribution of drugs, the partitioning of a weak acid ($pK_a = 4.4$) between plasma (pH = 7.4) and gastric juice (pH = 1.4) is depicted in Figure 1–2. It is assumed that the gastric mucosal membrane behaves as a simple lipid barrier that is permeable only to the lipid-soluble, nonionized form of the acid. The ratio of nonionized to ionized drug at each pH is readily calculated from the Henderson–Hasselbalch equation:

$$\log \frac{[\text{protonated form}]}{[\text{unprotonated form}]} = pK_a - \text{pH} \quad (1-1)$$

This equation relates the pH of the medium around the drug and the drug's acid dissociation constant (pK_a) to the ratio of the protonated (HA or BH^+) and unprotonated (A^- or B) forms, where $\text{HA} \leftrightarrow \text{A}^- + \text{H}^+$ ($K_a = [\text{A}^-][\text{H}^+]/[\text{HA}]$) describes the dissociation of an acid, and $\text{BH}^+ \leftrightarrow \text{B} + \text{H}^+$ ($K_a = [\text{B}][\text{H}^+]/[\text{BH}^+]$) describes the dissociation of the protonated form of a base.

Thus, in plasma, the ratio of nonionized to ionized drug is 1:1000; in gastric juice, the ratio is 1:0.001. These values are given in brackets in Figure 1–2. The total concentration ratio between the plasma and the gastric juice therefore would be 1000:1 if such a system came to a steady state. For a weak base with a pK_a of 4.4, the ratio would be reversed, as would the thick horizontal arrows in Figure 1–2, which indicate the predominant species at each pH. Accordingly,

at steady state, an acidic drug will accumulate on the more basic side of the membrane and a basic drug on the more acidic side—a phenomenon termed *ion trapping*. These considerations have obvious implications for the absorption and excretion of drugs, as discussed more specifically below. The establishment of concentration gradients of weak electrolytes across membranes with a pH gradient is a physical process and does not require an active electrolyte transport system. All that is necessary is a membrane preferentially permeable to one form of the weak electrolyte and a pH gradient across the membrane. The establishment of the pH gradient, however, is an active process.

Carrier-Mediated Membrane Transport. While passive diffusion through the bilayer is dominant in the disposition of most drugs, carrier-mediated mechanisms also play an important role. *Active transport* is characterized by a direct requirement for energy, movement against an electrochemical gradient, saturability, selectivity, and competitive inhibition by cotransported compounds. Na^+, K^+ -ATPase is an active transport mechanism. Secondary active transport uses the electrochemical energy stored in a gradient to move another molecule against a concentration gradient; e.g., the $\text{Na}^+ - \text{Ca}^{2+}$ exchange protein uses the energy stored in the Na^+ gradient established by the Na^+, K^+ -ATPase to export cytosolic Ca^{2+} and maintain it at a low basal level, approximately 100 nM in most cells (see Chapter 33); similarly, the Na^+ -dependent glucose transporters SGLT1 and SGLT2 move glucose across membranes of gastrointestinal (GI) epithelium and renal tubules by coupling glucose transport to downhill Na^+ flux. *Facilitated diffusion* describes a carrier-mediated transport process in which there is no input of energy, and therefore, enhanced movement of the involved substance is down an electrochemical gradient as in the permeation of glucose across a muscle cell membrane mediated by the insulin-sensitive glucose transporter protein GLUT4. Such mechanisms, which may be highly selective for a specific conformational structure of a drug, are involved in the transport of endogenous compounds whose rate of transport by passive diffusion otherwise would be too slow. In other cases, they function as a barrier system to protect cells from potentially toxic substances. Pharmacologically important transporters may mediate either drug uptake or efflux and often facilitate vectorial transport across polarized cells. An important efflux transporter present at many sites is the P-glycoprotein encoded by the multidrug resistance-1 (*MDR1*) gene. P-glycoprotein localized in the enterocyte limits the oral absorption of transported drugs because it exports compounds back into the GI tract subsequent to their absorption by passive diffusion. The P-glycoprotein also can confer resistance to some cancer chemotherapeutic agents (see Chapter 51). The importance of P-glycoprotein in the elimination of drugs is underscored by the presence of genetic polymorphisms in *MDR1* (see Chapters 2 and 4 and Marzolini *et al.*, 2004) that can affect therapeutic drug levels. Transporters and their roles in drug action are presented in detail in Chapter 2.

DRUG ABSORPTION, BIOAVAILABILITY, AND ROUTES OF ADMINISTRATION

Absorption is the movement of a drug from its site of administration into the central compartment (Figure 1–1)

Table 1-1
Some Characteristics of Common Routes of Drug Administration*

ROUTE	ABSORPTION PATTERN	SPECIAL UTILITY	LIMITATIONS AND PRECAUTIONS
Intravenous	Absorption circumvented Potentially immediate effects Suitable for large volumes and for irritating substances, or complex mixtures, when diluted	Valuable for emergency use Permits titration of dosage Usually required for high-molecular-weight protein and peptide drugs	Increased risk of adverse effects Must inject solutions <i>slowly</i> as a rule Not suitable for oily solutions or poorly soluble substances
Subcutaneous	Prompt, from aqueous solution Slow and sustained, from repository preparations	Suitable for some poorly soluble suspensions and for instillation of slow-release implants	Not suitable for large volumes Possible pain or necrosis from irritating substances
Intramuscular	Prompt, from aqueous solution Slow and sustained, from repository preparations	Suitable for moderate volumes, oily vehicles, and some irritating substances Appropriate for self-administration (<i>e.g.</i> , insulin)	Precluded during anticoagulant therapy May interfere with interpretation of certain diagnostic tests (<i>e.g.</i> , creatine kinase)
Oral ingestion	Variable, depends on many factors (<i>see</i> text)	Most convenient and economical; usually more safe	Requires patient compliance Bioavailability potentially erratic and incomplete

*See text for more complete discussion and for other routes.

and the extent to which this occurs. For solid dosage forms, absorption first requires dissolution of the tablet or capsule, thus liberating the drug. The clinician is concerned primarily with bioavailability rather than absorption. *Bioavailability* is a term used to indicate the fractional extent to which a dose of drug reaches its site of action or a biological fluid from which the drug has access to its site of action. For example, a drug given orally must be absorbed first from the stomach and intestine, but this may be limited by the characteristics of the dosage form and the drug's physicochemical properties. In addition, drug then passes through the liver, where metabolism and biliary excretion may occur before the drug enters the systemic circulation. Accordingly, a fraction of the administered and absorbed dose of drug will be inactivated or diverted before it can reach the general circulation and be distributed to its sites of action. If the metabolic or excretory capacity of the liver for the drug is large, bioavailability will be reduced substantially (the *first-pass effect*). This decrease in availability is a function of the anatomical site from which absorption takes place; other anatomical, physio-

logical, and pathological factors can influence bioavailability (*see* below), and the choice of the route of drug administration must be based on an understanding of these conditions.

Oral (Enteral) versus Parenteral Administration. Often there is a choice of the route by which a therapeutic agent may be given, and knowledge of the advantages and disadvantages of the different routes of administration is then of primary importance. Some characteristics of the major routes employed for systemic drug effect are compared in Table 1-1.

Oral ingestion is the most common method of drug administration. It also is the safest, most convenient, and most economical. Disadvantages to the oral route include limited absorption of some drugs because of their physical characteristics (*e.g.*, water solubility), emesis as a result of irritation to the GI mucosa, destruction of some drugs by digestive enzymes or low gastric pH, irregularities in absorption or propulsion in the presence of food or other drugs, and the need for cooperation on the part of the patient. In addition, drugs in the GI tract may be metabolized by the enzymes of the intestinal flora, mucosa, or liver before they gain access to the general circulation.

The parenteral injection of drugs has certain distinct advantages over oral administration. In some instances, parenteral administration is essential for the drug to be delivered in its active form, as in

the case of monoclonal antibodies such as *infliximab*, an antibody against tumor necrosis factor α (TNF- α) used in the treatment of rheumatoid arthritis. Availability usually is more rapid, extensive, and predictable when a drug is given by injection. The effective dose therefore can be delivered more accurately. In emergency therapy and when a patient is unconscious, uncooperative, or unable to retain anything given by mouth, parenteral therapy may be a necessity. The injection of drugs, however, has its disadvantages: Asepsis must be maintained, and this is of particular concern when drugs are given over time, such as in intravenous or intrathecal administration; pain may accompany the injection; and it is sometimes difficult for patients to perform the injections themselves if self-medication is necessary.

Oral Ingestion. Absorption from the GI tract is governed by factors such as surface area for absorption, blood flow to the site of absorption, the physical state of the drug (solution, suspension, or solid dosage form), its water solubility, and the drug's concentration at the site of absorption. For drugs given in solid form, the rate of dissolution may be the limiting factor in their absorption, especially if they have low water solubility. Since most drug absorption from the GI tract occurs by passive diffusion, absorption is favored when the drug is in the nonionized and more lipophilic form. Based on the pH-partition concept (Figure 1-2), one would predict that drugs that are weak acids would be better absorbed from the stomach (pH 1 to 2) than from the upper intestine (pH 3 to 6), and *vice versa* for weak bases. However, the epithelium of the stomach is lined with a thick mucous layer, and its surface area is small; by contrast, the villi of the upper intestine provide an extremely large surface area (approximately 200 m²). Accordingly, the rate of absorption of a drug from the intestine will be greater than that from the stomach even if the drug is predominantly ionized in the intestine and largely nonionized in the stomach. Thus, any factor that accelerates gastric emptying will be likely to increase the rate of drug absorption, whereas any factor that delays gastric emptying is expected to have the opposite effect, regardless of the characteristics of the drug. Gastric emptying is influenced in women by the effects of estrogen (*i.e.*, slower than in men for premenopausal women and those taking estrogen in replacement therapy).

Drugs that are destroyed by gastric secretions or that cause gastric irritation sometimes are administered in dosage forms with an enteric coating that prevents dissolution in the acidic gastric contents. However, some enteric-coated preparations of a drug also may resist dissolution in the intestine, reducing drug absorption. The use of enteric coatings is nonetheless helpful for drugs such as *aspirin* that can cause significant gastric irritation in many patients.

Controlled-Release Preparations. The rate of absorption of a drug administered as a tablet or other solid oral dosage form is partly dependent on its rate of dissolution in GI fluids. This is the basis for *controlled-release*, *extended-release*, *sustained-release*, and *prolonged-action* pharmaceutical preparations that are designed to produce slow, uniform absorption of the drug for 8 hours or longer. Such preparations are offered for medications in all major drug categories. Potential advantages of such preparations are reduction in the frequency of administration of the drug as compared with conventional dosage forms (possibly with improved compliance by the patient), maintenance of a therapeutic effect overnight, and decreased incidence and/or intensity of both undesired effects (by elimination of the peaks in drug concentration) and nontherapeutic blood levels of the drug (by elimination of troughs

in concentration) that often occur after administration of immediate-release dosage forms.

Many controlled-release preparations fulfill these expectations and may be preferred in some therapeutic situations such as antidepressant therapy (Nemeroff, 2003) or treatment with dihydropyridine Ca²⁺ entry blockers (*see* Chapter 32). However, such products have some drawbacks. Generally, interpatient variability in terms of the systemic concentration of the drug that is achieved is greater for controlled-release than for immediate-release dosage forms. During repeated drug administration, trough drug concentrations resulting from controlled-release dosage forms may not be different from those observed with immediate-release preparations, although the time interval between trough concentrations is greater for a well-designed controlled-release product. It is possible that the dosage form may fail, and "dose dumping" with resulting toxicity can occur because the total dose of drug ingested at one time may be several times the amount contained in the conventional preparation. Factors that may contribute to dose dumping for certain controlled-release preparations include stomach acidity and administration along with a high-fat meal. Controlled-release dosage forms are most appropriate for drugs with short half-lives (<4 hours). So-called controlled-release dosage forms are sometimes developed for drugs with long half-lives (>12 hours). These usually more expensive products should not be prescribed unless specific advantages have been demonstrated.

Sublingual Administration. Absorption from the oral mucosa has special significance for certain drugs despite the fact that the surface area available is small. Venous drainage from the mouth is to the superior vena cava, which protects the drug from rapid hepatic first-pass metabolism. For example, *nitroglycerin* is effective when retained sublingually because it is nonionic and has very high lipid solubility. Thus, the drug is absorbed very rapidly. Nitroglycerin also is very potent; relatively few molecules need to be absorbed to produce the therapeutic effect. If a tablet of nitroglycerin were swallowed, the accompanying hepatic metabolism would be sufficient to prevent the appearance of any active nitroglycerin in the systemic circulation.

Transdermal Absorption. Not all drugs readily penetrate the intact skin. Absorption of those that do is dependent on the surface area over which they are applied and their lipid solubility because the epidermis behaves as a lipid barrier (*see* Chapter 63). The dermis, however, is freely permeable to many solutes; consequently, systemic absorption of drugs occurs much more readily through abraded, burned, or denuded skin. Inflammation and other conditions that increase cutaneous blood flow also enhance absorption. Toxic effects sometimes are produced by absorption through the skin of highly lipid-soluble substances (*e.g.*, a lipid-soluble insecticide in an organic solvent). Absorption through the skin can be enhanced by suspending the drug in an oily vehicle and rubbing the resulting preparation into the skin. Because hydrated skin is more permeable than dry skin, the dosage form may be modified or an occlusive dressing may be used to facilitate absorption. Controlled-release topical patches have become increasingly available, including *nicotine* for tobacco-smoking withdrawal, *scopolamine* for motion sickness, nitroglycerin for angina pectoris, *testosterone* and *estrogen* for replacement therapy, and various estrogens and progestins for birth control.

Rectal Administration. The rectal route often is useful when oral ingestion is precluded because the patient is unconscious or when vomiting is present—a situation particularly relevant to young children. Approximately 50% of the drug that is absorbed from the rec-

tum will bypass the liver; the potential for hepatic first-pass metabolism thus is less than that for an oral dose. However, rectal absorption often is irregular and incomplete, and many drugs can cause irritation of the rectal mucosa.

Parenteral Injection. The major routes of parenteral administration are intravenous, subcutaneous, and intramuscular. Absorption from subcutaneous and intramuscular sites occurs by simple diffusion along the gradient from drug depot to plasma. The rate is limited by the area of the absorbing capillary membranes and by the solubility of the substance in the interstitial fluid. Relatively large aqueous channels in the endothelial membrane account for the indiscriminate diffusion of molecules regardless of their lipid solubility. Larger molecules, such as proteins, slowly gain access to the circulation by way of lymphatic channels.

Drugs administered into the systemic circulation by any route, excluding the intraarterial route, are subject to possible first-pass elimination in the lung prior to distribution to the rest of the body. The lungs serve as a temporary storage site for a number of agents, especially drugs that are weak bases and are predominantly nonionized at the blood pH, apparently by their partition into lipid. The lungs also serve as a filter for particulate matter that may be given intravenously, and they provide a route of elimination for volatile substances.

Intravenous. Factors relevant to absorption are circumvented by intravenous injection of drugs in aqueous solution because bioavailability is complete and rapid. Also, drug delivery is controlled and achieved with an accuracy and immediacy not possible by any other procedure. In some instances, as in the induction of surgical anesthesia, the dose of a drug is not predetermined but is adjusted to the response of the patient. Also, certain irritating solutions can be given only in this manner because the drug, if injected slowly, is greatly diluted by the blood.

There are both advantages and disadvantages to the use of this route of administration. Unfavorable reactions can occur because high concentrations of drug may be attained rapidly in both plasma and tissues. There are therapeutic circumstances where it is advisable to administer a drug by bolus injection (small volume given rapidly, *e.g.*, *tissue plasminogen activator* immediately following an acute myocardial infarction) and other circumstances where slower administration of drug is advisable, such as the delivery of drugs by intravenous “piggy-back” (*e.g.*, antibiotics). Intravenous administration of drugs warrants close monitoring of the patient’s response. Furthermore, once the drug is injected, there is often no retreat. Repeated intravenous injections depend on the ability to maintain a patent vein. Drugs in an oily vehicle, those that precipitate blood constituents or hemolyze erythrocytes, and drug combinations that cause precipitates to form must not be given by this route.

Subcutaneous. Injection of a drug into a subcutaneous site can be used only for drugs that are not irritating to tissue; otherwise, severe pain, necrosis, and tissue sloughing may occur. The rate of absorption following subcutaneous injection of a drug often is sufficiently constant and slow to provide a sustained effect. Moreover, altering the period over which a drug is absorbed may be varied intentionally, as is accomplished with *insulin* for injection using particle size, protein complexation, and pH to provide short- (3 to 6 hours), intermediate- (10 to 18 hours), and long-acting (18 to 24 hours) preparations. The incorporation of a vasoconstrictor agent in a solution of a drug to be injected subcutaneously also retards absorption. Thus, the injectable local anesthetic *lidocaine* incorporates *epinephrine* into the dosage form. Absorption of drugs

implanted under the skin in a solid pellet form occurs slowly over a period of weeks or months; some hormones (*e.g.*, contraceptives) are administered effectively in this manner.

Intramuscular. Drugs in aqueous solution are absorbed quite rapidly after intramuscular injection depending on the rate of blood flow to the injection site. This may be modulated to some extent by local heating, massage, or exercise. For example, while absorption of insulin generally is more rapid from injection in the arm and abdominal wall than the thigh, jogging may cause a precipitous drop in blood sugar when insulin is injected into the thigh rather than into the arm or abdominal wall because running markedly increases blood flow to the leg. A hot bath accelerates absorption from all these sites owing to vasodilation. Generally, the rate of absorption following injection of an aqueous preparation into the deltoid or vastus lateralis is faster than when the injection is made into the gluteus maximus. The rate is particularly slower for females after injection into the gluteus maximus. This has been attributed to the different distribution of subcutaneous fat in males and females and because fat is relatively poorly perfused. Very obese or emaciated patients may exhibit unusual patterns of absorption following intramuscular or subcutaneous injection. Slow, constant absorption from the intramuscular site results if the drug is injected in solution in oil or suspended in various other repository (*depot*) vehicles. Antibiotics often are administered in this manner. Substances too irritating to be injected subcutaneously sometimes may be given intramuscularly.

Intraarterial. Occasionally, a drug is injected directly into an artery to localize its effect in a particular tissue or organ, such as in the treatment of liver tumors and head/neck cancers. Diagnostic agents sometimes are administered by this route (*e.g.*, *technetium-labeled human serum albumin*). Intraarterial injection requires great care and should be reserved for experts. The first-pass and cleansing effects of the lung are not available when drugs are given by this route.

Intrathecal. The blood–brain barrier and the blood–cerebrospinal fluid (CSF) barrier often preclude or slow the entrance of drugs into the CNS. Therefore, when local and rapid effects of drugs on the meninges or cerebrospinal axis are desired, as in spinal anesthesia or treatment of acute CNS infections, drugs sometimes are injected directly into the spinal subarachnoid space. Brain tumors also may be treated by direct intraventricular drug administration.

Pulmonary Absorption. Provided that they do not cause irritation, gaseous and volatile drugs may be inhaled and absorbed through the pulmonary epithelium and mucous membranes of the respiratory tract. Access to the circulation is rapid by this route because the lung’s surface area is large. The principles governing absorption and excretion of anesthetic and other therapeutic gases are discussed in Chapters 13 and 15.

In addition, solutions of drugs can be atomized and the fine droplets in air (aerosol) inhaled. Advantages are the almost instantaneous absorption of a drug into the blood, avoidance of hepatic first-pass loss, and in the case of pulmonary disease, local application of the drug at the desired site of action. For example, owing to the ability to meter doses and create fine aerosols, drugs can be given in this manner for the treatment of allergic rhinitis or bronchial asthma (*see* Chapter 27). Pulmonary absorption is an important route of entry of certain drugs of abuse and of toxic environmental substances of varied composition and physical states. Both local and systemic reactions to allergens may occur subsequent to inhalation.

Topical Application. Mucous Membranes. Drugs are applied to the mucous membranes of the conjunctiva, nasopharynx, oropharynx,

vagina, colon, urethra, and urinary bladder primarily for their local effects. Occasionally, as in the application of synthetic *antidiuretic hormone* to the nasal mucosa, systemic absorption is the goal. Absorption through mucous membranes occurs readily. In fact, local anesthetics applied for local effect sometimes may be absorbed so rapidly that they produce systemic toxicity.

Eye. Topically applied ophthalmic drugs are used primarily for their local effects (see Chapter 63). Systemic absorption that results from drainage through the nasolacrimal canal is usually undesirable. Because drug that is absorbed *via* drainage is not subject to first-pass hepatic metabolism, unwanted systemic pharmacological effects may occur when β adrenergic receptor antagonists or corticosteroids are administered as ophthalmic drops. Local effects usually require absorption of the drug through the cornea; corneal infection or trauma thus may result in more rapid absorption. Ophthalmic delivery systems that provide prolonged duration of action (e.g., suspensions and ointments) are useful additions to ophthalmic therapy. Ocular inserts, such as the use of *pilocarpine*-containing inserts for the treatment of glaucoma, provide continuous delivery of small amounts of drug. Very little is lost through drainage; hence systemic side effects are minimized.

Novel Methods of Drug Delivery. Drug-eluting stents and other devices are being used to target drugs locally and minimize systemic exposure. The toxicity of potentially important compounds can be decreased significantly by combination with a variety of drug carrier vehicles that modify distribution. For example, the cytotoxic agent *calicheamicin*, when linked to an antibody directed to an antigen found on the surface of certain leukemic cells, can target drug to its intended site of action, improving the therapeutic index of calicheamicin.

Recent advances in drug delivery include the use of biocompatible polymers with functional monomers attached in such a way as to permit linkage of drug molecules to the polymer.

A drug-polymer conjugate can be designed to be a stable, long-circulating prodrug by varying the molecular weight of the polymer and the cleavable linkage between the drug and the polymer. The linkage is designed to keep the drug inactive until it released from the backbone polymer by a disease-specific trigger, typically enzyme activity in the targeted tissue that delivers the active drug at or near the site of pathology.

Bioequivalence. Drug products are considered to be pharmaceutical equivalents if they contain the same active ingredients and are identical in strength or concentration, dosage form, and route of administration. Two pharmaceutically equivalent drug products are considered to be *bioequivalent* when the rates and extents of bioavailability of the active ingredient in the two products are not significantly different under suitable test conditions. In the past, dosage forms of a drug from different manufacturers and even different lots of preparations from a single manufacturer sometimes differed in their bioavailability. Such differences were seen primarily among oral dosage forms of poorly soluble, slowly absorbed drugs such as the urinary anti-infective *metronidazole* (FLAGYL). When first introduced, the generic form was not bioequivalent because the generic manufacturer was not able to mimic the proprietary process used to microsize the drug for absorption initially. Differences in crystal form, particle size, or other physical characteristics of the drug that are not rigidly controlled in formulation and manufacture affect disintegration of the dosage form and dissolution of the drug and hence the rate and extent of drug absorption.

The potential nonequivalence of different drug preparations has been a matter of concern. Strengthened regulatory requirements have resulted in few, if any, documented cases of nonequivalence between approved drug products in recent years. The significance of possible nonequivalence of drug preparations is further discussed in connection with drug nomenclature and the choice of drug name in writing prescription orders (see Appendix I).

DISTRIBUTION OF DRUGS

Following absorption or systemic administration into the bloodstream, a drug distributes into interstitial and intracellular fluids. This process reflects a number of physiological factors and the particular physicochemical properties of the individual drug. Cardiac output, regional blood flow, capillary permeability, and tissue volume determine the rate of delivery and potential amount of drug distributed into tissues. Initially, liver, kidney, brain, and other well-perfused organs receive most of the drug, whereas delivery to muscle, most viscera, skin, and fat is slower. This second distribution phase may require minutes to several hours before the concentration of drug in tissue is in equilibrium with that in blood. The second phase also involves a far larger fraction of body mass than does the initial phase and generally accounts for most of the extravascularly distributed drug. With exceptions such as the brain, diffusion of drug into the interstitial fluid occurs rapidly because of the highly permeable nature of the capillary endothelial membrane. Thus, tissue distribution is determined by the partitioning of drug between blood and the particular tissue. Lipid solubility and transmembrane pH gradients are important determinants of such uptake for drugs that are either weak acids or bases. However, in general, ion trapping associated with transmembrane pH gradients is not large because the pH difference between tissue and blood (approximately 7.0 *versus* 7.4) is small. The more important determinant of blood-tissue partitioning is the relative binding of drug to plasma proteins and tissue macromolecules.

Plasma Proteins. Many drugs circulate in the bloodstream bound to plasma proteins. Albumin is a major carrier for acidic drugs; α_1 -acid glycoprotein binds basic drugs. Nonspecific binding to other plasma proteins generally occurs to a much smaller extent. The binding is usually reversible; covalent binding of reactive drugs such as alkylating agents occurs occasionally. In addition to the binding of drugs to carrier proteins such as albumin, certain drugs may bind to proteins that function as specific hormone carrier proteins, such as the binding of estrogen or testosterone to sex hormone-binding globulin or the binding of *thyroid hormone* to thyroxin-binding globulin.

The fraction of total drug in plasma that is bound is determined by the drug concentration, the affinity of binding sites for the drug, and the number of binding sites. Mass-action relationships determine the unbound and bound concentrations (*see* below). At low concentrations of drug (less than the plasma protein binding dissociation constant), the fraction bound is a function of the concentration of binding sites and the dissociation constant. At high drug concentrations (greater than the dissociation constant), the fraction bound is a function of the number of binding sites and the drug concentration. Therefore, plasma binding is a nonlinear, saturable process. For most drugs, the therapeutic range of plasma concentrations is limited; thus the extent of binding and the unbound fraction are relatively constant. The percentage values listed for protein binding in Appendix II refer to binding in the therapeutic range unless otherwise indicated. The extent of plasma protein binding also may be affected by disease-related factors. For example, hypoalbuminemia secondary to severe liver disease or the nephrotic syndrome results in reduced binding and an increase in the unbound fraction. Also, conditions resulting in the acute-phase reaction response (*e.g.*, cancer, arthritis, myocardial infarction, and Crohn's disease) lead to elevated levels of α_1 -acid glycoprotein and enhanced binding of basic drugs.

Because binding of drugs to plasma proteins such as albumin is nonselective, and because the number of binding sites is relatively large (high capacity), many drugs with similar physicochemical characteristics can compete with each other and with endogenous substances for these binding sites, resulting in noticeable displacement of one drug by another. For example, displacement of unconjugated bilirubin from binding to albumin by the sulfonamides and other organic anions is known to increase the risk of bilirubin encephalopathy in the newborn. Drug toxicities based on competition between drugs for binding sites is not of clinical concern for most therapeutic agents. Since drug responses, both efficacious and toxic, are a function of the concentrations of unbound drug, steady-state unbound concentrations will change significantly only when either drug input (dosing rate) or clearance of unbound drug is changed [*see* Equation (1–2) and discussion below]. Thus, steady-state unbound concentrations are independent of the extent of protein binding. However, for narrow-therapeutic-index drugs, a transient change in unbound concentrations occurring immediately following the dose of a competing drug could be of concern, such as with the anticoagulant *warfarin*. A more common problem resulting from competition of drugs for plasma protein binding sites is misinterpretation of measured concentrations of drugs in plasma because most assays do not distinguish free drug from bound drug.

Importantly, binding of a drug to plasma proteins limits its concentration in tissues and at its site of action because only unbound drug is in equilibrium across membranes. Accordingly, after distri-

bution equilibrium is achieved, the concentration of active, unbound drug in intracellular water is the same as that in plasma except when carrier-mediated transport is involved. Binding of a drug to plasma protein also limits the drug's glomerular filtration because this process does not immediately change the concentration of free drug in the plasma (water is also filtered). However, plasma protein binding generally does not limit renal tubular secretion or biotransformation because these processes lower the free drug concentration, and this is followed rapidly by dissociation of drug from the drug-protein complex, thereby reestablishing equilibrium between bound and free drug. Drug transport and metabolism also are limited by binding to plasma proteins, except when these are especially efficient, and drug clearance, calculated on the basis of unbound drug, exceeds organ plasma flow.

Tissue Binding. Many drugs accumulate in tissues at higher concentrations than those in the extracellular fluids and blood. For example, during long-term administration of the antimalarial agent *quinacrine*, the concentration of drug in the liver may be several thousandfold higher than that in the blood. Such accumulation may be a result of active transport or, more commonly, binding. Tissue binding of drugs usually occurs with cellular constituents such as proteins, phospholipids, or nuclear proteins and generally is reversible. A large fraction of drug in the body may be bound in this fashion and serve as a reservoir that prolongs drug action in that same tissue or at a distant site reached through the circulation. Such tissue binding and accumulation also can produce local toxicity, as in the case of the accumulation of the aminoglycoside antibiotic *gentamicin* in the kidney and vestibular system.

Fat as a Reservoir. Many lipid-soluble drugs are stored by physical solution in the neutral fat. In obese persons, the fat content of the body may be as high as 50%, and even in lean individuals it constitutes 10% of body weight; hence fat may serve as a reservoir for lipid-soluble drugs. For example, as much as 70% of the highly lipid-soluble barbiturate *thiopental* may be present in body fat 3 hours after administration. Fat is a rather stable reservoir because it has a relatively low blood flow. However, among highly lipophilic drugs (*e.g.*, *remifentanyl* and some β blockers), the degree of lipophilicity does not predict their distribution in obese individuals.

Bone. The *tetracycline* antibiotics (and other divalent metal-ion chelating agents) and heavy metals may accumulate in bone by adsorption onto the bone crystal surface and eventual incorporation into the crystal lattice. Bone can become a reservoir for the slow release of toxic agents such as lead or radium into the blood; their effects thus can persist long after exposure has ceased. Local destruction of the bone medulla also may lead to reduced blood flow and prolongation of the reservoir effect because the toxic agent becomes sealed off from the circulation; this may further enhance the direct local damage to the bone. A vicious cycle results, whereby the greater the exposure to the toxic agent, the slower is its rate of elimination. The adsorption of drug onto the bone crystal surface and incorporation into the crystal lattice have therapeutic advantag-

es for the treatment of osteoporosis. Phosphonates such as *sodium etidronate* bind tightly to hydroxyapatite crystals in mineralized bone matrix. However, unlike naturally occurring pyrophosphates, etidronate is resistant to degradation by pyrophosphatases and thus stabilizes the bone matrix.

Redistribution. Termination of drug effect after withdrawal of a drug usually is by metabolism and excretion but also may result from redistribution of the drug from its site of action into other tissues or sites. Redistribution is a factor in terminating drug effect primarily when a highly lipid-soluble drug that acts on the brain or cardiovascular system is administered rapidly by intravenous injection or by inhalation. A good example of this is the use of the intravenous anesthetic thiopental, a highly lipid-soluble drug. Because blood flow to the brain is so high, the drug reaches its maximal concentration in brain within a minute of its intravenous injection. After injection is concluded, the plasma concentration falls as thiopental diffuses into other tissues, such as muscle. The concentration of the drug in brain follows that of the plasma because there is little binding of the drug to brain constituents. Thus, in this example, the onset of anesthesia is rapid, but so is its termination. Both are related directly to the concentration of drug in the brain.

Central Nervous System and Cerebrospinal Fluid.

The distribution of drugs into the CNS from the blood is unique. One reason for this is that the brain capillary endothelial cells have continuous tight junctions; therefore, drug penetration into the brain depends on transcellular rather than paracellular transport. The unique characteristics of brain capillary endothelial cells and pericapillary glial cells constitute the blood–brain barrier. At the choroid plexus, a similar blood–CSF barrier is present except that it is epithelial cells that are joined by tight junctions rather than endothelial cells. The lipid solubility of the nonionized and unbound species of a drug is therefore an important determinant of its uptake by the brain; the more lipophilic a drug is, the more likely it is to cross the blood–brain barrier. This situation often is used in drug design to alter drug distribution to the brain; *e.g.*, the so-called second-generation antihistamines, such as *loratidine*, achieve far lower brain concentrations than do agents such as *diphenhydramine* and thus are nonsedating. Drugs may penetrate into the CNS by specific uptake transporters normally involved in the transport of nutrients and endogenous compounds from blood into the brain and CSF.

Another important factor in the functional blood–brain barrier involves membrane transporters that are

efflux carriers present in the brain capillary endothelial cell and capable of removing a large number of chemically diverse drugs from the cell. P-glycoprotein (P-gp, encoded by the *MDR1* gene) and the organic anion-transporting polypeptide (OATP) are two of the more notable of these. The effects of these exporters are to dramatically limit access of the drug to the tissue expressing the efflux transporter. Together, P-gp and the OATP family export a large array of structurally diverse drugs (Kim, 2003) (*see* Chapter 2). Expression of OATP isoforms in the GI tract, liver, and kidney, as well as the blood–brain barrier, has important implications for drug absorption and elimination, as well as tissue penetration. Expression of these efflux transporters accounts for the relatively restricted pharmacological access to the brain and other tissues such as the testes, where drug concentrations may be below those necessary to achieve a desired effect despite adequate blood flow. This situation occurs with HIV protease inhibitors and with *loperamide*, a potent, systemically active opioid that lacks any central effects characteristic of other opioids (*see* Chapter 21). Efflux transporters that actively secrete drug from the CSF into the blood also are present in the choroid plexus (*see* Chapters 2 and 3 for details of the contribution of drug transporters to barrier function). Drugs also may exit the CNS along with the bulk flow of CSF through the arachnoid villi. In general, the blood–brain barrier's function is well maintained; however, meningeal and encephalic inflammation increase local permeability. Recently, blood–brain barrier disruption has emerged as a treatment for certain brain tumors such as primary CNS lymphomas (Tyson *et al.*, 2003). The goal of this treatment is to enhance delivery of chemotherapy to the brain tumor while maintaining cognitive function that is often damaged by conventional radiotherapy (Dahlborg *et al.*, 1998).

Placental Transfer of Drugs. The transfer of drugs across the placenta is of critical importance because drugs may cause anomalies in the developing fetus. Administered immediately before delivery, as is often the case with the use of tocolytics in the treatment of preterm labor, they also may have adverse effects on the neonate. Lipid solubility, extent of plasma binding, and degree of ionization of weak acids and bases are important general determinants in drug transfer across the placenta. The fetal plasma is slightly more acidic than that of the mother (pH 7.0 to 7.2 *versus* 7.4), so that ion trapping of basic drugs occurs. As in the brain, P-gp and other export transporters are present in the placenta and function to limit fetal exposure to potentially toxic agents. The view that the

placenta is an absolute barrier to drugs is, however, completely inaccurate (Holcberg *et al.*, 2003), in part because a number of influx transporters are also present (Unadkat *et al.*, 2004). The fetus is to some extent exposed to all drugs taken by the mother.

EXCRETION OF DRUGS

Drugs are eliminated from the body either unchanged by the process of excretion or converted to metabolites. Excretory organs, the lung excluded, eliminate polar compounds more efficiently than substances with high lipid solubility. Lipid-soluble drugs thus are not readily eliminated until they are metabolized to more polar compounds.

The kidney is the most important organ for excreting drugs and their metabolites. Substances excreted in the feces are principally unabsorbed orally ingested drugs or drug metabolites excreted either in the bile or secreted directly into the intestinal tract and not reabsorbed. Excretion of drugs in breast milk is important not because of the amounts eliminated, but because the excreted drugs are potential sources of unwanted pharmacological effects in the nursing infant. Excretion from the lung is important mainly for the elimination of anesthetic gases (*see* Chapter 13).

Renal Excretion. Excretion of drugs and metabolites in the urine involves three distinct processes: glomerular filtration, active tubular secretion, and passive tubular reabsorption. Changes in overall renal function generally affect all three processes to a similar extent. Even in healthy persons, renal function is not constant. In neonates, renal function is low compared with body mass but matures rapidly within the first few months after birth. During adulthood, there is a slow decline in renal function, about 1% per year, so that in elderly patients a substantial degree of functional impairment may be present.

The amount of drug entering the tubular lumen by filtration depends on the glomerular filtration rate and the extent of plasma binding of the drug; only unbound drug is filtered. In the proximal renal tubule, active, carrier-mediated tubular secretion also may add drug to the tubular fluid. Transporters such as P-gp and the multi-drug-resistance-associated protein type 2 (MRP2), localized in the apical brush-border membrane, are responsible for the secretion of amphipathic anions and conjugated metabolites (such as glucuronides, sulfates,

and glutathione adducts), respectively (*see* Chapters 2 and 3). ATP-binding cassette (ABC) transporters that are more selective for organic cationic drugs are involved in the secretion of organic bases. Membrane transporters, mainly located in the distal renal tubule, also are responsible for any active reabsorption of drug from the tubular lumen back into the systemic circulation. However, most of such reabsorption occurs by nonionic diffusion.

In the proximal and distal tubules, the nonionized forms of weak acids and bases undergo net passive reabsorption. The concentration gradient for back-diffusion is created by the reabsorption of water with Na⁺ and other inorganic ions. Since the tubular cells are less permeable to the ionized forms of weak electrolytes, passive reabsorption of these substances depends on the pH. When the tubular urine is made more alkaline, weak acids are largely ionized and thus are excreted more rapidly and to a greater extent. When the tubular urine is made more acidic, the fraction of drug ionized is reduced, and excretion is likewise reduced. Alkalinization and acidification of the urine have the opposite effects on the excretion of weak bases. In the treatment of drug poisoning, the excretion of some drugs can be hastened by appropriate alkalinization or acidification of the urine. Whether or not alteration of urine pH results in a significant change in drug elimination depends on the extent and persistence of the pH change and the contribution of pH-dependent passive reabsorption to total drug elimination. The effect is greatest for weak acids and bases with pK_a values in the range of urinary pH (5 to 8). However, alkalinization of urine can produce a four- to sixfold increase in excretion of a relatively strong acid such as salicylate when urinary pH is changed from 6.4 to 8.0 and the fraction of nonionized drug is reduced from 1% to 0.04%.

Biliary and Fecal Excretion. Transporters analogous to those in the kidney also are present in the canalicular membrane of the hepatocyte, and these actively secrete drugs and metabolites into bile. P-gp transports a plethora of amphipathic lipid-soluble drugs, whereas MRP2 is mainly involved in the secretion of conjugated metabolites of drugs (*e.g.*, glutathione conjugates, glucuronides, and some sulfates). Ultimately, drugs and metabolites present in bile are released into the GI tract during the digestive process. Because secretory transporters also are expressed on the apical membrane of enterocytes, direct secretion of drugs and metabolites may occur from the systemic circulation into the intestinal lumen. Subsequently, drugs and metabolites can be reabsorbed back into the body from the intestine, which, in the case of conjugated metabolites such as glucuronides, may require their enzymatic hydrolysis by the intestinal microflora. Such enterohepatic recycling, if extensive, may prolong significantly the presence of a drug (or toxin) and its effects within

the body prior to elimination by other pathways. For this reason, drugs may be given orally to bind substances excreted in the bile. For example, in the case of mercury poisoning, a resin can be administered orally that binds with dimethylmercury excreted in the bile, thus preventing reabsorption and further toxicity. Enterohepatic recycling also can be an advantage in the design of drugs. *Ezetimibe* is the first of a new class of drugs that specifically reduces the intestinal absorption of cholesterol (Lipka, 2003). The drug is absorbed into the intestinal epithelial cell, where it is believed to interfere with the sterol transporter system. This prevents both free cholesterol and plant sterols (phytosterols) from being transported into the cell from the intestinal lumen. The drug is absorbed rapidly and glucuronidated in the intestinal cell before secretion into the blood. Ezetimibe is avidly taken up by the liver from the portal blood and excreted into the bile, resulting in low peripheral blood concentrations. The glucuronide conjugate is hydrolyzed and absorbed and is equally effective in inhibiting sterol absorption. This enterohepatic recycling is responsible for a half-life in the body of more than 20 hours. The principal benefit is a reduction in low-density lipoprotein cholesterol (*see* Chapter 35).

Excretion by Other Routes. Excretion of drugs into sweat, saliva, and tears is quantitatively unimportant. Elimination by these routes depends mainly on diffusion of the nonionized lipid-soluble form of drugs through the epithelial cells of the glands and depends on the pH. Drugs excreted in the saliva enter the mouth, where they are usually swallowed. The concentration of some drugs in saliva parallels that in plasma. Saliva therefore may be a useful biological fluid in which to determine drug concentrations when it is difficult or inconvenient to obtain blood. The same principles apply to excretion of drugs in breast milk. Since milk is more acidic than plasma, basic compounds may be slightly concentrated in this fluid; conversely, the concentration of acidic compounds in the milk is lower than in plasma. Nonelectrolytes, such as *ethanol* and *urea*, readily enter breast milk and reach the same concentration as in plasma, independent of the pH of the milk. Thus, the administration of drugs to breast-feeding women carries the general caution that the suckling infant will be exposed to some extent to the medication and/or its metabolites. In certain cases, such as treatment with the β blocker *atenolol*, the infant may be exposed to significant amounts of drug (Ito and Lee, 2003). Although excretion into hair and skin is quantitatively unimportant, sensitive methods of detection of drugs in these tissues have forensic significance.

METABOLISM OF DRUGS

The lipophilic characteristics of drugs that promote their passage through biological membranes and subsequent access to their site of action also serve to hinder their excretion from the body. Renal excretion of unchanged drug plays only a modest role in the overall elimination of most therapeutic agents because lipophilic compounds filtered through the glomerulus are largely reabsorbed into the systemic circulation during passage through the renal tubules. The metabolism of drugs and

other xenobiotics into more hydrophilic metabolites is essential for their elimination from the body, as well as for termination of their biological and pharmacological activity. In general, biotransformation reactions generate more polar, inactive metabolites that are readily excreted from the body. However, in some cases, metabolites with potent biological activity or toxic properties are generated. Many of the enzyme systems that transform drugs to inactive metabolites also generate biologically active metabolites of endogenous compounds, as in steroid biosynthesis.

Drug metabolism or biotransformation reactions are classified as either phase I functionalization reactions or phase II biosynthetic (conjugation) reactions. Phase I reactions introduce or expose a functional group on the parent compound such as occurs in hydrolysis reactions. Phase I reactions generally result in the loss of pharmacological activity, although there are examples of retention or enhancement of activity. In rare instances, metabolism is associated with an altered pharmacological activity. *Prodrugs* are pharmacologically inactive compounds designed to maximize the amount of the active species that reaches its site of action. Inactive prodrugs are converted rapidly to biologically active metabolites often by the hydrolysis of an ester or amide linkage. Such is the case with a number of angiotensin-converting enzyme (ACE) inhibitors employed in the management of high blood pressure. *Enalapril*, for instance, is relatively inactive until converted by esterase activity to the diacid enalaprilat. If not excreted rapidly into the urine, the products of phase I biotransformation reactions then can react with endogenous compounds to form a highly water-soluble conjugate.

Phase II conjugation reactions lead to the formation of a covalent linkage between a functional group on the parent compound or phase I metabolite and endogenously derived glucuronic acid, sulfate, glutathione, amino acids, or acetate. These highly polar conjugates generally are inactive and are excreted rapidly in the urine and feces. An example of an active conjugate is the 6-glucuronide metabolite of *morphine*, which is a more potent analgesic than its parent.

The enzyme systems involved in the biotransformation of drugs are localized primarily in the liver, although every tissue examined has some metabolic activity. Other organs with significant metabolic capacity include the GI tract, kidneys, and lungs. Following oral administration of a drug, a significant portion of the dose may be metabolically inactivated in either the intestinal epithelium or the liver before the drug reaches the systemic circulation. This so-called first-pass metabolism significantly limits the oral availability of highly metabolized drugs. Within a given cell, most drug-metabolizing activity is found in the smooth endoplasmic reticulum and the cytosol, although drug biotransformations also can occur in the mitochondria, nuclear envelope, and plasma membrane. The enzyme systems involved in phase I reactions are located primarily in the endoplasmic reticulum, whereas the phase II conjugation enzyme systems are mainly cytosolic. Often, drugs biotransformed through a phase I reaction in the endoplasmic reticulum are conjugated at this same site or in the cytosolic fraction of the same cell in a sequential fashion. These biotransforming reactions are carried out by cytochrome P450

isoforms (CYPs) and by a variety of transferases. These enzyme families, the major reactions they catalyze, and their role in drug metabolism and adverse drug responses are presented in detail in Chapter 3.

CLINICAL PHARMACOKINETICS

The fundamental tenet of clinical pharmacokinetics is that a relationship exists between the pharmacological effects of a drug and an accessible concentration of the drug (*e.g.*, in blood or plasma). This relationship has been documented for many drugs and is of benefit in the therapeutic management of patients. For some drugs, no clear or simple relationship has been found between pharmacological effect and concentration in plasma, whereas for other drugs, routine measurement of drug concentration is impractical as part of therapeutic monitoring. In most cases, as depicted in Figure 1–1, the concentration of drug at its sites of action will be related to the concentration of drug in the systemic circulation. The pharmacological effect that results may be the clinical effect desired, a toxic effect, or in some cases an effect unrelated to the known therapeutic efficacy or toxicity. Clinical pharmacokinetics attempts to provide both a quantitative relationship between dose and effect and a framework within which to interpret measurements of concentrations of drugs in biological fluids for the benefit of the patient. The importance of pharmacokinetics in patient care is based on the improvement in therapeutic efficacy and the avoidance of unwanted effects that can be attained by application of its principles when dosage regimens are chosen and modified.

The physiological and pathophysiological variables that dictate adjustment of dosage in individual patients often do so as a result of modification of pharmacokinetic parameters. The four most important parameters governing drug disposition are *clearance*, a measure of the body's efficiency in eliminating drug; *volume of distribution*, a measure of the apparent space in the body available to contain the drug; *elimination half-life*, a measure of the rate of removal of drug from the body; and *bioavailability*, the fraction of drug absorbed as such into the systemic circulation.

Clearance

Clearance is the most important concept to consider when designing a rational regimen for long-term drug administration. The clinician usually wants to maintain

steady-state concentrations of a drug within a *therapeutic window* associated with therapeutic efficacy and a minimum of toxicity for a given agent. Assuming complete bioavailability, the steady-state concentration of drug in the body will be achieved when the rate of drug elimination equals the rate of drug administration. Thus:

$$\text{Dosing rate} = CL \cdot C_{ss} \quad (1-2)$$

where CL is clearance of drug from the systemic circulation and C_{ss} is the steady-state concentration of drug. If the desired steady-state concentration of drug in plasma or blood is known, the rate of clearance of drug by the patient will dictate the rate at which the drug should be administered.

The concept of clearance is extremely useful in clinical pharmacokinetics because its value for a particular drug usually is constant over the range of concentrations encountered clinically. This is true because systems for elimination of drugs such as metabolizing enzymes and transporters (*see* Chapters 2 and 3) usually are not saturated, and thus the *absolute* rate of elimination of the drug is essentially a linear function of its concentration in plasma. That is, the elimination of most drugs follows first-order kinetics, where a constant *fraction* of drug in the body is eliminated per unit of time. If mechanisms for elimination of a given drug become saturated, the kinetics approach zero order, in which a constant *amount* of drug is eliminated per unit of time. Under such a circumstance, clearance (CL) will vary with the concentration of drug, often according to the equation

$$CL = v_m / (K_m + C) \quad (1-3)$$

where K_m represents the concentration at which half the maximal rate of elimination is reached (in units of mass/volume) and v_m is equal to the maximal rate of elimination (in units of mass/time). Thus, clearance is derived in units of volume/time. This equation is analogous to the Michaelis–Menten equation for enzyme kinetics. Design of dosage regimens for drugs with zero-order elimination kinetics is more complex than when elimination is first-order and clearance is independent of the drug's concentration (*see* below).

Principles of drug clearance are similar to those of renal physiology, where, for example, creatinine clearance is defined as the rate of elimination of creatinine in the urine relative to its concentration in plasma. At the simplest level, clearance of a drug is its rate of elimination by all routes normalized to the concentration of drug C in some biological fluid where measurement can be made:

$$CL = \text{rate of elimination} / C \quad (1-4)$$

Thus, when clearance is constant, the rate of drug elimination is directly proportional to drug concentration. It is important to recognize that clearance does not indicate how much drug is being

removed but rather the volume of biological fluid such as blood or plasma from which drug would have to be completely removed to account for the clearance (*e.g.*, milliliters per minute per kilogram). Clearance can be defined further as blood clearance (CL_b), plasma clearance (CL_p), or clearance based on the concentration of unbound drug (CL_u), depending on the measurement made (C_b , C_p , or C_u).

Clearance of drug by several organs is additive. Elimination of drug may occur as a result of processes that occur in the GI tract, kidney, liver, and other organs. Division of the rate of elimination by each organ by a concentration of drug (*e.g.*, plasma concentration) will yield the respective clearance by that organ. Added together, these separate clearances will equal systemic clearance:

$$CL_{renal} + CL_{hepatic} + CL_{other} = CL \quad (1-5)$$

Other routes of elimination could include loss of drug in saliva or sweat, secretion into the GI tract, volatile elimination from the lung, and metabolism at other sites such as skin.

Systemic clearance may be determined at steady state by using Equation (1-2). For a single dose of a drug with complete bioavailability and first-order kinetics of elimination, systemic clearance may be determined from mass balance and the integration of Equation (1-4) over time:

$$CL = \text{Dose}/AUC \quad (1-6)$$

where *AUC* is the total area under the curve that describes the measured concentration of drug in the systemic circulation as a function of time (from zero to infinity) as in Figure 1-5.

Examples. In Appendix II, the plasma clearance for the antibiotic *cephalexin* is reported as 4.3 ml/min per kilogram, with 90% of the drug excreted unchanged in the urine. For a 70-kg man, the clearance from plasma would be 301 ml/min, with renal clearance accounting for 90% of this elimination. In other words, the kidney is able to excrete cephalexin at a rate such that the drug is completely removed (cleared) from approximately 270 ml of plasma per minute (renal clearance = 90% of total clearance). Because clearance usually is assumed to remain constant in a medically stable patient, the rate of elimination of cephalexin will depend on the concentration of drug in the plasma (Equation 1-4).

The β adrenergic receptor antagonist *propranolol* is cleared from the blood at a rate of 16 ml/min per kilogram (or 1120 ml/min in a 70-kg man), almost exclusively by the liver. Thus the liver is able to remove the amount of propranolol contained in 1120 ml of blood in 1 minute. Even though the liver is the dominant organ for elimination, the plasma clearance of some drugs exceeds the rate of blood flow to this organ. Often this is so because the drug partitions readily into red blood cells (RBCs), and the rate of drug delivered to the eliminating organ is considerably higher than suspected from measurement of its concentration in plasma. The relationship between plasma (*p*) and blood (*b*) clearance at steady state is given by

$$\frac{CL_p}{CL_b} = \frac{C_b}{C_p} = 1 + H \left[\frac{C_{rbc}}{C_p} - 1 \right] \quad (1-7)$$

Clearance from the blood therefore may be estimated by dividing the plasma clearance by the drug's blood-to-plasma concentra-

tion ratio, obtained from knowledge of the hematocrit ($H = 0.45$) and the red cell-to-plasma concentration ratio. In most instances, the blood clearance will be less than liver blood flow (1.5 L/min) or, if renal excretion also is involved, the sum of the blood flows to each eliminating organ. For example, the plasma clearance of the immunomodulator *tacrolimus*, about 2 L/min, is more than twice the hepatic plasma flow rate and even exceeds the organ's blood flow despite the fact that the liver is the predominant site of this drug's extensive metabolism. However, after taking into account the extensive distribution of tacrolimus into red cells, its clearance from the blood is only about 63 ml/min, and it is actually a low- rather than high-clearance drug, as might be interpreted from the plasma clearance value alone. Sometimes, however, clearance from the blood by metabolism exceeds liver blood flow, and this indicates extrahepatic metabolism. In the case of the β_1 receptor antagonist *esmolol*, the blood clearance value (11.9 L/min) is greater than cardiac output (approximately 5.3 L/min) because the drug is metabolized efficiently by esterases present in red blood cells.

A further definition of clearance is useful for understanding the effects of pathological and physiological variables on drug elimination, particularly with respect to an individual organ. The rate of presentation of drug to the organ is the product of blood flow (Q) and the arterial drug concentration (C_A), and the rate of exit of drug from the organ is the product of blood flow and the venous drug concentration (C_V). The difference between these rates at steady state is the rate of drug elimination by that organ:

$$\begin{aligned} \text{Rate of elimination} &= Q \cdot C_A - Q \cdot C_V \\ &= Q(C_A - C_V) \end{aligned} \quad (1-8)$$

Division of Equation (1-8) by the concentration of drug entering the organ of elimination C_A yields an expression for clearance of the drug by the organ in question:

$$CL_{organ} = Q \left[\frac{C_A - C_V}{C_A} \right] = Q \cdot E \quad (1-9)$$

The expression $(C_A - C_V)/C_A$ in Equation (1-9) can be referred to as the *extraction ratio* (*E*) of the drug. While not employed in general medical practice, calculations of a drug's extraction ratio are useful for modeling the effects of disease of a given metabolizing organ on clearance and in the design of ideal therapeutic properties of drugs in development.

Hepatic Clearance. The concepts developed in Equation (1-9) have important implications for drugs that are eliminated by the liver. Consider a drug that is removed efficiently from the blood by hepatic processes—metabolism and/or excretion of drug into the bile. In this instance, the concentration of drug in the blood leaving the liver will be low, the extraction ratio will approach unity, and the clearance of the drug from blood will become limited by hepatic blood flow. Drugs that are cleared efficiently by the liver (*e.g.*, drugs in Appendix II with systemic clearances greater than 6 ml/min per kilogram, such as *diltiazem*, *imipramine*, lidocaine, morphine, and propranolol) are restricted in their rate of elimination not by intrahepatic processes, but by the rate at which they can be transported in the blood to the liver.

Additional complexities also may be considered. For example, the equations presented earlier do not account for drug binding to

components of blood and tissues, nor do they permit an estimation of the intrinsic capacity of the liver to eliminate a drug in the absence of limitations imposed by blood flow, termed *intrinsic clearance*. In biochemical terms and under first-order conditions, intrinsic clearance is a measure of the ratio of the Michaelis–Menten kinetic parameters for the eliminating process (*i.e.*, v_m/K_m) and thus reflects the maximum metabolic or transport capability of the clearing organ. Extensions of the relationships of Equation (1–9) to include expressions for protein binding and intrinsic clearance have been proposed for a number of models of hepatic elimination (Kwon and Morris, 1997). All these models indicate that when the capacity of the eliminating organ to metabolize the drug is large in comparison with the rate of presentation of drug to the organ, clearance will approximate the organ's blood flow. In contrast, when the drug-metabolizing capacity is small in comparison with the rate of drug presentation, clearance will be proportional to the unbound fraction of drug in blood and the drug's intrinsic clearance. Appreciation of these concepts allows understanding of a number of possibly puzzling experimental results. For example, enzyme induction or hepatic disease may change the rate of drug metabolism in an isolated hepatic microsomal enzyme system but not change clearance in the whole animal. For a drug with a high extraction ratio, clearance is limited by blood flow, and changes in intrinsic clearance owing to enzyme induction or hepatic disease should have little effect. Similarly, for drugs with high extraction ratios, changes in protein binding owing to disease or competitive binding interactions by other drugs should have little effect on clearance. By contrast, changes in intrinsic clearance and protein binding will affect the clearance of drugs with low intrinsic clearances such as warfarin, and thus extraction ratios, but changes in blood flow will have little effect.

Renal Clearance. Renal clearance of a drug results in its appearance in the urine. In considering the impact of renal disease on the clearance of a drug, complications that relate to filtration, active secretion by the kidney tubule, and reabsorption from it must be considered along with blood flow. The rate of filtration of a drug depends on the volume of fluid that is filtered in the glomerulus and the unbound concentration of drug in plasma because drug bound to protein is not filtered. The rate of secretion of drug by the kidney will depend on the drug's intrinsic clearance by the transporters involved in active secretion as affected by the drug's binding to plasma proteins, the degree of saturation of these transporters, and the rate of delivery of the drug to the secretory site. In addition, processes involved in drug reabsorption from the tubular fluid must be considered. The influences of changes in protein binding and blood flow and in the number of functional nephrons are analogous to the examples given earlier for hepatic elimination.

DISTRIBUTION

Volume of Distribution. Volume is a second fundamental parameter that is useful in considering processes of drug disposition. The volume of distribution (V) relates the amount of drug in the body to the concentration of drug (C) in the blood or plasma depending on the fluid

measured. This volume does not necessarily refer to an identifiable physiological volume but rather to the fluid volume that would be required to contain all the drug in the body at the same concentration measured in the blood or plasma:

$$\begin{aligned} \text{Amount of drug in body}/V &= C & \text{or} & \\ V &= \text{amount of drug in body}/C \end{aligned} \quad (1-10)$$

A drug's volume of distribution therefore reflects the extent to which it is present in extravascular tissues and not in the plasma. The plasma volume of a typical 70-kg man is 3 L, blood volume is about 5.5 L, extracellular fluid volume outside the plasma is 12 L, and the volume of total-body water is approximately 42 L.

Many drugs exhibit volumes of distribution far in excess of these values. For example, if 500 μg of the cardiac glycoside *digoxin* were in the body of a 70-kg subject, a plasma concentration of approximately 0.75 ng/ml would be observed. Dividing the amount of drug in the body by the plasma concentration yields a volume of distribution for digoxin of about 667 L, or a value approximately 10 times greater than the total-body volume of a 70-kg man. In fact, digoxin distributes preferentially to muscle and adipose tissue and to its specific receptors (Na^+, K^+ -ATPase), leaving a very small amount of drug in the plasma to be measured. For drugs that are bound extensively to plasma proteins but that are not bound to tissue components, the volume of distribution will approach that of the plasma volume because drug bound to plasma protein is measurable in the assay of most drugs. In contrast, certain drugs have high volumes of distribution even though most of the drug in the circulation is bound to albumin because these drugs are also sequestered elsewhere.

The volume of distribution may vary widely depending on the relative degrees of binding to high-affinity receptor sites, plasma and tissue proteins, the partition coefficient of the drug in fat, and accumulation in poorly perfused tissues. As might be expected, the volume of distribution for a given drug can differ according to patient's age, gender, body composition, and presence of disease. Total-body water of infants younger than 1 year of age, for example, is 75% to 80% of body weight, whereas that of adult males is 60% and that of females is 55%.

Several volume terms are used commonly to describe drug distribution, and they have been derived in a number of ways. The volume of distribution defined in Equation (1–10) considers the body as a single homogeneous compartment. In this *one-compartment model*, all drug administration occurs directly into the central compartment, and distribution of drug is instantaneous throughout the volume (V). Clearance of drug from this compartment occurs in a first-order fashion, as defined in Equation (1–4); *i.e.*, the amount of drug eliminated per unit of time depends on the amount (concentration) of drug in the body compartment. Figure 1–3A and Equation (1–11) describe the decline of plasma concentration with time for a drug introduced into this central compartment:

$$C = (\text{dose}/V) \cdot \exp(-kt) \quad (1-11)$$

where k is the rate constant for elimination that reflects the fraction of drug removed from the compartment per unit of time. This

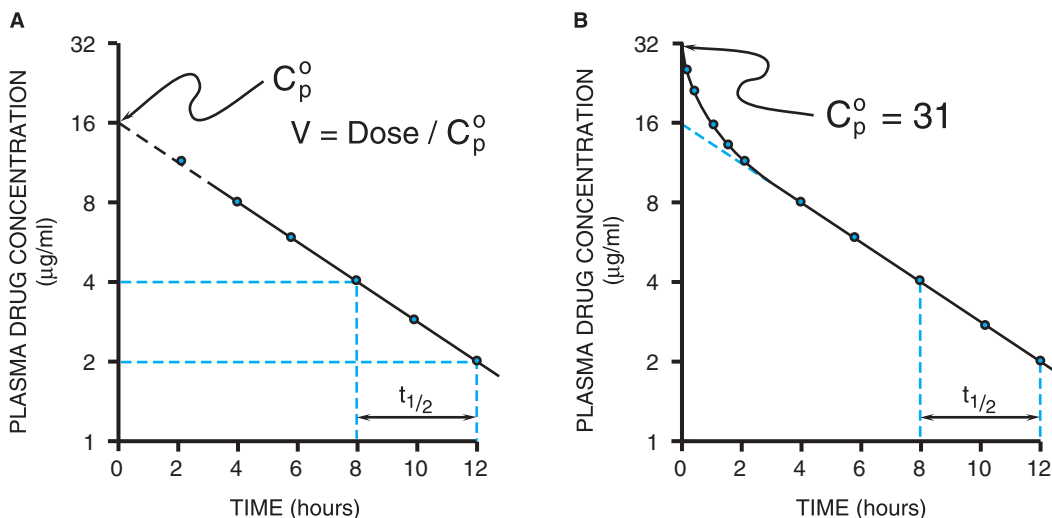

Figure 1-3. Plasma concentration–time curves following intravenous administration of a drug (500 mg) to a 70-kg patient. **A.** Drug concentrations are measured in plasma at 2-hour intervals following drug administration. The semilogarithmic plot of plasma concentration (C_p) versus time appears to indicate that the drug is eliminated from a single compartment by a first-order process (Equation 1-11) with a half-life of 4 hours ($k = 0.693/t_{1/2} = 0.173 \text{ h}^{-1}$). The volume of distribution (V) may be determined from the value of C_p obtained by extrapolation to $t = 0$ ($C_p^0 = 16 \text{ } \mu\text{g/ml}$). Volume of distribution (Equation 1-10) for the one-compartment model is 31.3 L, or 0.45 L/kg ($V = \text{dose}/C_p^0$). The clearance for this drug is 90 ml/min; for a one-compartment model, $CL = kV$. **B.** Sampling before 2 hours indicates that, in fact, the drug follows multiexponential kinetics. The terminal disposition half-life is 4 hours, clearance is 84 ml/min (Equation 1-6), V_{area} is 29 L (Equation 1-11), and V_{ss} is 26.8 L. The initial or “central” distribution volume for the drug ($V_1 = \text{dose}/C_p^0$) is 16.1 L. The example chosen indicates that multicompartment kinetics may be overlooked when sampling at early times is neglected. In this particular case, there is only a 10% error in the estimate of clearance when the multicompartment characteristics are ignored. For many drugs, multicompartment kinetics may be observed for significant periods of time, and failure to consider the distribution phase can lead to significant errors in estimates of clearance and in predictions of the appropriate dosage. Also, the difference between the “central” distribution volume and other terms reflecting wider distribution is important in deciding a loading dose strategy.

rate constant is inversely related to the half-life of the drug ($k = 0.693/t_{1/2}$).

The idealized one-compartment model discussed earlier does not describe the entire time course of the plasma concentration. That is, certain tissue reservoirs can be distinguished from the central compartment, and the drug concentration appears to decay in a manner that can be described by multiple exponential terms (Figure 1-3B). Nevertheless, the one-compartment model is sufficient to apply to most clinical situations for most drugs. Indeed, appreciation of the drug half-life in the central compartment has a direct and significant impact on the appropriate dosing interval for the drug.

Rate of Drug Distribution. The multiple exponential decay observed for a drug that is eliminated from the body with first-order kinetics results from differences in the rates at which the drug equilibrates to and within tissues. The rate of equilibration will depend on the ratio of the perfusion of the tissue to the partition of drug into the tissue. In many cases, groups of tissues with similar perfusion–partition ratios all equilibrate at essentially the same rate such that only one apparent phase of distribution is seen (rapid initial fall of concentration of intravenously injected drug, as in Figure 1-3B). It is as though the drug starts in a “central” volume (Figure 1-1), which consists of plasma and tissue reservoirs that are in rapid equilibrium with it, and distributes to a “final” volume, at which point

concentrations in plasma decrease in a log-linear fashion with a rate constant of k (Figure 1-3B). The multicompartment model of drug disposition can be viewed as though the blood and highly perfused lean organs such as heart, brain, liver, lung, and kidneys cluster as a single central compartment, whereas more slowly perfused tissues such as muscle, skin, fat, and bone behave as the final compartment (*i.e.*, the tissue compartment).

If the pattern or ratio of blood flow to various tissues changes within an individual or differs among individuals, rates of drug distribution to tissues also will change. However, changes in blood flow also may cause some tissues that were originally in the “central” volume to equilibrate sufficiently more slowly so as to appear only in the “final” volume. This means that central volumes will appear to vary with disease states that cause altered regional blood flow (such as would be seen in cirrhosis of the liver). After an intravenous bolus dose, drug concentrations in plasma may be higher in individuals with poor perfusion (*e.g.*, shock) than they would be if perfusion were better. These higher systemic concentrations, in turn, may cause higher concentrations (and greater effects) in tissues such as brain and heart, whose usually high perfusion has not been reduced by the altered hemodynamic state. Thus, the effect of a drug at various sites of action can vary depending on perfusion of these sites.

Multicompartment Volume Terms. Two different terms have been used to describe the volume of distribution for drugs that follow multiple exponential decay. The first, designated V_{area} , is calculated as the ratio of clearance to the rate of decline in concentration during the elimination (final) phase of the logarithmic concentration *versus* time curve:

$$V_{\text{area}} = \frac{CL}{k} = \frac{\text{dose}}{k \cdot AUC} \quad (1-12)$$

The estimation of this parameter is straightforward, and the volume term may be determined after administration of a single dose of drug by intravenous or oral route (where the value for the dose must be corrected for bioavailability). However, another multicompartment volume of distribution term may be more useful, especially when the effect of disease states on pharmacokinetics is to be determined. The volume of distribution at steady state (V_{ss}) represents the volume in which a drug would appear to be distributed during steady state if the drug existed throughout that volume at the same concentration as that in the measured fluid (plasma or blood). V_{ss} also may be appreciated as shown in Equation (1-13), where V_C is the volume of distribution of drug in the central compartment and V_T is the volume term for drug in the tissue compartment:

$$V_{\text{ss}} = V_C + V_T \quad (1-13)$$

Although V_{area} is a convenient and easily calculated parameter, it varies when the rate constant for drug elimination changes, even when there has been no change in the distribution space. This is so because the terminal rate of decline of the concentration of drug in blood or plasma depends not only on clearance but also on the rates of distribution of drug between the “central” and “final” volumes. V_{ss} does not suffer from this disadvantage. When using pharmacokinetics to make drug dosing decisions, the differences between V_{area} and V_{ss} usually are not clinically significant. Nonetheless, both are quoted in the table of pharmacokinetic data in Appendix II, depending on the availability of data in the published literature.

Half-Life

The half-life ($t_{1/2}$) is the time it takes for the plasma concentration or the amount of drug in the body to be reduced by 50%. For the simplest case, the one-compartment model (Figure 1-3A), half-life may be determined readily by inspection and used to make decisions about drug dosage. However, as indicated in Figure 1-3B, drug concentrations in plasma often follow a multiexponential pattern of decline; two or more half-life terms thus may be calculated.

In the past, the half-life that was usually reported corresponded to the terminal log-linear phase of elimination. However, as greater analytical sensitivity has been achieved, the lower concentrations measured appeared to yield longer and longer terminal half-lives. For example, a terminal half-life of 53 hours is observed for gentamicin (*versus* the more clinically relevant 2- to 3-hour value in Appendix II), and biliary cycling probably is responsible for the 120-hour terminal value for *indomethacin* (as compared with the

2.4-hour half-life listed in Appendix II). The appreciation of longer terminal half-lives for some medications may relate to their accumulation in tissues during chronic dosing or shorter periods of high-dose treatment. Such is the case for gentamicin, where the terminal half-life is associated with renal and ototoxicities. The relevance of a particular half-life may be defined in terms of the fraction of the clearance and volume of distribution that is related to each half-life and whether plasma concentrations or amounts of drug in the body are best related to measures of response. The single half-life values given for each drug in Appendix II are chosen to represent the most clinically relevant half-life.

In studies of pharmacokinetic properties of drugs in disease, the half-life is a derived parameter that changes as a function of both clearance and volume of distribution. A useful approximate relationship between the clinically relevant half-life, clearance, and volume of distribution at steady state is given by

$$t_{1/2} \cong 0.693 \cdot V_{\text{ss}} / CL \quad (1-14)$$

Clearance is the measure of the body’s ability to eliminate a drug; thus, as clearance decreases, owing to a disease process, for example, half-life would be expected to increase. However, this reciprocal relationship is valid only when the disease does not change the volume of distribution. For example, the half-life of *diazepam* increases with increasing age; however, it is not clearance that changes as a function of age but rather the volume of distribution. Similarly, changes in protein binding of a drug may affect its clearance as well as its volume of distribution, leading to unpredictable changes in half-life as a function of disease. The half-life of *tolbutamide*, for example, decreases in patients with acute viral hepatitis in a fashion opposite from what one might expect. The disease alters the drug’s protein binding in both plasma and tissues, causing no change in volume of distribution but an increase in clearance because higher concentrations of unbound drug are present in the bloodstream.

Although it can be a poor index of drug elimination from the body *per se* (disappearance of drug may be the result of formation of undetected metabolites that have therapeutic or unwanted effects), half-life does provide a good indication of the time required to reach steady state after a dosage regimen is initiated or changed (*i.e.*, four half-lives to reach approximately 94% of a new steady state), the time for a drug to be removed from the body, and a means to estimate the appropriate dosing interval (*see* below).

Steady State. Equation (1-2) (dosing rate = $CL \cdot C_{\text{ss}}$) indicates that a steady-state concentration eventually will be achieved when a drug is administered at a constant rate. At this point, drug elimination [the product of clearance and concentration; Equation (1-4)] will equal the

Figure 1-4. Fundamental pharmacokinetic relationships for repeated administration of drugs. The blue line is the pattern of drug accumulation during repeated administration of a drug at intervals equal to its elimination half-time when drug absorption is 10 times as rapid as elimination. As the rate of absorption increases, the concentration maxima approach 2 and the minima approach 1 during the steady state. The black line depicts the pattern during administration of equivalent dosage by continuous intravenous infusion. Curves are based on the one-compartment model. Average concentration (\bar{C}_{ss}) when the steady state is attained during intermittent drug administration is $\bar{C}_{ss} = \frac{F \cdot \text{dose}}{CL \cdot T}$

where F is fractional bioavailability of the dose and T is dosage interval (time). By substitution of infusion rate for $F \cdot \text{dose}/T$, the formula is equivalent to Equation (1-2) and provides the concentration maintained at steady state during continuous intravenous infusion.

rate of drug availability. This concept also extends to regular intermittent dosage (e.g., 250 mg of drug every 8 hours). During each interdose interval, the concentration of drug rises with absorption and falls by elimination. At steady state, the entire cycle is repeated identically in each interval (see Figure 1-4). Equation (1-2) still applies for intermittent dosing, but it now describes the average steady-state drug concentration (C_{ss}) during an interdose interval.

Extent and Rate of Bioavailability

Bioavailability. It is important to distinguish between the rate and extent of drug absorption and the amount of drug that ultimately reaches the systemic circulation. The amount of the drug that reaches the systemic circulation depends not only on the administered dose but also on the

fraction of the dose (F) that is absorbed and escapes any first-pass elimination. This fraction is the drug's *bioavailability*. Reasons for incomplete absorption were discussed earlier. Also, as noted previously, if the drug is metabolized in the intestinal epithelium or the liver or excreted in bile, some of the active drug absorbed from the GI tract will be eliminated before it can reach the general circulation and be distributed to its sites of action.

Knowing the extraction ratio (E_H) for a drug across the liver (see Equation 1-9), it is possible to predict the maximum oral availability (F_{max}), assuming that hepatic elimination follows first-order processes:

$$F_{max} = 1 - E_H = 1 - (CL_{hepatic}/Q_{hepatic}) \quad (1-15)$$

Thus, if the hepatic blood clearance for the drug is large relative to hepatic blood flow, the extent of availability will be low when the drug is given orally (e.g., lidocaine or propranolol). This reduction in availability is a function of the physiological site from which absorption takes place, and no modification of dosage form will improve the availability under conditions of linear kinetics. Incomplete absorption and/or intestinal metabolism following oral dosing will, in practice, reduce this predicted maximal value of F .

When drugs are administered by a route that is subject to first-pass loss, the equations presented previously that contain the terms *dose* or *dosing rate* (Equations 1-2, 1-6, 1-11, and 1-12) also must include the bioavailability term F such that the available dose or dosing rate is used. For example, Equation (1-2) is modified to

$$F \cdot \text{dosing rate} = CL \cdot C_{ss} \quad (1-16)$$

where the value of F is between 0 and 1. The value of F varies widely for drugs administered by mouth. Etidronate, a bisphosphonate used to stabilize bone matrix in the treatment of Paget's disease and osteoporosis, has an F of 0.03, meaning that only 3% of the drug appears in the bloodstream following oral dosing. In the case of etidronate, therapy using oral administration is still useful, and the dose of the drug administered per kilogram is larger than would be given by injection.

Rate of Absorption. Although the rate of drug absorption does not, in general, influence the average steady-state concentration of the drug in plasma, it may still influence drug therapy. If a drug is absorbed rapidly (e.g., a dose given as an intravenous bolus) and has a small "central" volume, the concentration of drug initially will be high. It will then fall as the drug is distributed to its "final" (larger) volume (Figure 1-3B). If the same drug is absorbed more slowly (e.g., by slow infusion), it will be distributed while it is being administered, and peak concentrations will be lower and will occur later. Controlled-release preparations are designed to provide a slow and sustained rate of absorption in order to produce smaller fluctuations in the plasma concentration-time

profile during the dosage interval compared with more immediate-release formulations. A given drug may act to produce both desirable and undesirable effects at several sites in the body, and the rates of distribution of drug to these sites may not be the same. The relative intensities of these different effects of a drug thus may vary transiently when its rate of administration is changed. Since the beneficial, nontoxic effects of drugs are based on knowledge of an ideal or desired plasma concentration range, maintaining that range while avoiding large swings between peak and trough concentrations can improve therapeutic outcome.

Nonlinear Pharmacokinetics

Nonlinearity in pharmacokinetics (*i.e.*, changes in such parameters as clearance, volume of distribution, and half-life as a function of dose or concentration of drug) usually is due to saturation of either protein binding, hepatic metabolism, or active renal transport of the drug.

Saturable Protein Binding. As the molar concentration of drug increases, the unbound fraction eventually also must increase (as all binding sites become saturated). This usually occurs only when drug concentrations in plasma are in the range of tens to hundreds of micrograms per milliliter. For a drug that is metabolized by the liver with a low intrinsic clearance–extraction ratio, saturation of plasma-protein binding will cause both V and CL to increase as drug concentrations increase; half-life thus may remain constant (Equation 1–14). For such a drug, C_{ss} will not increase linearly as the rate of drug administration is increased. For drugs that are cleared with high intrinsic clearance–extraction ratios, C_{ss} can remain linearly proportional to the rate of drug administration. In this case, hepatic clearance will not change, and the increase in V will increase the half-time of disappearance by reducing the fraction of the total drug in the body that is delivered to the liver per unit of time. Most drugs fall between these two extremes, and the effects of nonlinear protein binding may be difficult to predict.

Saturable Elimination. In this situation, the Michaelis–Menten equation (Equation 1–3) usually describes the nonlinearity. All active processes are undoubtedly saturable, but they will appear to be linear if values of drug concentrations encountered in practice are much less than K_m . When drug concentrations exceed K_m , nonlinear kinetics are observed. The major consequences of saturation of metabolism or transport are the opposite of those for saturation of protein binding. Saturation of protein binding will lead to increased CL because CL increases as drug concentration increases, whereas saturation of metabolism or transport may decrease CL . When both conditions are present simultaneously, they may virtually cancel each others' effects, and surprisingly linear kinetics may result; this occurs over a certain range of concentrations for *salicylic acid*, for example.

Saturable metabolism causes oral first-pass metabolism to be less than expected (higher F), and there is a greater fractional increase in C_{ss} than the corresponding fractional increase in the rate of drug administration. The latter can be seen most easily by substituting Equation (1–3) into Equation (1–2) and solving for the steady-state concentration:

$$C_{ss} = \frac{\text{dosing rate} \cdot K_m}{v_m - \text{dosing rate}} \quad (1-17)$$

As the dosing rate approaches the maximal elimination rate (v_m), the denominator of Equation (1–17) approaches zero, and C_{ss} increases disproportionately. Because saturation of metabolism should have no effect on the volume of distribution, clearance and the relative rate of drug elimination decrease as the concentration increases; therefore, the log C_p time curve is concave-decreasing until metabolism becomes sufficiently desaturated and first-order elimination is present. Thus, the concept of a constant half-life is not applicable to nonlinear metabolism occurring in the usual range of clinical concentrations. Consequently, changing the dosing rate for a drug with nonlinear metabolism is difficult and unpredictable because the resulting steady state is reached more slowly, and importantly, the effect is disproportionate to the alteration in the dosing rate.

The antiepileptic medication *phenytoin* provides an example of a drug for which metabolism becomes saturated in the therapeutic range of concentrations (*see* Appendix II), and half-life can vary between 7 and 42 hours. K_m (5 to 10 mg/L) is typically near the lower end of the therapeutic range (10 to 20 mg/L). For some individuals, especially young children and newborns being treated for emergent seizures, K_m may be as low as 1 mg/L. If, for an adult, the target concentration is 15 mg/L and this is attained at a dosing rate of 300 mg/day, then from Equation (1–17), v_m equals 320 mg/day. For such a patient, a dose that is 10% less than optimal (*i.e.*, 270 mg/day) will produce a C_{ss} of 5 mg/L, well below the desired value. In contrast, a dose that is 10% greater than optimal (330 mg/day) will exceed metabolic capacity (by 10 mg/day) and cause a long and slow but unending climb in concentration during which toxicity will occur. Dosage cannot be controlled so precisely (<10% error). Therefore, for patients in whom the target concentration for phenytoin is more than tenfold greater than the K_m , alternating between inefficacious therapy and toxicity is almost unavoidable. For a drug such as phenytoin that has a narrow therapeutic index and exhibits nonlinear metabolism, therapeutic drug monitoring (*see* below) is most important. When the patient is a neonate, appreciation of this concept is of particular concern because signs and symptoms of toxicity are particularly difficult to monitor. In such cases, a pharmacokinetic consult may be appropriate.

Design and Optimization of Dosage Regimens

Following administration of a dose of drug, its effects usually show a characteristic temporal pattern (Figure 1–5). Onset of the effect is preceded by a lag period, after which the magnitude of the effect increases to a maximum and then declines; if a further dose is not administered, the effect eventually disappears as the drug is eliminated. This time course reflects changes in the drug's concentration as determined by the pharmacokinetics of its absorption, distribution, and elimination. Accordingly, the intensity of a drug's effect is related to its concentration above a minimum effective concentration, whereas the duration of this effect reflects the length of time the drug level is above this value. These considerations, in general, apply to both desired and undesired (adverse) drug effects, and as a result, a *therapeutic window* exists reflecting a concentration range that provides efficacy without unacceptable toxicity. Similar considerations apply after multiple dosing associated with long-term therapy, and they determine the amount and frequency of drug administration to achieve an optimal therapeutic effect. In general, the lower limit of the therapeutic range appears to be approximately equal to the drug concentration that produces about half the greatest possible therapeutic effect, and the upper limit of the therapeutic range is such that no

Figure 1–5. Temporal characteristics of drug effect and relationship to the therapeutic window (e.g., single dose, oral administration). A lag period is present before the plasma drug concentration (C_p) exceeds the minimum effective concentration (MEC) for the desired effect. Following onset of the response, the intensity of the effect increases as the drug continues to be absorbed and distributed. This reaches a peak, after which drug elimination results in a decline in C_p and in the effect's intensity. Effect disappears when the drug concentration falls below the MEC. Accordingly, the duration of a drug's action is determined by the time period over which concentrations exceed the MEC. An MEC exists for each adverse response, and if drug concentration exceeds this, toxicity will result. The therapeutic goal is to obtain and maintain concentrations within the therapeutic window for the desired response with a minimum of toxicity. Drug response below the MEC for the desired effect will be subtherapeutic; above the MEC for an adverse effect, the probability of toxicity will increase. Increasing or decreasing drug dosage shifts the response curve up or down the intensity scale and is used to modulate the drug's effect. Increasing the dose also prolongs a drug's duration of action but at the risk of increasing the likelihood of adverse effects. Unless the drug is nontoxic (e.g., penicillins), increasing the dose is not a useful strategy for extending the duration of action. Instead, another dose of drug should be given, timed to maintain concentrations within the therapeutic window. The area under the blood concentration–time curve (*area under the curve*, or AUC, shaded in gray) can be used to calculate the clearance (see Equation 1–6) for first-order elimination. The AUC is also used as a measure of bioavailability (defined as 100% for an intravenously administered drug). Bioavailability will be <100% for orally administered drugs, due mainly to incomplete absorption and first-pass metabolism and elimination.

more than 5% to 10% of patients will experience a toxic effect. For some drugs, this may mean that the upper limit of the range is no more than twice the lower limit. Of course, these figures can be highly variable, and some patients may benefit greatly from drug concen-

trations that exceed the therapeutic range, whereas others may suffer significant toxicity at much lower values (e.g., digoxin).

For a limited number of drugs, some effect of the drug is easily measured (e.g., blood pressure, blood glucose), and this can be used to optimize dosage using a trial-and-error approach. Even in an ideal case, certain quantitative issues arise, such as how often to change dosage and by how much. These usually can be settled with simple rules of thumb based on the principles discussed (e.g., change dosage by no more than 50% and no more often than every three to four half-lives). Alternatively, some drugs have very little dose-related toxicity, and maximum efficacy usually is desired. For these drugs, doses well in excess of the average required will both ensure efficacy (if this is possible) and prolong drug action. Such a “maximal dose” strategy typically is used for *penicillins*.

For many drugs, however, the effects are difficult to measure (or the drug is given for prophylaxis), toxicity and lack of efficacy are both potential dangers, or the therapeutic index is narrow. In these circumstances, doses must be titrated carefully, and drug dosage is limited by toxicity rather than efficacy. Thus, the therapeutic goal is to maintain steady-state drug levels within the therapeutic window. For most drugs, the actual concentrations associated with this desired range are not and need not be known. It is sufficient to understand that efficacy and toxicity generally depend on concentration and how drug dosage and frequency of administration affect the drug level. However, for a small number of drugs for which there is a small (two- to threefold) difference between concentrations resulting in efficacy and toxicity (e.g., digoxin, *theophylline*, lidocaine, aminoglycosides, *cyclosporine*, warfarin, and anticonvulsants), a plasma concentration range associated with effective therapy has been defined. In these cases, a target-level strategy is reasonable, wherein a desired (target) steady-state concentration of the drug (usually in plasma) associated with efficacy and minimal toxicity is chosen, and a dosage is computed that is expected to achieve this value. Drug concentrations are subsequently measured, and dosage is adjusted if necessary to approximate the target more closely (see below).

Maintenance Dose. In most clinical situations, drugs are administered in a series of repetitive doses or as a continuous infusion to maintain a steady-state concentration of drug associated with the therapeutic window. Calculation of the appropriate maintenance dosage is a primary goal. To maintain the chosen steady-state or target concentration, the rate of drug administration is adjusted such that the rate of input equals the rate of loss. This relationship was defined previously in Equations (1–2) and (1–16) and is expressed here in terms of the desired target concentration:

$$\text{Dosing rate} = \text{target } C_p \cdot CL/F \quad (1-18)$$

If the clinician chooses the desired concentration of drug in plasma and knows the clearance and bioavailability for that drug in a particular patient, the appropriate dose and dosing interval can be calculated.

Example. Oral digoxin is to be used as a maintenance dose to gradually “digitalize” a 69-kg patient with congestive heart failure. A steady-state plasma concentration of 1.5 ng/ml is selected as an appropriate target based on prior knowledge of the action of the drug in patients with heart failure. Based on the fact that the patient's creatinine clearance (CL_{Cr}) is 100 ml/min, digoxin's clearance may be estimated from data in Appendix II.

$$\begin{aligned}
 CL &= 0.88 CL_{CR} + 0.33 \text{ ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1} \\
 &= 0.88 \times 100/69 + 0.33 \text{ ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1} \\
 &= 1.6 \text{ ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1} \\
 &= 110 \text{ ml} \cdot \text{min}^{-1} = 6.6 \text{ liters} \cdot \text{hr}^{-1}
 \end{aligned}$$

Equation (1–18) then is used to calculate an appropriate dosing rate knowing that the oral bioavailability of digoxin is 70% ($F = 0.7$).

$$\begin{aligned}
 \text{Dosing rate} &= \text{Target } C_p \cdot CL/F \\
 &= 1.5 \text{ ng} \cdot \text{ml}^{-1} \times 1.6/0.7 \text{ ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1} \\
 &= 3.43 \text{ ng} \cdot \text{ml}^{-1} \cdot \text{min}^{-1} \cdot \text{kg}^{-1} \\
 &\text{or } 236 \text{ ng} \cdot \text{ml}^{-1} \cdot \text{min}^{-1} \cdot \text{for a 69-kg patient} \\
 &= 236 \text{ ng} \cdot \text{ml}^{-1} \times 60 \text{ min} \times 24 \text{ hr} \\
 &= 340 \mu\text{g} = 0.34 \text{ mg}/24 \text{ hr}
 \end{aligned}$$

In practice, the dosing rate would be rounded to the closest dosage size, either 0.375 mg/24 h, which would result in a steady-state plasma concentration of 1.65 ng/ml ($1.5 \times 375/340$), or 0.25 mg/24 h, which would provide a value of 1.10 ng/ml ($1.5 \times 250/340$).

Dosing Interval for Intermittent Dosage. In general, marked fluctuations in drug concentrations between doses are not desirable. If absorption and distribution were instantaneous, fluctuations in drug concentrations between doses would be governed entirely by the drug's elimination half-life. If the dosing interval T were chosen to be equal to the half-life, then the total fluctuation would be twofold; this is often a tolerable variation.

Pharmacodynamic considerations modify this. If a drug is relatively nontoxic such that a concentration many times that necessary for therapy can be tolerated easily, the maximal-dose strategy can be used, and the dosing interval can be much longer than the elimination half-life (for convenience). The half-life of *amoxicillin* is about 2 hours, but dosing every 2 hours would be impractical. Instead, amoxicillin often is given in large doses every 8 or 12 hours. For some drugs with a narrow therapeutic range, it may be important to estimate the maximal and minimal concentrations that will occur for a particular dosing interval. The minimal steady-state concentration $C_{ss,\min}$ may be reasonably determined by the use of Equation (1–19):

$$C_{ss,\min} = \frac{F \cdot \text{dose}/V_{ss}}{1 - \exp(-kT)} \cdot \exp(-kT) \quad (1-19)$$

where k equals 0.693 divided by the clinically relevant plasma half-life and T is the dosing interval. The term $\exp(-kT)$ is, in fact, the fraction of the last dose (corrected for bioavailability) that remains in the body at the end of a dosing interval.

For drugs that follow multiexponential kinetics and are administered orally, estimation of the maximal steady-state concentration $C_{ss,\max}$ involves a complicated set of exponential constants for distribution and absorption. If these terms are ignored for multiple oral dosing, one easily may predict a maximal steady-state concentration by omitting the $\exp(-kT)$ term in the numerator of Equation (1–19) [see Equation (1–20) below]. Because of the approximation, the predicted maximal concentration from Equation (1–20) will be greater than that actually observed.

Example. In the patient with congestive heart failure discussed earlier, an oral maintenance dose of 0.375 mg digoxin per 24 hours

was calculated to achieve an average plasma concentration of 1.65 ng/ml during the dosage interval. Digoxin has a narrow therapeutic index, and plasma levels between 0.8 and 2.0 ng/ml usually are associated with efficacy and minimal toxicity. What are the maximum and minimum plasma concentrations associated with the preceding regimen? This first requires estimation of digoxin's volume of distribution based on available pharmacokinetic data (Appendix II).

$$\begin{aligned}
 V_{ss} &= 3.12 CL_{CR} + 3.84 \text{ liters} \cdot \text{kg}^{-1} \\
 &= 3.12 \times (100/69) + 3.84 \text{ liters} \cdot \text{kg}^{-1} \\
 &= 8.4 \text{ liters} \cdot \text{kg}^{-1}, \text{ or } 580 \text{ liters for a 69-kg patient}
 \end{aligned}$$

Combining this value with that of digoxin's clearance provides an estimate of digoxin's elimination half-life in the patient (Equations 1–2 through 1–14).

$$\begin{aligned}
 t_{1/2} &= 0.693 V_{ss}/CL \\
 &= \frac{0.693 \times 580 \text{ liters}}{6.6 \text{ liters} \cdot \text{hr}^{-1}} = 61 \text{ hr}
 \end{aligned}$$

Accordingly, the fractional rate constant of elimination is equal to 0.01136 h^{-1} ($0.693/61 \text{ h}$). Maximum and minimum digoxin plasma concentrations then may be predicted depending on the dosage interval. With $T = 48$ hours (i.e., $2 \times 0.375 \text{ mg}$ given every other day):

$$\begin{aligned}
 C_{ss,\max} &= \frac{F \cdot \text{dose}/V_{ss}}{1 - \exp(-kT)} \quad (1-20) \\
 &= \frac{0.7 \times 0.375 \times 2 \text{ mg}/580 \text{ liters}}{0.42} \\
 &= 2.15 \text{ ng/ml}
 \end{aligned}$$

$$\begin{aligned}
 C_{ss,\min} &= C_{ss,\max} \cdot \exp(-kT) \quad (1-21) \\
 &= (2.15 \text{ ng/ml})(0.58) = 1.25 \text{ ng/ml}
 \end{aligned}$$

Thus, the plasma concentrations would fluctuate about twofold, consistent with the similarity of the dosage interval to digoxin's half-life. Also, the peak concentration would be above the upper value of the therapeutic range, exposing the patient to possible adverse effects, and at the end of the dosing interval, the concentration would be above but close to the lower limit. By using the same dosing rate but decreasing the dosing interval, a much smoother plasma concentration *versus* time profile would be obtained while still maintaining an average steady-state value of 1.65 ng/ml. For example, with $T = 24$ hours, the predicted maximum and minimum plasma concentrations would be 1.90 and 1.44 ng/ml, respectively, which are in the upper portion of the therapeutic window. By contrast, administering a more conservative dosing rate of 0.25 ng every 24 hours would produce peak and trough values of 1.26 and 0.96 ng/ml, respectively, which would be associated with a steady-state value of 1.10 ng/ml. Of course, the clinician must balance the problem of compliance with regimens that involve frequent dosage against the problem of periods when the patient may be subjected to concentrations of the drug that could be too high or too low.

Loading Dose. The *loading dose* is one or a series of doses that may be given at the onset of therapy with the aim of achieving the target

concentration rapidly. The appropriate magnitude for the loading dose is

$$\text{Loading dose} = \text{target } C_p \cdot V_{ss} / F \quad (1-22)$$

A loading dose may be desirable if the time required to attain steady state by the administration of drug at a constant rate (four elimination half-lives) is long relative to the temporal demands of the condition being treated. For example, the half-life of lidocaine is usually 1 to 2 hours. Arrhythmias encountered after myocardial infarction obviously may be life-threatening, and one cannot wait 4 to 8 hours to achieve a therapeutic concentration of lidocaine by infusion of the drug at the rate required to attain this concentration. Hence, use of a loading dose of lidocaine in the coronary care unit is standard.

The use of a loading dose also has significant disadvantages. First, the particularly sensitive individual may be exposed abruptly to a toxic concentration of a drug. Moreover, if the drug involved has a long half-life, it will take a long time for the concentration to fall if the level achieved is excessive. Loading doses tend to be large, and they are often given parenterally and rapidly; this can be particularly dangerous if toxic effects occur as a result of actions of the drug at sites that are in rapid equilibrium with plasma. This occurs because the loading dose calculated on the basis of V_{ss} subsequent to drug distribution is at first constrained within the initial and smaller “central” volume of distribution. It is therefore usually advisable to divide the loading dose into a number of smaller fractional doses that are administered over a period of time. Alternatively, the loading dose should be administered as a continuous intravenous infusion over a period of time. Ideally, this should be given in an exponentially decreasing fashion to mirror the concomitant accumulation of the maintenance dose of the drug, and this is accomplished using computerized infusion pumps.

Example. Administration of digitalis (“digitalization”) in the patient described earlier is gradual if only a maintenance dose is administered (for at least 10 days based on a half-life of 61 hours). A more rapid response could be obtained (if deemed necessary by the physician; see Chapter 33) by using a loading-dose strategy and Equation (1-22):

$$\begin{aligned} \text{Loading dose} &= 1.5 \text{ ng} \cdot \text{ml}^{-1} \times 580 \text{ liters} / 0.7 \\ &= 1243 \text{ } \mu\text{g} \sim 1 \text{ mg} \end{aligned}$$

To avoid toxicity, this oral loading dose, which also could be administered intravenously, would be given as an initial 0.5-mg dose followed by a 0.25-mg dose 6 to 8 hours later, with careful monitoring of the patient. It also would be prudent to give the final 0.25-mg fractional dose, if necessary, in two 0.125-mg divided doses separated by 6 to 8 hours to avoid overdigitalization, particularly if there were a plan to initiate an oral maintenance dose within 24 hours of beginning digoxin therapy.

Individualizing Dosage. A rational dosage regimen is based on knowledge of F , CL , V_{ss} , and $t_{1/2}$ and some information about rates of absorption and distribution of the drug together with potential effects of the disease on these parameters. Recommended dosage regimens generally are designed for an “average” patient; usual values for the important determining parameters and appropriate

adjustments that may be necessitated by disease or other factors are presented in Appendix II. This “one size fits all” approach, however, overlooks the considerable and unpredictable interpatient variability that usually is present in these pharmacokinetic parameters. For many drugs, one standard deviation in the values observed for F , CL , and V_{ss} is about 20%, 50%, and 30%, respectively. This means that 95% of the time the C_{ss} that is achieved will be between 35% and 270% of the target; this is an unacceptably wide range for a drug with a low therapeutic index. Individualization of the dosage regimen to a particular patient therefore is critical for optimal therapy. The pharmacokinetic principles described earlier provide a basis for modifying the dosage regimen to obtain a desired degree of efficacy with a minimum of unacceptable adverse effects. In situations where the drug’s plasma concentration can be measured and related to the therapeutic window, additional guidance for dosage modification is obtained from blood levels taken during therapy and evaluated in a pharmacokinetic consult available in many institutional settings. Such measurement and adjustment are appropriate for many drugs with low therapeutic indices (e.g., cardiac glycosides, antiarrhythmic agents, anticonvulsants, theophylline, and warfarin).

Therapeutic Drug Monitoring

The major use of measured concentrations of drugs (at steady state) is to refine the estimate of CL/F for the patient being treated [using Equation (1-16) as rearranged below:

$$CL/F(\text{patient}) = \text{dosing rate} / C_{ss}(\text{measured}) \quad (1-23)$$

The new estimate of CL/F can be used in Equation (1-18) to adjust the maintenance dose to achieve the desired target concentration.

Certain practical details and pitfalls associated with therapeutic drug monitoring should be kept in mind. The first of these relates to the time of sampling for measurement of the drug concentration. If intermittent dosing is used, when during a dosing interval should samples be taken? It is necessary to distinguish between two possible uses of measured drug concentrations to understand the possible answers. A concentration of drug measured in a sample taken at virtually any time during the dosing interval will provide information that may aid in the assessment of drug toxicity. This is one type of therapeutic drug monitoring. It should be stressed, however, that such use of a measured concentration of drug is fraught with difficulties because of interindividual variability in sensitivity to the drug. When there is a question of toxicity, the drug concentration is just one of many items used to interpret the clinical situation.

Changes in the effects of drugs may be delayed relative to changes in plasma concentration because of a slow rate of distribution or pharmacodynamic factors. Concentrations of digoxin, for example, regularly exceed 2 ng/ml (a potentially toxic value) shortly after an oral dose, yet these peak concentrations do not cause toxicity; indeed, they occur well before peak effects. Thus, concentrations of drugs in samples obtained shortly after administration can be uninformative or even misleading.

When concentrations of drugs are used for purposes of adjusting dosage regimens, samples obtained shortly after administra-

tion of a dose almost invariably are misleading. The purpose of sampling during supposed steady state is to modify the estimate of CL/F and thus the choice of dosage. Early postabsorptive concentrations do not reflect clearance; they are determined primarily by the rate of absorption, the “central” (rather than the steady-state) volume of distribution, and the rate of distribution, all of which are pharmacokinetic features of virtually no relevance in choosing the long-term maintenance dosage. When the goal of measurement is adjustment of dosage, the sample should be taken well after the previous dose, as a rule of thumb, just before the next planned dose, when the concentration is at its minimum. The exceptions to this approach are drugs that are eliminated nearly completely between doses and act only during the initial portion of each dosing interval. If it is questionable whether efficacious concentrations of such drugs are being achieved, a sample taken shortly after a dose may be helpful. On the other hand, if a concern is whether low clearance (as in renal failure) may cause accumulation of drug, concentrations measured just before the next dose will reveal such accumulation and are considerably more useful for this purpose than is knowledge of the maximal concentration. For such drugs, determination of both maximal and minimal concentrations is recommended. These two values can offer a more complete picture of the behavior of the drug in a specific patient (particularly if obtained over more than one dosing period) can better support pharmacokinetic modeling.

A second important aspect of the timing of sampling is its relationship to the beginning of the maintenance-dosage regimen. When constant dosage is given, steady state is reached only after four half-lives have passed. If a sample is obtained too soon after dosage is begun, it will not reflect this state and the drug’s clearance accurately. Yet, for toxic drugs, if sampling is delayed until steady state is ensured, the damage may have been done. Some simple guidelines can be offered. When it is important to maintain careful control of concentrations, the first sample should be taken after two half-lives (as calculated and expected for the patient), assuming that no loading dose has been given. If the concentration already exceeds 90% of the eventual expected mean steady-state concentration, the dosage rate should be halved, another sample obtained in another two (supposed) half-lives, and the dosage halved again if this sample exceeds the target. If the first concentration is not too high, the initial rate of dosage is continued; even if the concentration is lower than expected, it is usually reasonable to await the attainment of steady state in another two estimated half-lives and then to proceed to adjust dosage as described earlier.

If dosage is intermittent, there is a third concern with the time at which samples are obtained for determination of drug concentrations. If the sample has been obtained just prior to the next dose, as recommended, concentration will be a minimal value, not the mean. However, as discussed earlier, the estimated mean concentration may be calculated by using Equation (1–16).

If a drug follows first-order kinetics, the average, minimum, and maximum concentrations at steady state are linearly related to dose and dosing rate [see Equations (1–16), (1–19), and (1–20)]. Therefore, the ratio between the measured and desired concentrations can be used to adjust the dose, consistent with available dosage sizes:

$$\frac{C_{ss}(\text{measured})}{C_{ss}(\text{desired})} = \frac{\text{dose (previous)}}{\text{dose (new)}} \quad (1-24)$$

In the previously described patient given 0.375 mg digoxin every 24 hours, for example, if the measured steady-state concentration were found to be 1.65 ng/ml rather than a desired level of 1.3 ng/ml, an appropriate, practical change in the dosage regimen would be to reduce the daily dose to 0.25 mg digoxin.

$$\begin{aligned} \text{Dose (new)} &= \frac{C_{ss}(\text{measured})}{C_{ss}(\text{desired})} \times \text{dose (previous)} \\ &= \frac{1.3}{1.65} \times 0.375 = 0.295 \sim 0.25 \text{ mg/24 hr} \end{aligned}$$

Compliance

Ultimately, therapeutic success depends on the patient actually taking the drug according to the prescribed dosage regimen—“Drugs don’t work if you don’t take them.” Noncompliance with the prescribed dosing schedule is a major reason for therapeutic failure, especially in the long-term treatment of disease using antihypertensive, antiretroviral, and anticonvulsant agents. When no special efforts are made to address this issue, only about 50% of patients follow the prescribed dosage regimen in a reasonably satisfactory fashion, approximately one-third comply only partly, and about 1 in 6 patients is essentially noncompliant. Missed doses are more common than too many doses. The number of drugs does not appear to be as important as the number of times a day doses must be remembered (Farmer, 1999). Reducing the number of required dosing occasions can improve adherence to a prescribed dosage regimen. Equally important is the need to involve patients in the responsibility for their own health using a variety of strategies based on improved communication regarding the nature of the disease and the overall therapeutic plan (see Appendix I).

II. PHARMACODYNAMICS

MECHANISMS OF DRUG ACTION AND THE RELATIONSHIP BETWEEN DRUG CONCENTRATION AND EFFECT

Pharmacodynamics deals with the study of the biochemical and physiological effects of drugs and their mechanisms of action. A thorough analysis of drug action can provide the basis for both the rational therapeutic use of a drug and the design of new and superior therapeutic agents. Basic research in pharmacodynamics also provides fundamental insights into biochemical and physiological regulation.

Mechanisms of Drug Action

The effects of most drugs result from their interaction with macromolecular components of the organism.

These interactions alter the function of the pertinent component and thereby initiate the biochemical and physiological changes that are characteristic of the response to the drug. The term *receptor* denotes the component of the organism with which the chemical agent is presumed to interact.

The concept of drugs acting on receptors generally is credited to John Langley (1878). While studying the antagonistic effects of *atropine* against *pilocarpine*-induced salivation, Langley observed, "There is some substance or substances in the nerve ending or gland cell with which both atropine and pilocarpine are capable of forming compounds." He later referred to this factor as a "receptive substance." The word *receptor* was introduced in 1909 by Paul Ehrlich. Ehrlich postulated that a drug could have a therapeutic effect only if it has the "right sort of affinity." Ehrlich defined a receptor in functional terms: ". . . that combining group of the protoplasmic molecule to which the introduced group is anchored will hereafter be termed *receptor*."

The notion that the receptor for a drug can be any functional macromolecular component of the organism has several fundamental corollaries. One is that a drug potentially is capable of altering both the extent and rate at which any bodily function proceeds. Another is that drugs do not create effects but instead modulate intrinsic physiological functions.

Drug Receptors

From a numerical standpoint, proteins form the most important class of drug receptors. Examples include the receptors for hormones, growth factors, transcription factors, and neurotransmitters; the enzymes of crucial metabolic or regulatory pathways (*e.g.*, dihydrofolate reductase, acetylcholinesterase, and cyclic nucleotide phosphodiesterases); proteins involved in transport processes (*e.g.*, Na⁺,K⁺-ATPase); secreted glycoproteins (*e.g.*, Wnts); and structural proteins (*e.g.*, tubulin). Specific binding properties of other cellular constituents also can be exploited for therapeutic purpose. Thus nucleic acids are important drug receptors, particularly for cancer chemotherapeutic agents.

A particularly important group of drug receptors consists of proteins that normally serve as receptors for endogenous regulatory ligands (*e.g.*, hormones and neurotransmitters). Many drugs act on such physiological receptors and often are particularly selective because physiological receptors are specialized to recognize and respond to individual signaling molecules with great selectivity. Drugs that bind to physiological receptors and mimic the regulatory effects of the endogenous signaling compounds are termed *agonists*. Other drugs bind to receptors without regulatory effect, but their binding blocks the binding of the endogenous agonist. Such compounds with no stimulatory action of their own that still may produce useful

effects by inhibiting the action of an agonist (*e.g.*, by competition for agonist-binding sites) are termed *antagonists*. Agents that are only partly as effective as agonists no matter the amount employed are termed *partial agonists*, and those which stabilize the receptor in its inactive conformation are termed *inverse agonists* (*see* "Quantitation of Drug–Receptor Interactions and Elicited Effect," below).

The binding of drugs to receptors can involve all known types of interactions—ionic, hydrogen bonding, hydrophobic, van der Waals, and covalent. Most interactions between drugs and their receptors involve bonds of multiple types. If binding is covalent, the duration of drug action is frequently, but not necessarily, prolonged. Non-covalent interactions of high affinity also may be essentially irreversible.

Structure–Activity Relationship and Drug Design.

The strength of the reversible interaction between a drug and its receptor, as measured by their dissociation constant, is defined as the *affinity* of one for the other. Both the affinity of a drug for its receptor and its intrinsic activity are determined by its chemical structure. This relationship frequently is quite stringent. Relatively minor modifications in the drug molecule may result in major changes in its pharmacological properties based on altered affinity for one or more receptors.

The stringent nature of chemical structure to specificity of binding of a drug to its receptor is illustrated by the capacity of receptors to interact selectively with optical isomers, as described for the antimuscarinic actions of L-hyoscyamine *versus* DL-hyoscyamine (*atropine*) by the classic studies of Arthur Cushney.

Exploitation of structure–activity relationships on many occasions has led to the synthesis of valuable therapeutic agents. Because changes in molecular configuration need not alter all actions and effects of a drug equally, it is sometimes possible to develop a congener with a more favorable ratio of therapeutic to adverse effects, enhanced selectivity among different cells or tissues, or more acceptable secondary characteristics than those of the parent drug. Therapeutically useful antagonists of hormones or neurotransmitters have been developed by chemical modification of the structure of the physiological agonist. Minor modifications of structure also can have profound effects on the pharmacokinetic properties of drugs. Addition of a phosphate ester, for example, at the N3 position in the antiseizure drug phenytoin (5,5-diphenyl-2,4-imidazolidinedione) produces a prodrug (*fosphenytoin*) that is more soluble in intravenous solutions than its parent. The modification results in far more reliable distribution in the body and a drug that must be cleaved by esterase to become active.

Given adequate information about both the molecular structures and the pharmacological activities of a relatively large group of congeners, it is possible to identify the chemical properties (*i.e.*, the pharmacophore) required for optimal action at the receptor: size, shape, position and orientation of charged groups or hydrogen bond donors,

and so on. Advances in molecular modeling of organic compounds and the methods for drug target (receptor) discovery and biochemical measurement of the primary actions of drugs at their receptors have enriched the quantitation of structure–activity relationships and its use in drug design (Carlson and McCammon, 2000). The importance of specific drug–receptor interactions can be evaluated further by analyzing the responsiveness of receptors that have been selectively mutated at individual amino acid residues. Such information increasingly is allowing the optimization or design of chemicals that can bind to a receptor with improved affinity, selectivity, or regulatory effect. Similar structure-based approaches also are used to improve pharmacokinetic properties of drugs, particularly with respect to knowledge of their metabolism. Knowledge of the structures of receptors and of drug–receptor complexes, determined at atomic resolution by x-ray crystallography, is even more helpful in the design of ligands and in understanding the molecular basis of drug resistance and circumventing it (*i.e.*, *imatinib*). Emerging technology in the fields of *pharmacogenetics* and *pharmacoproteomics* (Chapter 4) is improving our understanding of the nature of and variation in receptors and is positioned to permit molecular diagnostics in individual patients to predict those who will benefit from a particular drug (Jain, 2004).

Advances in combinatorial chemistry contribute to structure-motivated drug design through powerful, if random, generation of new drugs. In this approach, huge libraries of randomly synthesized chemicals are generated either by combining chemical groups in every possible combination by various chemical methodologies or by genetically engineered microbes. A library that can include proteins and even oligonucleotides then is screened for pharmacologically active agents using mammalian cells or microorganisms that have been engineered to express the receptor of therapeutic interest and the associated biochemical machinery necessary for detection of the response to receptor activation. Although libraries can contain on the order of a million compounds, automated high-throughput screening methods permit rapid assessment of putative new drugs. Active compounds initially discovered by such random screens then can be modified and improved using knowledge of their target receptor and essential principles of structure–function relationships.

Cellular Sites of Drug Action. Because drugs act by altering the activities of their receptors, the sites at which a drug acts and the extent of its action are determined by the location and functional capacity of its receptors. Selective localization of drug action within an organism therefore does not necessarily depend on selective distribution of the drug. If a drug acts on a receptor that serves functions common to most cells, its effects will be widespread. If the function is a vital one, the drug may be particularly difficult or dangerous to use. Nevertheless, such a drug may be important clinically. Digitalis glycosides, classically employed in the treatment of heart failure, are potent inhibitors of an ion transport process that is vital to most cells, Na^+, K^+ -ATPase. As such, cardiac glycosides can cause widespread toxicity, and their margin of safety is dangerously low. Indeed, some drugs are intentional poisons, such as the antifolate cancer drug *methotrexate*, which, when used in high dose for the treatment of osteo-

sarcoma, requires rescue with *leucovorin* (5-formyl tetrahydrofolic acid). If a drug interacts with receptors that are unique to only a few types of differentiated cells, its effects are more specific. Hypothetically, the ideal drug would cause its therapeutic effect by such a discrete action. Side effects would be minimized, but toxicity might not be. If the differentiated function were a vital one, this type of drug also could be very dangerous. Some of the most lethal agents known (*e.g.*, *botulinum toxin*) show such specificity. Even if the primary action of a drug is localized, the consequent physiological effects of the drug may be widespread.

Receptors for Physiological Regulatory Molecules

The term *receptor* has been used operationally to denote any cellular macromolecule to which a drug binds to initiate its effects. Among the most important drug receptors are cellular proteins, whose normal function is to act as receptors for endogenous regulatory ligands—particularly hormones, growth factors, and neurotransmitters. The function of such physiological receptors consists of binding the appropriate endogenous ligand and, in response, propagating its regulatory signal in the target cell.

Identification of the two functions of a receptor, ligand binding and message propagation (*i.e.*, signaling), correctly suggests the existence of functional domains within the receptor: a *ligand-binding domain* and an *effector domain*. The structure and function of these domains often can be deduced from high-resolution structures of receptor proteins and by analysis of the behavior of intentionally mutated receptors. Increasingly, the mechanism of intramolecular coupling of ligand binding with functional activation also can be learned. A case in point is knowledge of the crystal structure of the receptor/visual pigment *rhodopsin* that reveals details of the structure of the protein not expected from chemical modeling (Patel *et al.*, 2004). The biological importance of these functional domains is further indicated by the evolution both of different receptors for diverse ligands that act by similar biochemical mechanisms and of multiple receptors for a single ligand that act by unrelated mechanisms.

The regulatory actions of a receptor may be exerted directly on its cellular target(s), *effector protein(s)*, or may be conveyed by intermediary cellular signaling molecules called *transducers*. The receptor, its cellular target, and any intermediary molecules are referred to as a *receptor–effector system* or *signal-transduction pathway*. Frequently, the proximal cellular effector protein is not the ultimate physiological target but rather is an enzyme or trans-

port protein that creates, moves, or degrades a small metabolite (e.g., a cyclic nucleotide or inositol-trisphosphate) or ion (e.g., Ca^{2+}) known as a *second messenger*. Second messengers can diffuse in the proximity of their binding sites and convey information to a variety of targets, which can respond simultaneously to the output of a single receptor binding a single agonist molecule. Even though these second messengers originally were thought of as freely diffusible molecules within the cell, their diffusion and their intracellular actions are constrained by compartmentation—selective localization of receptor–transducer–effector–signal termination complexes—established *via* protein–lipid and protein–protein interactions (Buxton and Brunton, 1983; Wong and Scott, 2004; Baillie and Houslay, 2005).

Receptors and their associated effector and transducer proteins also act as integrators of information as they coordinate signals from multiple ligands with each other and with the metabolic activities of the cell (*see* below). This integrative function is particularly evident when one considers that the different receptors for scores of chemically unrelated ligands use relatively few biochemical mechanisms to exert their regulatory functions and that even these few pathways may share common signaling molecules.

An important property of physiological receptors that also makes them excellent targets for drugs is that they act catalytically and hence are biochemical signal amplifiers. The catalytic nature of receptors is obvious when the receptor itself is an enzyme, but all known physiological receptors are formally catalysts. For example, when a single agonist molecule binds to a receptor that is an ion channel, hundreds of thousands to millions of ions flow through the channel every second. The number of ions moving through the channel depends on the characteristic conductance of the channel, a property analogous to amplifier gain. Physiological receptor channels display conductance in the range of tens to hundreds of picosiemens. Similarly, a single steroid hormone molecule binds to its receptor and initiates the transcription of many copies of specific mRNAs, which, in turn, can give rise to multiple copies of a single protein.

Drug–Receptor Binding and Agonism. A receptor can exist in at least two conformational states, active (R_a), and inactive (R_i). If these states are in equilibrium and the inactive state predominates in the absence of drug, then the basal signal output will be low. The *extent* to which the equilibrium is shifted toward the active state is determined by the *relative* affinity of the drug for the two conformations (Figure 1–6). A drug that has a higher affinity for the active conformation than for the inactive conformation will drive the equilibrium to the active state and thereby activate the receptor. Such a drug will be an agonist. A full agonist is sufficiently selective for the active conformation that at a saturating concentration it will drive the receptor essentially completely to the active state (Figure 1–6). If a different but perhaps structurally similar compound binds

to the same site on R but with only moderately greater affinity for R_a than for R_i , its effect will be less, even at saturating concentrations. A drug that displays such intermediate effectiveness is referred to as a *partial agonist* because it cannot promote a full biological response at any concentration. In an absolute sense, all agonists are partial; selectivity for R_a over R_i cannot be total. A drug that binds with equal affinity to either conformation will not alter the activation equilibrium and will act as a competitive antagonist of any compound, agonist or antagonist, that does. A drug with preferential affinity for R_i actually will produce an effect opposite to that of an agonist; examples of such *inverse agonists* at G protein–coupled receptors (GPCRs) do exist (e.g., *famotidine*, *losartan*, *metoprolol*, and *risperidone*) (Milligan, 2003).

Inverse agonism may be measurable only in systems in which an equilibrium between R_i and R_a exists in the absence of drug such that a decrease in physiological or biochemical response can be measured in the presence of drug with a higher affinity for R_i than R_a . If the *preexisting* or basal equilibrium for unliganded receptors lies far in the direction of R_i , negative antagonism may be difficult to observe and to distinguish from simple competitive antagonism.

Figure 1–6. Regulation of the activity of a receptor with conformation-selective drugs. The ordinate is some activity of the receptor produced by R_a , the active receptor conformation (e.g., stimulation of adenylyl cyclase). If a drug D selectively binds to R_a , it will produce a maximal response. If D has equal affinity for R_i and R_a , it will not perturb the equilibrium between them and will have no effect on net activity; D would appear as an inactive compound. If the drug selectively binds to R_i , then the net amount of R_a will be diminished. If there is sufficient R_a to produce an elevated basal response in the absence of ligand (agonist-independent constitutive activity), then activity will be observably inhibited; D will be an inverse agonist. If D can bind to receptor in an active conformation R_a but also bind to inactive receptor R_i with lower affinity, the drug will produce a partial response; D will be a partial agonist.

Careful biochemical studies of receptor–drug interactions, coupled with the analysis of receptors in which the intrinsic R_a/R_i equilibrium has been shifted by mutation, have supported this general model of drug action. The model is readily applicable to experimental data through the use of appropriate computer-assisted analysis of the laws of mass action and is used frequently as a guide to understanding drug action. This approach has been particularly useful in understanding the interaction of agonists and antagonists with GPCRs and ion channels. Indeed, electrophysiological measurements, particularly those of single-channel behavior, create a moment-to-moment analysis of receptor function that permits detailed modeling of intermediate states of receptor conformation that have led to the design of more selective drugs (e.g., antiarrhythmics).

Current models for GPCR activation assume that receptors are in equilibrium between inactive (R_i) and active (R_a) conformations (Milligan, 2003). R_a is promoted by agonists but also may occur in their absence, leading to constitutive activity. In order to explain the behavior of recombinant receptors in model systems however, it is necessary to consider additional receptor conformations. The term *protean agonist* has been used to explain reversal from agonism to inverse agonism when an agonist produces an active conformation of lower efficacy than the constitutively active conformation of the receptor (Kenakin, 1995). Apparent protean agonism has been observed recently for native receptors under physiological conditions (Gbahou *et al.*, 2003).

Physiological Receptors: Structural and Functional Families. We have witnessed both an explosion in our appreciation of the number of physiological receptors and, in parallel, the development of our understanding of the fundamental structural motifs and biochemical mechanisms that characterize them. Molecular cloning has identified both completely novel receptors (and their regulatory ligands) and numerous isoforms, or subtypes, of previously known receptors. There now exist data banks devoted exclusively to structures of single classes of receptors. Members of various classes of receptors, transducers, and effector proteins have been purified, and their mechanisms of action are understood in considerable biochemical detail. Receptors, transducers, and effectors can be expressed or, conversely, repressed *via* molecular genetic strategies and the consequence of their alteration studied in cultured mammalian cells or systems of convenience such as yeast or *Candida elegans*. Furthermore, it is now possible to produce transgenic knockout animals (notably mice) that lack a particular receptor. Providing that the deletion is not lethal and that the resulting offspring can breed, much can be learned about the role of the missing receptor.

Receptors for physiological regulatory molecules can be assigned to a relatively few functional families whose members share both common mechanisms of action and similar molecular structures (Figure 1–7). For each receptor superfamily, there is now a context for understanding

the structures of ligand-binding domains and effector domains and how agonist binding influences the regulatory activity of the receptor. The relatively small number of biochemical mechanisms and structural formats used for cellular signaling is fundamental to the ways in which target cells integrate signals from multiple receptors to produce additive, sequential, synergistic, or mutually inhibitory responses.

Receptors as Enzymes: Receptor Protein Kinases and Guanylyl Cyclases. The largest group of receptors with intrinsic enzymatic activity consists of cell surface protein kinases, which exert their regulatory effects by phosphorylating diverse effector proteins at the inner face of the plasma membrane. Protein phosphorylation can alter the biochemical activities of an effector or its interactions with other proteins. Indeed, of all the possible reversible covalent modifications of proteins that regulate their function, phosphorylation is the most common. Most receptors that are protein kinases phosphorylate tyrosine residues in their substrates; these include receptors for insulin and diverse polypeptides that direct growth or differentiation, such as epidermal growth factor and nerve growth factor. A few receptor protein kinases phosphorylate serine or threonine residues. The most structurally simple receptor protein kinases are composed of an agonist-binding domain on the extracellular surface of the plasma membrane, a single membrane-spanning element, and a protein kinase domain on the inner membrane face. Many variations on this basic architecture exist, including assembly of multiple subunits in the mature receptor, obligate oligomerization of the liganded receptor, and the addition of multiple regulatory or protein-binding domains to the intracellular protein kinase domain that permit association of the liganded receptor with additional effector molecules (frequently *via* interaction of phosphotyrosine residues and SH₂ domains) and with substrates. Drugs designed to act at receptors in this diverse family include *insulin* for the treatment of diabetes mellitus and imatinib, designed to inhibit both receptor and non-receptor tyrosine kinases and approved for the treatment of chronic myelogenous leukemia.

Another family of receptors that are functionally linked to protein kinases contains a modification of the structure just described. Protein kinase–associated receptors lack the intracellular enzymatic domains but, in response to agonists, bind or activate distinct protein kinases on the cytoplasmic face of the plasma membrane. Receptors of this group include the cytokine receptors, several receptors for neurotrophic peptides, the growth hormone receptor, the multisubunit antigen receptors on T- and B-lymphocytes, and the interferon- γ receptor.

The domain structure described for cell surface protein kinases is varied in other receptors to use other signaling outputs. A family of protein tyrosine phosphatases has extracellular domains with a sequence reminiscent of cellular adhesion molecules. Although the extracellular ligands for many of these phosphatases are not known, the importance of their enzymatic activity has been demonstrated through genetic and biochemical experiments. Indeed, these receptor protein tyrosine phosphatases (RPTPs) appear to be activated by each other and by extracellular matrix proteins expressed by particular cell types, consistent with their role in regulating cell–cell interactions and tissue organization. For the receptors that bind atrial natriuretic peptides and the peptides guanylin and uroguanylin, the intracellular domain is not a protein kinase but rather a guanylyl

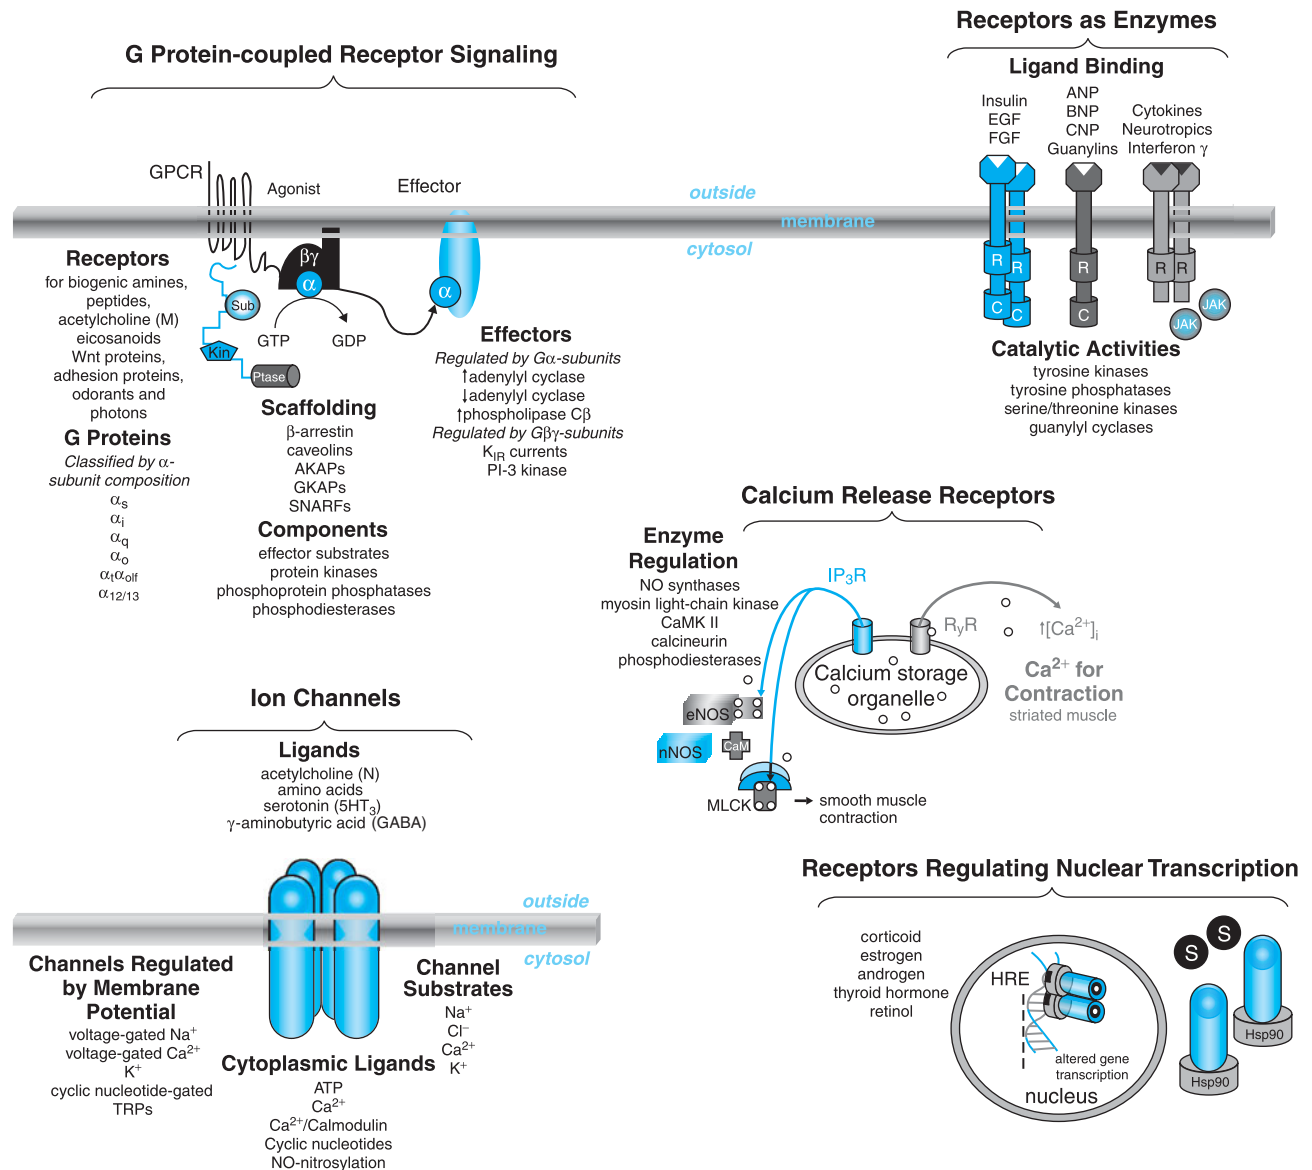

Figure 1–7. Structural motifs of physiological receptors and their relationships to signaling pathways. Schematic diagram of the diversity of mechanisms for control of cell function by receptors for endogenous agents acting *via* the cell surface or at calcium storage sites or in the nucleus. Detailed descriptions of these signaling pathway are given throughout the text in relation to the therapeutic actions of drugs affecting these pathways.

cyclase that synthesizes the second messenger cyclic guanosine monophosphate (GMP), which activates a cyclic GMP–dependent protein kinase (PKG) and modulates the activities of several nucleotide phosphodiesterases.

Protease-Activated Receptor Signaling. Some receptors are not presented by the cell in a form readily accessible to agonist. Proteases that are anchored to the plasma membrane or that are soluble in the extracellular fluid (*e.g.*, thrombin) can cleave ligands or receptors at the surfaces of cells to either initiate or terminate signal transduction. Peptide agonists often are processed by proteolysis to become active at their receptors. Tumor necrosis factor α (TNF- α)–

converting enzyme (TACE) cleaves the precursor of TNF- α at the plasma membrane, releasing a soluble form of this pro-inflammatory cytokine. Similarly, angiotensin-converting enzyme (ACE), which is also an integral membrane protein preferentially expressed by endothelial cells in the blood vessels of the lung, converts angiotensin I to angiotensin II (Ang II), thereby generating the active hormone near receptors for Ang II on vascular smooth muscle. In contrast, neutral endopeptidase degrades and inactivates the neuropeptide substance P (SP) in the vicinity of its receptors and thus terminates the biological effects of SP. Some GPCRs (*see* below) also can be activated or inactivated by proteases at the cell

surface. For example, the coagulation factor thrombin cleaves protease-activated platelet receptor 1 (PAR1), activating it to induce platelet aggregation. On the other hand, neutrophil-derived cathepsin G cleaves PAR1 at a site distinct from that of thrombin, generating a thrombin-insensitive receptor. Targeting the proteolytic regulation of receptor mechanisms has produced successful therapeutic strategies, such as the use of ACE inhibitors in the treatment of hypertension (see Chapters 30 and 32) and the generation of new anticoagulants targeting the action of thrombin (see Chapter 54).

Ion Channels. Receptors for several neurotransmitters form agonist-regulated ion-selective channels in the plasma membrane, termed *ligand-gated ion channels* or *receptor operated channels*, that convey their signals by altering the cell's membrane potential or ionic composition. This group includes the nicotinic cholinergic receptor, the γ -aminobutyric acid A (GABA_A) receptor, and receptors for glutamate, aspartate, and glycine (see Chapters 9, 12, and 16). They are all multisubunit proteins, with each subunit predicted to span the plasma membrane several times. Symmetrical association of the subunits allows each to form a segment of the channel wall, or pore, and to cooperatively control channel opening and closing. Agonist binding may occur on a particular subunit that may be represented more than once in the assembled multimer (e.g., the nicotinic acetylcholine receptor) or may be conferred by a separate single subunit of the assembled channel, as is the case with the so-called sulfonyleurea receptor (SUR) that associates with a K⁺ channel (Kir_{6.2}) to regulate the ATP-dependent K⁺ channel (K_{ATP}). The K_{ATP} channel is a receptor for compounds such as *glibenclamide* (a channel antagonist) in the treatment of diabetes type 2 (see Chapter 60). Openers of the same channel (*minoxidil*) are used as vascular smooth muscle relaxants. Receptor-operated channels also are regulated by other receptor-mediated events, such as protein kinase activation following activation of GPCRs (see below). Phosphorylation of the channel protein on one or more of its subunits can confer both activation and inactivation depending on the channel and the nature of the phosphorylation.

G Protein-Coupled Receptors. A large superfamily of receptors that accounts for many known drug targets interacts with distinct heterotrimeric GTP-binding regulatory proteins known as *G proteins*. G proteins are signal transducers that convey information (i.e., agonist binding) from the receptor to one or more effector proteins. GPCRs include those for a number of biogenic amines, eicosanoids and other lipid-signaling molecules, peptide hormones, opioids, amino acids such as GABA, and many other peptide and protein ligands. G protein-regulated effectors include enzymes such as adenylyl cyclase, phospholipase C, phosphodiesterases, and plasma membrane ion channels selective for Ca²⁺ and K⁺ (Figure 1–7). Because of their number and physiological importance, GPCRs are widely used targets for drugs; perhaps half of all nonantibiotic prescription drugs are directed toward these receptors that make up the third largest family of genes in humans.

GPCRs span the plasma membrane as a bundle of seven α -helices. Agonists bind to a cleft within the extracellular face of the bundle or to a globular ligand-binding domain sometimes found at the amino terminus. G proteins bind to the cytoplasmic face of the receptors. Receptors in this family respond to agonists by promoting the binding of GTP to the G protein α subunit. GTP activates the G protein and allows it, in turn, to activate the effector protein. The G protein remains active until it hydrolyzes the bound GTP to GDP and returns to its ground (inactive) state. G proteins are composed of a GTP-binding α subunit, which confers specific recognition by receptor and effector, and an associated dimer of β and γ subunits

that can confer both membrane localization of the G protein (e.g., *via* myristoylation) and direct signaling such as activation of inward rectifier K⁺ (GIRK) channels and binding sites for G protein receptor kinases (GRKs). Activation of the G _{α} subunit by GTP allows it to both regulate an effector protein and drive the release of G _{$\beta\gamma$} subunits, which can, in addition to regulating their own group of effectors, reassociate with GDP-liganded G _{α} , returning the system to the basal state.

A cell may express as many as twenty different GPCRs, each with distinctive specificity for one or several of half a dozen G proteins. Each subunit of the G protein complex is encoded by a member of one of three corresponding gene families. Currently, 16 different members of the α -subunit family, 5 different members of the β -subunit family, and 11 different members of the γ -subunit family have been described in mammals. A G protein can regulate one or more effectors, and multiple GPCRs can activate the same G protein. A receptor also may generate multiple signals by activating more than one G protein species. GPCRs can activate several signal-transduction systems as a consequence of G protein activation. From the classical view of G protein activation of adenylyl cyclase, accumulation of cyclic adenosine monophosphate (cAMP), and activation of cAMP-dependent protein kinase (PKA), we now know that the consequences of G protein activation have both direct and indirect effects on multiple pathways.

Central to the effect of many GPCRs is release of calcium (Ca²⁺) from intracellular stores. For example, α receptors for norepinephrine activate G _{q} specific for the activation of phospholipase C _{β} . Phospholipase C _{β} (PLC _{β}) is a membrane-bound enzyme that hydrolyzes a membrane phospholipid, phosphatidylinositol-4,5-bisphosphate, to generate inositol-1,4,5-trisphosphate (IP₃) and the lipid, diacylglycerol. IP₃ binds to receptors on Ca²⁺ release channels in the IP₃-sensitive Ca²⁺ stores of the endoplasmic reticulum, triggering the release of Ca²⁺ and rapidly raising [Ca²⁺]_i from approximately 100 nM into the micromolar range. When Ca²⁺ levels rise following release from intracellular stores, the elevation of Ca²⁺ is transient owing to avid reuptake of Ca²⁺ into stores. Ca²⁺ can bind to and directly regulate ion channels (e.g., large conductance Ca²⁺-activated K⁺ channels), or Ca²⁺ can bind to calmodulin, and the resulting Ca²⁺-calmodulin complex then can bind ion channels (e.g., small conductance Ca²⁺-activated K⁺ channels) or to intracellular enzymes such as Ca²⁺-calmodulin-dependent protein kinases (e.g., CaMKII, MLCK, and phosphorylase kinase).

Diacylglycerol (DAG), formed by the action of PLC _{β} , also participates in the response to G protein activation by binding to protein kinase C (PKC), thereby promoting its association with the cell membrane and lowering its requirement for activation by Ca²⁺. DAG binds to other proteins with cysteine-rich (C-1) domains that participate in non-kinase-mediated regulation of processes such as neurotransmitter release. PKC can regulate numerous cellular events by activating members of the mitogen-activated kinase (MAPK) family, which, depending on the cell type, includes extracellular signal-regulated kinases (ERKs), c-Jun N-terminal kinases (JNKs), and p38 MAPKs. The initial increase in intracellular diacylglycerol can be sustained by its activation of phospholipase D, which hydrolyzes membrane phosphatidylcholine to generate phosphatidic acid and choline. Phosphatidic acid, in turn, can be converted enzymatically to diacylglycerol or serve as a substrate for phospholipase A₂ (PLA₂), which generates lysophosphatidic acid (LPA) and frees 20-carbon fatty acids (e.g., C20:4, 5,8,11,14-eicosatetraenoic acid) for eicosanoid synthesis. Eicosanoids act as autocrine and paracrine agents frequently *via* specific GPCRs (see Chapters 26 and 35).

LPA can bind to specific GPCRs of the endothelial differentiating gene family (Edg receptors) that signal cell growth and differentiation and can regulate transcription factors such as the peroxisome proliferator-activated receptors (PPARs) that modulate nuclear transcription and are the receptors (PPAR γ) for the glitazones, newer oral hypoglycemic agents (*see* Chapter 60).

While the complexity of receptor signaling through G proteins is clear from the abundance of GPCRs present on a single cell, receptor–ligand interactions alone do not regulate all GPCR signaling. It is now clear that GPCRs undergo both homo- and heterodimerization and possibly oligomerization (Kroeger *et al.*, 2003; Milligan, 2004). Evidence of therapeutic importance for dimerization is suggested by many recent studies; heterodimerization can result in receptor units with altered pharmacology compared with either individual receptor. For example, heterodimerization between the γ aminobutyric acid receptor subunit protein GABA_{B1} and GABA_{B2} is required for receptor binding of agonist (GABA_{B1}) and trafficking (GABA_{B2}) to the cell surface and receptor function (these receptors mediate the metabotropic actions of the inhibitory neurotransmitter GABA). Dimerization also appears to be important in the actions of dopamine receptors (D₂ homodimers), where ligand preference appears to be conferred by dimerization, a finding that could have therapeutic implications. Evidence also is emerging that dimerization of receptors may regulate the affinity and specificity of the complex for G protein and regulate the sensitivity of the receptor to phosphorylation by receptor kinases and the binding of arrestin, events important in termination of the action of agonists and removal of receptors from the cell surface. Dimerization also may permit binding of receptors to other regulatory proteins such as transcription factors. Thus, the receptor–G protein effector systems are complex networks of convergent and divergent interactions involving both receptor–receptor and receptor–G protein coupling that permits extraordinarily versatile regulation of cell function.

Transcription Factors. Receptors for steroid hormones, thyroid hormone, vitamin D, and the retinoids are soluble DNA-binding proteins that regulate the transcription of specific genes (Wei, 2003). They are part of a larger family of transcription factors whose members may be regulated by phosphorylation, association with other cellular proteins, or binding to metabolites or cellular regulatory ligands (*e.g.*, heat shock proteins). These receptors act as dimers—some as homodimers and some as heterodimers—with homologous cellular proteins, but they may be regulated by higher-order oligomerization with other modulator molecules. Often bound to proteins in the cytoplasm that retain them in an inactive state, they provide examples of conservation of structure and mechanism in part because they are assembled as three largely independent domains. The region nearest the carboxyl terminus binds hormone and is called the *ligand-binding domain* (LBD) that confers a negative regulatory role; hormone binding relieves this inhibitory constraint. The central region of the receptor is the *DNA binding domain* (DBD) that mediates binding to specific sites on the genome to activate or inhibit transcription of the nearby gene. These regulatory sites in DNA are likewise receptor-specific: the sequence of a “glucocorticoid-response element,” with only slight variation, is associated with each glucocorticoid-response gene, whereas a “thyroid-response element” confers specificity of the actions of the thyroid hormone nuclear receptor. The amino-terminal region of the receptor provides the activation function (AF) domain essential for transcriptional regulation.

Steroid hormone receptors undergo a complex interaction with themselves and coregulators. There are at least three subfamilies of

proteins that form the steroid receptor coactivator (SRC) family. The specific set of proteins that assemble with a particular steroid hormone–liganded receptor in the regulation of transcription varies with the receptor in question (*see* Chapters 57 through 59). In general, the members of this family serve functions essential for DNA binding such as acetylation of histone proteins [*e.g.*, histone acetyltransferase activity (HAT)] that permit interaction of the receptor with the hormone response element to initiate transcription. Steroid hormone receptor regulation of transcription does not always result in transcriptional activation; in some cases, as in glucocorticoid action, the effect of the hormone is to decrease the production of steroid-responsive protein transcription.

Cytoplasmic Second Messengers. Binding of an agonist to a receptor provides the first message in receptor signal transduction to effector pathways and an eventual physiological outcome. The first messenger promotes the cellular production or mobilization of a second messenger, which initiates cellular signaling through a specific biochemical pathway. Physiological signals are integrated within the cell as a result of interactions between and among second-messenger pathways. Compared with the number of receptors and cytosolic signaling proteins, there are relatively few recognized cytoplasmic second messengers. However, their synthesis or release and degradation or excretion reflects the activities of many pathways. Well-studied second messengers include cyclic AMP, cyclic GMP, cyclic ADP-ribose, Ca²⁺, inositol phosphates, diacylglycerol, and nitric oxide. Second messengers influence each other both directly, by altering the other’s metabolism, and indirectly, by sharing intracellular targets. This pattern of regulatory pathways allows the cell to respond to agonists, singly or in combination, with an integrated array of cytoplasmic second messengers and responses.

Cyclic AMP. Cyclic AMP, the prototypical second messenger, remains a good example for understanding the regulation and function of most second messengers (for an overview of cyclic nucleotide action, *see* Beavo and Brunton, 2002). Cyclic AMP is synthesized by adenylyl cyclase under the control of many GPCRs; stimulation is mediated by G_s; inhibition, by G_i.

There are nine membrane-bound isoforms of adenylyl cyclase (AC) and one soluble isoform found in mammals (Hanoune and Defer, 2001). The membrane-bound ACs are glycoproteins of approximately 120 kDa with considerable sequence homology: a small cytoplasmic domain; two hydrophobic transmembrane domains, each with six membrane-spanning helices; and two large cytoplasmic domains. Membrane-bound ACs exhibit basal enzymatic activity that is modulated by binding of GTP-liganded α subunits of the stimulatory and inhibitory G proteins (G_s and G_i). Numerous other regulatory interactions are possible, and these enzymes are catalogued based on their structural homology and their distinct regulation by G protein α and $\beta\gamma$ subunits, Ca²⁺, protein kinases, and the actions of the diterpene forskolin. Because each AC isoform has its own tissue distribution and regulatory properties, different cell types respond differently to similar stimuli.

The role of agonists interacting at GPCRs is to accelerate the exchange of GDP for GTP on the α subunits of these G proteins, thereby promoting the dissociation of the heterotrimeric G proteins into α -GTP and $\beta\gamma$ subunits and resulting in modulation of adenylyl cyclase activity. Once activated by α_s -GTP, AC remains activated until α_s hydrolyses the bound GTP to GDP, which returns the system to its ground state (*see* Ross and Wilkie, 2000). As a consequence, there is amplification at this step, a single activation producing numerous molecules of cyclic AMP, which, in turn, can

activate PKA. Cyclic AMP is eliminated by a combination of hydrolysis, catalyzed by cyclic nucleotide phosphodiesterases, and extrusion by several plasma membrane transport proteins.

Phosphodiesterases (PDEs) form yet another family of important signaling proteins whose activities are regulated by controlled transcription as well as by second messengers (cyclic nucleotides and Ca^{2+}) and interactions with other signaling proteins such as β -arrestin and protein kinases (Brunton, 2003; Maurice *et al.*, 2003). PDEs are enzymes responsible for the hydrolysis of the cyclic 3',5'-phosphodiester bond found in cyclic AMP and cyclic GMP. PDEs comprise a superfamily with 11 subfamilies, having been characterized on the basis of amino acid sequence, substrate specificity, pharmacological properties, and allosteric regulation. The PDE superfamily encompasses 25 genes that are thought to give rise to more than 50 different PDE proteins. PDEs share a conserved catalytic domain at the carboxyl terminus, regulatory domains located most often at the amino terminus, and targeting domains that are the subject of active investigation. The substrate specificities of the PDEs include enzymes that are specific for cyclic AMP hydrolysis, cyclic GMP hydrolysis, and those that hydrolyze both. PDEs play a highly regulated role that is important in controlling the intracellular levels of cyclic AMP and cyclic GMP. The importance of the PDEs as regulators of signaling is evident from their development as drug targets in diseases such as asthma and chronic obstructive pulmonary disease, cardiovascular diseases such as heart failure and atherosclerotic peripheral arterial disease, neurological disorders, and erectile dysfunction (Mehats *et al.*, 2002).

Cyclic GMP. Cyclic GMP is generated by two distinct forms of guanylyl cyclase (GC). Nitric oxide (NO) stimulates soluble guanylyl cyclase (sGC), and the natriuretic peptides, guanylin, and heat-stable *Escherichia coli* enterotoxin stimulate members of the membrane-spanning GCs (*e.g.*, particulate GC).

Actions of Cyclic Nucleotides. In most cases, cyclic AMP functions by activating the isoforms of cyclic AMP-dependent protein kinase (PKA), and cyclic GMP activates a cGMP-dependent protein kinase (PKG). Recently, a number of additional actions of cyclic nucleotides have been described, all with pharmacological relevance.

Cyclic Nucleotide-Dependent Protein Kinases. PKA holoenzyme consists of two catalytic (C) subunits reversibly bound to a regulatory (R) subunit dimer. The holoenzyme is inactive. Binding of four cyclic AMP molecules, two to each R subunit, dissociates the holoenzyme, liberating two catalytically active C subunits that phosphorylate serine and threonine residues on specific substrate proteins.

PKA diversity lies in both its R and C subunits. Molecular cloning has revealed α and β isoforms of both the classically described PKA regulatory subunits (RI and RII), as well as three C subunit isoforms $C\alpha$, $C\beta$, and $C\gamma$. The R subunits exhibit different binding affinities for cyclic AMP, giving rise to PKA holoenzymes with different thresholds for activation. In addition to differential expression of R and C isoforms in various cells and tissues, PKA function is modulated by subcellular localization mediated by A-kinase-anchoring proteins (AKAPs) (*see* Wong and Scott, 2004).

PKA can phosphorylate both final physiological targets (metabolic enzymes or transport proteins) and numerous protein kinases and other regulatory proteins in multiple signaling pathways. This latter group includes transcription factors that allow cyclic AMP to regulate gene expression in addition to more acute cellular events. For instance, phosphorylation by PKA of serine 133 of CREB (the cyclic AMP response element-binding protein) recruits CREB-binding protein (CBP), a histone acetyltransferase that interacts with

PNA polymerase II (POLII) and leads to enhanced transcription of approximately 105 genes containing a cyclic AMP response element motif (CRE) in the promoter region (*e.g.*, tyrosine hydroxylase, iNOS, AHR, angiotensinogen, insulin, the glucocorticoid receptor, BCl2, and CFTR) (*see* Mayr and Montminy, 2001).

Cyclic GMP activates a protein kinase, PKG, that phosphorylates some of the same substrates as PKA and some that are PKG-specific. Unlike PKA, PKG does not disassociate on binding cyclic GMP. PKG is known to exist in two homologous forms. PKGI, with an acetylated N terminus, is associated with the cytoplasm and known to exist in two isoforms ($I\alpha$ and $I\beta$) that arise from alternate splicing. PKGII, with a myristylated N terminus, is membrane-associated and may be compartmentalized by PKG-anchoring proteins (Vo *et al.*, 1998) in a manner similar to that known for PKA. Pharmacologically important effects of elevated cyclic GMP include modulation of platelet activation and regulation of smooth muscle contraction (Rybalkin *et al.*, 2003; Buxton, 2004).

Cyclic Nucleotide-Gated Channels. In addition to activating a protein kinase, cyclic AMP also directly regulates the activity of plasma membrane cation channels referred to as *cyclic nucleotide-gated (CNG) channels*. CNG ion channels have been found in kidney, testis, heart, and the CNS (for a review, *see* Beavo and Brunton, 2002). These channels open in response to direct binding of intracellular cyclic nucleotides and contribute to cellular control of the membrane potential and intracellular Ca^{2+} levels. The CNG ion channels are multisubunit pore-forming channels that share structural similarity with the voltage-gated K^+ channels. Modulation of channel activity is the result of binding of as many as four molecules of cyclic nucleotide to the channel.

Cyclic AMP-Regulated GTPase Exchange Factors (GEFs). The small GTP-binding proteins are monomeric GTPases and key regulators of cell function. They integrate extracellular signals from membrane receptors with cytoskeletal changes and activation of diverse signaling pathways, regulating such processes as phagocytosis, progression through the cell cycle, cell adhesion, gene expression, and apoptosis (Etienne-Manneville and Hall, 2002). The small GTPases operate as binary switches that exist in GTP- or GDP-liganded conformations. The switch is activated when an upstream signal activates a GTPase exchange factor (GEF) that, on binding to the GDP-liganded GTPase, promotes the exchange of GDP for GTP. A number of extracellular stimuli signal to the small GTPases through second messengers such as cyclic AMP, Ca^{2+} , and DAG that regulate GEFs. Two of these proteins involved in the regulation of the Ras protein, termed *exchange proteins activated by cyclic AMP* (EPAC-1 and -2), are cyclic AMP GEFs. The EPAC pathway provides an additional effector system for cyclic AMP signaling and drug action. When GTP binds to the small GTP-binding protein, it induces a conformational change that promotes binding and modification of the activities of effector proteins. The switch is terminated by hydrolysis of GTP by the GTPase activity of the small GTP-binding protein. The rate of GTP hydrolysis is accelerated by interaction with GTPase-activating proteins (GAPs).

GAF Domains. GAF domains are a phylogenetically broad family of proteins that bind cyclic GMP and other ligands. In mammalian cells, GAF domains confer on a protein sensitivity to cyclic GMP. For instance, cyclic GMP binding to GAF domains activates PDE2, renders PDE5 phosphorylatable (and activatable) by PKG, and regulates the affinity of PDE6 for its autoinhibitory domain. Given the myriad important roles of PDE activities in physiology, GAF domains may be therapeutically useful drug targets (Martinez *et al.*, 2002).

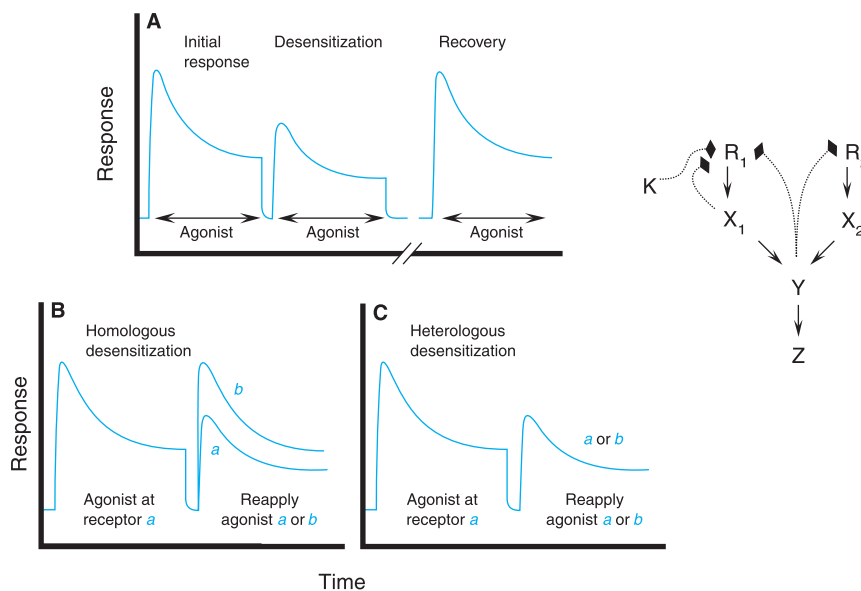

Figure 1-8. Desensitization in response to an agonist. **A.** After exposure to an agonist, the *initial response* usually peaks and then decreases to approach some tonic level elevated but below the maximum. If the drug is removed for a brief period, the state of *desensitization* is maintained such that a second addition of agonist also provokes a diminished response. Removal of the drug for a more extended period allows the cell to recover its capacity to respond. **B, C.** Desensitization may be *homologous* (**B**), affecting responses elicited only by the stimulated receptor, or *heterologous* (**C**), acting on several receptors or on a pathway that is common to many receptors. Agonist *a* acts at receptor *a* and agonist *b* at receptor *b*. Homologous desensitization can reflect feedback from a transducer (or effector) unique to the pathway of the receptor (X_1) or from an off-pathway component (K) that is sensitive to the activation state of the receptor. Heterologous desensitization is initiated by transducers or effectors common to multiple receptor signaling pathways (Y or Z).

Calcium. The entry of Ca^{2+} into the cytoplasm is mediated by diverse channels: Plasma membrane channels regulated by G proteins, membrane potential, K^+ or Ca^{2+} itself, and channels in specialized regions of endoplasmic reticulum that respond to IP_3 or, in excitable cells, to membrane depolarization and the state of the Ca^{2+} release channel and its Ca^{2+} stores in the sarcoplasmic reticulum. Ca^{2+} is removed both by extrusion (Na^+-Ca^{2+} exchanger and Ca^{2+} ATPase) and by reuptake into the endoplasmic reticulum (SERCA pumps). Ca^{2+} propagates its signals through a much wider range of proteins than does cyclic AMP, including metabolic enzymes, protein kinases, and Ca^{2+} -binding regulatory proteins (e.g., calmodulin) that regulate still other ultimate and intermediary effectors that regulate cellular processes as diverse as exocytosis of neurotransmitters and muscle contraction. Drugs such as *chlorpromazine* (an antipsychotic agent) are calmodulin inhibitors.

Regulation of Receptors

Receptors not only initiate regulation of biochemical events and physiological function but also are themselves subject to many regulatory and homeostatic controls. These controls include regulation of the synthesis and degradation of the receptor by multiple mechanisms, covalent modification, association with other regulatory proteins, and/or relocalization within the cell. Transducer and effector proteins are regulated similarly. Modulating

inputs may come from other receptors, directly or indirectly, and receptors are almost always subject to feedback regulation by their own signaling outputs.

Continued stimulation of cells with agonists generally results in a state of *desensitization* (also referred to as *adaptation*, *refractoriness*, or *down-regulation*) such that the effect that follows continued or subsequent exposure to the same concentration of drug is diminished (Figure 1-8). This phenomenon known as *tachyphylaxis* occurs rapidly and is very important in therapeutic situations; an example is attenuated response to the repeated use of β receptor agonists as bronchodilators for the treatment of asthma (see Chapters 10 and 27).

Desensitization can be the result of temporary inaccessibility of the receptor to agonist or the result of fewer receptors synthesized and available at the cell surface. Down-regulation of receptor number best describes this latter accommodation of the cell to the chronic presence of excess agonist. Agonist stimulation of GPCRs initiates regulatory processes that are often rapid, leading to desensitization to subsequent stimulation by agonist without immediately changing the total number of receptors. Phosphorylation of the receptor by specific GPCR kinases (GRKs) plays a key role in triggering rapid desensitization. Phosphorylation of agonist-occupied GPCRs by GRKs facilitates the binding of cytosolic proteins termed *arrestins* to the receptor, resulting in the uncoupling of G

protein from the receptor. The β -arrestins recruit proteins such as PDE4 (which limits cyclic AMP signaling), and others such as clathrin and β_2 -adaplin, promoting sequestration of receptor from the membrane (internalization) and providing a scaffold that permits additional signaling steps such as activation of the ERK/MAPK cascade associated with activation of some GPCRs (Baillie and Houslay, 2005; Tan *et al.*, 2004).

Feedback inhibition of signaling may be limited to output only from the stimulated receptor, a situation known as *homologous desensitization*. Attenuation extending to the action of all receptors that share a common signaling pathway is called *heterologous desensitization* (Figure 1–8). Homologous desensitization indicates feedback directed to the receptor molecule itself (*e.g.*, phosphorylation, internalization and proteolysis, decreased synthesis, etc.), whereas heterologous desensitization may involve inhibition or loss of one or more downstream proteins that participate in signaling from other receptors as well. Mechanisms involved in homologous and heterologous desensitization of specific receptors and signaling pathways are discussed in greater detail in later chapters related to individual receptor families.

Predictably, supersensitivity to agonists also frequently follows chronic reduction of receptor stimulation. Such situations can result, for example, following withdrawal from prolonged receptor blockade (*e.g.*, the long-term administration of β receptor antagonists such as propranolol (*see* Chapter 10) or in the case where chronic denervation of a preganglionic fiber induces an increase in neurotransmitter release per pulse, indicating postganglionic neuronal supersensitivity. Supersensitivity can be the result of tissue response to pathological conditions such as happens in cardiac ischemia and is due to synthesis and recruitment of new receptors to the surface of the myocyte.

Diseases Resulting from Receptor Malfunction. Considering the roles of receptors in mediating the actions of regulatory ligands acting on cells, it is not surprising that alteration in receptors and their immediate signaling effectors can be the cause of disease. The loss of a receptor in a highly specialized signaling system may cause a relatively limited, if dramatic, phenotypic disorder such as the genetic deficiency of the androgen receptor in the testicular feminization syndrome (*see* Chapter 58). Deficiencies in more widely used signaling systems have a broader spectrum of effects, as are seen in myasthenia gravis and some forms of insulin-resistant diabetes mellitus, which result from autoimmune depletion of nicotinic cholinergic receptors (*see* Chapter 9) or insulin receptors (*see* Chapter 60), respectively. A lesion in a component of a signaling pathway that is used by many receptors can cause a generalized endocrinopathy, as is seen in pseudohypoparathyroidism-1a owing to mutations in maternally inherited $G_s\alpha$. Heterozygous deficiency of $G_s\alpha$, the G protein that activates adenyl cyclase, causes multiple endocrine disorders (Spiegel and Weinstein, 2004). Homozygous deficiency in G_s presumably would be lethal.

The expression of aberrant or ectopic receptors, effectors, or coupling proteins potentially can lead to supersensitivity, subsensitivity,

or other untoward responses. Among the most significant events is the appearance of aberrant receptors as products of *oncogenes* that transform otherwise normal cells into malignant cells. Virtually any type of signaling system may have oncogenic potential. The *erbA* oncogene product is an altered form of a receptor for thyroid hormone, constitutively active because of the loss of its ligand-binding domain. The *ros* and *erbB* oncogene products are activated, uncontrolled forms of the receptors for insulin and epidermal growth factor, respectively, both known to enhance cellular proliferation. The *Mas* oncogene product is a GPCR that may regulate responses to angiotensins. Constitutive activation of GPCRs owing to subtle mutations in receptor structure has been shown to give rise to retinitis pigmentosa, precocious puberty, and malignant hyperthyroidism. G proteins themselves can be oncogenic when either overexpressed or constitutively activated by mutation (Spiegel and Weinstein, 2004).

Mutation of receptors can alter either acute responsiveness to drug therapy or its continuing efficacy. For example, a mutation of β_2 receptors, which mediate airway smooth muscle relaxation and bronchial airflow, accelerates desensitization to β_2 receptor agonists used to treat asthma (*see* Chapter 27). The cloning of mutant genes that mediate pathophysiological conditions should speed the development of suitable drugs to target them specifically. Ultimately, designing therapeutic agents that can be useful at mutant receptors will require the crystal structure of these altered proteins as well as their normal counterparts. To date, the only liganded GPCR to be crystallized is rhodopsin (Palczewski *et al.*, 2000).

Classification of Receptors and Drug Effects

In the years between editions of this book, pharmaceutical firms have invested heavily in high-throughput screening systems that rely on ligand binding rather than function to discover potential medicines. This investment has not paid off as handsomely as predicted, and the industry is now placing increased value on functional pharmacological assays that have been the cornerstone of pharmacology since its inception.

Traditionally, drug receptors have been identified and classified primarily on the basis of the effect and relative potency of selective agonists and antagonists. For example, the effects of acetylcholine that are mimicked by the alkaloid muscarine and that are selectively antagonized by atropine are termed *muscarinic effects*. Other effects of acetylcholine that are mimicked by nicotine are described as *nicotinic effects*. By extension, these two types of cholinergic effects are said to be mediated by muscarinic or nicotinic receptors. Although it frequently contributes little to delineation of the mechanism of drug action, such categorization provides a convenient basis for summarizing drug effects. A statement that a drug activates a specified type of receptor is a succinct summary of its spectrum of effects and of the agents that will regulate it. However, the accuracy of this statement may be altered when new receptors or receptor subtypes are identified or additional drug mechanisms or side effects are revealed.

Significance of Receptor Subtypes. As the diversity and selectivity of drugs increase, it is evident that multiple subtypes of receptors exist within many previously defined classes. Molecular cloning has further accelerated discovery of novel receptor subtypes, and their expression as recombinant proteins has facilitated discovery of subtype-selective drugs. Distinct but related receptors may, but may not, display distinctive patterns of selectivity among agonist or antagonist ligands. When selective ligands are not known, the receptors are more commonly referred to as *isoforms* rather than as *subtypes*. Receptor subtypes may display different mechanisms of signal output. For example, M_1 and M_3 muscarinic receptors activate the G_q -PLC-IP₃-Ca²⁺ pathway, and M_2 and M_4 muscarinic receptors activate G_i to reduce the activity of adenylyl cyclase. The distinction between classes and subtypes of receptors, however, often is arbitrary or historical. The α_1 , α_2 , and β receptors differ from each other both in ligand selectivity among drugs and in coupling to G proteins (G_q , G_i , and G_s , respectively), yet α and β are considered receptor classes and α_1 and α_2 are considered subtypes. The α_{1A} , α_{1B} , and α_{1C} receptor isoforms differ little in their biochemical properties, although their tissue distributions are distinct. The β_1 , β_2 , and β_3 adrenergic receptor subtypes exhibit both differences in tissue distribution; *e.g.*, β_3 receptors are localized to adipose tissue and are not phosphorylated by either GRKs or PKA, both known to phosphorylate β_1 and β_2 receptor subtypes (Hall, 2004).

Pharmacological differences among receptor subtypes are exploited therapeutically through the development and use of receptor-selective drugs. Such drugs may be used to elicit different responses from a single tissue when receptor subtypes initiate different intracellular signals, or they may serve to differentially modulate different cells or tissues that express one or another receptor subtype. Increasing the selectivity of a drug among tissues or among responses elicited from a single tissue may determine whether the drug's therapeutic benefits outweigh its unwanted effects.

The molecular biological search for novel receptors has moved well beyond the search for isoforms of known receptors toward the discovery of hundreds of genes for completely novel human receptors. Many of these receptors can be assigned to known families based on sequence, and their functions can be confirmed with appropriate ligands. However, many are "orphans," the designation given to receptors whose ligands are unknown. Discovery of the endogenous ligands and physiological functions of orphan receptors may lead to new drugs that can modulate currently intractable disease states.

The discovery of numerous receptor isoforms raises the question of their importance to the organism, particularly when their signaling mechanisms and specificity for endogenous ligands are indistinguishable. Perhaps this multiplicity of genes facilitates the independent, cell-specific, and temporally controlled expression of receptors according to the developmental needs of the organism. Regardless of their mechanistic implications (or lack thereof), discovery of isoform-selective ligands may improve our targeting of therapeutic drugs substantially.

Actions of Drugs Not Mediated by Receptors

If one restricts the definition of receptors to macromolecules, then several drugs may be said not to act on receptors as such. Some drugs specifically bind small molecules or ions that are found normally or abnormally

in the body. One example is the therapeutic neutralization of gastric acid by a base (antacid). Another example is the use of *2-mercaptoethane sulphonate (mesna)*, a free-radical scavenger eliminated rapidly by the kidneys, to bind to reactive metabolites associated with some cancer chemotherapeutic agents and thus to minimize their untoward effects on the urinary tract. Other agents act according to nonpharmacological colligative properties without a requirement for highly specific chemical structure. For example, certain relatively benign compounds, such as *mannitol*, can be administered in quantities sufficient to increase the osmolarity of various body fluids and thereby cause appropriate changes in the distribution of water (*see* Chapter 28). Depending on the agent and route of administration, this effect can be exploited to promote diuresis, catharsis, expansion of circulating volume in the vascular compartment, or reduction of cerebral edema. In a similar fashion, the introduction of cholesterol-binding agents orally (*e.g.*, *cholestyramine resin*) can be used in the management of hypercholesterolemia to decrease the amount of cholesterol absorbed from the diet.

Certain drugs that are structural analogs of normal biological chemicals may be incorporated into cellular components and thereby alter their function. This property has been termed a *counterfeit incorporation mechanism* and has been particularly useful with analogs of pyrimidines and purines that can be incorporated into nucleic acids; such drugs have clinical utility in antiviral and cancer chemotherapy (*see* Chapters 49 and 51).

QUANTITATION OF DRUG-RECEPTOR INTERACTIONS AND EFFECTS

Receptor Pharmacology

Receptor occupancy theory, in which it is assumed that response emanates from a receptor occupied by a drug, has its basis in the law of mass action, with modifying constants added to accommodate experimental findings. Receptor theory was originated by A.J. Clark, who was the first to apply mathematical rigor to the notions of drug action. Ariëns (1954) modified this model to describe the range of drug effect between full agonist and antagonist as a proportionality factor called *intrinsic activity*. Stephenson (1956) added the notion of stimulus-response to understanding drug efficacy, and Furchgott (1966) contributed a method of measuring the affinity of an agonist by comparing its concentration-response curve before and

Figure 1-9. Graded responses (y axis as a percent of maximal response) expressed as a function of the concentration of drug A present at the receptor. The hyperbolic shape of the curve in panel A becomes sigmoid when plotted semi-logarithmically, as in panel B. The concentration of drug that produces 50% of the maximal response quantifies drug activity and is referred to as the EC_{50} (effective concentration for 50% response).

after inactivating a proportion of the receptors with an irreversible antagonist. Antagonism was modeled by Gaddum (1937, 1957) and Schild (1957) to determine the affinity of antagonists. The history and principles of receptor pharmacology have been well reviewed by Limbird (2005).

The basic currency of receptor pharmacology is the dose–response curve, a depiction of the observed effect of a drug as a function of its concentration in the receptor compartment. Figure 1-9A shows a typical dose–response curve; it reaches a maximal asymptote value when the drug occupies all the receptor sites. The range of concentrations needed to fully depict the dose–response relationship (approximately $3\log_{10}[D]$) usually is too wide to be useful in the linear format shown in Figure 1-9A; thus most dose–response curves are constructed with the logarithm of the concentration plotted on the x axis (Figure 1-9B). Dose–response curves presented in this way are sigmoidal in shape and have three basic properties: threshold, slope, and maximal asymptote. These parameters characterize and quantify the activity of the drug. As noted below, this sigmoidal curve also depicts the law of mass action in its simplest form.

The response to drugs in biological systems does not always follow the classic concentration–response curve shown in Figure 1-9. On occasion, some drugs cause low-dose stimulation and high-dose inhibition of response. These U-shaped relationships for some receptor systems are said to display *hormesis*. Several drug–receptor systems can display this property (e.g., prostaglandins, endothelin, and purinergic and serotonergic agonists, among others). While no one mechanism can be used to explain this phenomenon or a particular patient type be described to judge the clinical relevance of the effect, hormesis is likely to be at the root of the toxicity of drugs in patients (Calabrese and Baldwin, 2003).

Potency and Relative Efficacy

In general, the drug–receptor interaction is characterized first by binding of drug to receptor and second by generation of a response in a biological system. The first function is governed by the chemical property of *affinity*, ruled by the chemical forces that cause the drug to associate reversibly with the receptor.

This simple relationship, derived for drug–receptor interactions from the Langmuir absorption isotherm, permits an appreciation of the reliance of the interaction of drug (D) with receptor (R) on both the forward or association rate constant (k_1) and the reverse or dissociation rate constant (k_2). At any given time, the concentration of agonist–receptor complex [DR] is equal to the product of $k_1[D][R]$ minus the product $k_2[DR]$. At equilibrium (i.e. when $\partial[DR]/\partial\tau = 0$), $k_1[D][R] = k_2[DR]$. The equilibrium dissociation constant (K_D) is then described by ratio of the off-rate and the on-rate (k_2/k_1).

$$\text{At equilibrium,} \quad K_D = \frac{[D][R]}{[DR]} = \frac{k_2}{k_1} \quad (1-26)$$

The affinity constant is the reciprocal of the equilibrium dissociation constant (affinity constant = $K_D = 1/K_A$). A high affinity means a small K_D . As a practical matter, the affinity of a drug is influenced most often by changes in its off-rate (k_2) rather than its on-rate (k_1). Although a number of assumptions are made in this analysis, it is generally useful for considering the interactions of drugs with their receptors. Using this simple model of Equation (1-26) permits us to write an expression of the fractional occupancy (f) of receptors by agonist:

$$f = \frac{[\text{drug-receptor complexes}]}{[\text{total receptors}]} = \frac{[DR]}{[R] + [DR]} \quad (1-27)$$

This can be expressed in terms of K_A (or K_D) and [D]:

$$f = \frac{K_A[D]}{1 + K_A[D]} = \frac{[D]}{[D] + K_D} \quad (1-28)$$

Thus, when $[D] = K_D$, a drug will occupy 50% of the receptors present. From this analysis, it is possible to relate a drug's potency in a particular receptor system to its K_D . Potent drugs are those which elicit a response by binding to a critical number of a particular receptor type at low concentrations (high affinity) compared with other drugs acting on the same system and having lower affinity and thus requiring more drug to bind to the same number of receptors.

The generation of a response from the drug–receptor complex is governed by a property described as *efficacy*. Where *agonism* is the information encoded in a drug’s chemical structure that causes the receptor to change conformation to produce a physiological or biochemical response when the drug is bound, *efficacy* is that property *intrinsic* to a particular drug that determines how “good” an agonist the drug is. Historically, efficacy has been treated as a proportionality constant that quantifies the extent of functional change imparted to a receptor-mediated response system on binding a drug. Thus, a drug with high efficacy may be a full agonist eliciting, at some concentration, a full response, whereas a drug with a lower efficacy at the same receptor may not elicit a full response at any dose. When it is possible to describe the relative efficacy of drugs at a particular receptor, a drug with a low intrinsic efficacy will be a partial agonist.

Since the effects of drugs in the human body often are compared as the physiological outcome of treatment (*e.g.*, diuresis) rather than comparisons of drugs at the same receptor, the term *relative efficacy* can be used to characterize one drug *versus* another. Thus, the relative efficacy of loop diuretics in the treatment of heart failure is high, making them therapeutically useful; the relative efficacy of thiazide diuretics (their capacity to produce significant diuresis) in this setting is low, and they are of no therapeutic value.

Quantifying Agonism. Drugs have two observable properties in biological systems: potency and magnitude of effect (when a biological response is produced). Potency is controlled by four factors: Two relate to the biological system containing the receptors (receptor density and efficiency of the stimulus–response mechanisms of the tissue), and two relate to the interaction of drug with its receptor (affinity and efficacy). When the relative potency of two agonists of equal efficacy is measured in the same biological system, downstream signaling events are the same for both drugs, and the comparison yields a relative measure of the affinity and efficacy of the two agonists (Figure 1–10A). It is convenient to describe agonist response by determining the half-maximally effective concentration (EC_{50}) for producing a given effect. Thus, measuring agonist potency by comparison of EC_{50} values is one method of measuring the capability of different agonists to induce a response in a test system and for predicting comparable activity in another. Another method of estimating agonist activity is to compare maximal asymptotes in systems where the agonists do not produce maximal response (Figure 1–10B). The advantage of using maxima is that this property depends solely on efficacy, whereas potency is a mixed function of both affinity and efficacy.

Quantifying Antagonism. Characteristic patterns of antagonism are associated with certain mechanisms of blockade of receptors. One is simple *competitive antagonism*, whereby a drug that lacks intrinsic efficacy but retains affinity competes with the agonist for the binding site on

Figure 1–10. Two ways of quantifying agonism. **A.** The relative potency of two agonists (drug x, gray line; drug y, blue line) obtained in the same tissue is a function of their relative affinities and intrinsic efficacies. The half-maximal effect of drug x occurs at a concentration that is one-tenth the half-maximally effective concentration of drug y. Thus, drug x is more potent than drug y. **B.** In systems where the two drugs do not both produce the maximal response characteristic of the tissue, the observed maximal response is a nonlinear function of their relative intrinsic efficacies. Drug x is more efficacious than drug y; their asymptotic fractional responses are 100% (drug x) and 50% (drug y).

the receptor. The characteristic pattern of such antagonism is the concentration-dependent production of a parallel shift to the right of the agonist dose–response curve with no change in the maximal asymptotic response. Competitive antagonism is surmountable by a sufficiently high concentration of agonist (Figure 1–11A). The magnitude of the rightward shift of the curve depends on the concentration of the antagonist and its affinity for the receptor. The affinity of a competitive antagonist for its receptor therefore can be determined according to its concentration-dependent capacity to shift the concentration–response curve for an agonist rightward, as analyzed by Schild (1957).

Note that a partial agonist similarly can compete with a “full” agonist for binding to the receptor. However, increasing concentrations of a partial agonist will inhibit response to a finite level characteristic of the drug’s intrinsic efficacy; a competitive antagonist will reduce the response to zero. Partial agonists thus can be used therapeutically to buffer a response by inhibiting untoward stimulation without totally abolishing the stimulus from the receptor. The β receptor agent *pindolol* is an example; it is a very weak partial agonist, a β -antagonist with “intrinsic sympathomimetic activity” (*see* Chapters 10 and 31 through 33).

An antagonist may dissociate so slowly from the receptor as to be essentially irreversible in its action. Under these circumstances, the maximal response to the agonist will be depressed at some antagonist concentrations (Figure 1–11B). Operationally, this is referred to as *noncompetitive antagonism*, although the molecular mechanism of action really cannot be inferred unequivocally.

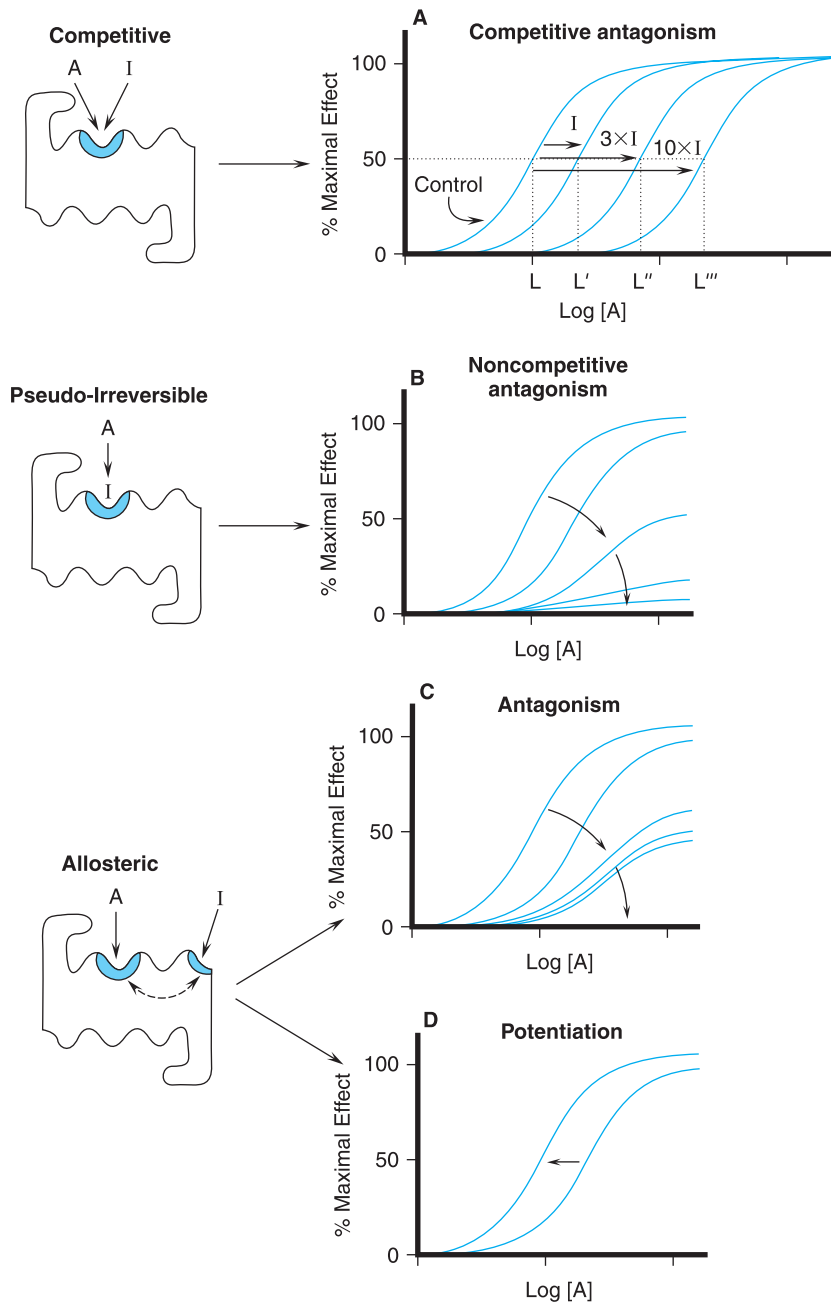

Figure 1-11. Mechanisms of receptor antagonism. **A.** Competitive antagonism occurs when the agonist A and antagonist I compete for the same binding site on the receptor. Response curves for the agonist are shifted to the right in a concentration-related manner by the antagonist such that the EC_{50} for the agonist increases (e.g., L versus L', L'', and L''') with the concentration of the antagonist. **B.** If the antagonist binds to the same site as the agonist but does so irreversibly or pseudo-irreversibly (slow dissociation but no covalent bond), it causes a shift of the dose–response curve to the right, with further depression of the maximal response. Allosteric effects occur when the ligand I binds to a different site on the receptor to either inhibit response (see panel C) or potentiate response (see panel D). This effect is saturable; inhibition reaches a limiting value when the allosteric site is fully occupied.

cally from the effect. An irreversible antagonist competing for the same binding site as the agonist also can produce the pattern of antagonism shown in Figure 1–11B.

Noncompetitive antagonism can be produced by another type of drug, referred to as an *allosteric antagonist*. This type of drug produces its effect by binding a site on the receptor distinct from that of the primary agonist and thereby changing the affinity of the receptor for the agonist. In the case of an allosteric antagonist, the affinity of the receptor for the agonist is decreased by the antagonist (Figure 1–11C). In contrast, some allosteric effects could potentiate the effects of agonists (Figure 1–11D). The interaction of benzodiazepines (anxiolytics) with the GABA_A receptor to increase the receptor's affinity for GABA is an example of allosteric potentiation.

The quantification of drug–receptor interactions in a binding assay can be used to estimate the affinity of agonist (K_D) and antagonist drugs (K_i) for receptors. In this approach, receptors are partially purified from a given cell or tissue (*e.g.*, as membrane preparations) and studied directly *in vitro* using a radioactive form of a drug with known specificity for the receptor. In the most straightforward use of the method for the quantification of antagonist affinity (K_i), a series of competition studies is performed at equilibrium in the presence of a single K_D concentration of radioligand (*e.g.*, that occupying 50% of the receptors present). Addition of the nonradioactive drug to be studied at increasing concentrations and then separating bound and free drug at equilibrium permit direct measurement of the amount of radioligand bound in the presence of increasing concentrations of the antagonist. When the interaction is a bimolecular competition between the radioligand and antagonist for binding to the same site on the receptor, a sigmoid competition curve is obtained (Figure 1–12). The antagonist concentration competing for 50% of the binding of the radioligand (IC_{50}) can be determined from inspection or mathematically from curve fitting, whereas the K_i for an antagonist can be determined knowing the concentration of the radioligand ($[L]$) employed and its K_D for the receptor.

$$K_i = \frac{IC_{50}}{1 + \frac{[L]}{K_D}} \quad (1-29)$$

This relationship, known as the *Cheng–Prusoff equation* (Cheng and Prusoff, 1973), can be employed for determining the potency of antagonists at a given receptor and, when performed using subtype-selective antagonists and nonselective radioligands, can quantify the presence of receptor subtypes and the relative affinity of various antagonists for them. Although the Cheng–Prusoff analysis assumes a bimolecular reaction obeying the laws of mass action, mathematical approaches are also available for cases where cooperativity rather than the presence of multiple receptor subtypes causes the Hill coefficient to differ from unity (Cheng, 2004).

A similar analysis can be performed in experiments measuring a functional response of a system to a drug and a competitive antagonist or inhibitor. Concentration curves are run with the agonist alone and with the agonist plus an effective concentration of the antagonist (Figure 1–11A). As noted in the figure, as more antagonist (I) is added, a higher concentration of the agonist (A) is needed to pro-

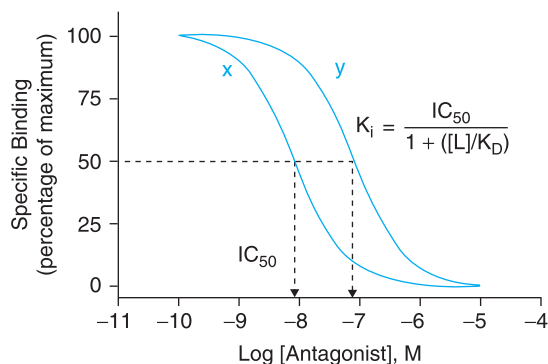

Figure 1–12. Radioligand binding method for determining antagonist affinity. Binding of a radioligand (L) to receptors in the presence of increasing concentrations of a nonradioactive competitive antagonist results in a competition curve, in this case, a curve consistent with binding to a single population of identical receptors. Determining the concentration of antagonist competing for 50% of the receptors present (IC_{50}) and knowing the concentration of radioligand $[L]$ and its affinity (K_D) for the receptor permits calculation of the antagonist affinity (K_i) for more (x) and less (y) potent antagonists. A constant amount of radioligand and equal portions of cellular material (receptor source) were placed in each reaction. Data are amount of radioligand bound, expressed as a percentage of maximal binding (*i.e.*, in the absence of any competing ligand).

duce an equivalent response (the half-maximal, or 50%, response is a convenient and accurately determined level of response). The extent of the rightward shift of the concentration-dependence curve is a measure of the effect of the inhibitor, and a more potent inhibitor will cause a greater rightward shift than a less potent inhibitor at the same concentration. One may write expressions of fractional occupancy (f) of the receptor by agonist for the control curve and each of the other curves.

For an agonist drug (D) alone,

$$f_{\text{control}} = \frac{[D]}{[D] + K_D} \quad (1-30)$$

For the case of agonist plus antagonist (I),

$$f_{+I} = \frac{[D]}{[D] + K_D + \left(1 + \frac{[I]}{K_i}\right)} \quad (1-31)$$

Assuming that equal responses result from equal fractional receptor occupancies in both the absence and presence of antagonist, one can set the fractional occupancies equal at agonist concentrations (L and L') that generate equivalent responses in Figure 1–11A. Thus,

$$\frac{L}{L + K_D} = \frac{L'}{L' + K_D + \left(1 + \frac{[I]}{K_i}\right)} \quad (1-32)$$

Simplifying, we get:

$$\frac{L'}{L} - 1 = \frac{[I]}{K_i} \quad (1-33)$$

where all values are known except K_i . Thus, one can determine the K_i for a reversible, competitive antagonist without knowing the K_D for the agonist and without needing to define the precise relationship between receptor and response.

Inverse Agonists. The overexpression of wild-type receptors and the creation of constitutively active mutant receptors have facilitated the study of a novel class of functional antagonists, the inverse agonists. As discussed earlier, receptors can adopt active conformations that produce a cellular response spontaneously. The fraction of unoccupied receptors in the active conformation usually is too low to allow observation of their agonist-independent activity, but this activity sometimes can be observed, especially when the receptor is expressed heterologously at high levels or when mutation shifts the conformational equilibrium toward the active form. In these situations, the tissue behaves as if there were an agonist present, and a conventional competitive antagonist has no effect. However, certain agents are capable of inhibiting agonist-independent or constitutive signaling. These agents are termed *inverse agonists*. Inverse agonists selectively bind to the inactive form of the receptor and shift the conformational equilibrium toward the inactive state. In systems that are not constitutively active, inverse agonists will behave like competitive antagonists, which in part explains why the properties of inverse agonists and the number of such agents previously described as competitive antagonists were not appreciated until recently. Milligan (2003) and Kenakin (2004) recently have reviewed inverse agonism.

It is not known to what extent constitutive receptor activity is a physiologically or pathologically important phenomenon, and it is therefore unclear to what extent inverse agonism is a therapeutically relevant property. In some cases, however, the preferability of an inverse agonist over a competitive antagonist is obvious. For example, the human herpesvirus KSHV encodes a constitutively active chemokine receptor that generates a second messenger that drives cell growth and viral replication (Verzijl *et al.*, 2004). In such a case, a conventional antagonist would not be useful because no chemokine agonist is involved; however, an inverse agonist could be an effective intervention. In most cases, the role of inverse agonists is less clear but may be of therapeutic benefit as we discover the importance of the various conformations in which receptors can exist. In this regard, there are two important examples to consider. First is the discovery that GPCRs exist in multiple states, as revealed by inverse agonists such as propranolol. In cells overexpressing the human β_2 adrenergic receptor (Azzi *et al.*, 2003), it is possible to measure both the antagonism of receptor activation of adenylyl cyclase produced by propranolol and the activation of extracellular signal-regulated kinase (ERK1/2). These data reveal that the inverse agonistic activity of propranolol puts the receptor in a conformation that is unable to interact with G_s protein but is capable of interacting with proteins such as β -arrestin to cause ERK activation. Similar conclusions are drawn by studies with histamine H_3 receptors and *proxifan* (Gbahou *et al.*, 2003). It is conceivable that the discovery of drugs that select a particular conformation of a receptor (*e.g.*, a ligand-directed conformation) can be used to select the profile of effect desired in a patient to improve therapy.

MEMBRANE TRANSPORTERS AND DRUG RESPONSE

Kathleen M. Giacomini and Yuichi Sugiyama

Transporters are membrane proteins that are present in all organisms. These proteins control the influx of essential nutrients and ions and the efflux of cellular waste, environmental toxins, and other xenobiotics. Consistent with their critical roles in cellular homeostasis, approximately 2000 genes in the human genome ~7 of the total number of genes code for transporters or transporter-related proteins. The functions of membrane transporters may be facilitated (equilibrative, not requiring energy) or active (requiring energy).

In considering the transport of drugs, pharmacologists generally focus on transporters from two major superfamilies, ABC (ATP binding cassette) and SLC (solute carrier) transporters. Most ABC proteins are primary active transporters, which rely on ATP hydrolysis to actively pump their substrates across membranes. There are 49 known genes for ABC proteins that can be grouped into seven subclasses or families (ABCA to ABCG) (Borst and Elferink, 2002). Among the best recognized transporters in the ABC superfamily are P-glycoprotein (P-gp, encoded by *ABCB1*, also termed *MDR1*) and the cystic fibrosis transmembrane regulator (CFTR, encoded by *ABCC7*). The SLC superfamily includes genes that encode facilitated transporters and ion-coupled secondary active transporters that reside in various cell membranes. Forty-three SLC families with approximately 300 transporters have been identified in the human genome (Hediger, 2004). Many serve as drug targets or in drug absorption and disposition. Widely recognized SLC transporters include the serotonin and dopamine transporters (SERT, encoded by *SLC6A4*; DAT, encoded by *SLC6A3*).

Drug-transporting proteins operate in pharmacokinetic and pharmacodynamic pathways, including pathways

involved in both therapeutic and adverse effects (Figure 2–1).

MEMBRANE TRANSPORTERS IN THERAPEUTIC DRUG RESPONSES

Pharmacokinetics. Transporters that are important in pharmacokinetics generally are located in intestinal, renal, and hepatic epithelia. They function in the selective absorption and elimination of endogenous substances and xenobiotics, including drugs (Dresser *et al.*, 2001; Kim, 2002). Transporters work in concert with drug-metabolizing enzymes to eliminate drugs and their metabolites (Figure 2–2). In addition, transporters in various cell types mediate tissue-specific drug distribution (drug targeting); conversely, transporters also may serve as protective barriers to particular organs and cell types. For example, P-glycoprotein in the blood–brain barrier protects the central nervous system (CNS) from a variety of structurally diverse compounds through its efflux mechanisms. Many of the transporters that are relevant to drug response control the tissue distribution as well as the absorption and elimination of drugs.

Pharmacodynamics: Transporters as Drug Targets. Membrane transporters are the targets of many clinically used drugs. For example, neurotransmitter transporters are the targets for drugs used in the treatment of neuropsychiatric disorders (Amara and Sonders, 1998; Inoue *et al.*, 2002). SERT (*SLC6A4*) is a target for a major class of antidepressant drugs, the serotonin selective reuptake inhibitors (SSRIs). Other neurotransmitter reuptake transporters serve

Figure 2–1. Roles of membrane transporters in pharmacokinetic pathways. Membrane transporters (T) play roles in pharmacokinetic pathways (drug absorption, distribution, metabolism, and excretion), thereby setting systemic drug levels. Drug levels often drive therapeutic and adverse drug effects.

as drug targets for the tricyclic antidepressants, various amphetamines (including amphetaminelike drugs used in the treatment of attention deficit disorder in children), and anticonvulsants (Amara and Sonders, 1998; Jones *et al.*, 1998; Elliott and Beveridge, 2005). These transporters also

may be involved in the pathogenesis of neuropsychiatric disorders, including Alzheimer's and Parkinson's diseases (Shigeri *et al.*, 2004). Transporters that are nonneuronal also may be potential drug targets, *e.g.*, cholesterol transporters in cardiovascular disease, nucleoside transporters in

Figure 2–2. Hepatic drug transporters. Membrane transporters, shown as hexagons with arrows, work in concert with phase 1 and phase 2 drug-metabolizing enzymes in the hepatocyte to mediate the uptake and efflux of drugs and their metabolites.

cancers, glucose transporters in metabolic syndromes, and Na⁺-H⁺ antiporters in hypertension (Damaraju *et al.*, 2003; Pascual *et al.*, 2004; Rader, 2003; Roskopf *et al.*, 1993).

Drug Resistance. Membrane transporters play a critical role in the development of resistance to anticancer drugs, antiviral agents, and anticonvulsants. For example, P-glycoprotein is overexpressed in tumor cells after exposure to cytotoxic anticancer agents (Gottesman *et al.*, 1996; Lin and Yamazaki, 2003; Leslie *et al.*, 2005). P-glycoprotein pumps out the anticancer drugs, rendering cells resistant to their cytotoxic effects. Other transporters, including breast cancer resistance protein (BCRP), the organic anion transporters, and several nucleoside transporters, also have been implicated in resistance to anticancer drugs (Clarke *et al.*, 2002; Suzuki *et al.*, 2001). The overexpression of multidrug-resistance protein 4 (MRP4) is associated with resistance to antiviral nucleoside analogs (Schuetz *et al.*, 1999).

MEMBRANE TRANSPORTERS AND ADVERSE DRUG RESPONSES

Through import and export mechanisms, transporters ultimately control the exposure of cells to chemical carcinogens, environmental toxins, and drugs. Thus, transporters play critical roles in the cellular toxicities of these agents. Transporter-mediated adverse drug responses generally can be classified into three categories, as shown in Figure 2–3.

Transporters in the liver and kidney affect the exposure of drugs in the toxicological target organs. Transporters expressed in the liver and kidney, as well as metabolic enzymes, are key determinants of drug exposure in the circulating blood (Mizuno *et al.*, 2003) (Figure 2–3, *top panel*). For example, after oral administration of an HMG-CoA reductase inhibitor (*e.g.*, *pravastatin*), the efficient first-pass hepatic uptake of the drug by the organic anion-transporting polypeptide OATP1B1 maximizes the effects of such drugs on hepatic HMG-CoA reductase. Uptake by OATP1B1 also minimizes the escape of these drugs into the systemic circulation, where they can cause adverse responses such as skeletal muscle myopathy. Transporters in the liver and kidney, which control the total clearance of drugs, thus have an influence on the plasma concentration profiles and subsequent exposure to the toxicological target.

Transporters in toxicological target organs or at barriers to such organs affect drug exposure by the target organs. Transporters expressed in tissues that may be targets for drug toxicity (*e.g.*, brain) or in barriers to such tissues

[*e.g.*, the blood–brain barrier (BBB)] can tightly control local drug concentrations and thus control the exposure of these tissues to the drug (Figure 2–3, *middle panel*). For example, to restrict the penetration of compounds into the brain, endothelial cells in the BBB are closely linked by tight junctions, and some efflux transporters are expressed on the blood-facing (luminal) side. The importance of the ABC transporter multidrug-resistance protein (*ABCB1*, MDR1; P-glycoprotein, P-gp) in the BBB has been demonstrated in *mdr1a* knockout mice (Schinkel *et al.*, 1994). The brain concentrations of many P-glycoprotein substrates, such as *digoxin*, used in the treatment of heart failure (*see* Chapters 33 and 34), and *cyclosporin A* (*see* Chapter 52), an immunosuppressant, are increased dramatically in *mdr1a*(*−/−*) mice, whereas their plasma concentrations are not changed significantly.

Another example of transporter control of drug exposure can be seen in the interactions of *loperamide* and *quinidine*. Loperamide is a peripheral opioid used in the treatment of diarrhea and is a substrate of P-glycoprotein. Coadministration of loperamide and the potent P-glycoprotein inhibitor quinidine results in significant respiratory depression, an adverse response to the loperamide (Sadeque *et al.*, 2000). Because plasma concentrations of loperamide are not changed in the presence of quinidine, it has been suggested that quinidine inhibits P-glycoprotein in the BBB, resulting in an increased exposure of the CNS to loperamide and bringing about the respiratory depression. Inhibition of P-glycoprotein-mediated efflux in the BBB thus would cause an increase in the concentration of substrates in the CNS and potentiate adverse effects.

Drug-induced toxicity sometimes is caused by the concentrative tissue distribution mediated by influx transporters. For example, biguanides (*e.g.*, *metformin* and *phenformin*), widely used as oral hypoglycemic agents for the treatment of type II diabetes mellitus, can produce lactic acidosis, a lethal side effect. Phenformin was withdrawn from the market for this reason. Biguanides are substrates of the organic cation transporter OCT1, which is highly expressed in the liver. After oral administration of metformin, the distribution of the drug to the liver in *oct1*(*−/−*) mice is markedly reduced compared with the distribution in wild-type mice. Moreover, plasma lactic acid concentrations induced by metformin are reduced in *oct1*(*−/−*) mice compared with wild-type mice, although the plasma concentrations of metformin are similar in the wild-type and knockout mice. These results indicate that the OCT1-mediated hepatic uptake of biguanides plays an important role in lactic acidosis (Wang *et al.*, 2003).

The organic anion transporter 1 (OAT1) provides another example of transporter-related toxicity. OAT1 is expressed

Figure 2-3. Major mechanisms by which transporters mediate adverse drug responses. Three cases are given. The left panel of each case provides a cartoon representation of the mechanism; the right panel shows the resulting effect on drug levels. (Top panel) Increase in the plasma concentrations of drug due to a decrease in the uptake and/or secretion in clearance organs such as the liver and kidney. (Middle panel) Increase in the concentration of drug in toxicological target organs due either to the enhanced uptake or to reduced efflux of the drug. (Bottom panel) Increase in the plasma concentration of an endogenous compound (e.g., a bile acid) due to a drug's inhibiting the influx of the endogenous compound in its eliminating or target organ. The diagram also may represent an increase in the concentration of the endogenous compound in the target organ owing to drug-inhibited efflux of the endogenous compound.

mainly in the kidney and is responsible for the renal tubular secretion of anionic compounds. Some reports have indicated that substrates of OAT1, such as *cephaloridine*, a β -lactam antibiotic, sometimes cause nephrotoxicity. *In vitro* experiments suggest that *cephaloridine* is a substrate of OAT1 and that OAT1-expressing cells are more susceptible to *cephaloridine* toxicity than control cells.

Transporters for endogenous ligands may be modulated by drugs and thereby exert adverse effects (Figure 2-3, bottom panel). For example, bile acids are taken up

mainly by Na^+ -taurocholate cotransporting polypeptide (NTCP) (Hagenbuch *et al.*, 1991) and excreted into the bile by the bile salt export pump (BSEP, *ABCB11*) (Gerloff *et al.*, 1998). Bilirubin is taken up by OATP1B1 and conjugated with glucuronic acid, and bilirubin glucuronide is excreted by the multidrug-resistance-associated protein (MRP2, *ABCC2*). Inhibition of these transporters by drugs may cause cholestasis or hyperbilirubinemia. *Troglitazone*, a thiazolidinedione insulin-sensitizing drug used for the treatment of type II diabetes mellitus, was withdrawn from the

market because it caused hepatotoxicity. The mechanism for this troglitazone-induced hepatotoxicity remains unclear. One hypothesis is that troglitazone and its sulfate conjugate induced cholestasis. Troglitazone sulfate potently inhibits the efflux of taurocholate ($K_i = 0.2 \mu\text{M}$) mediated by the ABC transporter BSEP. These findings suggest that troglitazone sulfate induces cholestasis by inhibition of BSEP function. BSEP-mediated transport is also inhibited by other drugs, including cyclosporin A and the antibiotics *rifamycin* and *rifampicin* (Stieger *et al.*, 2000).

Thus, uptake and efflux transporters determine the plasma and tissue concentrations of endogenous compounds and xenobiotics and thereby can influence the systemic or site-specific toxicity of drugs.

BASIC MECHANISMS OF MEMBRANE TRANSPORT

Transporters versus Channels. Both channels and transporters facilitate the membrane permeation of inorganic ions and organic compounds (Reuss, 2000). In general, channels have two primary states, *open* and *closed*, that are totally stochastic phenomena. Only

in the open state do channels appear to act as pores for the selected ions, allowing their permeation across the plasma membrane. After opening, channels return to the closed state as a function of time. In contrast, a transporter forms an intermediate complex with the substrate (solute), and subsequently a conformational change in the transporter induces translocation of the substrates to the other side of the membrane. Therefore, there is a marked difference in turnover rates between channels and transporters. The turnover rate constants of typical channels are 10^6 to 10^8 s^{-1} , whereas those of transporters are, at most, 10^1 to 10^3 s^{-1} . Because a particular transporter forms intermediate complexes with specific compounds (referred to as *substrates*), transporter-mediated membrane transport is characterized by saturability and inhibition by substrate analogs, as described below.

The basic mechanisms involved in solute transport across biological membranes include passive diffusion, facilitated diffusion, and active transport. Active transport can be further subdivided into primary and secondary active transport. These mechanisms are depicted in Figure 2–4 and described below.

Passive Diffusion. Simple diffusion of a solute across the plasma membrane consists of three processes: partition from the aqueous to the lipid phase, diffusion across the lipid bilayer, and repartition into the aqueous phase on the opposite side. Diffusion of any solute (including drugs) occurs down an electrochemical potential gradient $\Delta\mu$ of the solute, given by the equation:

Figure 2–4. Classification of membrane transport mechanisms. Light blue circles depict the substrate. Size of the circles is proportional to the concentration of the substrate. Arrows show the direction of flux. Black squares represent the ion that supplies the driving force for transport (size is proportional to the concentration of the ion). Dark blue ovals depict transporter proteins.

$$\Delta\mu = zE_m F + RT \ln\left(\frac{C_i}{C_o}\right) \quad (2-1)$$

where z is the charge valence of the solute, E_m is the membrane voltage, F is the Faraday constant, R is the gas constant, T is the absolute temperature, C is the concentration of the solute inside (i) and outside (o) of the plasma membrane. The first term on the right side in Eq. (2-1) represents the electrical potential, and the second represents the chemical potential.

For nonionized compounds, the flux J owing to simple diffusion is given by Fick's first law (permeability multiplied by the concentration difference). For ionized compounds, the difference in electrical potential across the plasma membrane needs to be taken into consideration. Assuming that the electrical field is constant, the flux is given by the Goldman-Hodgkin-Katz equation:

$$J = -P \frac{zE_m F}{RT} \left[\frac{C_i - C_o \exp(E_m F / RT)}{1 - \exp(E_m F / RT)} \right] \quad (2-2)$$

where P represents the permeability. The lipid and water solubility and the molecular weight and shape of the solute are determinants of the flux in passive diffusion; they are incorporated in the permeability constant P . The permeability constant positively correlates with the lipophilicity, determined by the partition between water and organic solvents, such as octanol, and is also related to the inverse of the square root of the molecular weight of the solute. At steady state, the electrochemical potentials of all compounds become equal across the plasma membrane. In the case of nonionized compounds, the steady-state concentrations are equal across the plasma membrane. For ionized compounds, however, the steady-state concentration ratio across the plasma membrane is affected by the membrane voltage and given by the Nernst equation (Eq. 2-3).

$$\frac{C_i}{C_o} = \exp\left(\frac{-zE_m F}{RT}\right) \quad (2-3)$$

The membrane voltage is maintained by the ion gradients across the membrane.

Facilitated Diffusion. Diffusion of ions and organic compounds across the plasma membrane may be facilitated by a membrane transporter. Facilitated diffusion is a form of transporter-mediated membrane transport that does not require energy input. Just as in passive diffusion, the transport of ionized and un-ionized compounds across the plasma membrane occurs down their electrochemical potential gradient. Therefore, steady state will be achieved when the electrochemical potentials of the compound on both sides of the membrane become equal.

Active Transport. Active transport is the form of membrane transport that requires the input of energy. It is the transport of solutes against their electrochemical gradients, leading to the concentration of solutes on one side of the plasma membrane and the creation of potential energy in the electrochemical gradient formed. Active transport plays an important role in the uptake and efflux of drugs and other solutes. Depending on the driving force, active transport can be subdivided into primary and secondary active transport (Figure 2-4).

Primary Active Transport. Membrane transport that directly couples with ATP hydrolysis is called *primary active transport*. ABC transporters are examples of primary active transporters. They contain one or two ATP binding cassettes and a highly conserved domain in the intracellular loop region that exhibits ATPase activity. In mammalian cells, primary active transporters mediate the unidirectional efflux of solutes across biological membranes. The molecular mechanism by which ATP hydrolysis is coupled to the active transport of substrates by ABC transporters is a subject of current investigation.

Secondary Active Transport. In secondary active transport, the transport across a biological membrane of one solute S_1 against its concentration gradient is energetically driven by the transport of another solute S_2 in accordance with its concentration gradient. The driving force for this type of transport therefore is stored in the electrochemical potential created by the concentration difference of S_2 across the plasma membrane. For example, an inwardly directed Na^+ concentration gradient across the plasma membrane is created by Na^+, K^+ -ATPase. Under these conditions, inward movement of Na^+ produces the energy to drive the movement of a substrate S_1 against its concentration gradient by a secondary active transporter as in $\text{Na}^+/\text{Ca}^{2+}$ exchange.

Depending on the transport direction of the solute, secondary active transporters are classified as either symporters or antiporters. *Symporters*, also termed *cotransporters*, transport S_2 and S_1 in the same direction, whereas *antiporters*, also termed *exchangers*, move their substrates in opposite directions (Figure 2-4). The free energy produced by one extracellular sodium ion (Na^+) is given by the difference in the electrochemical potential across the plasma membrane:

$$\Delta\mu_{\text{Na}} = E_m F + RT \ln\left(\frac{C_{\text{Na},i}}{C_{\text{Na},o}}\right) \quad (2-4)$$

The electrochemical potential of a nonionized compound $\Delta\mu_s$ acquired from one extracellular Na^+ is less than this value:

$$\Delta\mu_S + \Delta\mu_{Na} \leq 0 \quad (2-5)$$

Therefore, the concentration ratio of the compound is given by the following equation:

$$\frac{S_i}{S_o} \leq \left(\frac{C_{Na,o}}{C_{Na,i}} \right) \exp\left(\frac{-E_m F}{RT} \right) \quad (2-6)$$

Assuming that the concentration ratio of Na^+ is 10 and that E_m is -60 mV, ideally, symport of one nonionized organic compound with one Na^+ ion can achieve a one hundredfold difference in the intracellular substrate concentration compared with the extracellular concentration. When more than one Na^+ ion is coupled to the movement of the solute, a synergistic driving force results. For the case in which two Na^+ ions are involved,

$$\frac{S_i}{S_o} \leq \left(\frac{C_{Na,o}}{C_{Na,i}} \right)^2 \exp\left(\frac{-2E_m F}{RT} \right) \quad (2-7)$$

In this case, the substrate ideally is concentrated intracellularly one thousandfold relative to the extracellular space under the same conditions. The Na^+/Ca^{2+} antiporter shows the effect of this dependence in the square of the concentration ratio of Na^+ ; Ca^{2+} is transported from the cytosol ($0.1 \mu M < [Ca^{2+}] < 1 \mu M$) to the plasma $[Ca^{2+}]_{free} \sim 1.25$ mM.

KINETICS OF TRANSPORT

The flux of a substrate (rate of transport) across a biological membrane *via* transporter-mediated processes is characterized by saturability. The relationship between the flux v and substrate concentration C in a transporter-mediated process is given by the Michaelis–Menten equation:

$$v = \frac{V_{max} C}{K_m + C} \quad (2-8)$$

where V_{max} is the maximum transport rate and is proportional to the density of transporters on the plasma membrane, and K_m is the Michaelis constant, which represents the substrate concentration at which the flux is half the V_{max} value. K_m is an approximation of the dissociation constant of the substrate from the intermediate complex. When C is small compared with the K_m value, the flux is increased in proportion to the substrate concentration (roughly linear with substrate concentration). However, if C is large compared with the K_m value, the flux approaches a constant value (V_{max}). The K_m and V_{max} values can be determined by examining the flux at different substrate concentrations. The Eadie–Hofstee plot often is used for graphical interpretation of satura-

tion kinetics. Plotting clearance v/C on the y axis and flux v on the x axis gives a straight line. The y intercept represents the ratio V_{max}/K_m , and the slope of the line is the inverse of the K_m value:

$$\frac{v}{C} = \frac{V_{max}}{K_m} - \frac{C}{K_m} \quad (2-9)$$

Involvement of multiple transporters with different K_m values gives an Eadie–Hofstee plot that is curved. In algebraic terms, the Eadie–Hofstee plot of kinetic data is equivalent to the Scatchard plot of equilibrium binding data.

Transporter-mediated membrane transport of a substrate is also characterized by inhibition by other compounds. The manner of inhibition can be categorized as one of three types: competitive, noncompetitive, and uncompetitive.

Competitive inhibition occurs when substrates and inhibitors share a common binding site on the transporter, resulting in an increase in the apparent K_m value in the presence of inhibitor. The flux of a substrate in the presence of a competitive inhibitor is

$$v = \frac{V_{max} C}{K_m(1 + I/K_i) + C} \quad (2-10)$$

where I is the concentration of inhibitor, and K_i is the inhibition constant.

Noncompetitive inhibition assumes that the inhibitor has an allosteric effect on the transporter, does not inhibit the formation of an intermediate complex of substrate and transporter, but does inhibit the subsequent translocation process.

$$v = \frac{V_{max}/(1 + I/K_i) \cdot C}{K_m + C} \quad (2-11)$$

Uncompetitive inhibition assumes that inhibitors can form a complex only with an intermediate complex of the substrate and transporter and inhibit subsequent translocation.

$$v = \frac{V_{max}/(1 + I/K_i) \cdot C}{K_m/(1 + I/K_i) + C} \quad (2-12)$$

VECTORIAL TRANSPORT

The SLC type of transporter mediates either drug uptake or efflux, whereas ABC transporters mediate only unidirectional efflux. Asymmetrical transport across a monolayer of polarized cells, such as the epithelial and endothelial cells of brain capillaries, is called *vectorial transport* (Figure 2–5). Vectorial transport is important in

Figure 2–5. Transepithelial or transendothelial flux. Transepithelial or transendothelial flux of drugs requires distinct transporters at the two surfaces of the epithelial or endothelial barriers. These are depicted diagrammatically for transport across the small intestine (absorption), the kidney and liver (elimination), and the brain capillaries that comprise the blood–brain barrier.

the efficient transfer of solutes across epithelial or endothelial barriers. For example, vectorial transport is important for the absorption of nutrients and bile acids in the intestine. From the viewpoint of drug absorption and disposition, vectorial transport plays a major role in hepatobiliary and urinary excretion of drugs from the blood to the lumen and in the intestinal absorption of drugs. In addition, efflux of drugs from the brain *via* brain endothelial cells and brain choroid plexus epithelial cells involves vectorial transport.

For lipophilic compounds that have sufficient membrane permeability, ABC transporters alone are able to achieve vectorial transport by extruding their substrates to the outside of cells without the help of influx transporters (Horio *et al.*, 1990). For relatively hydrophilic organic anions and cations, coordinated uptake and efflux transporters in the polarized plasma membranes are necessary to achieve the vectorial movement of solutes across an epithelium. Common substrates of coordinated transporters are transferred efficiently across the epithelial barrier (Sasaki *et al.*, 2002). In the liver, a number of transporters with different substrate specificities are localized on the sinusoidal membrane (facing blood). These transporters are involved in the uptake of bile acids, amphipathic organic anions, and hydrophilic organic cations into the hepatocytes. Similarly, ABC transporters on the canalicular membrane (facing bile) export such compounds into the bile. Overlapping substrate specificities between the uptake transporters (OATP family) and efflux transporters (MRP family) make the vectorial transport of organic

anions highly efficient. Similar transport systems also are present in the intestine, renal tubules, and endothelial cells of the brain capillaries (Figure 2–5).

Regulation of Transporter Expression. Transporter expression can be regulated transcriptionally in response to drug treatment and pathophysiological conditions, resulting in induction or down-regulation of transporter mRNAs. Recent studies have described important roles of type II nuclear receptors, which form heterodimers with the 9-*cis*-retinoic acid receptor (RXR), in regulating drug-metabolizing enzymes and transporters (Kullak-Ublick *et al.*, 2004; Wang and LeCluyse, 2003). Such receptors include pregnane X receptor (PXR/NR1I2), constitutive androstane receptor (CAR/NR1I3), farnesoid X receptor (FXR/NR1H4), PPAR α (peroxisome proliferator-activated receptor α), and retinoic acid receptor (RAR). Except for CAR, these are ligand-activated nuclear receptors that, as heterodimers with RXR, bind specific elements in the enhancer regions of target genes. CAR has constitutive transcriptional activity that is antagonized by inverse agonists such as *androstenol* and *androstanol* and induced by barbiturates. PXR, also referred to as *steroid X receptor* (SXR) in humans, is activated by synthetic and endogenous steroids, bile acids, and drugs such as *clotrimazole*, *phenobarbital*, *rifampicin*, *sulfapyrazone*, *ritonavir*, *carbamazepine*, *phenytoin*, *sulfadimidine*, *taxol*, and *hyperforin* (a constituent of St. John's wort). Table 2–1 summarizes the effects of drug activation of type II nuclear receptors on expression of transporters. The potency of activators of PXR varies among species such that rodents are not necessarily a model for effects in humans. There is an overlap of substrates between CYP3A4 and P-glycoprotein, and PXR mediates coinduction of CYP3A4 and P-glycoprotein, supporting their synergistic cooperation in efficient detoxification. See Table 3–4 and Figure 3–13 for information on the role of type II nuclear receptors in induction of drug-metabolizing enzymes.

Table 2–1

Regulation of Transporter Expression by Nuclear Receptors

TRANSPORTER	SPECIES	TRANSCRIPTION FACTOR	LIGAND (DOSE)	EFFECT OF LIGAND
MDR1 (P-gp)	Human	PXR	Rifampicin (600 mg/day, 10 days)	↑ Transcription activity (promoter assay) ↑ Expression in duodenum in healthy subjects
			Rifampicin (600 mg/day, 10 days)	↓ Oral bioavailability of digoxin in healthy subjects
			Rifampicin (600 mg/day, 9 days)	↓ AUC of talinolol after IV and oral administration in healthy subjects
MRP2	Human	PXR	Rifampicin (600 mg/day, 9 days)	↑ Expression in duodenum in healthy subjects
		FXR	Rifampicin/hyperforin GW4064/chenodeoxycholate	↑ Expression in human hepatocytes ↑ Expression in HepG2 cells
	Mouse	PXR CAR	PCN/dexamethasone Phenobarbital	↑ Expression in mouse hepatocyte ↑ Expression in hepatocyte of PXR KO mice (promoter assay)
BSEP	Human	PXR/FXR/CAR	PCN/GW4064/phenobarbital	↑ Expression in rat hepatocytes
		FXR		Chenodeoxycholate, GW4064
Ntcp	Rat	SHP1		↓ RAR mediated transcription
OATP1B1	Human	SHP1		Indirect effect on HNF1a expression
OATP1B3	Human	FXR	Chenodeoxycholate	↑ Expression in hepatoma cells
MDR2	Mouse	PPARα	Ciprofibrate (0.05% w/w in diet)	↑ Expression in the liver

MOLECULAR STRUCTURES OF TRANSPORTERS

Predictions of secondary structure of membrane transporter proteins based on hydropathy analysis indicate that membrane transporters in the SLC and ABC superfamilies are multi-membrane-spanning proteins. A typical predicted secondary structure of the ABC transporter MRP2 (*ABCC2*) is shown in Figure 2–6. However, understanding the secondary structure of a membrane transporter provides little information on how the transporter functions to translocate its substrates. For this, information on the tertiary structure of the transporter is

needed, along with complementary molecular information about the residues in the transporter that are involved in the recognition, association, and dissociation of its substrates.

To obtain high-resolution structures of membrane proteins, the proteins first must be crystallized, and then the crystal structure must be deduced from analysis of x-ray diffraction patterns. Crystal structures generally are difficult to obtain for membrane proteins primarily because of their amphipathic needs for stabilization. Further, membrane proteins generally are in low abundance, so obtaining sufficient quantities for structural determination is difficult. The few membrane transporters that have been crystallized are bacterial proteins that can be expressed in high abundance. Information on two representative membrane transporters that have been crystallized and analyzed at relatively high resolu-

Figure 2–6. Predicted secondary structure of MRP2 based on hydropathy analysis. The dark blue circles depict glycosylation sites; Walker A motif is colored light blue; black boxes represent the Walker B motif. Light gray is the middle region between the two motifs. The Walker A motifs interact with α and β phosphates of di- and tri-nucleotides; the Walker B motifs help to coordinate Mg^{2+} .

tion ($<4 \text{ \AA}$) serves to illustrate some basic structural properties of membrane transporters. One of the transporters, MsbA, is an ABC transporter from *E. coli* with homology to multidrug-resistance efflux pumps in mammals. The second transporter, LacY, is a proton symporter, also from *E. coli*, that translocates lactose and other oligosaccharides. Each of these transporters is illustrative of a different transport mechanism.

Lipid Flippase (MsbA). MsbA is an ABC transporter in *E. coli* that, like other ABC transporters, hydrolyzes ATP to export its substrate. Based on an x-ray crystal structure, MsbA forms a homodimer consisting of two six-transmembrane units, each with a nucleotide-binding domain on the cytoplasmic surface (Chang and Roth, 2001) (Figure 2–7). The hexaspanning unit consists of six α -helices. There is a central chamber with an asymmetrical distribution of charged residues. A transport mechanism that is consistent with this asymmetrical distribution of charges is a “flippase” mechanism. That is, substrates in the inner leaflet of the bilayer are recognized by MsbA and then flipped to the outer leaflet of the bilayer. This hypothetical mechanism, although intriguing, leaves many questions unanswered. For example, how is the energy of ATP hydrolysis coupled to the flipping process? Once in the outer leaflet, how are substrates translocated to the extracellular space? Nevertheless, from this structure and other structures, we now know that transmembrane domains form α -helices, that six-unit dimers are central to the transport mechanism, and that there is an asymmetrical distribution of charged residues in a central chamber.

Lactose Permease Symporter (LacY). Lactose permease is a bacterial transporter that belongs to the major facilitator superfamily (MFS). This transporter is a proton-coupled symporter. A high-resolution X-ray crystal structure has been obtained for the proto-

type form of a mutant of LacY (C154G) at a 3.5-\AA α -resolution (Abramson *et al.*, 2003) (Figure 2–8). In brief, LacY is comprised of two units of six membrane-spanning α -helices. The crystal structure showed substrate located at the interface of the

Figure 2–7. Structure showing the backbone of MsbA from *E. coli*. The structure shows a central chamber and a homodimer formed by units of six-transmembrane α -helices. Structure was reconstructed by Libusha Kelly using the coordinates deposited in the Protein Data Bank (PDB; <http://www.rcsb.org/pdb/>).

two units and in the middle of the membrane. This location is consistent with an alternating-access transport mechanism in which the substrate recognition site is accessible to the cytosolic and then the extracellular surface but not to both simultaneously. Eight helices form the surface of the hydrophilic cavity, and each contains proline and glycine residues that result in kinks in the cavity. From LacY, we now know that as in the case of MsbA, six membrane-spanning α -helices are critical structural units for transport by LacY.

TRANSPORTER SUPERFAMILIES IN THE HUMAN GENOME

Two major gene superfamilies play critical roles in the transport of drugs across plasma and other biological membranes: the SLC and ABC superfamilies. Web sites that have information on these families include <http://nutrigene.4t.com/humanabc.htm> (ABC superfamily), <http://www.bioparadigms.org/slc/intro.asp> (SLC superfamily), <http://www.pharmaconference.org/slctable.asp> (SLC superfamily), and http://www.TP_Search.jp/ (drug transporters). Information on pharmacogenetics of these transporters can be found in Chapter 4 and at <http://www.pharmgkb.org> and <http://www.pharmacogenetics.ucsf.edu>.

SLC Transporters. The solute carrier (SLC) superfamily includes 43 families and represents approximately 300 genes in the human genome. The nomenclature of the transporters within each family is listed under the Human Genome Organization (HUGO) Nomenclature Committee database at <http://www.gene.ucl.ac.uk/nomenclature/>. Table 2–2 lists the families in the human SLC superfamily and some of the genetic diseases that are associated with members of selected families. The family name provides a description of the function(s) of each family. However, some caution should be exercised in interpretation of family names because individual family members may have vastly different specificities or functional roles. All the SLC families with members in the human genome were reviewed recently (Hediger, 2004). In brief, transporters in the SLC superfamily transport diverse ionic and nonionic endogenous compounds and xenobiotics. SLC superfamily transporters may be facilitated transporters or secondary active symporters or antiporters. The first SLC family transporter was cloned in 1987 by expression cloning in *Xenopus laevis* oocytes (Hediger *et al.*, 1987). Since then, many transporters in the SLC superfamily have been cloned and characterized functionally. Predictive models defining important characteristics of substrate binding and knockout mouse models defining the *in vivo* role of specific transporters

Figure 2–8. Structure of the protonated form of a mutant of LacY. Two units of six-membrane-spanning α -helices (shown as colored ribbons) are present. Substrate (depicted as gray and black balls) is bound to the interface of the two units and in the middle of the membrane. Structure has been redrawn from coordinates in Protein Data Bank (<http://www.rcsb.org/pdb/>).

have been constructed for many SLC transporters (Chang *et al.*, 2004; Ocheltree *et al.*, 2004). In general, in this chapter we focus on SLC transporters in the human genome, which are designated by capital letters (SLC transporters in rodent genomes are designated by lowercase letters).

ABC Superfamily. In 1976, Juliano and Ling reported that overexpression of a membrane protein in *colchicine*-resistant Chinese hamster ovary cells also resulted in acquired resistance to many structurally unrelated drugs (*i.e.*, multidrug resistance) (Juliano and Ling, 1976). Since the cDNA cloning of this first mammalian ABC protein (P-glycoprotein/MDR1/ABCB1), the ABC superfamily has continued to grow; it now consists of 49 genes, each containing one or two conserved ABC regions (Borst and Elferink, 2002). The ABC region is a core catalytic domain of ATP hydrolysis and contains Walker A and B sequences and an ABC transporter-specific signature C sequence (Figure 2–6). The ABC regions of these proteins bind and hydrolyze ATP, and the proteins use the energy for uphill transport of their substrates across the membrane. Although

Table 2-2
Families in the Human Solute Carrier Superfamily

GENE NAME	FAMILY NAME	NUMBER OF FAMILY MEMBERS	SELECTED DRUG SUBSTRATES	EXAMPLES OF LINKED HUMAN DISEASES
<i>SLC1</i>	High-affinity glutamate and neutral amino acid transporter	7		Amyotrophic lateral sclerosis
<i>SLC2</i>	Facilitative GLUT transporter	14		
<i>SLC3</i>	Heavy subunits of the heteromeric amino acid transporters	2	Melphalin	Classic cystinuria type I
<i>SLC4</i>	Bicarbonate transporter	10		Hemolytic anemia, blindness–auditory impairment
<i>SLC5</i>	Na ⁺ glucose cotransporter	8	Glucosfamide	Glucose–galactose malabsorption syndrome
<i>SLC6</i>	Na ⁺ - and Cl ⁻ -dependent neurotransmitter transporter	16	Paraoxetine, fluoxetine	X-linked creatine deficiency syndrome
<i>SLC7</i>	Cationic amino acid transporter	14	Melphalin	Lysinuric protein intolerance
<i>SLC8</i>	Na ⁺ /Ca ²⁺ exchanger	3	Asymmetrical dimethylarginine	
<i>SLC9</i>	Na ⁺ /H ⁺ exchanger	8	Thiazide diuretics	Congenital secretory diarrhea
<i>SLC10</i>	Na ⁺ bile salt cotransporter	6	Benzothiazepine	Primary bile salt malabsorption
<i>SLC11</i>	H ⁺ coupled metal ion transporter	2		Hereditary hemochromatosis
<i>SLC12</i>	Electroneutral cation–Cl ⁻ cotransporter family	9		Gitelman's syndrome
<i>SLC13</i>	Na ⁺ –sulfate/carboxylate cotransporter	5	Sulfate, cysteine conjugates	
<i>SLC14</i>	Urea transporter	2		Kidd antigen blood group
<i>SLC15</i>	H ⁺ –oligopeptide cotransporter	4	Valacyclovir	
<i>SLC16</i>	Monocarboxylate transporter	14	Salicylate, atorvastatin	Muscle weakness
<i>SLC17</i>	Vesicular glutamate transporter	8		Sialic acid storage disease
<i>SLC18</i>	Vesicular amine transporter	3	Reserpine	Myasthenic syndromes
<i>SLC19</i>	Folate/thiamine transporter	3	Methotrexate	Thiamine-responsive megaloblastic anemia
<i>SLC20</i>	Type III Na ⁺ –phosphate cotransporter	2		
<i>SLC21/SLC0</i>	Organic anion transporter	11	Pravastatin	
<i>SLC22</i>	Organic cation/anion/zwitterion transporter	18	Pravastatin, metformin	Systemic carnitine deficiency syndrome
<i>SLC23</i>	Na ⁺ -dependent ascorbate transporter	4	Vitamin C	
<i>SLC24</i>	Na ⁺ /(Ca ²⁺ -K ⁺) exchanger	5		
<i>SLC25</i>	Mitochondrial carrier	27		Senger's syndrome
<i>SLC26</i>	Multifunctional anion exchanger	10	Salicylate, ciprofloxacin	Congenital Cl ⁻ -losing diarrhea
<i>SLC27</i>	Fatty acid transporter protein	6

GENE NAME	FAMILY NAME	NUMBER OF FAMILY MEMBERS	SELECTED DRUG SUBSTRATES	EXAMPLES OF LINKED HUMAN DISEASES
<i>SLC28</i>	Na ⁺ -coupled nucleoside transport	3	Gemcitabine, cladribine	
<i>SLC29</i>	Facilitative nucleoside transporter	4	Dipyridamole, gemcitabine	
<i>SLC30</i>	Zinc efflux	9		
<i>SLC31</i>	Copper transporter	2	Cisplatin	
<i>SLC32</i>	Vesicular inhibitory amino acid transporter	1	Vigabatrin	
<i>SLC33</i>	Acetyl-CoA transporter	1		
<i>SLC34</i>	Type II Na ⁺ -phosphate cotransporter	3		Autosomal-dominant hypophosphatemic rickets
<i>SLC35</i>	Nucleoside-sugar transporter	17		Leukocyte adhesion deficiency type II
<i>SLC36</i>	H ⁺ -coupled amino acid transporter	4	D-Serine, D-cycloserine	
<i>SLC37</i>	Sugar-phosphate/phosphate exchanger	4		Glycogen storage disease non-1a
<i>SLC38</i>	System A and N, Na ⁺ -coupled neutral amino acid transporter	6		
<i>SLC39</i>	Metal ion transporter	14		Acrodermatitis enteropathica
<i>SLC40</i>	Basolateral iron transporter	1		Type IV hemochromatosis
<i>SLC41</i>	MgtE-like magnesium transporter	3		
<i>SLC42</i>	Rh ammonium transporter (pending)	3		Rh-null regulator
<i>SLC43</i>	Na ⁺ -independent system-L-like amino acid transporter	2		

some ABC superfamily transporters contain only a single ABC motif, they form homodimers (BCRP/ABCG2) or heterodimers (ABCG5 and ABCG8) that exhibit a transport function. ABC transporters (*e.g.*, MsbA) (Figure 2-7) also are found in prokaryotes, where they are involved predominantly in the import of essential compounds that cannot be obtained by passive diffusion (sugars, vitamins, metals, etc.). By contrast, most ABC genes in eukaryotes transport compounds from the cytoplasm to the outside or into an intracellular compartment (endoplasmic reticulum, mitochondria, peroxisomes).

ABC transporters can be divided into seven groups based on their sequence homology: ABCA (12 members), ABCB (11 members), ABCC (13 members), ABCD (4 members), ABCE (1 member), ABCF (3 members), and ABCG (5 members). ABC genes are essential for many

cellular processes, and mutations in at least 13 of these genes cause or contribute to human genetic disorders (Table 2-3).

In addition to conferring multidrug resistance (Sadee *et al.*, 1995), an important pharmacological aspect of these transporters is xenobiotic export from healthy tissues. In particular, MDR1/ABCB1, MRP2/ABCC2, and BCRP/ABCG2 have been shown to be involved in overall drug disposition (Leslie *et al.*, 2005).

Properties of ABC Transporters Related to Drug Action

The tissue distribution of drug-related ABC transporters in the body is summarized in Table 2-4 together with information about typical substrates.

Tissue Distribution of Drug-Related ABC Transporters. MDR1 (*ABCB1*), MRP2 (*ABCC2*), and BCRP (*ABCG2*) are all expressed in the apical side of the intestinal epithelia, where they serve to

Table 2-3*The ATP Binding Cassette (ABC) Superfamily in the Human Genome and Linked Genetic Diseases*

GENE NAME	FAMILY NAME	NUMBER OF FAMILY MEMBERS	EXAMPLES OF LINKED HUMAN DISEASES
<i>ABCA</i>	ABC A	12	Tangier disease (defect in cholesterol transport; ABCA1), Stargardt syndrome (defect in retinal metabolism; ABCA4)
<i>ABCB</i>	ABC B	11	Bare lymphocyte syndrome type I (defect in antigen-presenting; ABCB3 and ABCB4), progressive familial intrahepatic cholestasis type 3 (defect in biliary lipid secretion; MDR3/ABCB4), X-linked sideroblastic anemia with ataxia (a possible defect in iron homeostasis in mitochondria; ABCB7), progressive familial intrahepatic cholestasis type 2 (defect in biliary bile acid excretion; BSEP/ABCB11)
<i>ABCC</i>	ABC C	13	Dubin–Johnson syndrome (defect in biliary bilirubin glucuronide excretion; MRP2/ABCC2), pseudoxanthoma (unknown mechanism; ABCC6), cystic fibrosis (defect in chloride channel regulation; ABCC7), persistent hyperinsulinemic hypoglycemia of infancy (defect in inwardly rectifying potassium conductance regulation in pancreatic B cells; SUR1)
<i>ABCD</i>	ABC D	4	Adrenoleukodystrophy (a possible defect in peroxisomal transport or catabolism of very long-chain fatty acids; ABCD1)
<i>ABCE</i>	ABC E	1	
<i>ABCF</i>	ABC F	3	
<i>ABCG</i>	ABC G	5	Sitosterolemia (defect in biliary and intestinal excretion of plant sterols; ABCG5 and ABCG8)

pump out xenobiotics, including many clinically relevant drugs. The kidney and liver are major organs for overall systemic drug elimination from the body. The liver also plays a role in presystemic drug elimination. Key to the vectorial excretion of drugs into urine or bile, ABC transporters are expressed in the polarized tissues of kidney and liver: MDR1, MRP2, and MRP4 (*ABCC4*) on the brush-border membrane of renal epithelia, and MDR1, MRP2, and BCRP on the bile canalicular membrane of hepatocytes. Some ABC transporters are expressed specifically on the blood side of the endothelial or epithelial cells that form barriers to the free entrance of toxic compounds into naive tissues: the BBB (MDR1 and MRP4 on the luminal side of brain capillary endothelial cells), the blood–cerebrospinal fluid (CSF) barrier (MRP1 and MRP4 on the basolateral blood side of choroid plexus epithelia), the blood–testis barrier (MRP1 on the basolateral membrane of mouse Sertoli cells and MDR1 in several types of human testicular cells), and the blood–placenta barrier (MDR1, MRP2, and BCRP on the luminal maternal side and MRP1 on the antiluminal fetal side of placental trophoblasts).

Substrate Specificity of ABC Transporters. MDR1/ABCB1 substrates tend to share a hydrophobic planar structure with positively charged or neutral moieties as described in Table 2-4 (see also Ambudkar *et al.*, 1999). These include structurally and pharmacologically unrelated compounds, many of which are also substrates

of CYP3A4, a major drug-metabolizing enzyme in the human liver and GI tract. Such overlapping substrate specificity implies a synergistic role for MDR1 and CYP3A4 in protecting the body by reducing the intestinal absorption of xenobiotics (Zhang and Benet, 2001). After being taken up by enterocytes, some drug molecules are metabolized by CYP3A4. Drug molecules that escape metabolic conversion are eliminated from the cells *via* MDR1 and then reenter the enterocytes. The intestinal residence time of the drug is prolonged with the aid of MDR1, thereby increasing the chance of local metabolic conversion by the CYP3A4 (see Chapter 3).

MRP/ABCC Family. The substrates of transporters in the MRP/ABCC family are mostly organic anions. The substrate specificities of MRP1 and MRP2 are similar: Both accept glutathione and glucuronide conjugates, sulfated conjugates of bile salts, and nonconjugated organic anions of an amphipathic nature (at least one negative charge and some degree of hydrophobicity). They also transport neutral or cationic anticancer drugs, such as *vinca alkaloids* and *anthracyclines*, possibly *via* a cotransport or symport mechanism with reduced glutathione (GSH).

MRP3 also has a substrate specificity that is similar to that of MRP2 but with a lower transport affinity for glutathione conjugates compared with MRP1 and MRP2. Most characteristic MRP3 substrates are monovalent bile salts, which are never transported by MRP1 and MRP2. Because MRP3 is expressed on the

Table 2–4

ABC Transporters Involved in Drug Absorption, Distribution, and Excretion

TRANSPORTER NAME	TISSUE DISTRIBUTION	PHYSIOLOGICAL FUNCTION	SUBSTRATES
MDR1 (ABCB1)	Liver Kidney Intestine BBB BTB BPB	Detoxification of xenobiotics?	Characteristics: Neutral or cationic compounds with bulky structure Anticancer drugs: etoposide, doxorubicin, vincristine Ca²⁺ channel blockers: diltiazem, verapamil HIV protease inhibitors: indinavir, ritonavir Antibiotics/antifungals: erythromycin, ketoconazole Hormones: testosterone, progesterone Immunosuppressants: cyclosporine, FK506 (tacrolimus) Others: digoxin, quinidine
MRP1 (ABCC1)	Ubiquitous (kidney, BCSFB, BTB)	Leukotriene (LTC ₄) secretion from leukocyte	Characteristics: Amphiphilic with at least one negative net charge Anticancer drugs: vincristine (with GSH), methotrexate Glutathione conjugates: LTC ₄ , glutathione conjugate of ethacrynic acid Glucuronide conjugates: estradiol-17-D-glucuronide, bilirubin mono(or bis)glucuronide Sulfated conjugates: estrone-3-sulfate (with GSH) HIV protease inhibitors: saquinavir Antifungals: grepafloxacin Others: folate, GSH, oxidized glutathione
MRP2 (ABCC2)	Liver Kidney Intestine BPB	Excretion of bilirubin glucuronide and GSH into bile	Characteristics: Amphiphilic with at least one negative net charge (similar to MRP1) Anticancer drugs: methotrexate, vincristine Glutathione conjugates: LTC ₄ , GSH conjugate of ethacrynic acid Glucuronide conjugates: estradiol-17-D-glucuronide, bilirubin mono(or bis)glucuronide Sulfate conjugate of bile salts: tauroolithocholate sulfate HIV protease inhibitors: indinavir, ritonavir Others: pravastatin, GSH, oxidized glutathione
MRP3 (ABCC3)	Liver Kidney Intestine	?	Characteristics: Amphiphilic with at least one negative net charge (Glucuronide conjugates are better substrates than glutathione conjugates.) Anticancer drugs: etoposide, methotrexate Glutathione conjugates: LTC ₄ , glutathione conjugate of 15-deoxy-delta prostaglandin J2 Glucuronide conjugates: estradiol-17-D-glucuronide, etoposide glucuronide Sulfate conjugates of bile salts: tauroolithocholate sulfate Bile salts: glycocholate, taurocholate Others: folate, leucovorin

(Continued)

Table 2–4*ABC Transporters Involved in Drug Absorption, Distribution, and Excretion (Continued)*

TRANSPORTER NAME	TISSUE DISTRIBUTION	PHYSIOLOGICAL FUNCTION	SUBSTRATES
MRP4 (ABCC4)	Ubiquitous (kidney, prostate, lung, muscle, pancreas, testis, ovary, bladder, gallbladder, BBB, BCSFB)	?	Characteristics: Nucleotide analogues Anticancer drugs: 6-mercaptopurine, methotrexate Glucuronide conjugates: estradiol-17-D-glucuronide Cyclic nucleotides: cyclic AMP, cyclic GMP HIV protease inhibitors: adefovir Others: folate, leucovorin, taurocholate (with GSH)
MRP5 (ABCC5)	Ubiquitous	?	Characteristics: Nucleotide analogues Anticancer drugs: 6-mercaptopurine Cyclic nucleotides: cyclic AMP, cyclic GMP HIV protease inhibitors: adefovir
MRP6 (ABCC6)	Liver Kidney	?	Anticancer drugs: doxorubicin*, etoposide* Glutathione conjugate of: LTC ₄ Other: BQ-123 (cyclic peptide ET-1 antagonist)
BCRP (MXR) (ABCG2)	Liver Intestine BBB	Normal heme transport during maturation of erythrocytes	Anticancer drugs: methotrexate, mitoxantrone, camptothecin analogs (SN-38, etc.), topotecan Glucuronide conjugates: 4-methylumbelliferone glucuronide, estradiol-17-D-glucuronide Sulfate conjugates: dehydroepiandrosterone sulfate, estrone-3-sulfate Others: cholesterol, estradiol
MDR3 (ABCB4)	Liver	Excretion of phospholipids into bile	Characteristics: Phospholipids
BSEP (ABCB11)	Liver	Excretion of bile salts into bile	Characteristics: Bile salts
ABCG5 and ABCG8	Liver Intestine	Excretion of plant sterols into bile and intestinal lumen	Characteristics: Plant sterols

NOTE: Representative substrates and cytotoxic drugs with increased resistance (*) are included in this table (cytotoxicity with increased resistance is usually caused by the decreased accumulation of the drugs). Although MDR3 (ABCB4), BSEP (ABCB11), ABCG5, and ABCG8 are not directly involved in drug disposition, inhibition of these physiologically important ABC transporters will lead to unfavorable side effects.

sinusoidal side of hepatocytes and is induced under cholestatic conditions, backflux of toxic bile salts and bilirubin glucuronides into the blood circulation is considered to be its physiological function.

MRP4 and MRP5 have narrower substrate specificities. They accept nucleotide analogues and clinically important anti-human immunodeficiency virus (HIV) drugs. Although some transport substrates have been identified for MRP6, no physiologically important endogenous substrates have been identified that explain the mechanism of the MRP6-associated disease pseudoxanthoma.

BCRP/ABCG2. BCRP accepts both neutral and negatively charged molecules, including cytotoxic compounds (*e.g.*, mitoxantrone, topotecan, flavopiridol, and methotrexate), sulfated conjugates of therapeutic drugs and hormones (*e.g.*, estrogen sulfate), and toxic compounds found in normal food [2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP) and pheophorbide A, a chlorophyll catabolite].

Physiological Roles of ABC Transporters. The physiological significance of the ABC transporters is illustrated by studies involving knockout animals or patients with genetic defects in these transporters. Mice deficient in MDR1 function are viable and fer-

tile and do not display obvious phenotypic abnormalities other than hypersensitivity to toxic drugs, including the neurotoxic pesticide ivermectin (one hundredfold) and the carcinostatic drug *vinblastine* (threefold) (Schinkel *et al.*, 1994). *mrl1* ($-/-$) mice are also viable and fertile without any obvious difference in litter size. However, these mice are hypersensitive to the anticancer drug *etoposide*. Damage is especially severe in the testis, kidney, and oropharyngeal mucosa, where MRP1 is expressed on the basolateral membrane. Moreover, these mice have an impaired response to an arachidonic acid-induced inflammatory stimulus, which is likely due to a reduced secretion of leukotriene C4 from mast cells, macrophages, and granulocytes. MRP2-deficient rats (TR- and EHBR) and Dubin-Johnson syndrome patients are normal in appearance except for mild jaundice owing to impaired biliary excretion of bilirubin glucuronide (Ito *et al.*, 1997; Paulusma *et al.*, 1996).

BCRP knockout mice are viable but highly sensitive to the dietary chlorophyll catabolite phenophorbide, which induces phototoxicity. These mice also exhibit protoporphyria, with a tenfold increase in protoporphyrin IX accumulation in erythrocytes, resulting in photosensitivity. This protoporphyria is caused by the impaired function of BCRP in bone marrow: Knockout mice transplanted with bone marrow from wild-type mice become normal with respect to protoporphyrin IX level in the erythrocytes and photosensitivity.

As described earlier, complete absence of these drug-related ABC transporters is not lethal and even can remain unrecognized without exogenous perturbation owing to food, drugs, or toxins. Inhibition of physiologically important ABC transporters (especially those related directly to the genetic diseases described in Table 2-3) by drugs should be avoided to reduce the incidence of drug-induced side effects.

ABC Transporters in Drug Absorption and Elimination. With respect to clinical medicine, MDR1 is the most important ABC transporter yet identified, and digoxin is one of the most widely studied of its substrates. The systemic exposure to orally administered digoxin (as assessed by the area under the plasma digoxin concentration-time curve) is increased by coadministration of *rifampin* (an MDR1 inducer) and is negatively correlated with the MDR1 protein expression in the human intestine. MDR1 is also expressed on the brush-border membrane of renal epithelia, and its function can be monitored using digoxin as a probe drug. Digoxin undergoes very little degradation in the liver, and renal excretion is the major elimination pathway (>70%) in humans. Several studies in healthy subjects have been performed with MDR1 inhibitors (*e.g.*, quinidine, *verapamil*, *vaspodar*, *spironolactone*, *clarythromycin*, and *ritonavir*) with digoxin as a probe drug, and all resulted in a marked reduction in the renal excretion of digoxin. Similarly, the intestinal absorption of *cyclosporine* is also related mainly to the MDR1 level rather than to the CYP3A4 level, although cyclosporine is a substrate of both CYP3A4 and MDR1.

Alteration of MDR1 activity by inhibitors (drug-drug interactions) affects oral absorption and renal clearance. Drugs with narrow therapeutic windows (such as the cardiac glycoside digoxin and the immunosuppressants cyclosporine and *tacrolimus*) should be used with great care if MDR1-based drug-drug interactions are likely.

Despite the broad substrate specificity and distinct localization of MRP2 and BCRP in drug-handling tissues (both expressed on the

canalicular membrane of hepatocytes and the brush-border membrane of enterocytes), there has been very little integration of clinically relevant information. Part of the problem lies in distinguishing the biliary transport activities of MRP2 and BCRP from the contribution of the hepatic uptake transporters of the OATP family. Most MRP2 or BCRP substrates also can be transported by the OATP family transporters on the sinusoidal membrane. The rate-limiting process for systemic elimination is uptake in most cases. Under such conditions, the effect of drug-drug interactions (or genetic variants) in these biliary transporters may be difficult to identify. Despite such practical difficulties, there is a steady increase in the information about genetic variants and their effects on transporter expression and activity *in vitro*. Variants of BCRP with high allele frequencies (0.184 for V12M and 0.239 for Q141K) have been found to alter the substrate specificity in cellular assays. The clinical impact of these variants and drug-drug interactions needs to be studied in more detail in humans and under *in vivo* conditions using appropriate probe drugs.

GENETIC VARIATION IN MEMBRANE TRANSPORTERS: IMPLICATIONS FOR CLINICAL DRUG RESPONSE

Inherited defects in membrane transport have been known for many years, and the genes associated with several inherited disorders of membrane transport have been identified [Table 2-2 (SLC) and Table 2-3 (ABC)]. Reports of polymorphisms in membrane transporters that play a role in drug response have appeared only recently, but the field is growing rapidly. Cellular studies have focused on genetic variation in only a few drug transporters, but progress has been made in characterizing the functional impact of variants in these transporters. Further, large-scale studies in the area of single-nucleotide polymorphisms (SNPs) in membrane transporters and cellular characterization of transporter variants have been performed (Burman *et al.*, 2004; Gray *et al.*, 2004; Leabman *et al.*, 2003; Osato *et al.*, 2003; Shu *et al.*, 2003) (*see* Chapter 4). The clinical impact of membrane transporter variants on drug response has been studied only recently. Like the cellular studies, the clinical studies have focused on a limited number of transporters.

The most widely studied drug transporter is P-glycoprotein (MDR1, *ABCB1*), and results from clinical studies have been controversial. Associations of the *ABCB1* genotype with responses to anticancer drugs, antiviral agents, immunosuppressants, antihistamines, cardiac glycosides, and anticonvulsants have been described (Anglicheau *et al.*, 2003; Drescher *et al.*, 2002; Fellay *et al.*, 2002; Hoffmeyer *et al.*, 2000; Illmer *et al.*, 2002; Johnne *et al.*, 2002; Macphee *et al.*, 2002; Pauli-Magnus *et al.*, 2003; Sai *et al.*, 2003; Sakaeda *et al.*, 2003; Siddiqui *et al.*,

2003; Verstuyft *et al.*, 2003). *ABCB1* SNPs also have been associated with tacrolimus and *nortriptyline* neurotoxicity (Roberts *et al.*, 2002; Yamauchi *et al.*, 2002) and susceptibility for developing ulcerative colitis, renal cell carcinoma, and Parkinson's disease (Drozdik *et al.*, 2003; Schwab *et al.*, 2003; Siegsmond *et al.*, 2002).

Recently, two common SNPs in *SLCO1B1* (OATP1B1) have been associated with elevated plasma levels of pravastatin, a widely used drug for the treatment of hypercholesterolemia (Mwinyi *et al.*, 2004; Niemi *et al.*, 2004) (*see* Chapter 35).

TRANSPORTERS INVOLVED IN PHARMACOKINETICS

Hepatic Transporters

Drug transporters play an important role in pharmacokinetics (Koepsell, 1998; Zamek-Gliszczynski and Brouwer, 2004) (Figure 2–1). Hepatic uptake of organic anions (*e.g.*, drugs, leukotrienes, and bilirubin), cations, and bile salts is mediated by SLC-type transporters in the basolateral (sinusoidal) membrane of hepatocytes: OATPs (SLCO) (Abe *et al.*, 1999; Konig *et al.*, 2000) and OATs (SLC22) (Sekine *et al.*, 1998), OCTs (SLC22) (Koepsell, 1998) and NTCP (SLC10A1) (Hagenbuch *et al.*, 1991), respectively. These transporters mediate uptake by either facilitated or secondary active mechanisms.

ABC transporters such as MRP2, MDR1, BCRP, BSEP, and MDR2 in the bile canalicular membrane of hepatocytes mediate the efflux (excretion) of drugs and their metabolites, bile salts, and phospholipids against a steep concentration gradient from liver to bile. This primary active transport is driven by ATP hydrolysis. Some ABC transporters are also present in the basolateral membrane of hepatocytes and may play a role in the efflux of drugs back into the blood, although their physiological role remains to be elucidated. Drug uptake followed by metabolism and excretion in the liver is a major determinant of the systemic clearance of many drugs. Since clearance ultimately determines systemic blood levels, transporters in the liver play key roles in setting drug levels.

Vectorial transport of drugs from the circulating blood to the bile using an uptake transporter (OATP family) and an efflux transporter (MRP2) is important for determining drug exposure in the circulating blood and liver. Moreover, there are many other uptake and efflux transporters in the liver (Figure 2–9). Two examples illustrate the

importance of vectorial transport in determining drug exposure in the circulating blood and liver: HMG-CoA reductase inhibitors and angiotensin-converting enzyme (ACE) inhibitors.

HMG-CoA Reductase Inhibitors. Statins are cholesterol-lowering agents that reversibly inhibit HMG-CoA reductase, which catalyzes a rate-limiting step in cholesterol biosynthesis (*see* Chapter 35). Statins affect serum cholesterol by inhibiting cholesterol biosynthesis in the liver, and this organ is their main target. On the other hand, exposure of extrahepatic cells in smooth muscle to these drugs may cause adverse effects. Among the statins, pravastatin, *fluvastatin*, *cerivastatin*, *atorvastatin*, *rosuvastatin*, and *pitavastatin* are given in a biologically active open-acid form, whereas *simvastatin* and *lovastatin* are administered as inactive prodrugs with lactone rings. The open-acid statins are relatively hydrophilic and have low membrane permeabilities. However, most of the statins in the acid form are substrates of uptake transporters, so they are taken up efficiently by the liver and undergo enterohepatic circulation (Figures 2–5 and 2–9). In this process, hepatic uptake transporters such as OATP1B1 and efflux transporters such as MRP2 act cooperatively to produce vectorial transcellular transport of bisubstrates in the liver. The efficient first-pass hepatic uptake of these statins by OATP1B1 after their oral administration helps to exert the pharmacological effect and also minimizes the escape of drug molecules into the circulating blood, thereby minimizing the exposure in a target of adverse response, smooth muscle. Recent studies indicate that the genetic polymorphism of OATP1B1 also affects the function of this transporter (Tirona *et al.*, 2001).

Temocapril. *Temocapril* is an ACE inhibitor (*see* Chapter 30). Its active metabolite, temocaprilat, is excreted both in the bile and in the urine *via* the liver and kidney, respectively, whereas other ACE inhibitors are excreted mainly *via* the kidney. The special feature of temocapril among ACE inhibitors is that the plasma concentration of temocaprilat remains relatively unchanged even in patients with renal failure. However, the plasma area under the curve *AUC* of *enalaprilat* and other ACE inhibitors is markedly increased in patients with renal disorders. Temocaprilat is a bisubstrate of the OATP family and MRP2, whereas other ACE inhibitors are not good substrates of MRP2 (although they are taken up into the liver by the OATP family). Taking these findings into consideration, the affinity for MRP2 may dominate in determining the biliary excretion of any series of ACE inhibitors. Drugs that are excreted into both the bile and urine to the same degree thus are expected to exhibit minimum interindividual differences in their pharmacokinetics.

Irinotecan (CPT-11). *Irinotecan hydrochloride* (CPT-11) is a potent anticancer drug, but late-onset gastrointestinal toxic effects, such as severe diarrhea, make it difficult to use CPT-11 safely. After intravenous administration, CPT-11 is converted to SN-38, an active metabolite, by carboxy esterase. SN-38 is subsequently conjugated with glucuronic acid in the liver. SN-38 and SN-38 glucuronide are then excreted into the bile by MRP2. Some studies have shown that the inhibition of MRP2-mediated biliary excretion of SN-38 and its glucuronide by coadministration of *probenecid* reduces the drug-induced diarrhea, at least in rats. For additional details, *see* Figures 3–5 and 3–7.

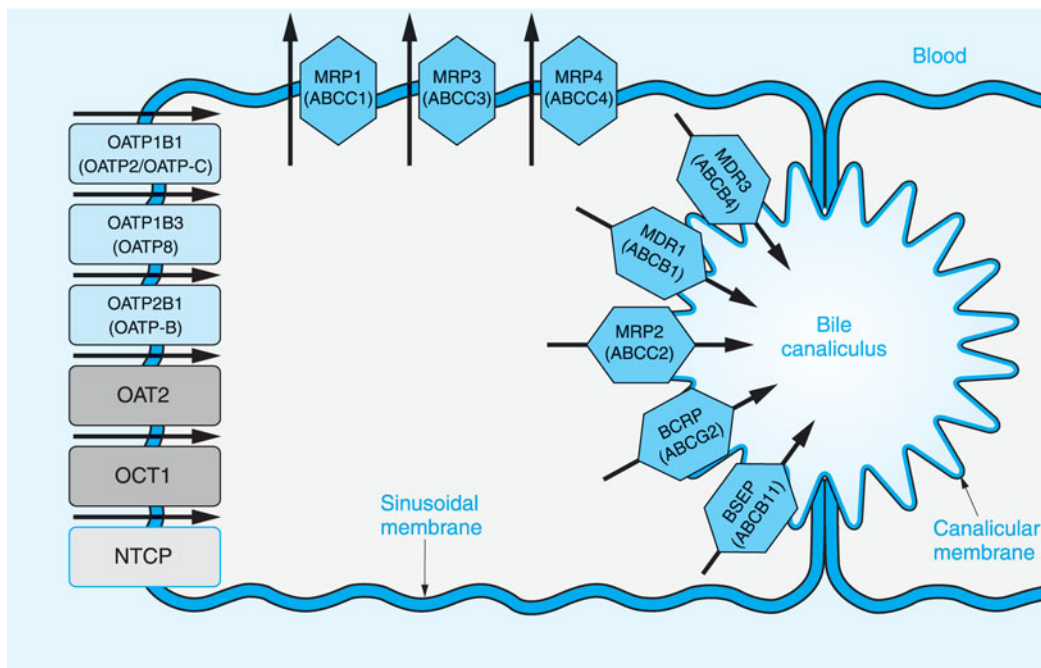

Figure 2–9. Transporters in the hepatocyte that function in the uptake and efflux of drugs across the sinusoidal membrane and efflux of drugs into the bile across the canalicular membrane. See text for details of the transporters pictured.

Drug–Drug Interactions Involving Transporter-Mediated Hepatic Uptake. Since drug transporters are determinants of the elimination rate of drugs from the body, transporter-mediated hepatic uptake can be the cause of drug–drug interactions involving drugs that are actively taken up into the liver and metabolized and/or excreted in the bile.

Cerivastatin (currently withdrawn), an HMG-CoA reductase inhibitor, is taken up into the liver via transporters (especially OATP1B1) and subsequently metabolized by CYP2C8 and CYP3A4. Its plasma concentration is increased four- to fivefold when coadministered with cyclosporin A. Transport studies using cryopreserved human hepatocytes and OATP1B1-expressing cells suggest that this clinically relevant drug–drug interaction is caused by inhibition of OATP1B1-mediated hepatic uptake (Shitara *et al.*, 2003). However, cyclosporin A inhibits the metabolism of cerivastatin only to a limited extent, suggesting a low possibility of serious drug–drug interactions involving the inhibition of metabolism. Cyclosporin A also increases the plasma concentrations of other HMG-CoA reductase inhibitors. It markedly increases the plasma *AUC* of pravastatin, pitavastatin, and rosuvastatin, which are minimally metabolized and eliminated from the body by transporter-mediated mechanisms. Therefore, these pharmacokinetic interactions also may be due to transporter-mediated hepatic uptake. However, the interactions of cyclosporin A with pro-drug-like statins (lactone form) such as simvastatin and lovastatin are mediated by CYP3A4.

Gemfibrozil is another cholesterol-lowering agent that acts by a different mechanism and also causes a severe pharmacokinetic interaction with cerivastatin. *Gemfibrozil glucuronide* inhibits the CYP2C8-mediated metabolism and OATP1B1-mediated uptake of cerivastatin more

potently than does *gemfibrozil*. Laboratory data show that the glucuronide is highly concentrated in the liver *versus* plasma probably owing to transporter-mediated active uptake and intracellular formation of the conjugate. Therefore, it may be that *gemfibrozil* glucuronide, concentrated in the hepatocytes, inhibits the CYP2C8-mediated metabolism of cerivastatin. *Gemfibrozil* markedly (four- to fivefold) increases the plasma concentration of cerivastatin but does not greatly increase (1.3 to 2 times) that of unmetabolized statins pravastatin, pitavastatin, and rosuvastatin, a result that also suggests that this interaction is caused by inhibition of metabolism. Thus, when an inhibitor of drug-metabolizing enzymes is highly concentrated in hepatocytes by active transport, extensive inhibition of the drug-metabolizing enzymes may be observed because of the high concentration of the inhibitor in the vicinity of the drug-metabolizing enzymes.

The Contribution of Specific Transporters to the Hepatic Uptake of Drugs.

Estimating the contribution of transporters to the total hepatic uptake is necessary for understanding their importance in drug disposition. This estimate can help to predict the extent to which a drug–drug interaction or a genetic polymorphism of a transporter may affect drug concentrations in plasma and liver. The contribution to hepatic uptake has been estimated successfully for CYP-mediated metabolism by using neutralizing antibody and specific chemical inhibitors. Unfortunately, specific inhibitors or antibodies for important transporters have not been identified yet, although some *relatively specific* inhibitors have been discovered.

The contribution of transporters to hepatic uptake can be estimated from *in vitro* studies. Injection of cRNA results in transporter expression on the plasma membrane of *Xenopus laevis* oocytes (Hagenbuch *et al.*, 1996). Subsequent hybridization of the cRNA with its antisense oligonucleotide specifically reduces its expression. Comparison of the drug uptake into cRNA-injected oocytes in the presence and absence of antisense oligonucleotides clarifies the contribution of a specific transporter. Second, a method using reference compounds for specific transporters has been proposed. The reference compounds should be specific substrates for a particular transporter. The contribution of a specific transporter can be calculated from the uptake of test compounds and reference compounds into hepatocytes and transporter-expressing systems (Hirano *et al.*, 2004):

$$\text{Contribution} = \frac{CL_{\text{hep,ref}}/CL_{\text{exp,ref}}}{CL_{\text{hep,test}}/CL_{\text{exp,test}}} \quad (2-13)$$

where $CL_{\text{hep,ref}}$ and $CL_{\text{exp,ref}}$ represent the uptake of reference compounds into hepatocytes and transporter-expressing cells, respectively, and $CL_{\text{hep,test}}$ and $CL_{\text{exp,test}}$ represent the uptake of test compounds into the corresponding systems. For example, the contributions of OATP1B1 and OATP1B3 to the hepatic uptake of pitavastatin have been estimated using estrone 3-sulfate and cholecystokinin octapeptide (CCK8) as reference compounds for OATP1B1 and OATP1B3, respectively. However, for many transporters, reference compounds specific to the transporter are not available.

Renal Transporters

Secretion in the kidney of structurally diverse molecules including many drugs, environmental toxins and carcinogens is critical in the body's defense against foreign substances. The specificity of secretory pathways in the nephron for two distinct classes of substrates, organic anions and cations, was first described decades ago, and these pathways were well characterized using a variety of physiological techniques including isolated perfused nephrons and kidneys, micro-puncture techniques, cell culture methods, and isolated renal plasma membrane vesicles. However, not until the mid-1990s were the molecular identities of the organic anion and cation transporters revealed. During the past decade, molecular studies have identified and characterized the renal transporters that play a role in drug elimination, toxicity, and response. Thus, we now can describe the overall secretory pathways for organic cations and their molecular and functional characteristics. Although the pharmacological focus is often on the kidney, there is useful information on the tissue distribution of these transporters. Molecular studies using site-directed mutagenesis have identified substrate-recognition and other functional domains of the transporters, and genetic studies of knockout mouse models have been used to characterize the physiological roles of individual transporters. Recently, studies have iden-

tified and functionally analyzed genetic polymorphisms and haplotypes of the relevant transporters in humans. Our understanding of organic anion transport has progressed in a similar fashion. In some cases, transporters that are considered organic anion or organic cation transporters have dual specificity for anions and cations. The following section summarizes recent work on human transporters and includes some information on transporters in other mammals. An excellent review of renal organic anion and cation transport has been published recently (Wright and Dantzer, 2004).

Organic Cation Transport. Structurally diverse organic cations are secreted in the proximal tubule (Dresser *et al.*, 2001; Koepsell and Endou, 2004; Wright and Dantzer, 2004). Many secreted organic cations are endogenous compounds (*e.g.*, choline, *N*-methylnicotinamide, and dopamine), and renal secretion appears to be important in eliminating excess concentrations of these substances. However, a primary function of organic cation secretion is ridding the body of xenobiotics, including many positively charged drugs and their metabolites (*e.g.*, *cimetidine*, *raniitidine*, metformin, *procainamide*, and *N-acetylprocainamide*), and toxins from the environment (*e.g.*, *nicotine*). Organic cations that are secreted by the kidney may be either hydrophobic or hydrophilic. Hydrophilic organic drug cations generally have molecular weights of less than 400 daltons; a current model for their secretion in the proximal tubule of the nephron is shown in Figure 2-10.

For the transepithelial flux of a compound (*e.g.*, secretion), it is essential for the compound to traverse two membranes sequentially, the basolateral membrane facing the blood side and the apical membrane facing the tubular lumen. Distinct transporters on each membrane mediate each step of transport. Organic cations appear to cross the basolateral membrane by three distinct transporters in the SLC family 22 (SLC22): OCT1 (*SLC22A1*), OCT2 (*SLC22A2*), and OCT3 (*SLC22A3*). Organic cations are transported across this membrane down their electrochemical gradient (-70 mV). Previous studies in isolated basolateral membrane vesicles demonstrate the presence of a potential-sensitive mechanism for organic cations. The cloned transporters OCT1, OCT2, and OCT3 are all potential sensitive and mechanistically coincide with previous studies of isolated basolateral membrane vesicles.

Transport of organic cations from cell to tubular lumen across the apical membrane occurs *via* an electroneutral proton-organic cation exchange mechanism in a variety of species, including human, dog, rabbit, and cat. Transporters assigned to the apical membrane are in the SLC22 family and termed *novel organic cation transporters* (OCTNs). In humans, these include OCTN1 (*SLC22A4*) and OCTN2 (*SLC22A5*). These bifunctional transporters are involved not only in organic cation secretion but also in carnitine reabsorption. In the reuptake mode, the transporters function as Na^+ cotransporters, relying on the inwardly driven Na^+ gradient

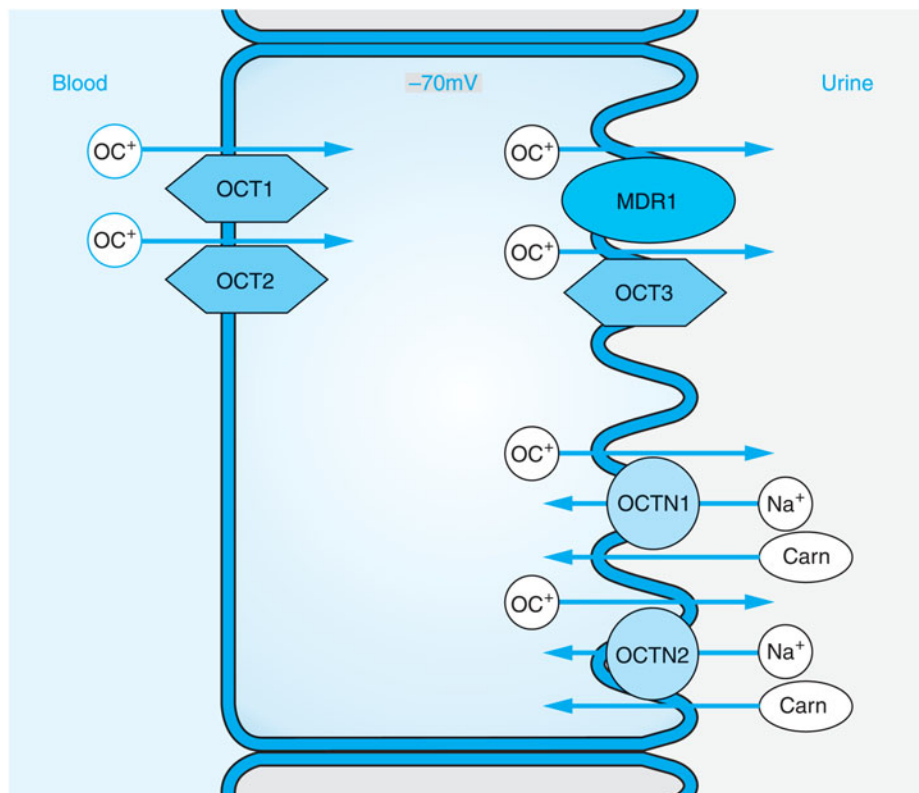

Figure 2–10. Model of organic cation secretory transporters in the proximal tubule. Hexagons depict transporters in the SLC22 family, *SLC22A1* (OCT1), *SLC22A2* (OCT2), and *SLC22A3* (OCT3). Circles show transporters in the same family, *SLC22A4* (OCTN1) and *SLC22A5* (OCTN2). MDR1 (*ABCB1*) is depicted as a dark blue oval. Carn, carnitine; OC⁺, organic cation.

created by Na⁺,K⁺-ATPase to move carnitine from tubular lumen to cell. In the secretory mode, the transporters appear to function as proton–organic cation exchangers. That is, protons move from tubular lumen to cell interior in exchange for organic cations, which move from cytosol to tubular lumen. The inwardly directed proton gradient (from tubular lumen to cytosol) is maintained by transporters in the SLC9 family (NHEs), which are Na⁺/H⁺ exchangers (antiporters). The bifunctional mechanism of OCTN1 and OCTN2 may not totally explain the organic cation–proton exchange mechanism that has been described in many studies in isolated plasma membrane vesicles. Of the two steps involved in secretory transport, transport across the luminal membrane appears to be rate-limiting.

OCT1 (*SLC22A1*). OCT1 (*SLC22A1*) was first cloned from a rat cDNA library (Koepsell and Endou, 2004). Subsequently, orthologs were cloned from mouse, rabbit, and humans. Mammalian isoforms of OCT1, which vary in length from 554 to 556 amino acids, have 12 putative transmembrane domains (Figure 2–11) and include several *N*-linked glycosylation sites. A long extracellular loop between transmembrane domains 1 and 2 is characteristic of the OCTs. The gene for the human OCT1 is mapped to chromosome 6 (6q26). There are four splice variants in human tissues, one of which is functionally active, OCT1G/L554 (Hayer *et al.*, 1999). In humans, OCT1 is expressed primarily in the liver, with some expression in heart, intestine, and skeletal muscle. In mouse

and rat, OCT1 is also abundant in the kidney, whereas in humans, very modest levels of OCT1 mRNA transcripts are detected in kidney. The transport mechanism of OCT1 is electrogenic and saturable for transport of model small-molecular-weight organic cations including tetraethylammonium (TEA) and dopamine. Interestingly, OCT1 also can operate as an exchanger, mediating organic cation–organic cation exchange. That is, loading cells with organic cations such as unlabeled TEA can trans-stimulate the inward flux of organic cations such as MPP⁺. It also should be noted that organic cations can transinhibit OCT1. In particular, the hydrophobic organic cations quinine and quinidine, which are poor substrates of OCT1, when present on the cytosolic side of a membrane, can inhibit (*transinhibit*) influx of organic cations *via* OCT1.

The human OCT1 generally accepts a wide array of monovalent organic cations with molecular weights of less than 400 daltons, including many drugs (*e.g.*, procainamide, metformin, and *pindolol*) (Dresser *et al.*, 2001). Species differences in the substrate specificity of OCT1 mammalian orthologs have been described. Inhibitors of OCT1 are generally more hydrophobic. Detailed structure–activity relationships have established that the pharmacophore of OCT1 consists of three hydrophobic arms and a single cationic recognition site. The kinetics of uptake and inhibition of model compounds with human OCT1 differ among studies and may be related to experi-

Figure 2–11. Secondary structure of OCT1 (SLC22A1) constructed from hydropathy analysis. The transmembrane topology diagram was rendered using transmembrane protein display software available at the UCSF Sequence Analysis Consulting Group Web site, <http://www.sacs.ucsf.edu/TOPO/topo.html>. The blue circles show putative *N*-glycosylation sites.

mental techniques, including a range of heterologous expression systems. Key residues that contribute to the charge specificity of OCT1 have been identified by site-directed mutagenesis studies and include a highly conserved aspartate residue (corresponding to position 475 in the rat ortholog of OCT1) that appears to be part of the monoamine recognition site. Since OCT1 mammalian orthologs have greater than 80% amino acid identity, evolutionarily nonconserved residues among mammalian species clearly are involved in specificity differences (Wright and Dantzler, 2004).

OCT2 (SLC22A2). OCT2 (SLC22A2) was first cloned from a rat kidney cDNA library in 1996 (Okuda *et al.*, 1996). Human, rabbit, mouse, and pig orthologs all have been cloned. Mammalian orthologs range in length from 553 through 555 amino acids. Similar to OCT1, OCT2 is predicted to have 12 transmembrane domains, including one *N*-linked glycosylation site. OCT2 is located adjacent to OCT1 on chromosome 6 (6q26). A single splice variant of human OCT2, termed OCT2-A, has been identified in human kidney. OCT2-A, which is a truncated form of OCT2, appears to have a lower K_m (or greater affinity) for substrates than OCT2, although a lower affinity has been observed for some inhibitors (Urakami *et al.*, 2002). Human, mouse, and rat orthologs of OCT2 are expressed in abundance in human kidney and to some extent in neuronal tissue such as choroid plexus. In the kidney, OCT2 is localized to the proximal tubule and to distal tubules and collecting ducts. In the proximal tubule, OCT2 is restricted to the basolateral membrane. OCT2 mammalian species orthologs are greater than 80% identical, whereas OCT1 and OCT2 paralogs are approximately 70% identical. The transport mechanism of OCT2 is similar to that of OCT1. In particular, OCT2-mediated transport of model organic cations MPP⁺ and TEA is electrogenic, but like OCT1, OCT2 can support organic cation–organic cation exchange (Koepsell *et al.*, 2003). Some studies show modest proton–organic cation exchange. More hydrophobic organic cations may inhibit OCT2 but may not be translocated by it.

Like OCT1, OCT2 generally accepts a wide array of monovalent organic cations with molecular weights of less than 400 daltons. The apparent affinities of the human OCT1 and OCT2 paralogs for some organic cation substrates and inhibitors have been shown to be different in side-by-side comparison studies. Isoform-specific inhibi-

tors of the OCTs are needed to determine the relative importance of OCT1 and OCT2 in the renal clearance of compounds in rodents, in which both isoforms are present in kidney. OCT2 is also present in neuronal tissues. However, studies with monoamine neurotransmitters demonstrate that dopamine, serotonin, histamine, and norepinephrine have low affinities for OCT2. These studies suggest that OCT2 may play a housekeeping role in neurons, taking up only excess concentrations of neurotransmitters. OCT2 also may be involved in recycling of neurotransmitters by taking up breakdown products, which in turn enter monoamine synthetic pathways.

OCT3 (SLC22A3). OCT3 (SLC22A3) was cloned initially from rat placenta (Kekuda *et al.*, 1998). Human and mouse orthologs have also been cloned. OCT3 consists of 551 amino acids and is predicted to have 12 transmembrane domains, including three *N*-linked glycosylation sites. hOCT3 is located in tandem with OCT1 and OCT2 on chromosome 6. Tissue distribution studies suggest that human OCT3 is expressed in liver, kidney, intestine, and placenta, although it appears to be expressed in considerably less abundance than OCT2 in the kidney. Like OCT1 and OCT2, OCT3 appears to support electrogenic potential-sensitive organic cation transport. Although the specificity of OCT3 is similar to that of OCT1 and OCT2, it appears to have quantitative differences in its affinities for many organic cations. Some studies have suggested that OCT3 is the extraneuronal monoamine transporter based on its substrate specificity and potency of interaction with monoamine neurotransmitters. Because of its relatively low abundance in the kidney, OCT3 may play only a limited role in renal drug elimination.

OCTN1 (SLC22A4). OCTN1, cloned originally from human fetal liver, is expressed in the adult kidney, trachea, and bone marrow (Tamai *et al.*, 1997). The functional characteristics of OCTN1 suggest that it operates as an organic cation–proton exchanger. OCTN1-mediated influx of model organic cations is enhanced at alkaline pH, whereas efflux is increased by an inwardly directed proton gradient. OCTN1 contains a nucleotide-binding sequence motif, and transport of its substrates appears to be stimulated by cellular ATP content. OCTN1 also can function as an organic cation–organic cation exchanger. Although the subcellular localization of OCTN1 has not been demonstrated clearly, available data collectively suggest that OCTN1 functions as a bidirectional pH- and

ATP-dependent transporter at the apical membrane in renal tubular epithelial cells. Its physiological role is not yet known because studies in *octn1* knockout mice are not available.

OCTN2 (SLC22A5). OCTN2 was first cloned from human kidney and determined to be the transporter responsible for systemic carnitine deficiency (Tamai *et al.*, 1998). Rat OCTN2 mRNA is expressed predominantly in the cortex, with very little expression in the medulla, and is localized to the apical membrane of the proximal tubule.

OCTN2 is a bifunctional transporter. That is, it transports L-carnitine with high affinity in an Na⁺-dependent manner, whereas, Na⁺ does not influence OCTN2-mediated transport of organic cations such as TEA. Thus, OCTN2 is thought to function as both an Na⁺-dependent carnitine transporter and an Na⁺-independent organic cation transporter. Similar to OCTN1, OCTN2 transport of organic cations is sensitive to pH, suggesting that it may function as an organic cation exchanger. Studies in mice containing a missense mutation in *Slc22a5* suggest that organic cations are transported in a secretory direction by OCTN2, whereas carnitine is transported in a reabsorptive direction (Ohashi *et al.*, 2001). Therefore, transport of L-carnitine by OCTN2 is an Na⁺-dependent electrogenic process. Mutations in OCTN2 have been found to be the cause of primary systemic carnitine deficiency (OMIM 212140) (Nezu *et al.*, 1999).

Polymorphisms of OCTs. Polymorphisms of OCTs have been identified in large post-human genome SNP discovery projects (Kerb *et al.*, 2002; Leabman *et al.*, 2003; Shu *et al.*, 2003). OCT1 exhibits the greatest number of amino acid polymorphisms, followed by OCT2 and then OCT3. Furthermore, allele frequencies of OCT1 amino acid variants in human populations generally are greater than those of OCT2 and OCT3 amino acid variants. Functional studies of OCT1 and OCT2 polymorphisms have been performed. OCT1 exhibits five variants with reduced function. These variants may have important implications clinically in terms of hepatic drug disposition and targeting of OCT1 substrates. In particular, individuals with OCT1 variants may have reduced liver uptake of OCT1 substrates and therefore reduced metabolism. Clinical studies need to be performed to ascertain the implications of OCT1 variants to drug disposition and response. For OCT2, several polymorphisms exhibited altered kinetic properties when expressed in *Xenopus laevis* oocytes. These variants may lead to alterations in renal secretion of OCT2 substrates.

Organic Anion Transport. A wide variety of structurally diverse organic anions are secreted in the proximal tubule (Burckhardt and Burckhardt, 2003; Dresser *et al.*, 2001; Wright and Dantzer, 2004). As with organic cation transport, the primary function of organic anion secretion appears to be the removal from the body of xenobiotics, including many weakly acidic drugs [*e.g.*, pravastatin, captopril, *p*-aminohippurate (PAH), and penicillins] and toxins (*e.g.*, ochratoxin). Organic anion transporters move both hydrophobic and hydrophilic anions but also may interact with cations and neutral compounds.

A current model for the transepithelial flux of organic anions in the proximal tubule is shown in Figure 2–12. Two primary transporters on the basolateral membrane mediate the flux of organic anions from interstitial fluid to tubule cell: OAT1 (*SLC22A6*) and OAT3 (*SLC22A8*). Energetically, hydrophilic organic anions are transported

across the basolateral membrane against an electrochemical gradient in exchange with intracellular α -ketoglutarate, which moves down its concentration gradient from cytosol to blood. The outwardly directed gradient of α -ketoglutarate is maintained at least in part by a basolateral Na⁺-dicarboxylate transporter (NaDC3). The Na⁺ gradient that drives NaDC3 is maintained by Na⁺,K⁺-ATPase. Transport of small-molecular-weight organic anions by the cloned transporters OAT1 and OAT3 can be driven by α -ketoglutarate. Coupled transport of α -ketoglutarate and small-molecular-weight organic anions (*e.g.*, *p*-aminohippurate) has been demonstrated in many studies in isolated basolateral membrane vesicles. The molecular pharmacology and molecular biology of OATs have recently been reviewed (Eraly *et al.*, 2004).

The mechanism responsible for the apical membrane transport of organic anions from tubule cell cytosol to tubular lumen remains controversial. Some studies suggest that OAT4 may serve as the luminal membrane transporter for organic anions. However, recent studies show that the movement of substrates *via* this transporter can be driven by exchange with α -ketoglutarate, suggesting that OAT4 may function in the reabsorptive, rather than secretory, flux of organic anions. Other studies have suggested that in the pig kidney, OATV1 serves as an electrogenic facilitated transporter on the apical membrane (Jutabha *et al.*, 2003). The human ortholog of OATV1 is NPT1, or NaPi-1, originally cloned as a phosphate transporter. NPT1 can support the low-affinity transport of hydrophilic organic anions such as PAH. Other transporters that may play a role in transport across the apical membrane include MRP2 and MRP4, multidrug-resistance transporters in the ATP binding cassette family C (ABCC). Both transporters interact with some organic anions and may actively pump their substrates from tubule cell cytosol to tubular lumen.

OAT1 (SLC22A6). OAT1 was cloned from rat kidney (Sekine *et al.*, 1997; Sweet *et al.*, 1997). This transporter is greater than 30% identical to OCTs in the SLC22 family. Mouse, human, pig, and rabbit orthologs have been cloned and are approximately 80% identical to human OAT1. Mammalian isoforms of OAT1 vary in length from 545 to 551 amino acids, with features similar to those shown in Figure 2–11. The gene for the human OAT1 is mapped to chromosome 11 and is found in an SLC22 cluster that includes OAT3 and OAT4. There are four splice variants in human tissues, termed *OAT1-1*, *OAT1-2*, *OAT1-3*, and *OAT1-4*. *OAT1-2*, which includes a 13-amino-acid deletion, transports PAH at a rate comparable with *OAT1-1*. These two splice variants use the alternative 5'-splice sites in exon 9. *OAT1-3* and *OAT1-4*, which result from a 132-bp (44-amino-acid) deletion near the carboxyl terminus of OAT1, do not transport PAH. In humans, rat, and mouse, OAT1 is expressed primarily in the kidney, with some expression in brain and skeletal muscle.

Immunohistochemical studies suggest that OAT1 is expressed on the basolateral membrane of the proximal tubule in human and rat, with highest expression in the middle segment, S2. Based on a quantitative polymerase chain reaction (PCR), OAT1 is expressed at a third of the level of OAT3, the other major basolateral membrane organic anion transporter. OAT1 exhibits saturable transport of organic anions such as PAH. This transport is trans-stimulated by

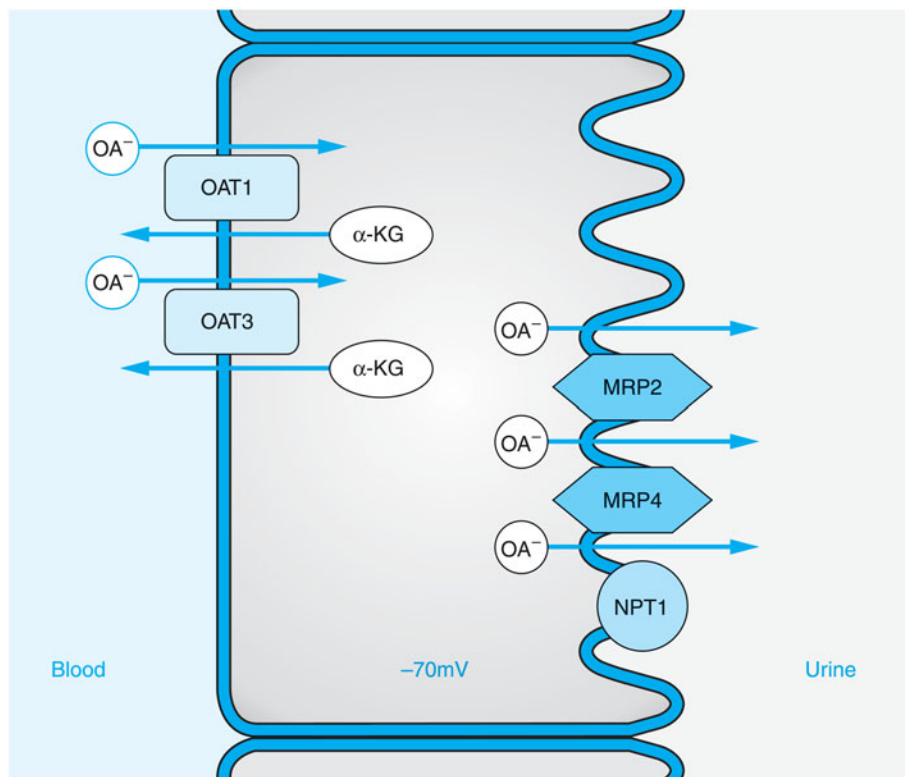

Figure 2–12. Model of organic anion secretory transporters in the proximal tubule. Rectangles depict transporters in the SLC22 family, OAT1 (*SLC22A6*) and OAT3 (*SLC22A8*), and hexagons depict transporters in the ABC superfamily, MRP2 (*ABCC2*) and MRP4 (*ABCC4*). NPT1 (*SLC17A1*) is depicted as a circle. OA^- , organic anion; $\alpha\text{-KG}$, α -ketoglutarate.

other organic anions, including α -ketoglutarate. Thus, the inside negative-potential difference drives the efflux of the dicarboxylate α -ketoglutarate, which, in turn, supports the influx of monocarboxylates such as PAH. Regulation of expression levels of OAT1 in the kidney appears to be controlled by sex steroids.

OAT1 generally transports small-molecular-weight organic anions that may be endogenous (e.g., PGE_2 and urate) or ingested drugs and toxins. Some neutral compounds are also transported by OAT1 at a lower affinity (e.g., cimetidine). Key residues that contribute to transport by OAT1 include the conserved K394 and R478, which are involved in the PAH–glutarate exchange mechanism.

OAT2 (*SLC22A7*). OAT2 was cloned first from rat liver (and named *NLT* at the time) (Sekine *et al.*, 1998; Simonson *et al.*, 1994). This transporter has a gender-based tissue distribution between the liver and the kidney in rodents but not in humans, OAT2 is present in both kidney and liver. In the kidney, the transporter is localized to the basolateral membrane of the proximal tubule. Efforts to stimulate organic anion–organic anion exchange via OAT2 have not been successful, leading to the speculation that OAT2 is a basolateral membrane transporter that serves in the reabsorptive flux of organic anions from tubule cell cytosol to interstitial fluids. OAT2 transports many organic anions, including PAH, methotrexate, *ochratoxin A*, and glutarate. Human, mouse, and rat orthologs of OAT2 have high affinities for the endogenous prostaglandin, PGE_2 .

OAT3 (*SLC22A8*). OAT3 (*SLC22A8*) was cloned originally from rat kidney (Kusuhara *et al.*, 1999). Human OAT3 consists of two variants, one of which transports a wide variety of organic anions, including PAH and *estrone sulfate*. The longer OAT3 in humans, a 568-amino-acid protein, does not support transport. It is likely that the two OAT3 variants are splice variants. Northern blotting suggests that the human ortholog of OAT3 is primarily in the kidney. Mouse and rat orthologs show some expression in the brain and liver. OAT3 mRNA levels are higher than those of OAT1, which in turn are higher than those of OAT2 or OAT4. Human OAT3 is confined to the basolateral membrane of the proximal tubule.

OAT3 clearly has overlapping specificities with OAT1, although kinetic parameters differ. For example, *estrone sulfate* is transported by both OAT1 and OAT3, but OAT3 has a much higher affinity in comparison with OAT1. The weak base cimetidine (an H_2 -receptor antagonist) is transported with high affinity by OAT1, whereas the cation TEA is not transported. Domains and residues involved in the charge specificity of OAT3 have been identified in several studies. Interestingly, changing two basic amino acid residues in OAT3 (R454D and K370A) shifts the charge specificity of OAT3 from anionic to cationic. Like OAT1, OAT3 appears to be an exchanger that couples the outward flux of α -ketoglutarate to the inward flux of organic anions: The inside negative-potential difference repels α -ketoglutarate from the cells

via OAT3, which in turn transports its substrates against a concentration gradient into the tubule cell cytosol.

OAT4 (SLC22A9). OAT4 (*SLC22A9*) was cloned from a human kidney cDNA library (Cha *et al.*, 2000). Quantitative PCR indicates that the expression level of OAT4 in human kidneys is approximately 5% to 10% of the level of OAT1 and OAT3 and is comparable with OAT2. OAT4 is expressed in human kidney and placenta; in human kidney, OAT4 is present on the luminal membrane of the proximal tubule. At first, OAT4 was thought to be involved in the second step of secretion of organic anions, *i.e.*, transport across the apical membrane from cell to tubular lumen. However, recent studies demonstrate that organic anion transport by OAT4 can be stimulated by transgradients of α -ketoglutarate (Ekaratanawong *et al.*, 2004), suggesting that OAT4 may be involved in the reabsorption of organic anions from tubular lumen into cell. The specificity of OAT4 is narrow but includes estrone sulfate and PAH. Interestingly, the affinity for PAH is low (>1 mM). Collectively, emerging studies suggest that OAT4 may be involved not in secretory flux of organic anions but in reabsorption instead.

Other Anion Transporters. URAT1 (*SLC22A12*), first cloned from human kidney, is a kidney-specific transporter confined to the apical membrane of the proximal tubule (Enomoto *et al.*, 2002). Data suggest that URAT1 is primarily responsible for urate reabsorption, mediating electroneutral urate transport that can be transstimulated by Cl^- gradients. The mouse ortholog of URAT1 is involved in the renal secretory flux of organic anions including *benzylpenicillin* and urate.

NPT1 (*SLC17A1*), cloned originally as a phosphate transporter in humans, is expressed in abundance on the luminal membrane of the proximal tubule as well as in the brain (Werner *et al.*, 1991). NPT1 transports PAH, probenecid, and *penicillin G*. It appears to be part of the system involved in organic anion efflux from tubule cell to lumen.

MRP2 (*ABCC2*), an ABC transporter, initially called the *GS-X pump* (Ishikawa *et al.*, 1990), has been considered to be the primary transporter involved in efflux of many drug conjugates such as glutathione conjugates across the canalicular membrane of the hepatocyte. However, MRP2 is also found on the apical membrane of the proximal tubule, where it is thought to play a role in the efflux of organic anions into the tubular lumen. Its role in the kidney may be to secrete glutathione conjugates of drugs, but it also may support the translocation (with glutathione) of various nonconjugated substrates. In general, MRP2 transports larger, bulkier compounds than do most of the organic anion transporters in the SLC22 family.

MRP4 (*ABCC4*) is found on the apical membrane of the proximal tubule and transports a wide array of conjugated anions, including glucuronide and glutathione conjugates. However, unlike MRP2, MRP4 appears to interact with various drugs, including methotrexate, cyclic nucleotide analogs, and antiviral nucleoside analogs. It is possible that MRP4 is involved in the apical flux of many drugs from cell to tubule lumen. Other MRP efflux transporters also have been identified in human kidney, including MRP3 and MRP6, both on the basolateral membrane. Their roles in the kidney are not yet known.

Polymorphisms of OATs. Polymorphisms in OAT1 and OAT3 have been identified in ethnically diverse human populations. Two amino acid polymorphisms (allele frequencies greater than 1%) in OAT1 have been identified in African-American populations (OAT1-R50H). Three amino acid polymorphisms and seven rare amino acid

variants in OAT3 have been identified in ethnically diverse U.S. populations (*see www.pharmgkb.org*).

TRANSPORTERS INVOLVED IN PHARMACODYNAMICS: DRUG ACTION IN THE BRAIN

Neurotransmitters are packaged in vesicles in presynaptic neurons, released in the synapse by fusion of the vesicles with the plasma membrane, and, excepting acetylcholine, are then taken back into the presynaptic neurons or postsynaptic cells (*see* Chapter 6). Transporters involved in the neuronal reuptake of the neurotransmitters and the regulation of their levels in the synaptic cleft belong to two major superfamilies, SLC1 and SLC6. Transporters in both families play roles in reuptake of γ -aminobutyric acid (GABA), glutamate, and the monoamine neurotransmitters norepinephrine, serotonin, and dopamine. These transporters may serve as pharmacologic targets for neuropsychiatric drugs.

SLC6 family members localized in the brain and involved in the reuptake of neurotransmitters into presynaptic neurons include the norepinephrine transporters (NET, *SLC6A2*), the dopamine transporter (DAT, *SLC6A3*), the serotonin transporter (SERT, *SLC6A4*), and several GABA reuptake transporters (GAT1, GAT2, and GAT3) (Chen *et al.*, 2004; Hediger, 2004; Elliott and Beveridge, 2005). Each of these transporters appears to have 12 transmembrane secondary structures and a large extracellular loop with glycosylation sites between transmembrane domains 3 and 4. These proteins are typically approximately 600 amino acids in length. SLC6 family members depend on the Na^+ gradient to actively transport their substrates into cells. Cl^- is also required, although to a variable extent depending on the family member. Residues and domains that form the substrate recognition and permeation pathways are currently being identified.

Through reuptake mechanisms, the neurotransmitter transporters in the SLC6A family regulate the concentrations and dwell times of neurotransmitters in the synaptic cleft; the extent of transmitter uptake also influences subsequent vesicular storage of transmitters. It is important to note that many of these transporters are present in other tissues (*e.g.*, kidney and platelets) and may serve other roles. Further, the transporters can function in the reverse direction. That is, the transporters can export neurotransmitters in an Na^+ -independent fashion. The characteristics of each member of the SLC6A family of transporters that play a role in reuptake of monoamine neurotransmitters and GABA merit a brief description.

SLC6A1 (GAT1), SLC6A11 (GAT3), and SLC6A13 (GAT2). GAT1 (599 amino acids) is the most important GABA transporter in the brain, expressed in GABAergic neurons and found largely on presynaptic neurons (Chen *et al.*, 2004). GAT1 is found in abundance in the neocortex, cerebellum, basal ganglia, brainstem, spinal cord, retina, and olfactory bulb. GAT3 is found only in the brain, largely in glial cells. GAT2 is found in peripheral tissues, including the kidney and liver, and within the CNS in the choroid plexus and meninges.

GAT1, GAT2, and GAT3 are approximately 50% identical in amino acid sequence. Functional analysis indicates that GAT1 transports GABA with a 2:1 Na⁺:GABA⁻ stoichiometry. Cl⁻ is required. Residues and domains responsible for the recognition of GABA and subsequent translocation have been identified: Tyr140 appears to be crucial for binding GABA. Physiologically, GAT1 appears to be responsible for regulating the interaction of GABA at receptors. The presence of GAT2 in the choroid plexus and its absence in presynaptic neurons suggest that this transporter may play a primary role in maintaining the homeostasis of GABA in the CSF. GAT1 and GAT3 are drug targets. GAT1 is the target of the antiepileptic drug *tiagabine*, which presumably acts to increase GABA levels in the synaptic cleft of GABAergic neurons by inhibiting the reuptake of GABA. GAT3 is the target for the nipecotic acid derivatives that are anticonvulsants.

SLC6A2 (NET). NET (617 amino acids) is found in central and peripheral nervous tissues as well as in adrenal chromaffin tissue (Chen *et al.*, 2004). In the brain, NET colocalizes with neuronal markers, consistent with a role in reuptake of monoamine neurotransmitters. The transporter functions in the Na⁺-dependent reuptake of norepinephrine and dopamine and as a higher-capacity norepinephrine channel. A major role of NET is to limit the synaptic dwell time of norepinephrine and to terminate its actions, salvaging norepinephrine for subsequent repackaging. NET knockout mice exhibit a prolonged synaptic half-life of norepinephrine (Xu *et al.*, 2000). Ultimately, through its reuptake function, NET participates in the regulation of many neurological functions, including memory and mood. NET serves as a drug target; the antidepressant *desipramine* is considered a selective inhibitor of NET. Other drugs that interact with NET include other tricyclic antidepressants and *cocaine*. Orthostatic intolerance, a rare familial disorder characterized by an abnormal blood pressure and heart rate response to changes in posture, has been associated with a mutation in NET.

SLC6A3 (DAT). DAT is located primarily in the brain in dopaminergic neurons. Although present on presynaptic neurons at the neurosynaptic junction, DAT is also present in abundance along the neurons, away from the synaptic cleft. This distribution suggests that DAT may play a role

in clearance of excess dopamine in the vicinity of neurons. The primary function of DAT is the reuptake dopamine, terminating its actions, although DAT also weakly interacts with norepinephrine. Physiologically, DAT is involved in the various functions that are attributed to the dopaminergic system, including mood, behavior, reward, and cognition. The half-life of dopamine in the extracellular spaces of the brain is prolonged considerably in DAT knockout mice (Uhl, 2003), which are hyperactive and have sleep disorders. Drugs that interact with DAT include cocaine and its analogs, *amphetamines*, and the neurotoxin *MPTP*.

SLC6A4 (SERT). SERT is located in peripheral tissues and in the brain along extrasynaptic axonal membranes (Chen *et al.*, 2004; Olivier *et al.*, 2000). SERT clearly plays a role in the reuptake and clearance of serotonin in the brain. Like the other SLC6A family members, SERT transports its substrates in an Na⁺-dependent fashion and is dependent on Cl⁻ and possibly on the countertransport of K⁺. Substrates of SERT include serotonin (5-HT), various tryptamine derivatives, and neurotoxins such as *3,4-methylene-dioxymethamphetamine* (MDMA; ecstasy) and *fenfluramine*. The serotonin transporter has been one of the most widely studied proteins in the human genome. First, it is the specific target of the antidepressants in the selective serotonin reuptake inhibitor class (*e.g.*, *fluoxetine* and *paroxetine*) and one of several targets of tricyclic antidepressants (*e.g.*, *amitriptyline*). Further, because of the important role of serotonin in neurological function and behavior, genetic variants of SERT have been associated with an array of behavioral and neurological disorders. In particular, a common promoter region variant that alters the length of the upstream region of *SLC6A4* has been the subject of many studies. The short form of the variant results in a reduced rate of transcription of SERT in comparison with the long form. These differences in the rates of transcription alter the quantity of mRNA and, ultimately, the expression and activity of SERT. The short form has been associated with a variety of neuropsychiatric disorders (Lesch *et al.*, 1996). The precise mechanism by which a reduced activity of SERT, caused by either a genetic variant or an antidepressant, ultimately affects behavior, including depression, is not known.

BLOOD-BRAIN BARRIER AND BLOOD-CSF BARRIER

Drugs acting in the CNS have to cross the BBB or blood-CSF barrier. These two barriers are formed by

brain capillary endothelial cells and epithelial cells of the choroid plexus, respectively. Recent studies have shown that this is not only a static anatomical barrier but also a dynamic one in which efflux transporters play a role (Begley and Brightman, 2003; Sun *et al.*, 2003). P-glycoprotein was identified initially as an efflux transporter, and it extrudes its substrate drugs on the luminal membrane of the brain capillary endothelial cells into the blood. Thus, recognition by P-glycoprotein as a substrate is a major disadvantage for drugs used to treat CNS diseases. In addition to P-glycoprotein, there is accumulating evidence for the presence of efflux transport systems for anionic drugs. The transporters involved in the efflux transport of organic anions from the CNS are being identified in the BBB and the blood–CSF barrier and include the members of organic anion transporting polypeptide (OATP1A4 and OATP1A5) and organic anion transporter (OAT3) families (Kikuchi *et al.*, 2004; Mori *et al.*, 2003). They facilitate the uptake process of organic compounds such as β -lactam antibiotics, statins, *p*-aminohippurate, H₂ antagonists, and bile acids on the plasma membrane facing the brain–CSF. The transporters involved in the efflux on the membranes that face the blood still remain to be identified, although several candidate primary active transporters, such as MRP and BCRP, already have been proposed. Members of the organic anion transporting polypeptide family also mediate uptake from the blood on the plasma membrane facing blood. Further clarification of influx and efflux transporters in the barriers will enable delivery of CNS drugs efficiently into the brain while avoiding undesirable CNS side effects and help to define the mechanisms of drug–drug interactions and interindividual differences in the therapeutic CNS effects.

DRUG METABOLISM

Frank J. Gonzalez and Robert H. Tukey

How Humans Cope with Exposure to Xenobiotics.

The ability of humans to metabolize and clear drugs is a natural process that involves the same enzymatic pathways and transport systems that are utilized for normal metabolism of dietary constituents. Humans come into contact with scores of foreign chemicals or xenobiotics (substances foreign to the body) through exposure to environmental contaminants as well as in our diets. Fortunately, humans have developed a means to rapidly eliminate xenobiotics so they do not cause harm. In fact, one of the most common sources of xenobiotics in the diet is from plants that have many structurally diverse chemicals, some of which are associated with pigment production and others that are actually toxins (called phytoalexins) that protect plants against predators. A common example is poisonous mushrooms that have many toxins that are lethal to mammals, including amanitin, gyromitrin, orellanine, muscarine, ibotenic acid, muscimol, psilocybin, and coprine. Animals must be able to metabolize and eliminate such chemicals in order to consume vegetation. While humans can now choose their dietary source, a typical animal does not have this luxury and as a result is subject to its environment and the vegetation that exists in that environment. Thus, the ability to metabolize unusual chemicals in plants and other food sources is critical for survival.

Drugs are considered xenobiotics and most are extensively metabolized in humans. It is worth noting that many drugs are derived from chemicals found in plants, some of which had been used in Chinese herbal medicines for thousands of years. Of the prescription drugs in use today for cancer treatment, many derive from plant species (*see* Chapter 51); investigating folklore claims led to the discovery of most of these drugs. It is therefore not surprising that animals utilize a means for disposing of human-made drugs that mimics the disposition of chemi-

cals found in the diet. This capacity to metabolize xenobiotics, while mostly beneficial, has made development of drugs very time consuming and costly due in large part to (1) interindividual variations in the capacity of humans to metabolize drugs, (2) drug-drug interactions, and (3) species differences in expression of enzymes that metabolize drugs. The latter limits the use of animal models in drug development.

A large number of diverse enzymes have evolved in animals that apparently only function to metabolize foreign chemicals. As will be discussed below, there are such large differences among species in the ability to metabolize xenobiotics that animal models cannot be relied upon to predict how humans will metabolize a drug. Enzymes that metabolize xenobiotics have historically been called drug-metabolizing enzymes, although they are involved in the metabolism of many foreign chemicals to which humans are exposed. Dietary differences among species during the course of evolution could account for the marked species variation in the complexity of the drug-metabolizing enzymes.

Today, most xenobiotics to which humans are exposed come from sources that include environmental pollution, food additives, cosmetic products, agrochemicals, processed foods, and drugs. In general, these are lipophilic chemicals, that in the absence of metabolism would not be efficiently eliminated, and thus would accumulate in the body, resulting in toxicity. With very few exceptions, all xenobiotics are subjected to one or multiple pathways that constitute the phase 1 and phase 2 enzymatic systems. As a general paradigm, metabolism serves to convert these hydrophobic chemicals into derivatives that can easily be eliminated through the urine or the bile.

In order to be accessible to cells and reach their sites of action, drugs generally must possess physical properties that allow them to move down a concentration gradient

into the cell. Thus, most drugs are hydrophobic, a property that allows entry through the lipid bilayers into cells where drugs interact with their target receptors or proteins. Entry into cells is facilitated by a large number of transporters on the plasma membrane (see Chapter 2). This property of hydrophobicity would render drugs difficult to eliminate, since in the absence of metabolism, they would accumulate in fat and cellular phospholipid bilayers in cells. The xenobiotic-metabolizing enzymes convert drugs and xenobiotics into compounds that are hydrophilic derivatives that are more easily eliminated through excretion into the aqueous compartments of the tissues. Thus, the process of drug metabolism that leads to elimination plays a major role in diminishing the biological activity of a drug. For example, (*S*)-phenytoin, an anticonvulsant used in the treatment of epilepsy, is virtually insoluble in water. Metabolism by the phase 1 cytochrome P450 isoenzymes (CYPs) followed by phase 2 uridine diphosphate-glucuronosyltransferase (UGT) enzymes produces a metabolite that is highly water soluble and readily eliminated from the body (Figure 3–1). Metabolism also terminates the biological activity of the drug. In the case of phenytoin, metabolism also increases the molecular weight of the compound, which allows it to be eliminated more efficiently in the bile.

While xenobiotic-metabolizing enzymes are responsible for facilitating the elimination of chemicals from the body, paradoxically these same enzymes can also convert certain chemicals to highly reactive toxic and carcinogenic metabolites. This occurs when an unstable intermediate is formed that has reactivity toward other compounds found in the cell. Chemicals that can be converted by xenobiotic metabolism to cancer-causing derivatives are called carcinogens. Depending on the structure of the chemical substrate, xenobiotic-metabolizing enzymes produce electrophilic metabolites that can react with nucleophilic cellular macromolecules such as DNA, RNA, and protein. This can cause cell death and organ toxicity. Reaction of these electrophiles with DNA can sometimes result in cancer through the mutation of genes such as oncogenes or tumor suppressor genes. It is generally believed that most human cancers are due to exposure to chemical carcinogens. This potential for carcinogenic activity makes testing the safety of drug candidates of vital importance. Testing for potential cancer-causing activity is particularly critical for drugs that will be used for the treatment of chronic diseases. Since each species has evolved a unique combination of xenobiotic-metabolizing enzymes, nonprimate rodent models cannot be solely used during drug development for testing the safety of new drug candi-

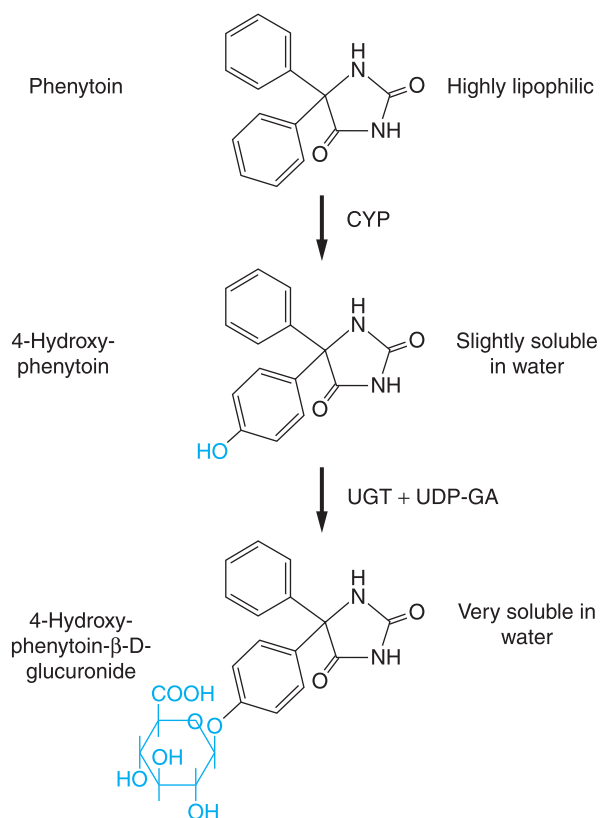

Figure 3–1. Metabolism of phenytoin by phase 1 cytochrome P450 (CYP) and phase 2 uridine diphosphate-glucuronosyltransferase (UGT). CYP facilitates 4-hydroxylation of phenytoin to yield 5-(4-hydroxyphenyl)-5-phenylhydantoin (HPPH). The hydroxy group serves as a substrate for UGT that conjugates a molecule of glucuronic acid using UDP-glucuronic acid (UDP-GA) as a cofactor. This converts a very hydrophobic molecule to a larger hydrophilic derivative that is eliminated via the bile.

dates targeted for human diseases. Nevertheless, testing in rodent models such as mice and rats can usually identify potential carcinogens.

The Phases of Drug Metabolism. Xenobiotic metabolizing enzymes have historically been grouped into the phase 1 reactions, in which enzymes carry out oxidation, reduction, or hydrolytic reactions, and the phase 2 reactions, in which enzymes form a conjugate of the substrate (the phase 1 product) (Table 3–1). The phase 1 enzymes lead to the introduction of what are called functional groups, resulting in a modification of the drug, such that it now carries an –OH, –COOH, –SH, –O– or NH₂ group. The addition of functional groups does little to increase the water solubility of the drug, but can dra-

Table 3–1

Xenobiotic Metabolizing Enzymes

ENZYMES	REACTIONS
<i>Phase 1 “oxygenases”</i>	
Cytochrome P450s (P450 or CYP)	C and O oxidation, dealkylation, others
Flavin-containing monooxygenases (FMO)	N, S, and P oxidation
Epoxide hydrolases (mEH, sEH)	Hydrolysis of epoxides
<i>Phase 2 “transferases”</i>	
Sulfotransferases (SULT)	Addition of sulfate
UDP-glucuronosyltransferases (UGT)	Addition of glucuronic acid
Glutathione-S-transferases (GST)	Addition of glutathione
<i>N</i> -acetyltransferases (NAT)	Addition of acetyl group
Methyltransferases (MT)	Addition of methyl group
<i>Other enzymes</i>	
Alcohol dehydrogenases	Reduction of alcohols
Aldehyde dehydrogenases	Reduction of aldehydes
NADPH-quinone oxidoreductase (NQO)	Reduction of quinones

mEH and sEH are microsomal and soluble epoxide hydrolase. UDP, uridine diphosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate.

matically alter the biological properties of the drug. Phase 1 metabolism is classified as the functionalization phase of drug metabolism; reactions carried out by phase 1 enzymes usually lead to the inactivation of an active drug. In certain instances, metabolism, usually the hydrolysis of an ester or amide linkage, results in bioactivation of a drug. Inactive drugs that undergo metabolism to an active drug are called prodrugs. An example is the anti-tumor drug *cyclophosphamide*, which is bioactivated to a cell-killing electrophilic derivative (see Chapter 51). Phase 2 enzymes facilitate the elimination of drugs and the inactivation of electrophilic and potentially toxic metabolites produced by oxidation. While many phase 1 reactions result in the biological inactivation of the drug, phase 2 reactions produce a metabolite with improved water solubility and increased molecular weight, which serves to facilitate the elimination of the drug from the tissue.

Superfamilies of evolutionarily related enzymes and receptors are common in the mammalian genome; the enzyme systems responsible for drug metabolism are good examples. The phase 1 oxidation reactions are carried out by CYPs, flavin-containing monooxygenases (FMO), and epoxide hydrolases (EH). The CYPs and FMOs are composed of superfamilies of enzymes. Each superfamily contains multiple genes. The phase 2 enzymes include several superfamilies of conjugating enzymes. Among the more

important are the glutathione-S-transferases (GST), UDP-glucuronosyltransferases (UGT), sulfotransferases (SULT), *N*-acetyltransferases (NAT), and methyltransferases (MT). These conjugation reactions usually require the substrate to have oxygen (hydroxyl or epoxide groups), nitrogen, and sulfur atoms that serve as acceptor sites for a hydrophilic moiety, such as glutathione, glucuronic acid, sulfate, or an acetyl group, that is covalently conjugated to an acceptor site on the molecule. The example of phase 1 and phase 2 metabolism of phenytoin is shown in Figure 3–1. The oxidation by phase 1 enzymes either adds or exposes a functional group, permitting the products of phase 1 metabolism to serve as substrates for the phase 2 conjugating or synthetic enzymes. In the case of the UGTs, glucuronic acid is delivered to the functional group, forming a glucuronide metabolite that is now more water soluble with a higher molecular weight that is targeted for excretion either in the urine or bile. When the substrate is a drug, these reactions usually convert the original drug to a form that is not able to bind to its target receptor, thus attenuating the biological response to the drug.

Sites of Drug Metabolism. Xenobiotic metabolizing enzymes are found in most tissues in the body with the highest levels located in the tissues of the gastrointestinal tract (liver, small and large intestines). Drugs that are orally administered, absorbed by the gut, and taken to the

liver, can be extensively metabolized. The liver is considered the major “metabolic clearing house” for both endogenous chemicals (*e.g.*, cholesterol, steroid hormones, fatty acids, and proteins), and xenobiotics. The small intestine plays a crucial role in drug metabolism since most drugs that are orally administered are absorbed by the gut and taken to the liver through the portal vein. The high concentration of xenobiotic-metabolizing enzymes located in the epithelial cells of the GI tract is responsible for the initial metabolic processing of most oral medications. This should be considered the initial site for first-pass metabolism of drugs. The absorbed drug then enters the portal circulation for its first pass through the liver, where metabolism may be prominent, as it is for β adrenergic receptor antagonists, for example. While a portion of active drug escapes this first-pass metabolism in the GI tract and liver, subsequent passes through the liver result in more metabolism of the parent drug until the agent is eliminated. Thus, drugs that are poorly metabolized remain in the body for longer periods of time and their pharmacokinetic profiles show much longer elimination

half-lives than drugs that are rapidly metabolized. Other organs that contain significant xenobiotic-metabolizing enzymes include the tissues of the nasal mucosa and lung, which play important roles in the first-pass metabolism of drugs that are administered through aerosol sprays. These tissues are also the first line of contact with hazardous chemicals that are airborne.

Within the cell, xenobiotic-metabolizing enzymes are found in the intracellular membranes and in the cytosol. The phase 1 CYPs, FMOs, and EHs, and some phase 2 conjugating enzymes, notably the UGTs, are all located in the endoplasmic reticulum of the cell (Figure 3–2). The endoplasmic reticulum consists of phospholipid bilayers organized as tubes and sheets throughout the cytoplasm of the cell. This network has an inner lumen that is physically distinct from the rest of the cytosolic components of the cell and has connections to the plasma membrane and nuclear envelope. This membrane localization is ideally suited for the metabolic function of these enzymes: hydrophobic molecules enter the cell and become embedded in the lipid bilayer where they come into direct contact with

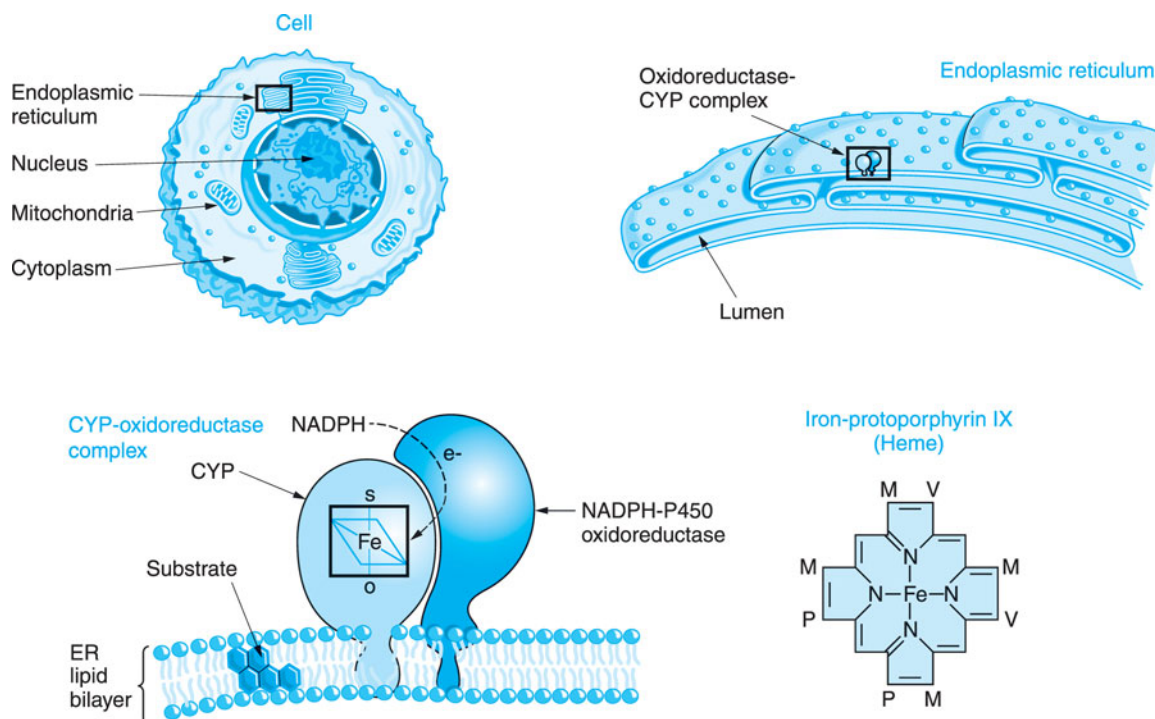

Figure 3–2. Location of CYPs in the cell. The figure shows increasingly microscopic levels of detail, sequentially expanding the areas within the black boxes. CYPs are embedded in the phospholipid bilayer of the endoplasmic reticulum (ER). Most of the enzyme is located on the cytosolic surface of the ER. A second enzyme, NADPH-cytochrome P450 oxidoreductase, transfers electrons to the CYP where it can, in the presence of O_2 , oxidize xenobiotic substrates, many of which are hydrophobic and dissolved in the ER. A single NADPH-CYP oxidoreductase species transfers electrons to all CYP isoforms in the ER. Each CYP contains a molecule of iron-protoporphyrin IX that functions to bind and activate O_2 . Substituents on the porphyrin ring are methyl (M), propionyl (P), and vinyl (V) groups.

the phase 1 enzymes. Once subjected to oxidation, drugs can be conjugated in the membrane by the UGTs or by the cytosolic transferases such as GST and SULT. The metabolites can then be transported out of the cell through the plasma membrane where they are deposited into the bloodstream. Hepatocytes, which constitute more than 90% of the cells in the liver, carry out most drug metabolism and can produce conjugated substrates that can also be transported through the bile canalicular membrane into the bile from which they are eliminated into the gut (*see* Chapter 2).

The CYPs. The CYPs are a superfamily of enzymes, all of which contain a molecule of heme that is noncovalently bound to the polypeptide chain (Figure 3–2). Many other enzymes that use O_2 as a substrate for their reactions contain heme. Heme is the oxygen-binding moiety, also found in hemoglobin, where it functions in the binding and transport of molecular oxygen from the lung to other tissues. Heme contains one atom of iron in a hydrocarbon cage that functions to bind oxygen in the CYP active site as part of the catalytic cycle of these enzymes. CYPs use O_2 , plus H^+ derived from the cofactor-reduced nicotinamide adenine dinucleotide phosphate (NADPH), to carry out the oxidation of substrates. The H^+ is supplied through the enzyme NADPH-cytochrome P450 oxidoreductase. Metabolism of a substrate by a CYP consumes one molecule of molecular oxygen and produces an oxidized substrate and a molecule of water as a by-product. However, for most CYPs, depending on the nature of the substrate, the reaction is “uncoupled,” consuming more O_2 than substrate metabolized and producing what is called activated oxygen or O_2^- . The O_2^- is usually converted to water by the enzyme superoxide dismutase.

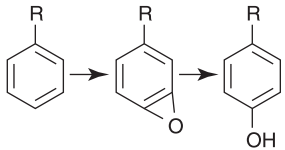

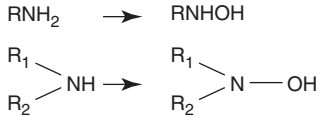

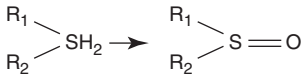

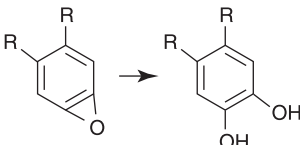

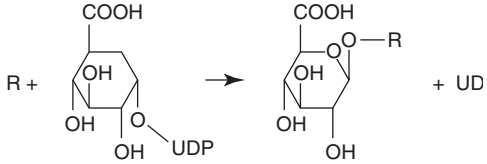

Among the diverse reactions carried out by mammalian CYPs are *N*-dealkylation, *O*-dealkylation, aromatic hydroxylation, *N*-oxidation, *S*-oxidation, deamination, and dehalogenation (Table 3–2). More than 50 individual CYPs have been identified in humans. As a family of enzymes, CYPs are involved in the metabolism of dietary and xenobiotic agents, as well as the synthesis of endogenous compounds such as steroids and the metabolism of bile acids, which are degradation by-products of cholesterol. In contrast to the drug-metabolizing CYPs, the CYPs that catalyze steroid and bile acid synthesis have very specific substrate preferences. For example, the CYP that produces estrogen from testosterone, CYP19 or aromatase, can metabolize only testosterone and does not metabolize xenobiotics. Specific inhibitors for aromatase, such as *anastrozole*, have been developed for use in the

treatment of estrogen-dependent tumors (*see* Chapter 51). The synthesis of bile acids from cholesterol occurs in the liver, where, subsequent to CYP-catalyzed oxidation, the bile acids are conjugated and transported through the bile duct and gallbladder into the small intestine. CYPs involved in bile acid production have strict substrate requirements and do not participate in xenobiotic or drug metabolism.

The CYPs that carry out xenobiotic metabolism have a tremendous capacity to metabolize a large number of structurally diverse chemicals. This is due both to multiple forms of CYPs and to the capacity of a single CYP to metabolize many structurally distinct chemicals. A single compound can also be metabolized, albeit at different rates, by different CYPs. In addition, CYPs can metabolize a single compound at different positions on the molecule. In contrast to enzymes in the body that carry out highly specific reactions involved in the biosynthesis and degradation of important cellular constituents in which there is a single substrate and one or more products, or two simultaneous substrates, the CYPs are considered promiscuous in their capacity to bind and metabolize multiple substrates (Table 3–2). This property, which is due to large and fluid substrate binding sites in the CYP, sacrifices metabolic turnover rates; CYPs metabolize substrates at a fraction of the rate of more typical enzymes involved in intermediary metabolism and mitochondrial electron transfer. As a result, drugs have, in general, half-lives of the order of 3 to 30 hours, while endogenous compounds have half-lives of the order of seconds or minutes (*e.g.*, dopamine and insulin). Even though CYPs have slow catalytic rates, their activities are sufficient to metabolize drugs that are administered at high concentrations in the body. This unusual feature of extensive overlapping substrate specificities by the CYPs is one of the underlying reasons for the predominance of drug-drug interactions. When two coadministered drugs are both metabolized by a single CYP, they compete for binding to the enzyme's active site. This can result in the inhibition of metabolism of one or both of the drugs, leading to elevated plasma levels. If there is a narrow therapeutic index for the drugs, the elevated serum levels may elicit unwanted toxicities. Drug-drug interactions are among the leading causes of adverse drug reactions.

The CYPs are the most actively studied of the xenobiotic metabolizing enzymes since they are responsible for metabolizing the vast majority of therapeutic drugs. CYPs are complex and diverse in their regulation and catalytic activities. Cloning and sequencing of CYP complementary DNAs, and more recently total genome sequencing, have revealed the existence of 102 putatively functional genes and 88 pseudogenes in the mouse, and 57 putatively functional

Table 3-2
Major Reactions Involved in Drug Metabolism

REACTION	EXAMPLES	
I. Oxidative reactions		
<i>N</i> -Dealkylation	$\text{RNHCH}_3 \rightarrow \text{RNH}_2 + \text{CH}_2\text{O}$	Imipramine, diazepam, codeine, erythromycin, morphine, tamoxifen, theophylline, caffeine
<i>O</i> -Dealkylation	$\text{ROCH}_3 \rightarrow \text{ROH} + \text{CH}_2\text{O}$	Codeine, indomethacin, dextromethorphan
Aliphatic hydroxylation	$\text{RCH}_2\text{CH}_3 \rightarrow \text{RCHOHCH}_3$	Tolbutamide, ibuprofen, phenobarbital, meprobamate, cyclosporine, midazolam
Aromatic hydroxylation		Phenytoin, phenobarbital, propranolol, ethinyl estradiol, amphetamine, warfarin
<i>N</i> -Oxidation	$\text{RNH}_2 \rightarrow \text{RNHOH}$ 	Chlorpheniramine, dapsone, meperidine
<i>S</i> -Oxidation		Cimetidine, chlorpromazine, thioridazine, omeprazole
Deamination	$\text{RCHCH}_3 \xrightarrow{\text{NH}_2} \text{R}-\overset{\text{OH}}{\underset{\text{NH}_2}{\text{C}}}-\text{CH}_3 \rightarrow \text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{CH}_3 + \text{NH}_3$	Diazepam, amphetamine
II. Hydrolysis reactions		
		Carbamazepine
	$\text{R}_1\text{COR}_2 \rightarrow \text{R}_1\text{COOH} \rightarrow \text{R}_2\text{OH}_2$	Procaine, aspirin, clofibrate, meperidine, enalapril, cocaine
	$\text{R}_1\text{CNR}_2 \rightarrow \text{R}_1\text{COOH} \rightarrow \text{R}_2\text{NH}_2$	Lidocaine, procainamide, indomethacin
III. Conjugation reactions		
Glucuronidation	 <p>UDP-glucuronic acid</p>	Acetaminophen, morphine, oxazepam, lorazepam

(Continued)

Table 3-2
Major Reactions Involved in Drug Metabolism (Continued)

	REACTION	EXAMPLES
Sulfation	$\text{PAPS} + \text{ROH} \longrightarrow \text{R-O-SO}_2\text{-OH} + \text{PAP}$ <p style="text-align: center;"> <small>3'-phosphoadenosine-5'-phosphosulfate</small> <small>3'-phosphoadenosine-5'-phosphate</small> </p>	Acetaminophen, steroids, methyl dopa
Acetylation	$\text{CoAS-CO-CH}_3 + \text{RNH}_2 \longrightarrow \text{RNH-CO-CH}_3 + \text{CoA-SH}$	Sulfonamides, isoniazid, dapsone, clonazepam (<i>see</i> Table 3-3)
Methylation	$\text{RO-}, \text{RS-}, \text{RN-} + \text{AdoMet} \longrightarrow \text{RO-CH}_3 + \text{AdoHomCys}$	L-Dopa, methyl dopa, mercaptopurine, captopril
Glutathione conjugation	$\text{GSH} + \text{R} \longrightarrow \text{R-GSH}$	Adriamycin, fosfomycin, busulfan

genes and 58 pseudogenes in humans. These genes are grouped, based on amino acid sequence similarity, into a large number of families and subfamilies. CYPs are named with the root CYP followed by a number designating the family, a letter denoting the subfamily, and another number designating the CYP form. Thus, CYP3A4 is family 3, subfamily A, and gene number 4. While several CYP families are involved in the synthesis of steroid hormones and bile acids, and the metabolism of retinoic acid and fatty acids, including prostaglandins and eicosanoids, a limited number of CYPs (15 in humans) that fall into families 1 to 3 are primarily involved in xenobiotic metabolism (Table 3-1). Since a single CYP can metabolize a large number of structurally diverse compounds, these enzymes can collectively metabolize scores of chemicals found in the diet, environment, and administered as drugs. In humans, 12 CYPs (CYP1A1, 1A2, 1B1, 2A6, 2B6, 2C8, 2C9, 2C19, 2D6, 2E1, 3A4, and 3A5) are known to be important for metabolism of xenobiotics. The liver contains the greatest abundance of xenobiotic-metabolizing CYPs, thus ensuring efficient first-pass metabolism of drugs. CYPs are also expressed throughout the GI tract, and in lower amounts in lung, kidney, and even in the CNS. The expression of the different CYPs can differ markedly as a result of dietary and environmental exposure to inducers, or through interindividual changes resulting from heritable polymorphic differences in gene structure, and tissue-specific expression patterns can impact on overall drug metabolism and clearance. The most active CYPs for drug metabolism are those in the CYP2C, CYP2D, and CYP3A subfamilies. CYP3A4 is the most abundantly expressed and involved in the metabolism of about 50% of clinically used drugs (Figure 3-3A). The CYP1A, CYP1B, CYP2A, CYP2B, and CYP2E subfamilies are not significantly involved in the metabolism of therapeutic drugs, but they do catalyze the metabolic activation of many protoxins and procarcinogens to their ultimate reactive metabolites.

There are large differences in levels of expression of each CYP between individuals as assessed both by clinical pharmacologic studies and by analysis of expression in human liver samples. This large interindividual variability in CYP expression is due to the presence of genetic polymorphisms and differences in gene regula-

tion (*see* below). Several human CYP genes exhibit polymorphisms, including *CYP2A6*, *CYP2C9*, *CYP2C19*, and *CYP2D6*. Allelic variants have been found in the *CYP1B1* and *CYP3A4* genes, but they are present at low frequencies in humans and appear not to have a major role in interindividual levels of expression of these enzymes. However, homozygous mutations in the *CYP1B1* gene are associated with primary congenital glaucoma.

Drug-Drug Interactions. Differences in the rate of metabolism of a drug can be due to drug interactions. Most commonly, this occurs when two drugs (*e.g.*, a statin and a macrolide antibiotic or antifungal) are coadministered and are metabolized by the same enzyme. Since most of these drug-drug interactions are due to CYPs, it becomes important to determine the identity of the CYP that metabolizes a particular drug and to avoid coadministering drugs that are metabolized by the same enzyme. Some drugs can also inhibit CYPs independently of being substrates for a CYP. For example, the common antifungal agent, *ketoconazole* (NIZORAL), is a potent inhibitor of CYP3A4 and other CYPs, and coadministration of ketoconazole with the anti-HIV viral protease inhibitors reduces the clearance of the protease inhibitor and increases its plasma concentration and the risk of toxicity. For most drugs, descriptive information found on the package insert lists the CYP that carries out its metabolism and the potential for drug interactions. Some drugs are CYP inducers that can induce not only their own metabolism, but also induce metabolism of other coadministered drugs (*see* below and Figure 3-13). Steroid hormones and herbal products such as St. John's wort can increase hepatic levels of CYP3A4, thereby increasing the metabolism of

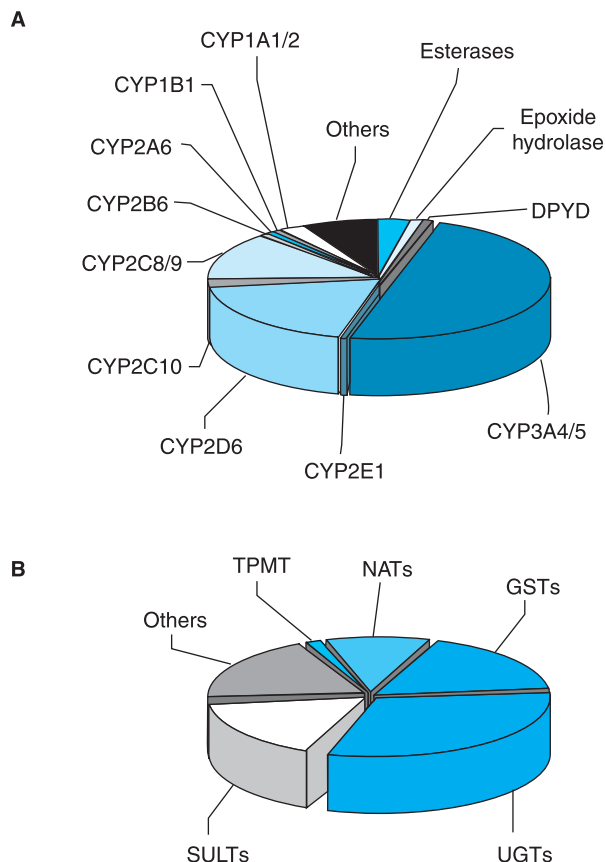

Figure 3-3. The fraction of clinically used drugs metabolized by the major phase 1 and phase 2 enzymes. The relative size of each pie section represents the estimated percentage of drugs metabolized by the major phase 1 (panel **A**) and phase 2 (panel **B**) enzymes, based on studies in the literature. In some cases, more than a single enzyme is responsible for metabolism of a single drug. CYP, cytochrome P450; DPYD, dihydropyrimidine dehydrogenase; GST, glutathione-S-transferase; NAT, N-acetyltransferase; SULT, sulfotransferase; TPMT, thiopurine methyltransferase; UGT, UDP-glucuronosyltransferase.

many orally administered drugs. Drug metabolism can also be influenced by diet. CYP inhibitors and inducers are commonly found in foods and in some cases these can influence the toxicity and efficacy of a drug. Components found in grapefruit juice (*e.g.*, naringin, furanocoumarins) are potent inhibitors of CYP3A4, and thus some drug inserts recommend not taking medication with grapefruit juice because it could increase the bioavailability of a drug.

Terfenadine, a once popular antihistamine, was removed from the market because its metabolism was blocked by CYP3A4 sub-

strates such as *erythromycin* and grapefruit juice. *Terfenadine* is actually a prodrug that requires oxidation by CYP3A4 to its active metabolite, and at high doses the parent compound caused arrhythmias. Thus, elevated levels of parent drug in the plasma as a result of CYP3A4 inhibition caused ventricular tachycardia in some individuals, which ultimately led to its withdrawal from the market. In addition, interindividual differences in drug metabolism are significantly influenced by polymorphisms in CYPs. The CYP2D6 polymorphism has led to the withdrawal of several clinically used drugs (*e.g.*, *debrisoquine* and *perhexiline*) and the cautious use of others that are known CYP2D6 substrates (*e.g.*, *encainide* and *flecainide* [antiarrhythmics], *desipramine* and *nortriptyline* [antidepressants], and *codeine*).

Flavin-Containing Monooxygenases (FMOs). The FMOs are another superfamily of phase 1 enzymes involved in drug metabolism. Similar to CYPs, the FMOs are expressed at high levels in the liver and are bound to the endoplasmic reticulum, a site that favors interaction with and metabolism of hydrophobic drug substrates. There are six families of FMOs, with FMO3 being the most abundant in liver. FMO3 is able to metabolize nicotine as well as H₂-receptor antagonists (*cimetidine* and *ranitidine*), antipsychotics (*clozapine*), and antiemetics (*itopride*). A genetic deficiency in this enzyme causes the fish-odor syndrome due to a lack of metabolism of trimethylamine *N*-oxide (TMAO) to trimethylamine (TMA); in the absence of this enzyme, TMAO accumulates in the body and causes a socially offensive fish odor. TMAO is found at high concentrations, up to 15% by weight, in marine animals where it acts as an osmotic regulator. FMOs are considered minor contributors to drug metabolism and they almost always produce benign metabolites. In addition, FMOs are not induced by any of the xenobiotic receptors (*see below*) or easily inhibited; thus, in distinction to CYPs, FMOs would not be expected to be involved in drug-drug interactions. In fact, this has been demonstrated by comparing the pathways of metabolism of two drugs used in the control of gastric motility, *itopride* and *cisapride*. *Itopride* is metabolized by FMO3 while *cisapride* is metabolized by CYP3A4; thus, *itopride* is less likely to be involved in drug-drug interactions than is *cisapride*. CYP3A4 participates in drug-drug interactions through induction and inhibition of metabolism, whereas FMO3 is not induced or inhibited by any clinically used drugs. It remains a possibility that FMOs may be of importance in the development of new drugs. A candidate drug could be designed by introducing a site for FMO oxidation with the knowledge that selected metabolism and pharmacokinetic properties could be accurately calculated for efficient drug-based biological efficacy.

Hydrolytic Enzymes. Two forms of *epoxide hydrolase* carry out hydrolysis of epoxides produced by CYPs. The soluble epoxide hydrolase (sEH) is expressed in the cytosol while the microsomal epoxide hydrolase (mEH) is localized to the membrane of the endoplasmic reticulum. Epoxides are highly reactive electrophiles that can bind to cellular nucleophiles found in protein, RNA, and DNA, resulting in cell toxicity and transformation. Thus, epoxide hydrolases participate in the deactivation of potentially toxic derivatives generated by CYPs. There are a few examples of the influence of mEH on drug metabolism. The antiepileptic drug *carbamazepine* is a prodrug that is converted to its pharmacologically active derivative, carbamazepine-10,11-epoxide by CYP. This metabolite is efficiently hydrolyzed to a dihydrodiol by mEH, resulting in inactivation of the drug (Figure 3–4). Inhibition of mEH can cause an elevation in plasma concentrations of the active metabolite, causing side effects. The tranquilizer *valnoctamide* and anticonvulsant *valproic acid* inhibit mEH, resulting in clinically significant drug interactions with carbamazepine. This has led to efforts to develop new antiepileptic drugs such as *gabapentin* and *levetiracetam* that are metabolized by CYPs and not by EHs.

The *carboxylesterases* comprise a superfamily of enzymes that catalyze the hydrolysis of ester- and amide-

Figure 3–4. Metabolism of carbamazepine by CYP and microsomal epoxide hydrolase (mEH). Carbamazepine is oxidized to the pharmacologically-active metabolite carbamazepine-10,11-epoxide by CYP. The epoxide is converted to a trans-dihydrodiol by mEH. This metabolite is biologically inactive and can be conjugated by phase 2 enzymes.

Figure 3–5. Metabolism of irinotecan (CPT-11). The prodrug CPT-11 is initially metabolized by a serum esterase (CES2) to the topoisomerase inhibitor SN-38, which is the active camptothecin analog that slows tumor growth. SN-38 is then subject to glucuronidation, which results in loss of biological activity and facilitates elimination of the SN-38 in the bile.

containing chemicals. These enzymes are found in both the endoplasmic reticulum and the cytosol of many cell types and are involved in detoxification or metabolic activation of various drugs, environmental toxicants, and carcinogens. Carboxylesterases also catalyze the activation of prodrugs to their respective free acids. For example, the prodrug and cancer chemotherapeutic agent *irinotecan* is a *camptothecin* analog that is bioactivated by plasma and intracellular carboxylesterases to the potent topoisomerase inhibitor SN-38 (Figure 3–5).

Conjugating Enzymes. There are a large number of phase 2 conjugating enzymes, all of which are considered to be synthetic in nature since they result in the formation of a metabolite with an increased molecular mass. Phase 2 reactions also terminate the biological activity of the drug. The contributions of different phase 2 reactions to drug metabolism are shown in Figure 3–3B. Two of the phase 2 reactions, glucuronidation and sulfation, result in the formation of metabolites with a significantly increased water-to-lipid partition coefficient, resulting in hydrophilicity and facilitating their transport into the aqueous compartments of the cell and the body. Glucuronidation also markedly increases the molecular weight of the compound, a modification that favors biliary excretion. While sulfation and acetylation terminate the biological activity of drugs, the solubility properties of these metabolites are altered through minor changes in the overall charge of the molecule. Characteristic of the phase 2 reactions is the dependency on the catalytic reactions for cofactors such as UDP-glucuronic acid (UDP-GA) and 3'-phosphoadenosine-5'-phosphosulfate (PAPS), for UDP-glucuronosyltransferases (UGT) and sulfotransferases (SULT), respectively, which react with available functional groups on the substrates. The reactive functional groups are often generated by the phase 1 CYPs. All of the phase 2 reactions are carried out in the cytosol of the cell, with the exception of glucuronidation, which is localized to the luminal side of the endoplasmic reticulum. The catalytic rates of phase 2 reactions are significantly faster than the rates of the CYPs. Thus, if a drug is targeted for phase 1 oxidation through the CYPs, followed by a phase 2 conjugation reaction, usually the rate of elimination will depend upon the initial (phase 1) oxidation reaction. Since the rate of conjugation is faster and the process leads to an increase in hydrophilicity of the drug, phase 2 reactions are generally considered to assure the efficient elimination and detoxification of most drugs.

Glucuronidation. Among the more important of the phase 2 reactions in the metabolism of drugs is that catalyzed by UDP-glucuronosyltransferases (UGTs) (Figure 3–3B). These enzymes catalyze the transfer of glucuronic acid from the cofactor UDP-glucuronic acid to a substrate to form β -D-glucopyranosiduronic acids (glucuronides), metabolites that are sensitive to cleavage by β -glucuronidase. The generation of glucuronides can be formed through alcoholic and phenolic hydroxyl groups, carboxyl, sulfonyl, and carbonyl moieties, as well as through primary, secondary, and tertiary amine linkages. Examples of glucuronidation reactions are shown in Table 3–2 and Figure 3–5. The structural diversity in the many different types of drugs and xenobiotics that are processed through

glucuronidation assures that most clinically efficacious therapeutic agents will be excreted as glucuronides.

There are 19 human genes that encode the UGT proteins. Nine are encoded by the *UGT1* locus and 10 are encoded by the *UGT2* family of genes. Both families of proteins are involved in the metabolism of drugs and xenobiotics, while the UGT2 family of proteins appears to have greater specificity for the glucuronidation of endogenous substances such as steroids. The UGT2 proteins are encoded by unique genes on chromosome 4 and the structure of each gene includes six exons. The clustering of the UGT2 genes on the same chromosome with a comparable organization of the regions encoding the open reading frames is evidence that gene duplication has occurred, a process of natural selection that has resulted in the multiplication and eventual diversification of the potential to detoxify the plethora of compounds that are targeted for glucuronidation.

The nine functional UGT1 proteins are all encoded by the *UGT1* locus (Figure 3–6), which is located on chromosome 2. The *UGT1* locus spans nearly 200 kb, with over 150 kb encoding a tandem array of cassette exonic regions that encode approximately 280 amino acids of the amino terminal portion of the UGT1A proteins. Four exons are located at the 3' end of the locus that encode the carboxyl 245 amino acids that combine with one of the consecutively numbered array of first exons to form the individual *UGT1* gene products. Since exons 2 to 5 encode the same sequence for each UGT1A protein, the variability in substrate specificity for each of the UGT1A proteins results from the significant divergence in sequence encoded by the exon 1 regions. The 5' flanking region of each first-exon cassette contains a fully functional promoter capable of initiating transcription in an inducible and tissue-specific manner.

From a clinical perspective, the expression of UGT1A1 assumes an important role in drug metabolism since the glucuronidation of bilirubin by UGT1A1 is the rate-limiting step in assuring efficient bilirubin clearance, and this rate can be affected by both genetic variation and competing substrates (drugs). Bilirubin is the breakdown product of heme, 80% of which originates from circulating hemoglobin and 20% from other heme-containing proteins such as the CYPs. Bilirubin is

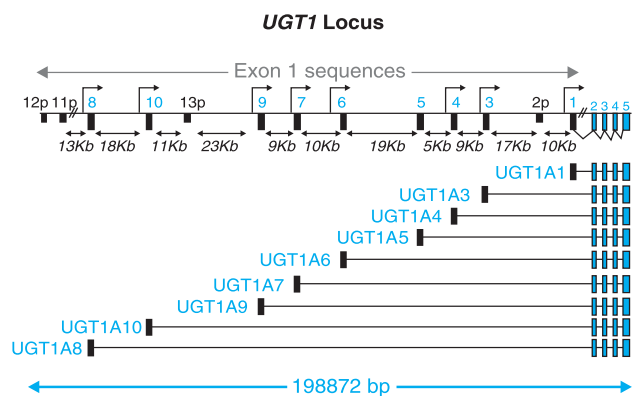

Figure 3–6. Organization of the UGT1A Locus. Transcription of the *UGT1A* genes commences with the activation of PolII, which is controlled through tissue-specific events. Conserved exons 2 to 5 are spliced to each respective exon 1 sequence resulting in the production of unique *UGT1A* sequences. The *UGT1A* locus encodes nine functional proteins.

hydrophobic, associates with serum albumin, and must be metabolized further by glucuronidation to assure its elimination. The failure to efficiently metabolize bilirubin by glucuronidation leads to elevated serum levels and a clinical symptom called hyperbilirubinemia or jaundice. There are more than 50 genetic lesions in the *UGT1A1* gene that can lead to inheritable unconjugated hyperbilirubinemia. Crigler-Najjar syndrome type I is diagnosed as a complete lack of bilirubin glucuronidation, while Crigler-Najjar syndrome type II is differentiated by the detection of low amounts of bilirubin glucuronides in duodenal secretions. Types I and II Crigler-Najjar syndrome are rare, and result from genetic polymorphisms in the open reading frames of the *UGT1A1* gene, resulting in abolished or highly diminished levels of functional protein.

Gilbert's syndrome is a generally benign condition that is present in up to 10% of the population; it is diagnosed clinically because circulating bilirubin levels are 60% to 70% higher than those seen in normal subjects. The most common genetic polymorphism associated with Gilbert's syndrome is a mutation in the *UGT1A1* gene promoter, which leads to reduced expression levels of UGT1A1. Subjects diagnosed with Gilbert's syndrome may be predisposed to adverse drug reactions resulting from a reduced capacity to metabolize drugs by UGT1A1. If a drug undergoes selective metabolism by UGT1A1, competition for drug metabolism with bilirubin glucuronidation will exist, resulting in pronounced hyperbilirubinemia as well as reduced clearance of metabolized drug. *Tranilast* [N-(3',4'-demethoxycinnamoyl)-anthranilic acid] is an investigational drug used for the prevention of restenosis in patients that have undergone transluminal coronary revascularization (intracoronary stents). Tranilast therapy in

patients with Gilbert's syndrome has been shown to lead to hyperbilirubinemia as well as potential hepatic complications resulting from elevated levels of tranilast.

Gilbert's syndrome also alters patient responses to irinotecan. Irinotecan, a prodrug used in chemotherapy of solid tumors (see Chapter 51), is metabolized to its active form, SN-38, by serum carboxylesterases (Figure 3–5). SN-38, a potent topoisomerase inhibitor, is inactivated by UGT1A1 and excreted in the bile (Figures 3–7 and 3–8). Once in the lumen of the intestine, the SN-38 glucuronide undergoes cleavage by bacterial β -glucuronidase and re-enters the circulation through intestinal absorption. Elevated levels of SN-38 in the blood lead to hematological toxicities characterized by leukopenia and neutropenia, as well as damage to the intestinal epithelial cells (Figure 3–8), resulting in acute and life-threatening diarrhea. Patients with Gilbert's syndrome who are receiving irinotecan therapy are predisposed to the hematological and gastrointestinal toxicities resulting from elevated serum levels of SN-38, the net result of insufficient UGT1A activity and the consequent accumulation of a toxic drug in the GI epithelium.

The UGTs are expressed in a tissue-specific and often inducible fashion in most human tissues, with the highest concentration of enzymes found in the GI tract and liver. Based upon their physicochemical properties, glucuronides are excreted by the kidneys into the urine or through active transport processes through the apical surface of the liver hepatocytes into the bile ducts where they are transported to the duodenum for excretion with components of the bile. Most of the bile acids that are glucuronidated are reabsorbed back to the liver for reutilization by "enterohepatic

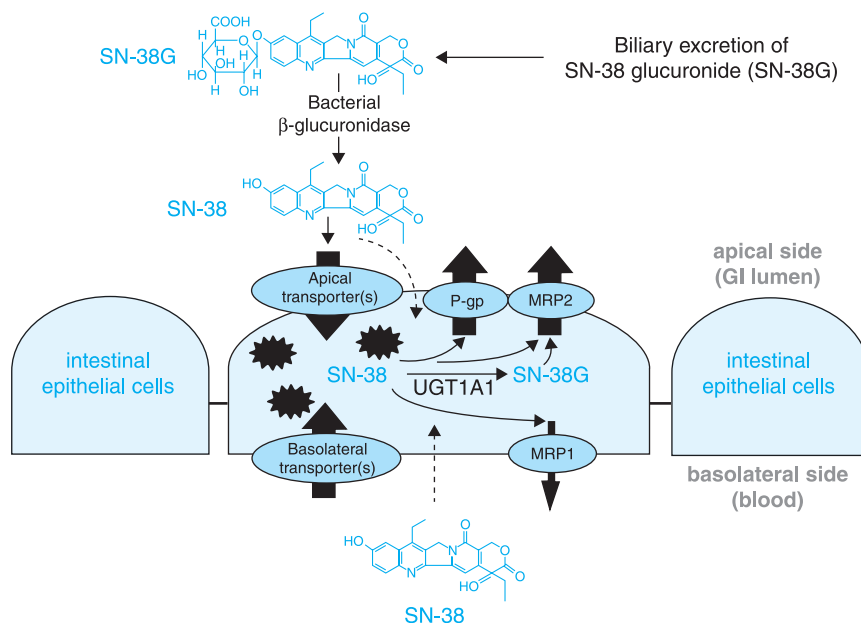

Figure 3–7. Routes of SN-38 transport and exposure to intestinal epithelial cells. SN-38 is transported into the bile following glucuronidation by liver UGT1A1 and extrahepatic UGT1A7. Following cleavage of luminal SN-38 glucuronide (SN-38G) by bacterial β -glucuronidase, reabsorption into epithelial cells can occur by passive diffusion (indicated by the dashed arrows entering the cell) as well as by apical transporters. Movement into epithelial cells may also occur from the blood by basolateral transporters. Intestinal SN-38 can efflux into the lumen through P-glycoprotein (P-gp) and multidrug resistance protein 2 (MRP2) and into the blood via MRP1. Excessive accumulation of the SN-38 in intestinal epithelial cells, resulting from reduced glucuronidation, can lead to cellular damage and toxicity (Tukey *et al.*, 2002).

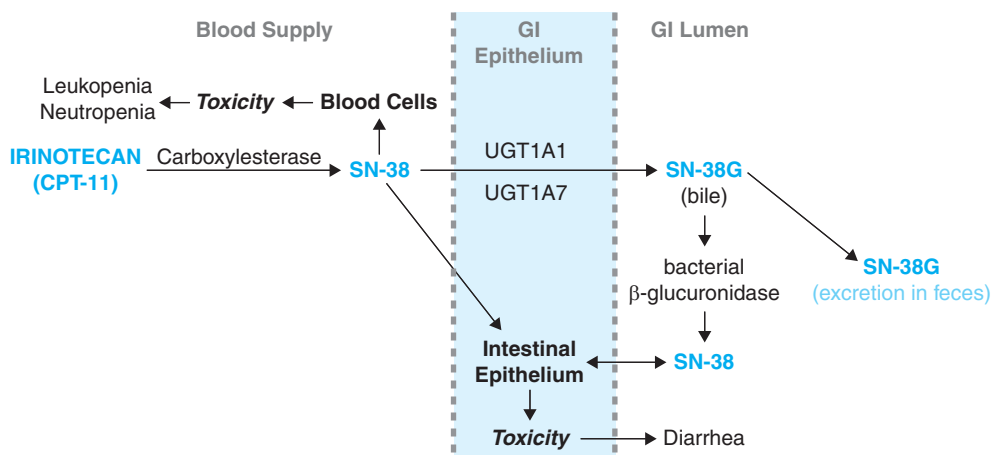

Figure 3–8. Cellular targets of SN-38 in the blood and intestinal tissues. Excessive accumulation of SN-38 can lead to blood toxicities such as leukopenia and neutropenia, as well as damage to the intestinal epithelium. These toxicities are pronounced in individuals that have reduced capacity to form the SN-38 glucuronide, such as patients with Gilbert’s syndrome. Note the different body compartments and cell types involved (Tukey *et al.*, 2002).

recirculation”; many drugs that are glucuronidated and excreted in the bile can re-enter the circulation by this same process. The β -D-glucopyranosiduronic acids are targets for β -glucuronidase activity found in resident strains of bacteria that are common in the lower GI tract, liberating the free drug into the intestinal lumen. As water is reabsorbed into the large intestine, free drug can then be transported by passive diffusion or through apical transporters back into the intestinal epithelial cells, from which the drug can then re-enter the circulation. Through portal venous return from the large intestine to the liver, the reabsorption process allows for the re-entry of drug into the systemic circulation (Figures 3–7 and 3–8).

Sulfation. The sulfotransferases (SULTs) are located in the cytosol and conjugate sulfate derived from 3′-phosphoadenosine-5′-phosphosulfate (PAPS) to the hydroxyl groups of aromatic and aliphatic compounds. Like all of the xenobiotic metabolizing enzymes, the SULTs metabolize a wide variety of endogenous and exogenous substrates. In humans, 11 SULT isoforms have been identified, and, based on evolutionary projections, have been classified into the SULT1 (SULT1A1, SULT1A2, SULT1A3, SULT1B1, SULT1C2, SYLT1C4, SULT1E1), SULT2 (SULT2A1, SULT2B1-v1, SULT2B1-v2), and SULT4 (SULT4A1) families. SULTs play an important role in normal human homeostasis. For example, SULT1B1 is the predominant form expressed in skin and brain, carrying out the catalysis of cholesterol and thyroid hormones. Cholesterol sulfate is an essential metabolite in regulating keratinocyte differentiation and skin development. SULT1A3 is highly selective for catecholamines, while estrogens are sulfated by SULT1E1 and dehydroepi-

androsterone (DHEA) is selectively sulfated by SULT2A1. In humans, significant fractions of circulating catecholamines, estrogens, iodothyronines, and DHEA exist in the sulfated form.

The different human SULTs display a variety of unique substrate specificities. The SULT1 family isoforms are considered to be the major forms involved in drug metabolism, with SULT1A1 being the most important and displaying extensive diversity in its capacity to catalyze the sulfation of a wide variety of structurally heterogeneous xenobiotics. The isoforms in the SULT1 family have been recognized as phenol SULTs, since they have been characterized to catalyze the sulfation of phenolic molecules such as *acetaminophen*, *minoxidil*, and *17 α -ethinyl estradiol*. While two SULT1C isoforms exist, little is known about their substrate specificity toward drugs, although SULT1C4 is capable of sulfating the hepatic carcinogen N-OH-2-acetylaminofluorene. Both SULT1C2 and SULT1C4 are expressed abundantly in fetal tissues and decline in abundance in adults, yet little is known about their substrate specificities. SULT1E catalyzes the sulfation of endogenous and exogenous steroids, and has been found localized in liver as well as in hormone-responsive tissues such as the testis, breast, adrenal gland, and placenta.

The conjugation of drugs and xenobiotics is considered primarily a detoxification step, assuring that these agents are compartmented into the water compartments of the body for targeted elimination. However, drug metabolism through sulfation often leads to the generation of chemically reactive metabolites, where the sulfate is electron withdrawing and may be heterolytically cleaved, leading to the formation of an electrophilic cation. Most examples of the generation by sulfation of a carcinogenic or toxic response in animal or test mutagenicity assays have been documented with chemicals derived from the environment or from food mutagens generated from well-cooked meat. Thus, it is important to understand whether genetic linkages can be made by

associating known human SULT polymorphisms to cancer episodes that are felt to originate from environmental sources. Since SULT1A1 is the most abundant in human tissues and displays broad substrate specificity, the polymorphic profiles associated with this gene and the onset of various human cancers is of considerable interest. An appreciation of the structure of the proteins of the SULT family will aid in drug design and advance an understanding of the linkages relating sulfation to cancer susceptibility, reproduction, and development. The SULTs from the SULT1 and SULT2 families were among the first xenobiotic-metabolizing enzymes to be crystallized and the data indicate a highly conserved catalytic core (Figure 3–9A). The structures reveal the role of the co-substrate PAPS in catalysis, identifying the conserved amino acids that facilitate the 3' phosphate's role in sulfuryl transfer to the protein and in turn to the substrate (Figure 3–9B). Crystal structures of the different SULTs indicate that while conservation in the PAPS binding region is maintained, the organization of the substrate binding region differs, helping to explain the observed differences in catalytic potential displayed with the different SULTs.

Glutathione Conjugation. The glutathione-S-transferases (GSTs) catalyze the transfer of glutathione to reactive electrophiles, a function that serves to protect cellular macromolecules from interacting with electrophiles that contain electrophilic heteroatoms (-O, -N, and -S) and in turn protects the cellular environment from damage. The co-substrate in the reaction is the tripeptide glutathione, which is synthesized from γ -glutamic acid, cysteine, and glycine (Figure 3–10). Glutathione exists in the cell as oxidized (GSSG) or reduced (GSH), and the ratio of GSH:GSSG is critical in maintaining a cellular environment in the reduced state. In addition to affecting xenobiotic conjugation with GSH, a severe reduction in GSH content can predispose cells to oxidative damage, a state that has been linked to a number of human health issues.

In the formation of glutathione conjugates, the reaction generates a thioether linkage with drug or xenobiotic to the cysteine moiety of the tripeptide. Characteristically, all GST substrates contain an electrophilic atom and are hydrophobic, and by nature will associate with cellular proteins. Since the concentration of glutathione in cells is usually very high, typically $\sim 7 \mu\text{mol/g}$ of liver, or in the 10 mM range, many drugs and xenobiotics can react non-enzymatically with glutathione. However, the GSTs have been found to occupy up to 10% of the total cellular protein concentration, a property that assures efficient conjugation of glutathione to reactive electrophiles. The high concentration of GSTs also provides the cells with a sink of cytosolic protein, a property that facilitates noncovalent and sometimes covalent interactions with compounds that are not substrates for glutathione conjugation. The cytosolic pool of GSTs, once identified as *ligandin*, has been

shown to bind steroids, bile acids, bilirubin, cellular hormones, and environmental toxicants, in addition to complexing with other cellular proteins.

Over 20 human GSTs have been identified and divided into two subfamilies: the cytosolic and the microsomal forms. The major differences in function between the microsomal and cytosolic GSTs reside in the selection of substrates for conjugation; the cytosolic forms have more importance in the metabolism of drugs and xenobiotics, whereas the microsomal GSTs are important in the endogenous metabolism of leukotrienes and prostaglandins. The cytosolic GSTs are divided into seven classes termed alpha (GSTA1 and 2), mu (GSTM1 through 5), omega (GSTO1), pi (GSTP1), sigma (GSTS1), theta (GSTT1 and 2), and zeta (GSTZ1). Those in the alpha and mu classes can form heterodimers, allowing for a large number of active transferases to form. The cytosolic forms of GST catalyze conjugation, reduction, and isomerization reactions.

The high concentrations of GSH in the cell, as well as the overabundance of GSTs, means that few reactive molecules escape detoxification. However, while there appears to be an overcapacity of enzyme and reducing equivalents, there is always concern that some reactive intermediates will escape detoxification, and by nature of their electrophilicity, will bind to cellular components and cause toxicity. The potential for such an occurrence is heightened if GSH is depleted or if a specific form of GST is polymorphic. While it is difficult to deplete cellular GSH levels, therapeutic agents that require large doses to be clinically efficacious have the greatest potential to lower cellular GSH levels. Acetaminophen, which is normally metabolized by glucuronidation and sulfation, is also a substrate for oxidative metabolism by CYP2E1, which generates the toxic metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI). An overdose of acetaminophen can lead to depletion of cellular GSH levels, thereby increasing the potential for NAPQI to interact with other cellular components. Acetaminophen toxicity is associated with increased levels of NAPQI and tissue necrosis.

Like many of the enzymes involved in drug and xenobiotic metabolism, all of the GSTs have been shown to be polymorphic. The mu (GSTM1*0) and theta (GSTT1*0) genotypes express a null phenotype; thus, individuals that are polymorphic at these loci are predisposed to toxicities by agents that are selective substrates for these GSTs. For example, the GSTM1*0 allele is observed in 50% of the Caucasian population and has been linked genetically to human malignancies of the lung, colon, and bladder. Null activity in the GSTT1 gene has been associated with adverse side effects and toxicity in cancer chemotherapy with cytostatic drugs; the toxicities result from insufficient clearance of the drugs *via* GSH conjugation. Expression of the null genotype can be as high as 60% in Chinese and Korean populations. Therapies may alter efficacies, with an increase in severity of adverse side effects.

While the GSTs play an important role in cellular detoxification, their activities in cancerous tissues have been linked to the development of drug resistance toward chemotherapeutic agents that are both substrates and nonsubstrates for the GSTs. Many anticancer drugs are effective because they initiate cell death or apoptosis, which is linked to the activation of mitogen-activated protein (MAP) kinases such as JNK and p38. Investigational studies have demonstrated that overexpression of GSTs is associated with resistance to apoptosis and the inhibition of MAP kinase activity. In a variety of tumors, the levels of GSTs are overexpressed, which

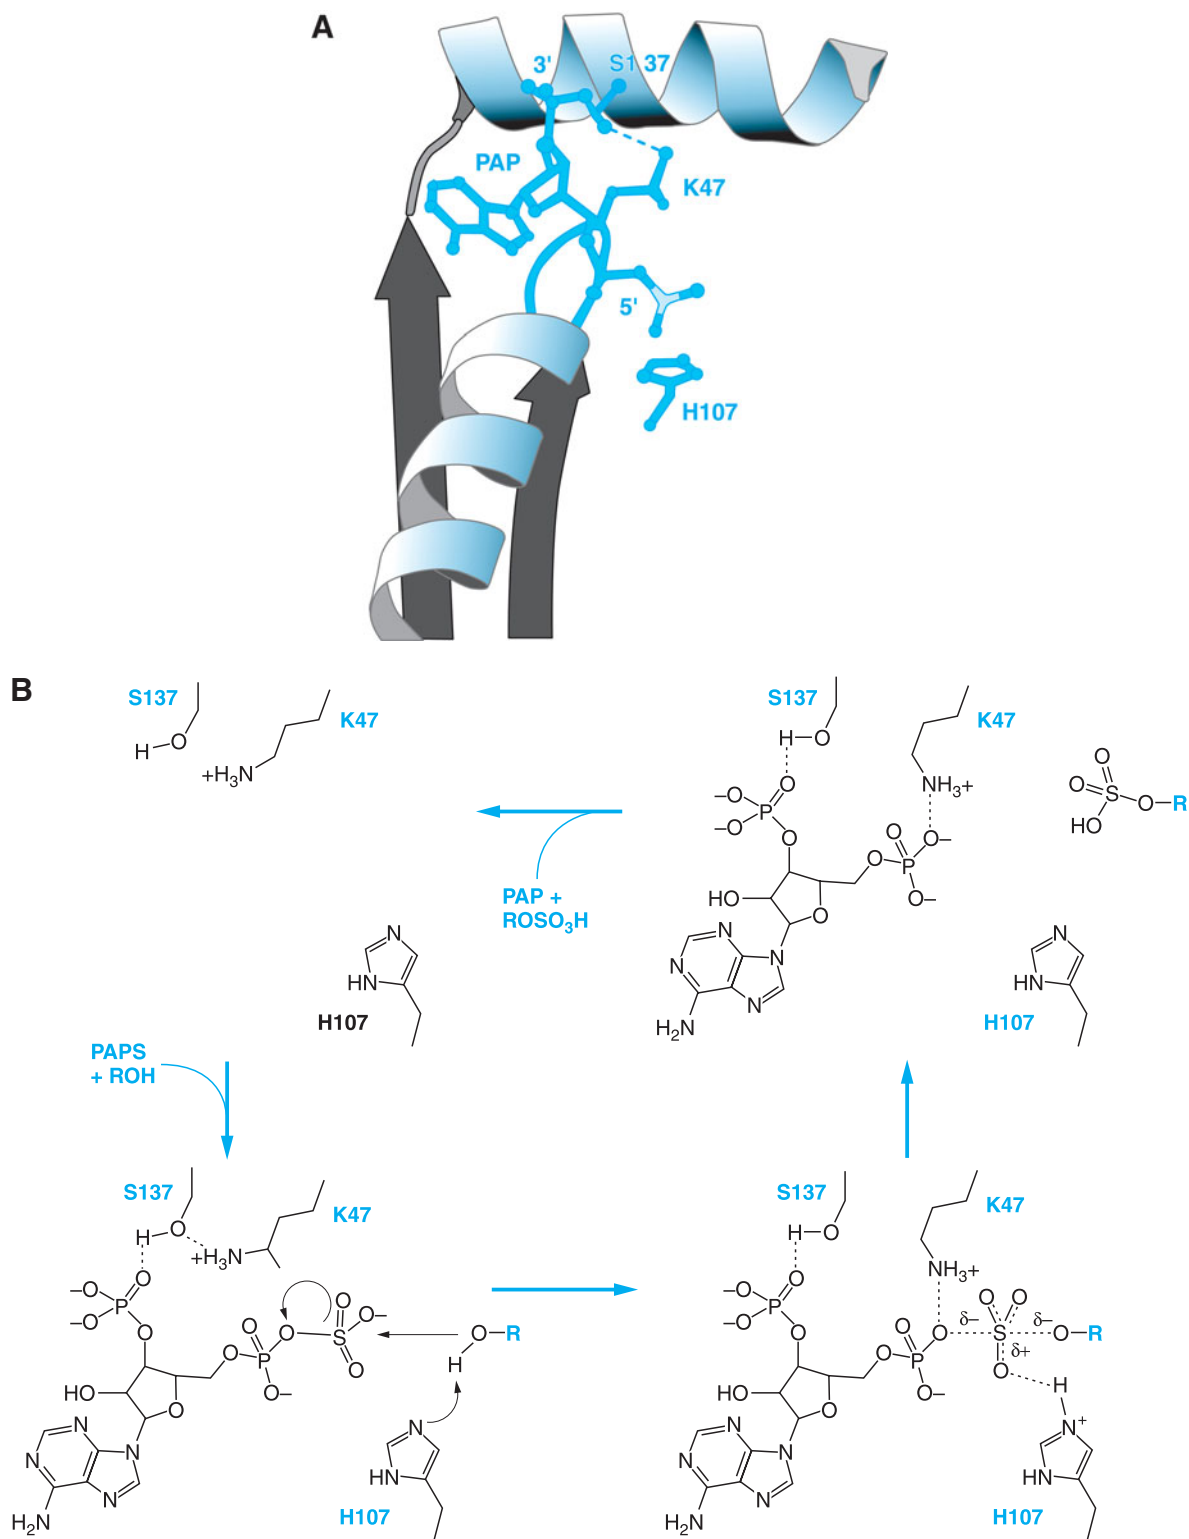

Figure 3-9. The proposed reaction mechanism of sulfuryl transfer catalyzed by the sulfotransferases (SULTs). **A.** Shown in this figure are the conserved strand-loop-helix and strand-turn-helix structure of the catalytic core of all SULTs where PAPS and xenobiotics bind. Shown is the hydrogen bonding interaction of PAPS with Lys⁴⁷ and Ser¹³⁷ with His¹⁰⁷ which complexes with substrate (xenobiotic). **B.** The proposed reaction mechanism shows the transfer of the sulfuryl group from PAPS to the OH-group on the substrate and the interactions of the conserved SULT residues in this reaction. (For additional information see Negishi *et al.*, 2001.)

Figure 3–10. Glutathione as a co-substrate in the conjugation of a drug or xenobiotic (*X*) by glutathione-S-transferase (GST).

leads to a reduction in MAP kinase activity and reduced efficacy of chemotherapy. Taking advantage of the relatively high levels of GST in tumor cells, inhibition of GST activity has been exploited as a therapeutic strategy to modulate drug resistance by sensitizing tumors to anticancer drugs. TLK199, a glutathione analog, serves as a prodrug that undergoes activation by plasma esterases to a GST inhibitor, TLK117, which potentiates the toxicity of different anticancer agents (Figure 3–11). Alternatively, the elevated level of GST activity in cancerous cells has been utilized to develop prodrugs that can be activated by the GSTs to form electrophilic intermediates. TLK286 is a substrate for GST that undergoes a β -elimination reaction, forming a glutathione conjugate and a nitrogen mustard (Figure 3–12) that is capable of alkylating cellular nucleophiles, resulting in antitumor activity.

N-Acetylation. The cytosolic N-acetyltransferases (NATs) are responsible for the metabolism of drugs and environmental agents that contain an aromatic amine or hydrazine group. The addition of the acetyl group from the cofactor acetyl-coenzyme A often leads to a metabolite that is less water soluble because the potential ionizable amine is neutralized by the covalent addition of the acetyl group. NATs are among the most polymorphic of all the human xenobiotic drug-metabolizing enzymes.

The characterization of an acetylator phenotype in humans was one of the first hereditary traits identified, and was responsible for the development of the field of pharmacogenetics (*see* Chapter 4). Following the discovery that isonicotinic acid hydrazide (*isoniazid*) could be used in the cure of tuberculosis, a significant proportion of the patients (5% to 15%) experienced toxicities that ranged from numbness and tingling in their fingers to CNS damage. After finding that isoniazid was metabolized by acetylation and excreted in the urine, researchers noted that individuals suffering from the toxic effects of the drug excreted the largest amount of unchanged drug and the least amount of acetylated isoniazid. Pharmacoge-

netic studies led to the classification of “rapid” and “slow” acetylators, with the “slow” phenotype being predisposed to toxicity. Purification and characterization of N-acetyltransferase and the eventual cloning of its RNA provided sequence characterization of the gene for slow and fast acetylators, revealing polymorphisms that correspond to the “slow” acetylator phenotype. There are two functional NAT genes in humans, *NAT1* and *NAT2*. Over 25 allelic variants of *NAT1* and *NAT2* have been characterized, and in individuals in whom acetylation of drugs is compromised, homozygous genotypes for at least two variant alleles are required to predispose a patient to lowered drug metabolism. Polymorphism in the *NAT2* gene and its association with the slow acetylation of isoniazid was one of the first completely characterized genotypes shown to impact drug metabolism, thereby linking pharmacogenetic phenotype to a genetic polymorphism. Although nearly as many mutations have been identified in the *NAT1* gene as the *NAT2* gene, the frequency of the *slow* acetylation patterns are attributed mostly to polymorphism in the *NAT2* gene.

A list of drugs that are subject to acetylation and their known toxicities are listed in Table 3–3. The therapeutic relevance of NAT polymorphisms is in avoiding drug-induced toxicities. The adverse drug response in a slow acetylator resembles a drug overdose; thus, reducing the dose or increasing the dosing interval is recommended. Drugs containing an aromatic amine or a hydrazine group

Figure 3–11. Activation of TLK199 by cellular esterases to the glutathione-S-transferase (GST) inhibitor TLK117. (For additional information, *see* Townsend and Tew, 2003.)

Figure 3–12. Generation of the reactive alkylating agent following the conjugation of glutathione to TLK286. GST interacts with the prodrug and GSH analog, TLK286, via a tyrosine in the active site of GST. GSH portion is shown in blue. The interaction promotes β -elimination and cleavage of the prodrug to a vinyl sulfone and an active alkylating fragment. (See Townsend and Tew, 2003.)

exist in many classes of clinically used drugs, and if a drug is known to be subject to drug metabolism through acetylation, confirming an individual's phenotype can be important. For example, *hydralazine*, a once popular orally active antihypertensive (vasodilator) drug, is metabolized by NAT2. The administration of therapeutic doses of hydralazine to a slow acetylator can result in extreme hypotension and tachycardia. Several drugs, such as the sulfonamides, that are known targets for acetylation have been implicated in idiosyncratic hypersensitivity reactions; in such instances, an appreciation of a patient's acetylating phenotype is particularly important. Sulfonamides are transformed into hydroxylamines that interact with cellular proteins, generating haptens that can elicit autoimmune responses. Individuals who are slow acetylators are predisposed to drug-induced autoimmune disorders.

Tissue-specific expression patterns of NAT1 and NAT2 have a significant impact on the fate of drug metabolism and the potential for eliciting a toxic episode. NAT1 seems to be ubiquitously expressed among most human tissues, whereas NAT2 is found in liver and the GI tract. Characteristic of both NAT1 and NAT2 is the ability to form N-hydroxy-acetylated metabolites from bicyclic

aromatic hydrocarbons, a reaction that leads to the nonenzymatic release of the acetyl group and the generation of highly reactive nitrenium ions. Thus, N-hydroxy acetylation is thought to activate certain environmental toxicants. In contrast, direct N-acetylation of the environmentally generated bicyclic aromatic amines is stable and leads to detoxification. Individuals who are NAT2 fast acetylators are able to efficiently metabolize and detoxify bicyclic aromatic amine through liver-dependent acetylation. Slow acetylators (NAT2 deficient), however, accumulate bicyclic aromatic amines, which then become substrates for CYP-dependent N-oxidation. These N-OH metabolites are eliminated in the urine. In tissues such as bladder epithelium, NAT1 is highly expressed and can efficiently catalyze the N-hydroxy acetylation of bicyclic aromatic amines, a process that leads to de-acetylation and the formation of the mutagenic nitrenium ion, especially in NAT2-deficient subjects. Epidemiological studies have shown that slow acetylators are predisposed to bladder cancer if exposed environmentally to bicyclic aromatic amines.

Methylation. In humans, drugs and xenobiotics can undergo O-, N-, and S-methylation. The identification of the individual methyltransferase (MT) is based on the substrate and methyl conjugate. Humans express three N-methyltransferases, one catechol-O-methyltransferase (COMT) a phenol-O-methyltransferase (POMT), a thio-purine S-methyltransferase (TPMT), and a thiol methyl-

Table 3-3

Indications and Unwanted Side Effects of Drugs Metabolized by N-Acetyltransferases

DRUG	INDICATION	MAJOR SIDE EFFECTS
Acebutolol	Arrhythmias, hypertension	Drowsiness, weakness, insomnia
Amantadine	Influenza A, parkinsonism	Appetite loss, dizziness, headache, nightmares
Aminobenzoic acid	Skin disorders, sunscreens	Stomach upset, contact sensitization
Aminoglutethimide	Adrenal cortex carcinoma, breast cancer	Clumsiness, nausea, dizziness, agranulocytosis
Aminosalicyclic acid	Ulcerative colitis	Allergic fever, itching, leukopenia
Amonafide	Prostate cancer	Myelosuppression
Amrinone	Advanced heart failure	Thrombocytopenia, arrhythmias
Benzocaine	Local anesthesia	Dermatitis, itching, rash, methemoglobinemia
Caffeine	Neonatal respiratory distress syndrome	Dizziness, insomnia, tachycardia
Clonazepam	Epilepsy	Ataxia, dizziness, slurred speech
Dapsone	Dermatitis, leprosy, AIDS-related complex	Nausea, vomiting, hyperexcitability, methemoglobinemia, dermatitis
Dipyrone, metamizole	Analgesic	Agranulocytosis
Hydralazine	Hypertension	Hypotension, tachycardia, flush, headache
Isoniazid	Tuberculosis	Peripheral neuritis, hepatotoxicity
Nitrazepam	Insomnia	Dizziness, somnolence
Phenelzine	Depression	CNS excitation, insomnia, orthostatic hypotension, hepatotoxicity
Procainamide	Ventricular tachyarrhythmia	Hypotension, systemic lupus erythematosus
Sulfonamides	Antibacterial agents	Hypersensitivity, hemolytic anemia, fever, lupuslike syndromes

For details, see Meisel, 2002.

transferase (TMT). All of the MTs exist as monomers and use S-adenosyl-methionine (SAM; AdoMet) as the methyl donor. With the exception of a signature sequence that is conserved among the MTs, there is limited conservation in sequence, indicating that each MT has evolved to display a unique catalytic function. Although the common theme among the MTs is the generation of a methylated product, substrate specificity is high and distinguishes the individual enzymes.

Nicotinamide N-methyltransferase (NNMT) methylates serotonin and tryptophan, and pyridine-containing compounds such as nicotinamide and nicotine. Phenylethanolamine N-methyltransferase (PNMT) is responsible for the methylation of the neurotransmitter norepinephrine, forming epinephrine; the histamine N-methyltransferase (HNMT) metabolizes drugs containing an imidazole ring such as that found in histamine. COMT methylates neurotransmitters containing a catechol moiety such as dopamine and norepinephrine, drugs such as *methylidopa*, and drugs of abuse such as *ecstasy* (MDMA; 3,4-methylenedioxymethamphetamine).

From a clinical perspective, the most important MT may be TPMT, which catalyzes the S-methylation of aromatic and hetero-

cyclic sulfhydryl compounds, including the thiopurine drugs *azathioprine* (AZA), *6-mercaptopurine* (6-MP), and *thioguanine*. AZA and 6-MP are used for the management of inflammatory bowel disease (see Chapter 38) as well as autoimmune disorders such as systemic lupus erythematosus and rheumatoid arthritis. Thioguanine is used in acute myeloid leukemia, and 6-MP is used worldwide for the treatment of childhood acute lymphoblastic leukemia (see Chapter 51). Because TPMT is responsible for the detoxification of 6-MP, a genetic deficiency in TPMT can result in severe toxicities in patients taking these drugs. When given orally at clinically established doses, 6-MP serves as a prodrug that is metabolized by hypoxanthine guanine phosphoribosyl transferase (HGPRT) to 6-thioguanine nucleotides (6-TGNs), which become incorporated into DNA and RNA, resulting in arrest of DNA replication and cytotoxicity. The toxic side effects arise when a lack of 6-MP methylation by TPMT causes a build-up of 6-MP, resulting in the generation of toxic levels of 6-TGNs. The identification of the inactive TPMT alleles and the development of a genotyping test to identify homozygous carriers of the defective allele have now made it possible to identify individuals who may be predisposed to the toxic side effects of 6-MP therapy. Simple adjustments in the patient's dosage regimen have been shown to be a life-saving intervention for those with TPMT deficiencies.

The Role of Xenobiotic Metabolism in the Safe and Effective Use of Drugs. Any compound entering the body must be eliminated through metabolism and excretion *via* the urine or bile/feces. This mechanism keeps foreign compounds from accumulating in the body and possibly causing toxicity. In the case of drugs, metabolism results in the inactivation of their therapeutic effectiveness and facilitates their elimination. The extent of metabolism can determine the efficacy and toxicity of a drug by controlling its biological half-life. Among the most serious considerations in the clinical use of drugs are adverse drug reactions. If a drug is metabolized too quickly, it rapidly loses its therapeutic efficacy. This can occur if specific enzymes involved in metabolism are overly active or are induced by dietary or environmental factors. If a drug is metabolized too slowly, the drug can accumulate in the bloodstream; as a consequence, the pharmacokinetic parameter AUC (area under the plasma concentration–time curve) is elevated and the plasma clearance of the drug is decreased. This increase in AUC can lead to overstimulation of some target receptors or undesired binding to other receptors or cellular macromolecules. An increase in AUC often results when specific xenobiotic-metabolizing enzymes are inhibited, which can occur when an individual is taking a combination of different therapeutic agents and one of those drugs targets the enzyme involved in drug metabolism. For example, the consumption of grapefruit juice with drugs taken orally can inhibit intestinal CYP3A4, blocking the metabolism of many of these drugs. The inhibition of specific CYPs in the gut by dietary consumption of grapefruit juice alters the oral bioavailability of many classes of drugs, such as certain antihypertensives, immunosuppressants, antidepressants, antihistamines, and the statins, to name a few. Among the components of grapefruit juice that inhibit CYP3A4 are naringin and furanocoumarins.

While environmental factors can alter the steady-state levels of specific enzymes or inhibit their catalytic potential, these phenotypic changes in drug metabolism are also observed clinically in groups of individuals that are genetically predisposed to adverse drug reactions because of pharmacogenetic differences in the expression of xenobiotic-metabolizing enzymes (*see* Chapter 4). Most of the xenobiotic-metabolizing enzymes display polymorphic differences in their expression, resulting from heritable changes in the structure of the genes. For example, as discussed above, a significant population was found to be hyperbilirubinemic, resulting from a reduction in the ability to glucuronidate circulating bilirubin due to a lowered

expression of the *UGT1A1* gene (Gilbert's syndrome). Drugs that are subject to glucuronidation by UGT1A1, such as the topoisomerase inhibitor SN-38 (Figures 3–5, 3–7, and 3–8), will display an increased AUC because individuals with Gilbert's syndrome are unable to detoxify these drugs. Since most cancer chemotherapeutic agents have a very narrow therapeutic index, increases in the circulating levels of the active form can result in significant toxicities. There are a number of genetic differences in CYPs that can have a major impact on drug therapy.

Nearly every class of therapeutic agent has been reported to initiate an adverse drug response (ADR). In the United States, the cost of such response has been estimated at \$100 billion and to be the cause of over 100,000 deaths annually. It has been estimated that 56% of drugs that are associated with adverse responses are subjected to metabolism by the xenobiotic-metabolizing enzymes, notably the CYPs, which metabolize 86% of these compounds. Since many of the CYPs are subject to induction as well as inhibition by drugs, dietary factors, and other environmental agents, these enzymes play an important role in most ADRs. Thus, it has become mandatory that before a new drug application (NDA) is filed with the Food and Drug Administration, the route of metabolism and the enzymes involved in the metabolism must be known. As a result, it has become routine practice in the pharmaceutical industry to establish which enzymes are involved in metabolism of a drug candidate and to identify the metabolites and determine their potential toxicity.

Induction of Drug Metabolism. Xenobiotics can influence the extent of drug metabolism by activating transcription and inducing the expression of genes encoding drug-metabolizing enzymes. Thus, a foreign compound may induce its own metabolism, as may certain drugs. One potential consequence of this is a decrease in plasma drug concentration over the course of treatment, resulting in loss of efficacy, as the auto-induced metabolism of the drug exceeds the rate at which new drug enters the body. A list of ligands and the receptors through which they induce drug metabolism is shown in Table 3–4. A particular receptor, when activated by a ligand, can induce the transcription of a battery of target genes. Among these target genes are certain CYPs and drug transporters. Thus, any drug that is a ligand for a receptor that induces CYPs and transporters could lead to drug interactions. Figure 3–13 shows the scheme by which a drug may interact with nuclear receptors to induce its own metabolism.

The aryl hydrocarbon receptor (AHR) is a member of a superfamily of transcription factors with diverse roles in mammals, such as a regulatory role in the development of the mammalian CNS and modulating the response to chemical and oxidative stress. This

Table 3–4
Nuclear Receptors That Induce Drug Metabolism

RECEPTOR	LIGANDS
Aryl hydrocarbon receptor (AHR)	Omeprazole
Constitutive androstane receptor (CAR)	Phenobarbital
Pregnane X receptor (PXR)	Rifampin
Farnesoid X receptor (FXR)	Bile acids
Vitamin D receptor	Vitamin D
Peroxisome proliferator activated receptor (PPAR)	Fibrates
Retinoic acid receptor (RAR)	<i>all-trans</i> -Retinoic acid
Retinoid X receptor (RXR)	<i>9-cis</i> -Retinoic acid

superfamily of transcription factors includes Per and Sim, two transcription factors involved in development of the CNS, and the hypoxia-inducible factor 1 α (HIF1 α) that activates genes in response to low cellular O₂ levels. The AHR induces expression of genes encoding

CYP1A1 and CYP1A2, two CYPs that are able to metabolically activate chemical carcinogens, including environmental contaminants and carcinogens derived from food. Many of these substances are inert unless metabolized by CYPs. Thus, induction of these CYPs by a drug could potentially result in an increase in the toxicity and carcinogenicity of procarcinogens. For example, *omeprazole*, a proton pump inhibitor used to treat gastric and duodenal ulcers (*see* Chapter 36), is a ligand for the AHR and can induce CYP1A1 and CYP1A2, with the possible consequences of toxin/carcinogen activation as well as drug-drug interactions in patients receiving agents that are substrates for either of these CYPs.

Another important induction mechanism is due to type 2 nuclear receptors that are in the same superfamily as the steroid hormone receptors. Many of these receptors, identified on the basis of their structural similarity to steroid hormone receptors, were originally termed “orphan receptors,” because no endogenous ligands were known to interact with them. Subsequent studies revealed that some of these receptors are activated by xenobiotics, including drugs. The type 2 nuclear receptors of most importance to

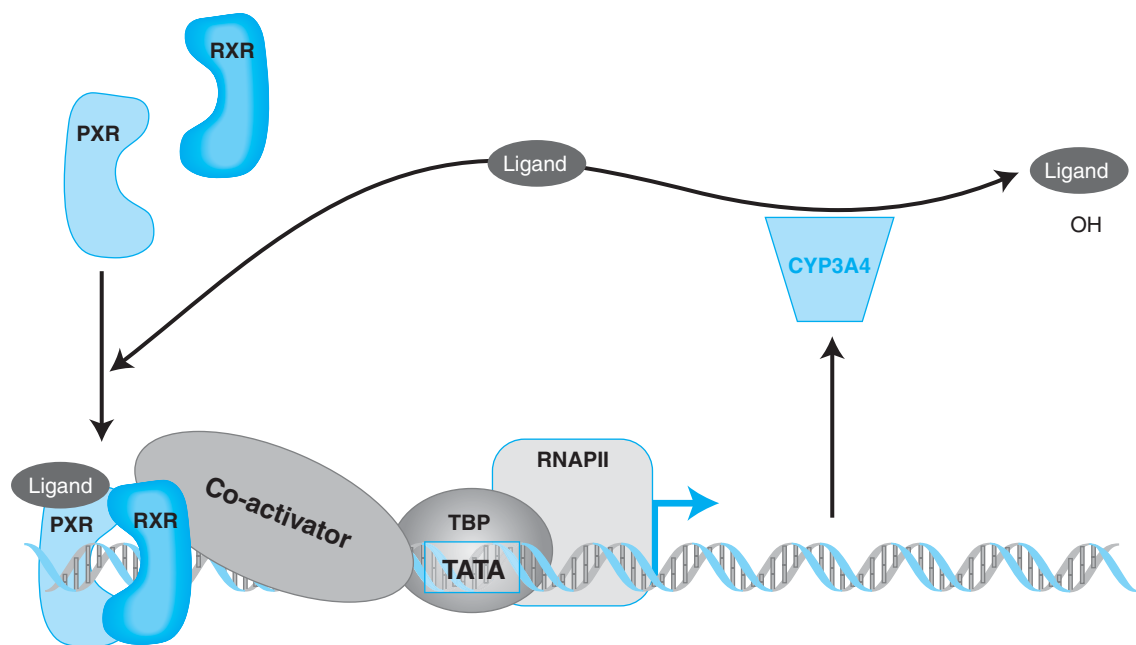

Figure 3–13. Induction of drug metabolism by nuclear receptor–mediated signal transduction. When a drug such as atorvastatin (Ligand) enters the cell, it can bind to a nuclear receptor such as the pregnane X receptor (PXR). PXR then forms a complex with the retinoid X receptor (RXR), binds to DNA upstream of target genes, recruits coactivator (which binds to the TATA box binding protein, TBP), and activates transcription. Among PXR target genes are CYP3A4, which can metabolize the atorvastatin and decrease its cellular concentration. Thus, atorvastatin induces its own metabolism. Atorvastatin undergoes both ortho and para hydroxylation. (*See* Handschin and Meyer, 2003.)

drug metabolism and drug therapy include the pregnane X receptor (PXR), constitutive androstane receptor (CAR), and the peroxisome proliferator activated receptor (PPAR). PXR, discovered based on its ability to be activated by the synthetic steroid pregnane 16 α -carbonitrile, is activated by a number of drugs including, antibiotics (*rifampicin* and *troleandomycin*), Ca²⁺ channel blockers (*nifedipine*), statins (*mevastatin*), antidiabetic drugs (*troglitazone*), HIV protease inhibitors (*ritonavir*), and anti-cancer drugs (*paclitaxel*). Hyperforin, a component of St. John's wort, an over-the-counter herbal remedy used for depression, also activates PXR. This activation is thought to be the basis for the increase in failure of oral contraceptives in individuals taking St. John's wort: activated PXR is an inducer of CYP3A4, which can metabolize steroids found in oral contraceptives. PXR also induces the expression of genes encoding certain drug transporters and phase 2 enzymes including SULTs and UGTs. Thus, PXR facilitates the metabolism and elimination of xenobiotics, including drugs, with notable consequences (Figure 3–13).

The nuclear receptor CAR was discovered based on its ability to activate genes in the absence of ligand. Steroids such as *androstanol*, the antifungal agent *clotrimazole*, and the antiemetic *meclizine* are inverse agonists that inhibit gene activation by CAR, while the pesticide 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene, the steroid 5 β -pregnane-3,20-dione, and probably other endogenous compounds, are agonists that activate gene expression when bound to CAR. Genes induced by CAR include those encoding several CYPs (CYP2B6, CYP2C9, and CYP3A4), various phase 2 enzymes (including GSTs, UGTs, and SULTs), and drug and endobiotic transporters. CYP3A4 is induced by both PXR and CAR and thus its level is highly influenced by a number of drugs and other xenobiotics. In addition to a potential role in inducing the degradation of drugs including the over-the-counter analgesic acetaminophen, this receptor may function in the control of bilirubin degradation, the process by which the liver decomposes heme.

Clearly, PXR and CAR have a capacity for binding a great variety of ligands. As with the xenobiotic-metabolizing enzymes, species differences also exist in the ligand specificities of these receptors. For example, rifampicin activates human PXR but not mouse or rat PXR. Meclizine preferentially activates mouse CAR but inhibits gene induction by human CAR. These findings further establish that rodent model systems do not reflect the response of humans to drugs.

The peroxisome proliferator activated receptor (PPAR) family is composed of three members, α , β , and γ .

PPAR α is the target for the fibrate class of hyperlipidemic drugs, including the widely prescribed *gemfibrozil* and *fenofibrate*. While activation of PPAR α results in induction of target genes encoding fatty acid metabolizing enzymes that result in lowering of serum triglycerides, it also induces CYP4 enzymes that carry out the oxidation of fatty acids and drugs with fatty acid-containing side chains, such as *leukotriene* and *arachidonic acid* analogs.

Role of Drug Metabolism in the Drug Development Process. There are two key elements associated with successful drug development: efficacy and safety. Both depend on drug metabolism. It is necessary to determine how and by which enzymes a potential new drug is metabolized. This knowledge allows prediction of whether the compound may cause drug-drug interactions or be susceptible to marked interindividual variation in metabolism due to genetic polymorphisms.

Historically, drug candidates have been administered to rodents at doses well above the human target dose in order to predict acute toxicity. For drug candidates to be used chronically in humans, such as for lowering serum triglycerides and cholesterol or for treatment of type 2 diabetes, long-term carcinogenicity studies are carried out in rodent models. For determination of metabolism, the compound is subjected to analysis by human liver cells or extracts from these cells that contain the drug-metabolizing enzymes. Such studies determine how humans will metabolize a particular drug, and to a limited extent, predict the rate of metabolism. If a CYP is involved, a panel of recombinant CYPs can be used to determine which CYP predominates in the metabolism of the drug. If a single CYP, such as CYP3A4, is found to be the sole CYP that metabolizes a drug candidate, then a decision can be made about the likelihood of drug interactions. Interactions become a problem when multiple drugs are simultaneously administered, for example in elderly patients, who on a daily basis may take prescribed antiinflammatory drugs, cholesterol-lowering drugs, blood pressure medications, a gastric acid suppressant, an anticoagulant, and a number of over-the-counter medications. Ideally, the best drug candidate would be metabolized by several CYPs so that variability in expression levels of one CYP or drug-drug interactions would not significantly impact its metabolism and pharmacokinetics.

Similar studies can be carried out with phase 2 enzymes and drug transporters in order to predict the metabolic fate of a drug. In addition to the use of recombinant human xenobiotic-metabolizing enzymes in predicting drug metabolism, human receptor-based (PXR and CAR) systems should also be used to determine whether a particular drug candidate could be a ligand for PXR, CAR, or PPAR α .

Computer-based computational (*in silico*) prediction of drug metabolism may also be a prospect for the future, since the structures of several CYPs have been determined, including those of CYPs 2A6, 2C9, and 3A4. These structures may be used to predict metabolism of a drug candidate by fitting the compound to the enzyme's active site and determining oxidation potentials of sites on the molecule. However, the structures, determined by x-ray analysis

of crystals of enzyme-substrate complexes, are static, whereas enzymes are flexible, and this vital distinction may be limiting. The large size of the CYP active sites, which permits them to metabolize many different compounds, also renders them difficult to model. The potential for modeling ligand or activator for the nuclear receptors also exists with limitations similar to those discussed for the CYPs. With refinement of structures and more powerful modeling software, *in silico* drug metabolism may be a reality in the future.

PHARMACOGENETICS

Mary V. Relling and Kathleen M. Giacomini

Pharmacogenetics is the study of the genetic basis for variation in drug response. In this broadest sense, pharmacogenetics encompasses pharmacogenomics, which employs tools for surveying the entire genome to assess multigenic determinants of drug response. Until the technical advances in genomics of the last few years, pharmacogenetics proceeded using a forward genetic, phenotype-to-genotype approach. Drug response outliers were compared to individuals with “normal” drug response to identify the pharmacologic basis of altered response. An inherited component to response was demonstrated using family studies or imputed through intra- vs. intersubject reproducibility studies. With the explosion of technology in genomics, a reverse genetic, genotype-to-phenotype approach is feasible whereby genomic polymorphisms can serve as the starting point to assess whether genomic variability translates into phenotypic variability.

Historical Context. In the pre-genomics era, the frequency of genetic variation was hypothesized to be relatively uncommon, and the demonstration of inherited drug-response traits applied to a relatively small number of drugs and pathways (Eichelbaum and Gross, 1990; Evans and Relling, 2004; Johnson and Lima, 2003). Historically, uncommon severe drug-induced phenotypes served as the triggers to investigate and document pharmacogenetic phenotypes. Prolonged neuromuscular blockade following normal doses of *succinylcholine*, neurotoxicity following *isoniazid* therapy (Hughes *et al.*, 1954), and methemoglobinemia in glucose-6-phosphate dehydrogenase (G6PD) deficiency (Alving *et al.*, 1956) (see Chapter 39) were discovered to have a genetic basis in the first half of the 20th century. In the 1970s and 1980s, *debrisoquine* hydroxylation and exaggerated hypotensive effects from that drug were related to an autosomal recessive inherited deficiency in the cytochrome P450 isoenzyme 2D6 (CYP2D6) (Evans and Relling, 2004). Since the elucidation of the molecular basis of the phenotypic polymorphism in CYP2D6 (Gonzalez *et al.*, 1988), the molecular bases of many other monogenic pharmacogenetic traits have been identified (Meyer and Zanger, 1997).

Individuals differ from each other approximately every 300 to 1000 nucleotides, with an estimated total of 3.2 million single

nucleotide polymorphisms (SNPs; single base pair substitutions found at frequencies $\geq 1\%$ in a population) in the genome (Sachidanandam *et al.*, 2001; The International SNP Map Working Group, 2001). Identifying which of these variants or combinations of variants have functional consequence for drug effects is the task of modern pharmacogenetics.

Importance of Pharmacogenetics to Variability in Drug Response

Drug response is considered to be a gene-by-environment phenotype. That is, an individual's response to a drug depends on the complex interplay between environmental factors and genetic factors (Figure 4–1). Variation in drug response therefore may be explained by variation in environmental and genetic factors, alone or in combination. What proportion of drug-response variability is likely to be genetically determined? Classical family studies provide some information (Weinshilboum and Wang, 2004). Because estimating the fraction of phenotypic variability that is attributable to genetic factors in pharmacogenetics usually requires administration of a drug to twins or trios of family members, data are somewhat limited. Twin studies have shown that drug metabolism is highly heritable, with genetic factors accounting for most of the variation in metabolic rates for many drugs (Vesell, 2000). Results from a twin study in which the half-life of *antipyrine* was measured are typical (Figure 4–2). Antipyrine, a pyrazolone analgesic, is eliminated exclusively by metabolism and is a substrate for multiple CYPs. There is considerably greater concordance in the half-life of antipyrine between the monozygotic (identical) twin pairs in comparison to the dizygotic (fraternal) twin pairs. Comparison of intra-twin vs. inter-pair variability suggests that approximately 75% to 85% of the variability in pharmacokinetic half-lives for drugs that are eliminated by metabolism is heritable (Penno *et al.*, 1981). It has also

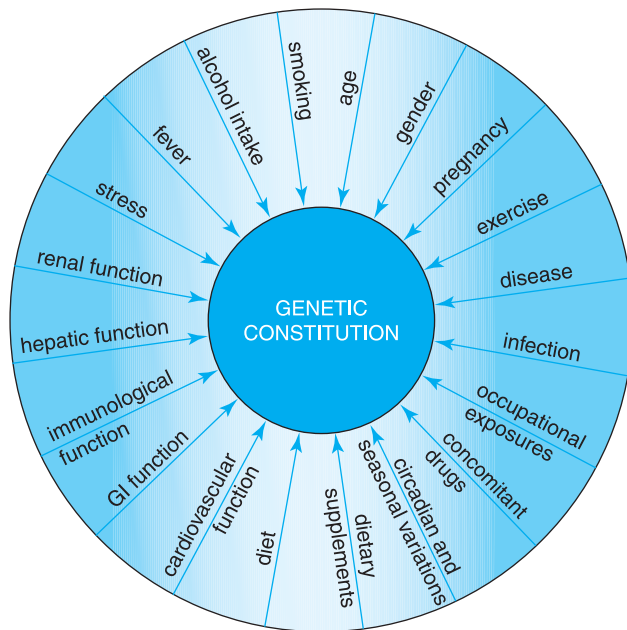

Figure 4-1. Exogenous and endogenous factors contribute to variation in drug response. (Reproduced with permission from Vesell, 1991.)

been proposed that heritability can be estimated by comparing intra-subject *vs.* inter-subject variability in drug response or disposition in unrelated individuals (Kalow *et al.*, 1998), with the assumption that high intra-subject reproducibility translates into high heritability; the validity of this method across pharmacologic phenotypes remains to be established. In any case, such studies provide only an estimate of the overall contribution of inheri-

Figure 4-2. Pharmacogenetic contribution to pharmacokinetic parameters. Half-life of antipyrine is more concordant in identical in comparison to fraternal twin pairs. Bars show the half-life of antipyrine in identical (monozygotic) and fraternal (dizygotic) twin pairs. (Redrawn from data in Vesell and Page, 1968.)

tance to the phenotype; because multiple gene products contribute to antipyrine disposition, most of which have unelucidated mechanisms of genetic variability, the predictability of antipyrine disposition based on known genetic variability is poor.

Another approach to estimating the degree of heritability of a pharmacogenetic phenotype uses *ex vivo* experiments with cell lines derived from related individuals. Inter- *vs.* intrafamily variability and relationships among members of a kindred are used to estimate heritability. Using this approach with lymphoblastoid cells, cytotoxicity from chemotherapeutic agents was shown to be heritable, with about 20% to 70% of the variability in sensitivity to 5-fluorouracil and docetaxel estimated as inherited, depending upon dose (Watters *et al.*, 2004).

For the “monogenic” phenotypic traits of G6PD deficiency, CYP2D6 or thiopurine methyltransferase (TPMT) metabolism, it is possible to predict phenotype based on genotype. Several genetic polymorphisms of drug metabolizing enzymes result in monogenic traits. Based on a retrospective study, 49% of adverse drug reactions were associated with drugs that are substrates for polymorphic drug metabolizing enzymes, a proportion larger than estimated for all drugs (22%) or for top-selling drugs (7%) (Phillips *et al.*, 2001). Prospective genotype determinations may result in the ability to prevent adverse drug reactions (Meyer, 2000).

Defining multigenic contributors to drug response will be much more challenging. For some multigenic phenotypes, such as response to antihypertensives, the large numbers of candidate genes will necessitate a large patient sample size to produce the statistical power required to solve the “multigene” problem.

GENOMIC BASIS OF PHARMACOGENETICS

Phenotype-Driven Terminology

Because initial discoveries in pharmacogenetics were driven by variable phenotypes and defined by family and twin studies, the classic genetic terms for monogenic traits apply to some pharmacogenetic polymorphisms. A trait (e.g., CYP2D6 “poor metabolism”) is deemed autosomal recessive if the responsible gene is located on an autosome (i.e., it is not sex-linked) and a distinct phenotype is evident only with nonfunctional alleles on both the maternal and paternal chromosomes. For many of the earliest identified pharmacogenetic polymorphisms, phenotype did not differ enough between heterozygotes and homozygous “wild-type” individuals to distinguish that heterozygotes exhibited an intermediate (or codominant) phenotype (e.g., for CYP2D6-mediated debrisoquine metabolism). Other traits, such as TPMT, exhibit three relatively distinct phenotypes, and thus were deemed codominant even in the pre-molecular era. With the advances in molecular characterization of polymorphisms and a genotype-to-phenotype approach, additional polymorphic traits (e.g., CYP2C19 metabolism of drugs such as *mephenytoin* and *omeprazole*) are now recognized to exhibit some degree of codominance. Some pharmacogenetic traits, such as the long QT syndrome, segregate as dominant traits; the long QT syndrome is associated with heterozygous loss-of-function mutations of ion channels. A prolonged QT interval is seen on the electrocardiogram, either basally or in the presence of certain drugs, and the individual is predisposed to cardiac arrhythmias (see Chapter 34).

In an era of detailed molecular characterization, two major factors complicate the historical designation of recessive, codominant, and dominant traits. First, even within a single gene, a vast array of polymorphisms (promoter, coding, noncoding, completely inactivating, or modestly modifying) are possible, making the assignment of “variant” vs. “wild-type” to an allele a designation that depends upon a complete survey of the gene’s polymorphisms and is not necessarily easily assigned. Secondly, most traits (pharmacogenetic and otherwise) are multigenic, not monogenic. Thus, even if the designations of recessive, codominant, and dominant are informative for a given gene, their utility in describing the genetic variability that underlies variability in drug response phenotype is diminished, because most phenotypic variability is likely to be multigenic.

Types of Genetic Variants

A *polymorphism* is a variation in the DNA sequence that is present at an allele frequency of 1% or greater in a population. Two major types of sequence variation have been associated with variation in human phenotype: *single nucleotide polymorphisms* (SNPs) and *insertions/deletions* (indels) (Figure 4–3). In comparison to base pair substitutions, indels are much less frequent in the genome and are of particularly low frequency in coding regions of genes (Cargill *et al.*, 1999; Stephens *et al.*, 2001). Single base pair substitutions that are present at frequencies of 1% or greater in a population are termed single nucleotide polymorphisms (SNPs) and are present in the human genome at approximately 1 SNP every few hundred to a thousand base pairs, depending on the gene region (Stephens *et al.*, 2001).

SNPs in the coding region are termed *cSNPs*. cSNPs are further classified as nonsynonymous (or *missense*) if the base pair change results in an amino acid substitution, or synonymous (or *sense*) if the base pair substitution within a codon does not alter the encoded amino acid. Typically, substitutions of the third base pair, termed the *wobble position*, in a three base pair codon, such as the G to A substitution in proline shown in Figure 4–3, do not alter the encoded amino acid. Base pair substitutions that lead to a stop codon are termed *nonsense* mutations. In addition, about 10% of SNPs can have more than two possible alleles (e.g., a C can be replaced by either an A or G), so that the same polymorphic site can be associated with amino acid substitutions in some alleles but not others.

Polymorphisms in noncoding regions of genes may occur in the 3' and 5' untranslated regions, in promoter or enhancer regions, in intronic regions, or in large regions between genes, intergenic regions (Figure 4–4). Polymorphisms in introns found near exon-intron boundaries are often treated as a separate category from other intronic polymorphisms since these may affect splicing, and thereby affect function. Noncoding SNPs in promoters or enhancers may alter *cis*- or *trans*-acting elements that regulate gene transcription or transcript stability. Noncoding SNPs in introns or exons may create alternative exon splicing sites, and the altered transcript may have fewer or more exons, or shorter or larger exons, than the wild-type transcript. Introduction or deletion of exonic sequence can cause a frame shift in the translated protein and thereby change protein structure or function, or result in an early stop codon, which makes an unstable or nonfunctional protein. Because 95% of the genome is intergenic, most polymorphisms are unlikely to directly affect the encoded transcript or protein. However, intergenic polymorphisms

Figure 4–3. Molecular mechanisms of genetic polymorphisms. The most common genetic variants are single nucleotide polymorphism substitutions (SNPs). *Coding nonsynonymous* SNPs result in a nucleotide substitution that changes the amino acid codon (here proline to glutamine), which could change protein structure, stability, substrate affinities, or introduce a stop codon. *Coding synonymous* SNPs do not change the amino acid codon, but may have functional consequences (transcript stability, splicing). Noncoding SNPs may be in promoters, introns, or other regulatory regions that may affect transcription factor binding, enhancers, transcript stability, or splicing. The second major type of polymorphism is *indels* (*insertion/deletions*). SNP indels can have any of the same effects as SNP substitutions: short repeats in the promoter (which can affect transcript amount), or larger insertions/deletions that add or subtract amino acids. Indels can also involve gene duplications, stably transmitted inherited germline gene replication that causes increased protein expression and activity, or gene deletions that result in the complete lack of protein production. All of these mechanisms have been implicated in common germline pharmacogenetic polymorphisms. TPMT, thiopurine methyltransferase; ABCB1, the multidrug resistance transporter (P-glycoprotein); CYP, cytochrome P450; CBS, cystathionine β -synthase; UGT, UDP-glucuronyl transferase; GST, glutathione-S-transferase.

may have biological consequences by affecting DNA tertiary structure, interaction with chromatin and topoisomerases, or DNA replication. Thus, intergenic polymorphisms cannot be assumed to be without pharmacogenetic importance.

A remarkable degree of diversity in the types of insertions/deletions that are tolerated as germline polymorphisms is evident. A common glutathione-S-transferase M1 (*GSTM1*) polymorphism is caused by a 50-kilobase (kb) germline deletion, and the null allele has a population frequency of 0.3 to 0.5, depending on race/ethnicity. Biochemical studies indicate that livers from homozygous null individuals have only ~50% of the glutathione conjugating capacity of those with at least one copy of the *GSTM1* gene (Townsend and Tew, 2003a). The number of TA repeats in the *UGT1A1* promoter affects the quantitative expression of this crucial glucuronosyl transferase in liver; although 4 to 9 TA repeats exist in germline-inherited alleles, 6 or 7 repeats constitute the most common alleles (Monaghan *et al.*, 1996). Cystathionine β -synthase has a common 68 base pair insertion/deletion polymorphism that has been linked to folate levels (Kraus *et al.*, 1998). Although in many of these cases the local sequence context of these insertions/deletions strongly suggests mechanisms underlying the genomic alterations (*e.g.*, homologous recombination sites bracket the *GSTM1* deletion), high allele frequencies are maintained due to Mendelian inheritance.

A *haplotype*, which is defined as a series of alleles found at a linked locus on a chromosome, specifies the DNA sequence variation in a gene or a gene region on one chromosome. For example, consider two SNPs in *ABCB1*, which encodes for the multidrug resistance protein, P-glycoprotein. One SNP is a T to A base pair substitution at position 3421 and the other is a C to T change at position 3435. Possible haplotypes would be $T_{3421}C_{3435}$, $T_{3421}T_{3435}$, $A_{3421}C_{3435}$, and $A_{3421}T_{3435}$. For any gene, individuals will have two haplotypes, one maternal and one paternal in origin, which may or may not be identical. Haplotypes are important because they are the functional unit of the gene. That is, a haplotype represents the constellation of variants that occur together for the gene on

Figure 4–4. Nomenclature of genomic regions.

each chromosome. In some cases, this constellation of variants, rather than the individual variant or allele, may be functionally important. In others, however, a single mutation may be functionally important regardless of other linked variants within the haplotype(s).

Ethnic Diversity

Polymorphisms differ in their frequencies within human populations (Burchard *et al.*, 2003; Rosenberg *et al.*, 2002; Rosenberg *et al.*, 2003). Among coding region SNPs, synonymous SNPs are present, on average, at higher frequencies than nonsynonymous SNPs. Thus, for most genes, the nucleotide diversity, which reflects the number of SNPs and the frequency of the SNPs, is greater for synonymous than for nonsynonymous SNPs. This fact reflects selective pressures (termed *negative* or *purifying selection*), which act to preserve the functional activity of proteins, and therefore the amino acid sequence. Frequencies of polymorphisms in ethnically or racially diverse human populations have been examined in whole genome scanning studies (Cargill *et al.*, 1999; Stephens *et al.*, 2001). In these studies, polymorphisms have been classified as either cosmopolitan or population (or race and ethnic) specific. Cosmopolitan polymorphisms are those polymorphisms present in all ethnic groups, although frequencies may differ among ethnic groups. Cosmopolitan polymorphisms are usually found at higher allele frequencies in comparison to population-specific polymorphisms. Likely to have arisen before migrations of humans from Africa, cosmopolitan polymorphisms are generally older than population-specific polymorphisms.

The presence of ethnic and race-specific polymorphisms is consistent with geographical isolation of human populations (Xie *et al.*, 2001). These polymorphisms probably arose in isolated populations and then reached a certain frequency because they are advantageous (positive selection) or more likely, neutral, conferring no advantage or disadvantage to a population. Large-scale sequence studies in ethnically diverse populations in the United States demonstrate that African Americans have the highest number of population-specific polymorphisms in comparison to European Americans, Mexican Americans, and Asian Americans (Leabman *et al.*, 2003; Stephens *et al.*, 2001). Africans are believed to be the oldest population and therefore have both recently derived, population-specific polymorphisms, and older polymorphisms that occurred before migrations out of Africa.

Consider the coding region variants of two membrane transporters identified in 247 ethnically diverse DNA samples (Figure 4-5). Shown are nonsynonymous

and synonymous SNPs; population-specific nonsynonymous cSNPs are indicated in the figure. The multidrug resistance associated protein, MRP2, has a large number of nonsynonymous cSNPs. There are fewer synonymous variants than nonsynonymous variants, but the allele frequencies of the synonymous variants are greater than those of the nonsynonymous variants (Leabman *et al.*, 2003). By comparison, DAT, the dopamine transporter, has a number of synonymous variants but no nonsynonymous variants, suggesting that selective pressures have acted against substitutions that led to changes in amino acids.

In a survey of coding region haplotypes in 313 different genes in 80 ethnically diverse DNA samples, most genes were found to have between 2 and 53 haplotypes, with the average number of haplotypes in a gene being 14 (Stephens *et al.*, 2001). Like SNPs, haplotypes may be cosmopolitan or population specific and about 20% of the over 4000 identified haplotypes were cosmopolitan (Stephens *et al.*, 2001). Considering the frequencies of the haplotypes, cosmopolitan haplotypes actually accounted for over 80% of all haplotypes, whereas population-specific haplotypes accounted for only 8%.

Polymorphism Selection

Genetic variation that results in penetrant and constitutively evident biological variation sometimes causes a “disease” phenotype. Cystic fibrosis, sickle-cell anemia, and Crigler-Najjar syndrome are examples of inherited diseases caused by single gene defects (Pani *et al.*, 2000). In the case of Crigler-Najjar syndrome, the same gene (*UGT1A1*) that is targeted by rare inactivating mutations (and associated with a serious disease) is also targeted by modest polymorphisms (and associated with modest hyperbilirubinemia and altered drug clearance) (Monaghan *et al.*, 1996). Due to the disease, some evolutionary selection against these single-gene polymorphisms is present. Polymorphisms in other genes have highly penetrant effects in the drug-challenged but not in the constitutive state, which are the causes of monogenic pharmacogenetic traits. There is unlikely to be any selective pressure for or against these polymorphisms (Evans and Relling, 2004; Meyer, 2000; Weinshilboum, 2003). The vast majority of genetic polymorphisms have a modest impact on the affected genes, are part of a large array of multigenic factors that impact on drug effect, or affect genes whose products play a minor role in drug action relative to a large nongenetic effect. For example, phenobarbital induction of metabolism may be such an overwhelming “environmental” effect that polymorphisms in the

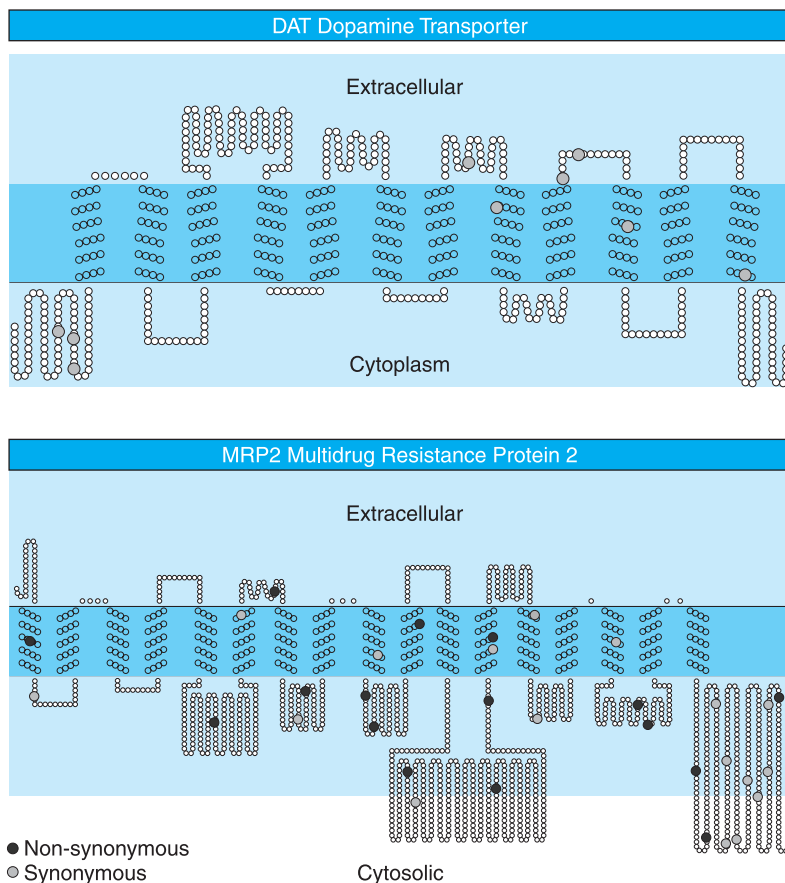

Figure 4–5. Coding region polymorphisms in two membrane transporters. Shown are the dopamine transporter, DAT (encoded by *SLCGA3*) and multidrug resistance associated protein, MRP2 (encoded by *ABCC2*). Coding region variants were identified in 247 ethnically diverse DNA samples (100 African Americans, 100 European Americans, 30 Asians, 10 Mexicans, and 7 Pacific Islanders). Shown in light gray are synonymous variants, and in black, nonsynonymous variants. (Reproduced with permission from Shu *et al.*, 2003.)

affected transcription factors and drug-metabolizing genes have modest effects in comparison.

PHARMACOGENETIC STUDY DESIGN CONSIDERATIONS

Pharmacogenetic Measures

What are pharmacogenetic traits and how are they measured? A *pharmacogenetic trait* is any measurable or discernible trait associated with a drug. Thus, enzyme activity, drug or metabolite levels in plasma or urine, blood pressure or lipid lowering produced by a drug, and drug-induced gene expression patterns are examples of pharmacogenetic traits. Directly measuring a trait (*e.g.*, enzyme activity) has

the advantage that the net effect of the contributions of all genes that influence the trait is reflected in the phenotypic measure. However, it has the disadvantage that it is also reflective of nongenetic influences (*e.g.*, diet, drug interactions, diurnal or hormonal fluctuation) and thus, may be “unstable.” For CYP2D6, if a patient is given an oral dose of *dextromethorphan*, and the urinary ratio of parent drug to metabolite is assessed, the phenotype is reflective of the genotype for CYP2D6 (Meyer and Zanger, 1997). However, if *dextromethorphan* is given with *quinidine*, a potent inhibitor of CYP2D6, the phenotype may be consistent with a poor metabolizer genotype, even though the subject carries wild-type CYP2D6 alleles. In this case, *quinidine* administration results in a drug-induced haplo-insufficiency, and the assignment of a CYP2D6 poor metabolizer phenotype would not be accurate for that subject in the absence of *quinidine*. If a phenotypic measure, such as the erythromycin

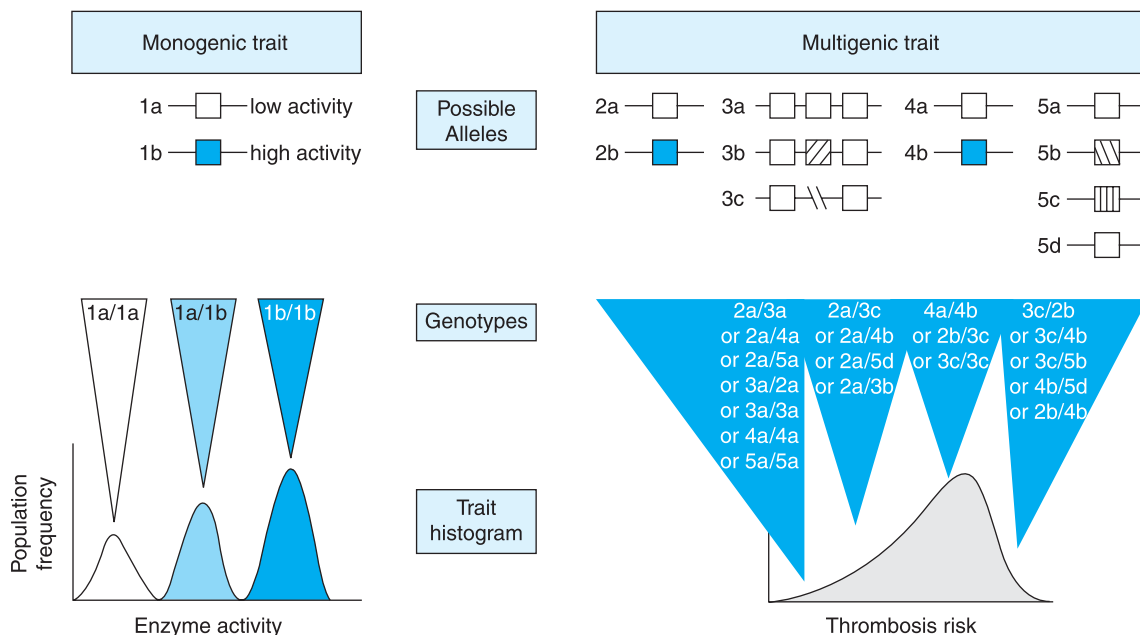

Figure 4-6. Monogenic versus multigenic pharmacogenetic traits. Possible alleles for a monogenic trait (*upper left*), in which a single gene has a low-activity (1a) and a high-activity (1b) allele. The population frequency distribution of a monogenic trait (*bottom left*), here depicted as enzyme activity, may exhibit a trimodal frequency distribution with relatively distinct separation among low activity (homozygosity for 1a), intermediate activity (heterozygote for 1a and 1b), and high activity (homozygosity for 1b). This is contrasted with multigenic traits (*e.g.*, an activity influenced by up to four different genes, genes 2 through 5), each of which has 2, 3, or 4 alleles (a through d). The population histogram for activity is unimodal-skewed, with no distinct differences among the genotypic groups. Multiple combinations of alleles coding for low activity and high activity at several of the genes can translate into low-, medium-, and high-activity phenotypes.

breath test (for CYP3A), is not stable within a subject, this is an indication that the phenotype is highly influenced by nongenetic factors, and may indicate a multigenic or weakly penetrant effect of a monogenic trait. Because most pharmacogenetic traits are multigenic rather than monogenic (Figure 4-6), considerable effort is being made to identify the important genes and their polymorphisms that influence variability in drug response.

Most genotyping methods use germline DNA, that is, DNA extracted from any somatic, diploid cells, usually white blood cells or buccal cells (due to their ready accessibility). DNA is extremely stable if appropriately extracted and stored, and unlike many laboratory tests, genotyping need be performed only once, because DNA sequence is generally invariant throughout an individual's lifetime. Although tremendous progress has been made in molecular biological techniques to determine genotypes, relatively few are used routinely in patient care. Genotyping tests are directed at each specific known polymorphic site using a variety of strategies that generally depend at some level on the specific and avid annealing of at least one oligonucleotide to a region of DNA flanking or overlapping

the polymorphic site (Koch, 2004). Because genomic variability is so common (with polymorphic sites every few hundred nucleotides), “cryptic” or unrecognized polymorphisms may interfere with oligonucleotide annealing, thereby resulting in false positive or false negative genotype assignments. Full integration of genotyping into therapeutics will require high standards for genotyping technology, perhaps with more than one method required for each polymorphic site.

One method to assess the reliability of genotype determinations in a group of individuals is to assess whether the relative number of homozygotes to heterozygotes is consistent with the overall allele frequency at each polymorphic site. *Hardy-Weinberg equilibrium* is maintained when mating within a population is random and there is no natural selection effect on the variant. Such assumptions are described mathematically when the proportions of the population that are observed to be homozygous for the variant genotype (q^2), homozygous for the wild-type genotype (p^2), and heterozygous ($2*p*q$) are not significantly different from that predicted from the overall allele frequencies ($p = \text{fre-$

quency of wild-type allele; q = frequency of variant allele) in the population. If proportions of the observed three genotypes, which must add up to one, differ significantly from those predicted, it may indicate that a genotyping error may be present.

Because polymorphisms are so common, haplotype (the allelic structure that indicates whether polymorphisms within a gene are on the same or different alleles) may also be important. Thus far, experimental methods to unambiguously confirm whether polymorphisms are allelic has proven to be feasible but technically challenging (McDonald *et al.*, 2002). Most investigators use statistical probability to assign putative or inferred haplotypes; *e.g.*, because the two most common SNPs in *TPMT* (at 460 and 719) often are allelic, a genotyping result showing heterozygosity at both SNPs will have a >95% chance of reflecting one allele wild-type and one allele variant at both SNP positions (resulting in a “heterozygote” genotype for *TPMT*). However, the remote prospect that each of the two alleles carries a single SNP variant, thereby conferring a homozygous variant/deficient phenotype, is a theoretical possibility.

Candidate Gene versus Genome-Wide Approaches

Because pathways involved in drug response are often known or at least partially known, pharmacogenetic studies are highly amenable to candidate gene association

studies. After genes in drug response pathways are identified, the next step in the design of a candidate gene association pharmacogenetic study is to identify the genetic polymorphisms that are likely to contribute to the therapeutic and/or adverse responses to the drug. There are several databases that contain information on polymorphisms and mutations in human genes (Table 4–1), which allow the investigator to search by gene for polymorphisms that have been reported. Some of the databases, such as the Pharmacogenetics and Pharmacogenomics Knowledge Base (PharmGKB), include phenotypic as well as genotypic data.

Because it is currently not practical to analyze all polymorphisms in a candidate gene association study, it is important to select polymorphisms that are likely to be associated with the drug-response phenotype. For this purpose, there are two categories of polymorphisms. The first are polymorphisms that do not, in and of themselves, cause altered function of the expressed protein (*e.g.*, an enzyme that metabolizes the drug or the drug receptor). Rather, these polymorphisms are linked to the variant allele that produces the altered function. These polymorphisms serve as biomarkers for drug-response phenotype. However, their major shortcoming is that unless they are in 100% linkage with the causative polymorphism, they are not the best markers for the drug-response phenotype.

The second type of polymorphism is the *causative polymorphism*, which directly precipitates the pheno-

type. For example, a causative SNP may change an amino acid residue at a site that is highly conserved throughout evolution. This substitution may result in a protein that is nonfunctional or has reduced function. Whenever possible, it is desirable to select polymorphisms for pharmacogenetic studies that are likely to be causative (Tabor *et al.*, 2002). If biological information indicates that a particular polymorphism alters function, for example, in cellular assays of nonsynonymous variants, this polymorphism is an excellent candidate to use in an association study.

A potential drawback of the candidate gene approach is that the wrong genes may be studied. Genome-wide approaches, using gene expression arrays, genome-wide scans, or proteomics, can complement the candidate gene approach by providing a relatively unbiased survey of the genome to identify previously unrecognized candidate genes. For example, RNA, DNA, or protein from patients who have unacceptable toxicity from a drug can be compared with identical material from identically treated patients who did not have such toxicity. Patterns of gene expression, clusters of polymorphisms or heterozygosity, or relative amounts of proteins can be ascertained using computational tools, to identify genes, genomic regions, or proteins that can be further assessed for germline polymorphisms differentiating the phenotype. Gene expression and proteomic approaches have the advantage that the abundance of signal may itself directly reflect some of the relevant genetic variation; however, both types of expression are highly influenced by choice of tissue type, which may not be available from the relevant tissue; for example, it may not be feasible to obtain biopsies of brain tissue for studies on CNS toxicity. DNA has the advantage that it is readily available and independent of tissue type, but the vast majority of genomic variation is not in genes, and the large number of SNPs raises the danger of type I error (finding differences that are false-positives). Nonetheless, technology is rapidly evolving for genome-wide surveys of RNA, DNA, and protein, and such approaches hold promise for future pharmacogenomic discoveries.

Functional Studies of Polymorphisms

For most polymorphisms, functional information is not available. Therefore, to select polymorphisms that are likely to be causative, it is important to predict whether a polymorphism may result in a change in protein function, stability, or subcellular localization. One way that we can gain an understanding of the functional effects of various types of genomic variations is to survey the

mutations that have been associated with human Mendelian disease. The greatest number of DNA variations associated with diseases or traits are missense and nonsense mutations, followed by deletions (Figure 4–7). Further studies have suggested that of amino acid replacements associated with human disease, there is a high representation at residues that are most evolutionarily conserved (Miller and Kumar, 2001; Ng and Henikoff, 2003). These data have been supplemented by a large survey of genetic variation in membrane transporters important in drug response (Leabman *et al.*, 2003). That survey shows that nonsynonymous SNPs that alter evolutionarily conserved amino acids are present at lower allele frequencies on average than those that alter residues that are not conserved across species. This suggests that SNPs that alter evolutionarily conserved residues are most deleterious. The nature of chemical change of an amino acid substitution determines the functional effect of an amino acid variant. More radical changes in amino acids are more likely to be associated with disease than more conservative changes. For example, substitution of a charged amino acid (Arg) for a nonpolar, uncharged amino acid (Cys) is more likely to affect function than substitution of residues that are more chemically similar (*e.g.*, Arg to Lys).

Among the first pharmacogenetic examples to be discovered was glucose-6-phosphate dehydrogenase (G6PD) deficiency, an X-linked monogenic trait that results in severe hemolytic anemia in individuals after ingestion of fava beans or various drugs, including many antimalarial agents (Alving *et al.*, 1956). G6PD is normally present in red blood cells and helps to regulate levels of glutathione (GSH), an antioxidant. Antimalarials such as *primaquine*

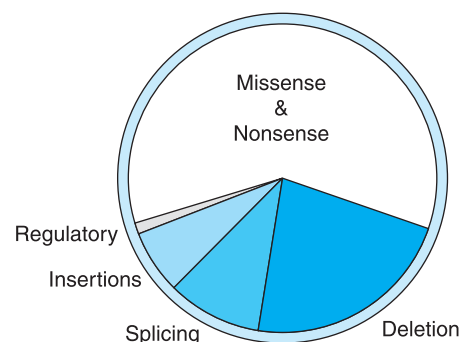

Figure 4–7. DNA mutations associated with human diseases. Among the 27,027 DNA variations studied, 1,222 were associated with diseases. These 1,222 variations are sorted into functional groups in the proportions indicated by the pie chart. Missense and nonsense mutations account for the greatest fraction of DNA variations associated with Mendelian disease (Botstein and Risch, 2003).

Table 4–2

The Predicted Functional Effect and Relative Risk That a Variant Will Alter Function of SNP Types in the Human Genome

TYPE OF VARIANT	LOCATION	FREQUENCY IN GENOME	PREDICTED RELATIVE RISK OF PHENOTYPE	FUNCTIONAL EFFECT
<i>Nonsense</i>	Coding region	Very low	Very high	Stop codon
<i>Nonsynonymous</i> Evolutionarily conserved	Coding region	Low	High	Amino acid substitution of a residue conserved across evolution
<i>Nonsynonymous</i> Evolutionarily unconserved	Coding region	Low	Low to moderate	Amino acid substitution of a residue not conserved across evolution
<i>Nonsynonymous</i> Radical chemical change	Coding region	Low	Moderate to high	Amino acid substitution of a residue that is chemically dissimilar to the original residue
<i>Nonsynonymous</i> Low to moderate chemical change	Coding region	Low	Low to high	Amino acid substitution of a residue that is chemically similar to the original residue
<i>Insertion/deletion</i>	Coding/noncoding region	Low	Low to high	Coding region: can cause frameshift
<i>Synonymous</i>	Coding region	Medium	Low	Can change mRNA stability or affect splicing
<i>Regulatory region</i>	Promoter, 5'UTR, 3'UTR	Medium	Low	Can affect the level of mRNA transcript by changing rate of transcription or stability of transcript
<i>Intron/exon boundary</i>	Within 8 bp of intron	Low	High	May affect splicing
<i>Intronic</i>	Deep within intron	Medium	Very low	No known function; may affect mRNA transcript levels through enhancer mechanism
<i>Intergenic</i>	Noncoding region between genes	High	Very low	No known function

Data adapted from Tabor *et al.*, 2002.

increase red blood cell fragility in individuals with G6PD deficiency, leading to profound hemolytic anemia. Interestingly, the severity of the deficiency syndrome varies among individuals and is related to the amino acid variant in G6PD. The severe form of G6PD deficiency is associated with changes at residues that are highly conserved across evolutionary history. Chemical change is also more radical on average in mutations associated with severe G6PD deficiency in comparison to mutations associated with milder forms of the syndrome. Collectively, studies of Mendelian traits and polymorphisms suggest that nonsynonymous SNPs that alter residues that are highly conserved among species and those that result in more radical changes in the nature of the amino acid are likely to be the best candidates for causing functional changes. The infor-

mation in Table 4–2 (categories of polymorphisms and the likelihood of each polymorphism to alter function) can be used as a guide for prioritizing polymorphisms in candidate gene association studies.

With the increasing number of SNPs that have been identified in large-scale SNP discovery projects, it is clear that computational methods are needed to predict the functional consequences of SNPs. To this end, predictive algorithms have been developed to identify potentially deleterious amino acid substitutions. These methods can be classified into two groups. The first group relies on sequence comparisons alone to identify and score substitutions according to their degree of conservation across multiple species; different scoring matrices have been used (*e.g.*, BLOSUM62 and SIFT)

Figure 4–8. Functional activity of natural variants of two membrane transporters. Data for the organic cation transporter (OCT1, left panel) and the nucleoside transporter (CNT3, right panel). Variants, identified in ethnically diverse populations, were constructed by site-directed mutagenesis and expressed in *Xenopus laevis* oocytes. Dark shaded bars represent uptake of the model compounds by variant transporters. Blue bars represent uptake of the model compounds by reference transporters (Shu *et al.*, 2003).

(Henikoff and Henikoff, 1992; Ng and Henikoff, 2003). The second group of methods relies on mapping of SNPs onto protein structures, in addition to sequence comparisons (Mirkovic *et al.*, 2004). For example, rules have been developed that classify SNPs in terms of their impact on folding and stability of the native protein structure as well as shapes of its binding sites. Such rules depend on the structural context in which SNPs occur (*e.g.*, buried in the core of the fold or exposed to the solvent, in the binding site or not), and are inferred by machine learning methods from many functionally annotated SNPs in test proteins.

Functional activity of amino acid variants for many proteins can be studied in cellular assays. An initial step in characterizing the function of a nonsynonymous variant would be to isolate the variant gene or construct the variant by site-directed mutagenesis, express it in cells, and compare its functional activity to that of the reference or most common form of the protein. In the past few years, large-scale functional analyses have been performed on genetic variants in membrane transporters and phase II enzymes. Figure 4–8 shows the function of all nonsynonymous variants and coding region insertions and deletions of two membrane transporters, the organic cation transporter, OCT1 (encoded by *SLC22A1*) and the nucleoside transporter, CNT3 (encoded by *SLC28A3*). As shown, most of the naturally occurring variants have similar functional activity as that of

the reference transporters. However, several variants exhibit reduced function; in the case of OCT1, a gain-of-function variant is also present. Results such as these indicate heterogeneity exists in the functionality of natural amino acid variants in normal healthy human populations.

For many proteins, including enzymes, transporters, and receptors, the mechanisms by which amino acid substitutions alter function have been characterized in kinetic studies. Figure 4–9 shows simulated curves depicting the rate of metabolism of a substrate by two amino acid variants of an enzyme and the most common genetic form of the enzyme. The kinetics of metabolism of substrate by one variant enzyme, Variant A, is characterized by an increased K_m . Such an effect can occur if the amino acid substitution alters the binding site of the enzyme leading to a decrease in its affinity for the substrate. An amino acid variant may also alter the maximum rate of metabolism (V_{max}) of substrate by the enzyme, as exemplified by Variant B. The mechanisms for a reduced V_{max} are generally related to a reduced expression level of the enzyme, which may occur because of decreased stability of the protein or changes in protein trafficking or recycling (Shu *et al.*, 2003; Tirona *et al.*, 2001; Xu *et al.*, 2002).

In contrast to the studies with SNPs in coding regions, predicting the function of SNPs in noncoding regions of genes represents a major new challenge in

Figure 4–9. Simulated concentration–dependence curves showing the rate of metabolism of a hypothetical substrate by the common genetic form of an enzyme and two nonsynonymous variants. Variant A exhibits an increased K_m and likely reflects a change in the substrate binding site of the protein by the substituted amino acid. Variant B exhibits a change in the maximum rate of metabolism (V_{max}) of the substrate. This may be due to reduced expression level of the enzyme.

human genetics and pharmacogenetics. The principles of evolutionary conservation that have been shown to be important in predicting the function of nonsynonymous variants in the coding region need to be refined and tested as predictors of function of SNPs in noncoding regions. New methods in comparative genomics are being refined to identify conserved elements in noncoding regions of genes that may be functionally important (Bejerano *et al.*, 2004; Boffelli *et al.*, 2004; Brudno *et al.*, 2003).

Pharmacogenetic Phenotypes

Candidate genes for therapeutic and adverse response can be divided into three categories: pharmacokinetic, receptor/target, and disease-modifying.

Pharmacokinetics. Germline variability in genes that encode determinants of the pharmacokinetics of a drug, in particular enzymes and transporters, affect drug concentrations, and are therefore major determinants of therapeutic and adverse drug response (Table 4–3; Nebert *et al.*, 1996). Multiple enzymes and transporters may be involved in the pharmacokinetics of a single drug. Several polymorphisms in drug metabolizing enzymes were discovered as monogenic phenotypic trait variations, and thus may be referenced using their phenotypic designations (*e.g.*, slow *vs.* fast acetylation, extensive *vs.* poor metabolizers of debrisoquine or *sparteine*) rather

than their genotypic designations that reference the gene that is the target of polymorphisms in each case (NAT2 and CYP2D6 polymorphisms, respectively) (Grant *et al.*, 1990). CYP2D6 is now known to catabolize the two initial probe drugs (sparteine and debrisoquine), each of which was associated with exaggerated responses in 5% to 10% of treated individuals. The exaggerated responses are an inherited trait (Eichelbaum *et al.*, 1975; Mahgoub *et al.*, 1977). At present, a very large number of medications (estimated at 15% to 25% of all medicines in use) have been shown to be substrates for CYP2D6 (Table 4–3). The molecular and phenotypic characterization of multiple racial and ethnic groups has shown that seven variant alleles account for well over 90% of the “poor metabolizer” low-activity alleles for this gene in most racial groups; that the frequency of variant alleles varies with geographic origin; and that a small percentage of individuals carry stable duplications of CYP2D6, with “ultra-rapid” metabolizers having up to 13 copies of the active gene (Ingelman-Sundberg and Evans, 2001). Phenotypic consequences of the deficient CYP2D6 phenotype include increased risk of toxicity of antidepressants or antipsychotics (catabolized by the enzyme), and lack of analgesic effects of codeine (anabolized by the enzyme); conversely, the ultra-rapid phenotype is associated with extremely rapid clearance and thus inefficacy of antidepressants (Kirchheiner *et al.*, 2001).

A promoter region variant in the enzyme UGT1A1, UGT1A1*28, which has an additional TA in comparison to the more common form of the gene, has been associated with a reduced transcription rate of *UGT1A1* and lower glucuronidation activity of the enzyme. This reduced activity has been associated with higher levels of the active metabolite of the cancer chemotherapeutic agent *irinotecan* (*see* Chapters 3 and 51). The metabolite, SN38, which is eliminated by glucuronidation, is associated with the risk of toxicity (Iyer *et al.*, 2002), which will be more severe in individuals with genetically lower UGT1A1 activity.

CYP2C19 codes for a cytochrome P450, historically termed mephenytoin hydroxylase, that displays penetrant pharmacogenetic variability, with just a few SNPs accounting for the majority of the deficient, poor metabolizer phenotype (Mallal *et al.*, 2002). The deficient phenotype is much more common in Chinese and Japanese populations. Several proton pump inhibitors, including omeprazole and *lansoprazole*, are inactivated by CYP2C19. Thus, the deficient patients have higher exposure to active parent drug, a greater pharmacodynamic effect (higher gastric pH), and a higher probability of ulcer cure than

Table 4–3**Examples of Genetic Polymorphisms Influencing Drug Response**

GENE PRODUCT (GENE)	DRUGS	RESPONSES AFFECTED
<i>Drug metabolizers</i>		
CYP2C9	Tolbutamide, warfarin, phenytoin, nonsteroidal antiinflammatories	Anticoagulant effect of warfarin (Aithal <i>et al.</i> , 1999; Roden, 2003; Weinshilboum, 2003)
CYP2C19	Mephenytoin, omeprazole, hexobarbital, mephobarbital, propranolol, proguanil, phenytoin	Peptic ulcer response to omeprazole (Kirchheiner <i>et al.</i> , 2001)
CYP2D6	β blockers, antidepressants, antipsychotics, codeine, debrisoquine, dextromethorphan, encainide, flecainide, fluoxetine, guanoxan, N-propylajmaline, perhexiline, phenacetin, phenformin, propafenone, sparteine	Tardive dyskinesia from antipsychotics, narcotic side effects, codeine efficacy, imipramine dose requirement, β blocker effect (Kirchheiner <i>et al.</i> , 2001; Weinshilboum, 2003)
CYP3A4/3A5/3A7	Macrolides, cyclosporine, tacrolimus, Ca ²⁺ channel blockers, midazolam, terfenadine, lidocaine, dapson, quinidine, triazolam, etoposide, teniposide, lovastatin, alfentanil, tamoxifen, steroids	Efficacy of immunosuppressive effects of tacrolimus (Evans and Relling, 2004)
Dihydropyrimidine dehydrogenase	Fluorouracil	5-Fluorouracil neurotoxicity (Chibana <i>et al.</i> , 2002)
N-acetyltransferase (NAT2)	Isoniazid, hydralazine, sulfonamides, amonafide, procainamide, dapson, caffeine	Hypersensitivity to sulfonamides, amonafide toxicity, hydralazine-induced lupus, isoniazid neurotoxicity (Roden, 2003; Grant <i>et al.</i> , 1990)
Glutathione transferases (GSTM1, GSTT1, GSTP1)	Several anticancer agents	Decreased response in breast cancer, more toxicity and worse response in acute myelogenous leukemia (Townsend and Tew, 2003b)
Thiopurine methyltransferase (TPMT)	Mercaptopurine, thioguanine, azathioprine	Thiopurine toxicity and efficacy, risk of second cancers (Relling and Dervieux, 2001; Weinshilboum, 2003)
UDP-glucuronosyl-transferase (UGT1A1)	Irinotecan, bilirubin	Irinotecan toxicity (Iyer <i>et al.</i> , 1998; Relling and Dervieux, 2001)
P-glycoprotein (ABCB1)	Natural product anticancer drugs, HIV protease inhibitors, digoxin	Decreased CD4 response in HIV-infected patients, decreased digoxin AUC, drug resistance in epilepsy (Fellay <i>et al.</i> , 2002; Quirk <i>et al.</i> , 2004; Roden, 2003; Siddiqui <i>et al.</i> , 2003)
UGT2B7	Morphine	Morphine plasma levels (Sawyer <i>et al.</i> , 2003)
COMT	Levodopa	Enhanced drug effect (Weinshilboum, 2003)
CYP2B6	Cyclophosphamide	Ovarian failure (Takada <i>et al.</i> , 2004)
<i>Targets and receptors</i>		
Angiotensin-converting enzyme (ACE)	ACE inhibitors (<i>e.g.</i> , enalapril)	Renoprotective effects, hypotension, left ventricular mass reduction, cough (van Essen <i>et al.</i> , 1996; Roden, 2003)

(Continued)

Table 4–3

Examples of Genetic Polymorphisms Influencing Drug Response (Continued)

GENE PRODUCT (GENE)	DRUGS	RESPONSES AFFECTED
Thymidylate synthase	Methotrexate	Leukemia response, colorectal cancer response (Krajinovic <i>et al.</i> , 2002; Relling and Dervieux, 2001)
β_2 Adrenergic receptor (ADBR2)	β_2 Antagonists (e.g., albuterol, terbutaline)	Bronchodilation, susceptibility to agonist-induced desensitization, cardiovascular effects (e.g., increased heart rate, cardiac index, peripheral vasodilation) (Roden, 2003; Tan <i>et al.</i> , 1997)
β_1 Adrenergic receptor (ADBR1)	β_1 Antagonists	Response to β_1 antagonists (Johnson and Lima, 2003)
5-Lipoxygenase (ALOX5)	Leukotriene receptor antagonists	Asthma response (Drazen <i>et al.</i> , 1999)
Dopamine receptors (D ₂ , D ₃ , D ₄)	Antipsychotics (e.g., haloperidol, clozapine, thioridazine, nemonapride)	Antipsychotic response (D ₂ , D ₃ , D ₄), antipsychotic-induced tardive dyskinesia (D ₃) and acute akathisia (D ₃), hyperprolactinemia in females (D ₂) (Arranz <i>et al.</i> , 2000; Evans and McLeod, 2003)
Estrogen receptor α	Estrogen hormone replacement therapy	High-density lipoprotein cholesterol (Herrington <i>et al.</i> , 2002)
Serotonin transporter (5-HTT)	Antidepressants (e.g., clomipramine, fluoxetine, paroxetine, fluvoxamine)	Clozapine effects, 5-HT neurotransmission, antidepressant response (Arranz <i>et al.</i> , 2000)
Serotonin receptor (5-HT _{2A})	Antipsychotics	Clozapine antipsychotic response, tardive dyskinesia, paroxetine antidepressant response, drug discrimination (Arranz <i>et al.</i> , 2000) (Murphy <i>et al.</i> , 2003)
HMG-CoA reductase	Pravastatin	Reduction in serum cholesterol
<i>Modifiers</i>		
Adducin	Diuretics	Myocardial infarction or strokes (Roden, 2003)
Apolipoprotein E	Statins (e.g., simvastatin), tacrine	Lipid-lowering; clinical improvement in Alzheimer's (Evans and McLeod, 2003)
Human leukocyte antigen	Abacavir	Hypersensitivity reactions (Mallal <i>et al.</i> , 2002)
Cholesteryl ester transfer protein	Statins (e.g., pravastatin)	Slowing atherosclerosis progression (Evans and McLeod, 2003)
Ion channels (HERG, KvLQT1, Mink, MiRPI)	Erythromycin, cisapride, clarithromycin, quinidine	Increased risk of drug-induced torsades de pointes, increased QT interval (Roden, 2003; Roden, 2004)
Methylguanine-deoxyribonucleic acid methyltransferase	Carmustine	Response of glioma to carmustine (Evans and McLeod, 2003)
Parkin	Levodopa	Parkinson's disease response (Evans and McLeod, 2003)
MTHFR	Methotrexate	Gastrointestinal toxicity (Ulrich <i>et al.</i> , 2001)
Prothrombin, factor V	Oral contraceptives	Venous thrombosis risk (Evans and McLeod, 2003)
Stromelysin-1	Statins (e.g., pravastatin)	Reduction in cardiovascular events and in repeat angioplasty (Evans <i>et al.</i> , 2003)
Vitamin D receptor	Estrogen	Bone mineral density (Hustmyer <i>et al.</i> , 1994)

Figure 4–10. Effect of *CYP2C19* genotype on proton pump inhibitor (PPI) pharmacokinetics (AUC), gastric pH, and ulcer cure rates. Depicted are the average variables for *CYP2C19* homozygous extensive metabolizers (homEM), heterozygotes (hetEM), and poor metabolizers (PM). (Reproduced with permission from Furuta *et al.*, 2004.)

heterozygotes or homozygous wild-type individuals (Figure 4–10).

The anticoagulant *warfarin* is catabolized by *CYP2C9*. Inactivating polymorphisms in *CYP2C9* are common (Goldstein, 2001), with 2% to 10% of most populations being homozygous for low-activity variants, and are associated with lower *warfarin* clearance, a higher risk of bleeding complications, and lower dose requirements (Aithal *et al.*, 1999).

Thiopurine methyltransferase (TPMT) methylates thiopurines such as *mercaptopurine* (an antileukemic drug that is also the product of *azathioprine* metabolism). Inactivating polymorphisms in *CYP2C9* are common (Goldstein, 2001), with 2% to 10% of most populations being homozygous for low-activity variants, and are associated with lower *warfarin* clearance, a higher risk of bleeding complications, and lower dose requirements (Aithal *et al.*, 1999). Thiopurine methyltransferase (TPMT) methylates thiopurines such as *mercaptopurine* (an antileukemic drug that is also the product of *azathioprine* metabolism). One in 300 individuals is homozygous deficient, 10% are heterozygotes, and about 90% are homozygous for the wild-type alleles for *TPMT* (Weinshilboum and Sladek, 1980). Three SNPs account for over 90% of the inactivating alleles (Yates *et al.*, 1997). Because methylation of *mercaptopurine* competes with activation of the drug to thioguanine nucleotides, the concentration of the active (but also toxic) thioguanine metabolites is inversely related to TPMT activity and directly related to the probability of pharmacologic effects. Dose reductions (from the “average” population dose) may be required to avoid myelosuppression in 100% of homozygous deficient patients, 35% of heterozygotes, and only 7% to 8% of those with homozygous wild-type activity (Relling *et al.*, 1999). The rare homozygous deficient patients can tolerate 10% or less of the *mercaptopurine* doses tolerated by the homozygous wild-type patients, with heterozygotes often requiring an intermediate dose. *Mercaptopurine* has a narrow therapeutic range, and dosing by trial and error can place patients at higher risk of

toxicity; thus, prospective adjustment of *thiopurine* doses based on *TPMT* genotype has been suggested (Lesko and Woodcock, 2004). Life-threatening toxicity has also been reported when *azathioprine* has been given to patients with nonmalignant conditions (such as Crohn’s disease, arthritis, or for prevention of solid organ transplant rejection) (Evans and Johnson, 2001; Evans and Relling, 2004; Weinshilboum, 2003).

Pharmacogenetics and Drug Targets. Gene products that are direct targets for drugs have an important role in pharmacogenetics (Johnson and Lima, 2003). Whereas highly penetrant variants with profound functional consequences in some genes may cause disease phenotypes that confer negative selective pressure, more subtle variations in the same genes can be maintained in the population without causing disease, but nonetheless causing variation in drug response. For example, complete inactivation *via* rare point mutations in methylenetetrahydrofolate reductase (*MTHFR*) causes severe mental retardation, cardiovascular disease, and a shortened lifespan (Goyette *et al.*, 1994). *MTHFR* reduces 5,10-CH₂- to 5-CH₃-tetrahydrofolate, and thereby interacts with folate-dependent one-carbon synthesis reactions, including homocysteine/methionine metabolism and pyrimidine/purine synthesis (*see* Chapter 51). This pathway is the target of several antifolate drugs (Figure 4–11). Whereas rare variants in *MTHFR* may result in early death, the 677C→T SNP causes an amino acid substitution that is maintained in the population at a high frequency (variant allele, q, frequency in most white populations = 0.4). This variant is associated with modestly lower *MTHFR*

Figure 4–11. Gene products involved in the pharmacogenetics of a single drug, methotrexate. Those involved directly in pharmacokinetics (transport and metabolism) of methotrexate are circled (e.g., *SLC19A1*, *FPGS*, *MRPs*, *GGH*); direct targets of the drug are outlined in solid rectangles (e.g., *DHFR*, *TYMS*, *GART*, *ATIC*); and a gene product that may indirectly modulate the effect of methotrexate (e.g., *MTHFR*) is outlined with a dotted line. DHFR, dihydrofolate reductase; TYMS, thymidylate synthetase; GART, glycinamide ribonucleotide transformylase; ATIC, aminoimidazole carboxamide transformylase; MTHFR, methylenetetrahydrofolate reductase.

activity (about 30% less than the 677C allele) and modest but significantly elevated plasma homocysteine concentrations (about 25% higher) (Klerk *et al.*, 2002). This polymorphism does not alter drug pharmacokinetics, but does appear to modulate pharmacodynamics by predisposing to gastrointestinal toxicity to the antifolate drug *methotrexate* in stem cell transplant recipients. Following prophylactic treatment with methotrexate for graft-versus-host disease, mucositis was three times more common among patients homozygous for the 677T allele than those homozygous for the 677C allele (Ulrich *et al.*, 2001).

Methotrexate is a substrate for transporters and anabolizing enzymes that affect its intracellular pharmacokinetics and that are subject to common polymorphisms (Figure 4–11). Several of the direct targets (dihydrofolate reductase, purine transformylases, and thymidylate synthase [*TYMS*]) are also subject to common polymorphisms. A polymorphic indel in *TYMS* (two vs. three repeats of a 28–base pair repeat in the enhancer) affects the amount of enzyme expression in both normal and

tumor cells. The polymorphism is quite common, with alleles equally split between the lower-expression two-repeat and the higher-expression three-repeat alleles. The *TYMS* polymorphism can affect both toxicity and efficacy of anticancer agents (e.g., fluorouracil and methotrexate) that target *TYMS* (Krajinovic *et al.*, 2002). Thus, the genetic contribution to variability in the pharmacokinetics and pharmacodynamics of methotrexate cannot be understood without assessing genotypes at a number of different loci.

Many drug target polymorphisms have been shown to predict responsiveness to drugs (Table 4–3). Serotonin receptor polymorphisms predict not only the responsiveness to antidepressants (Figure 4–12), but also the overall risk of depression (Murphy *et al.*, 2003). β adrenergic receptor polymorphisms have been linked to asthma responsiveness (degree of change in one-second forced expiratory volume after use of a β agonist) (Tan *et al.*, 1997), renal function following angiotensin-converting enzyme (ACE) inhibitors (van Essen *et al.*, 1996), and heart rate following β -blockers (Tay-

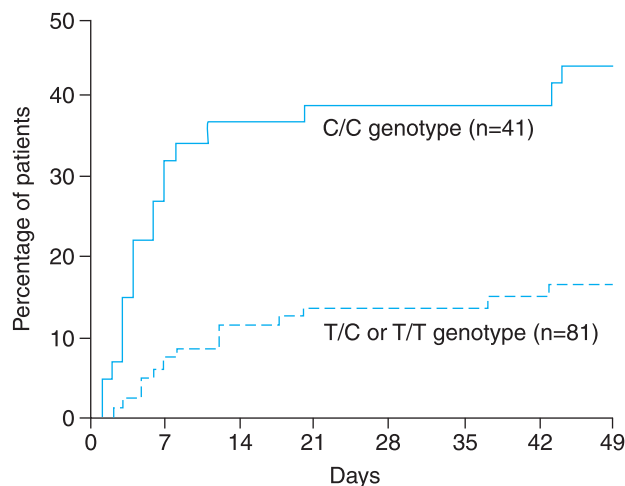

Figure 4–12. Pharmacodynamics and pharmacogenetics.

The proportion of patients requiring a dosage decrease for the antidepressant drug paroxetine was greater ($p = 0.001$) in the approximately one-third of patients who have the C/C genotype for the serotonin 2A receptor ($5HT_{2A}$) compared to the two-thirds of patients who have either the T/C or T/T genotype at position 102 (Murphy *et al.*, 2003). The major reason for dosage decreases in paroxetine was the occurrence of adverse drug effects. (Reproduced with permission from Greer *et al.*, 2003.)

lor and Kennedy, 2001). Polymorphisms in 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase have been linked to the degree of lipid lowering following statins, which are HMG-CoA reductase inhibitors (*see* Chapter 35), and to the degree of positive effects on high-density lipoproteins among women on estrogen

replacement therapy (Herrington *et al.*, 2002; Figure 4–13). Ion channel polymorphisms have been linked to a risk of cardiac arrhythmias in the presence and absence of drug triggers (Roden, 2004).

Polymorphism-Modifying Diseases and Drug Responses.

Some genes may be involved in an underlying disease being treated, but do not directly interact with the drug. Modifier polymorphisms are important for the *de novo* risk of some events and for the risk of drug-induced events. The *MTHFR* polymorphism, for example, is linked to homocysteinemia, which in turn affects thrombosis risk (den Heijer, 2003). The risk of a drug-induced thrombosis is dependent not only on the use of prothrombotic drugs, but on environmental and genetic predisposition to thrombosis, which may be affected by germline polymorphisms in *MTHFR*, factor V, and prothrombin (Chanock, 2003). These polymorphisms do not directly act on the pharmacokinetics or pharmacodynamics of prothrombotic drugs, such as glucocorticoids, estrogens, and asparaginase, but may modify the risk of the phenotypic event (thrombosis) in the presence of the drug.

Likewise, polymorphisms in ion channels (*e.g.*, *HERG*, *KvLQT1*, *Mink*, and *MiRP1*) may affect the overall risk of cardiac dysrhythmias, which may be accentuated in the presence of a drug that can prolong the QT interval in some circumstances (*e.g.*, macrolide antibiotics, antihistamines) (Roden, 2003). These modifier polymorphisms may impact on the risk of “disease” phenotypes even in the absence of drug challenges; in the presence of drug, the “disease” phenotype may be elicited.

Figure 4–13. Effect of genotype on response to estrogen hormone replacement therapy. Depicted are pretreatment (base line) and posttreatment (follow-up) high-density lipoprotein (HDL) cholesterol levels in women of the C/C vs. C/T or T/T HMG-CoA reductase genotype. (Reproduced with permission from Herrington *et al.*, 2002.)

Cancer pharmacogenetics have an unusual aspect in that tumors exhibit somatically-acquired mutations in addition to the underlying germline variation of the host. Thus, the efficacy of some anticancer drugs depends on the genetics of both the host and the tumor. For example, non-small-cell lung cancer is treated with an inhibitor of epidermal growth factor receptor (EGFR), *gefitinib* (see Chapter 51). Patients whose tumors have activating mutations in the tyrosine kinase domain of *EGFR* appear to respond better to gefitinib than those without the mutations (Lynch *et al.*, 2004). Thus, the receptor is altered, and at the same time, individuals with the activating mutations may be considered to have a distinct category of non-small-cell lung cancer. As another example, the *TYMS* enhancer repeat polymorphism affects not only host toxicity, but also tumor susceptibility to thymidylate synthase inhibitors (Evans and McLeod, 2003; Villafranca *et al.*, 2001; Relling and Dervieux, 2001).

Pharmacogenetics and Drug Development

Pharmacogenetics will likely impact drug regulatory considerations in several ways (Evans and Relling, 2004; Lesko and Woodcock, 2004; Weinshilboum and Wang, 2004). Genome-wide approaches hold promise for identification of new drug targets and therefore new drugs. In addition, accounting for genetic/genomic interindividual variability may lead to genotype-specific development of new drugs, and to genotype-specific dosing regimens.

Pharmacogenomics can identify new targets. For example, genome-wide assessments using microarray technology could identify genes whose expression differentiates inflammatory processes; a compound could be identified that changes expression of that gene; and then that compound could serve as a starting point for anti-inflammatory drug development. Proof of principle has been demonstrated for identification of antileukemic agents (Stegmaier *et al.*, 2004) and antifungal drugs (Parsons *et al.*, 2004), among others.

Pharmacogenetics may identify subsets of patients who will have a very high or a very low likelihood of responding to an agent. This will permit testing of the drug in a selected population that is more likely to respond, minimizing the possibility of adverse events in patients who derive no benefit, and more tightly defining the parameters of response in the subset more likely to benefit. Somatic mutations in the *EGFR* gene strongly identify patients with lung cancer who are likely to respond to the tyrosine kinase inhibitor gefitinib (Lynch *et al.*, 2004); germline variations in 5-lipoxygenase (*ALOX5*) determine

which asthma patients are likely to respond to ALOX inhibitors (Drazen *et al.*, 1999); and vasodilation in response to β_2 agonists has been linked to β_2 adrenergic receptor polymorphisms (Johnson and Lima, 2003).

A related role for pharmacogenomics in drug development is to identify which genetic subset of patients is at highest risk for a serious adverse drug effect, and to avoid testing the drug in that subset of patients (Lesko and Woodcock, 2004). For example, the identification of HLA subtypes associated with hypersensitivity to the HIV-1 reverse transcriptase inhibitor *abacavir* (Mallal *et al.*, 2002) could theoretically identify a subset of patients who should receive alternative therapy, and thereby minimize or even abrogate hypersensitivity as an adverse effect of this agent. Children with acute myeloid leukemia who are homozygous for germline deletions in GSH transferase (*GSTT1*) are almost three times as likely to die of toxicity as those patients who have at least one wild-type copy of *GSTT1* following intensively timed antileukemic therapy but not after “usual” doses of antileukemic therapy (Davies *et al.*, 2001). These latter results suggest an important principle: pharmacogenetic testing may help to identify patients who require altered dosages of medications, but will not necessarily preclude the use of the agents completely.

Pharmacogenetics in Clinical Practice

Despite considerable research activity, pharmacogenetics is rarely utilized in clinical practice (Evans and Johnson, 2001; Weinshilboum and Wang, 2004). There are three major types of evidence that should accumulate in order to implicate a polymorphism in clinical care (Figure 4–14): screens of tissues from multiple humans linking the polymorphism to a trait; complementary preclinical functional studies indicating that the polymorphism is plausibly linked with the phenotype; and multiple supportive clinical phenotype/genotype studies. Because of the high probability of type I error in genotype/phenotype association studies, replication of clinical findings will generally be necessary. Although the impact of the polymorphism in TPMT on mercaptopurine dosing in childhood leukemia is a good example of a polymorphism for which all three types of evidence are available, proactive individualized dosing of thiopurines based on genotype has not been widely incorporated into clinical practice (Lesko *et al.*, 2004).

Most drug dosing takes place using a population “average” dose of drug. Adjusting dosages for variables such as renal or liver dysfunction is often accepted in drug dosing, even in cases in which the clinical outcome

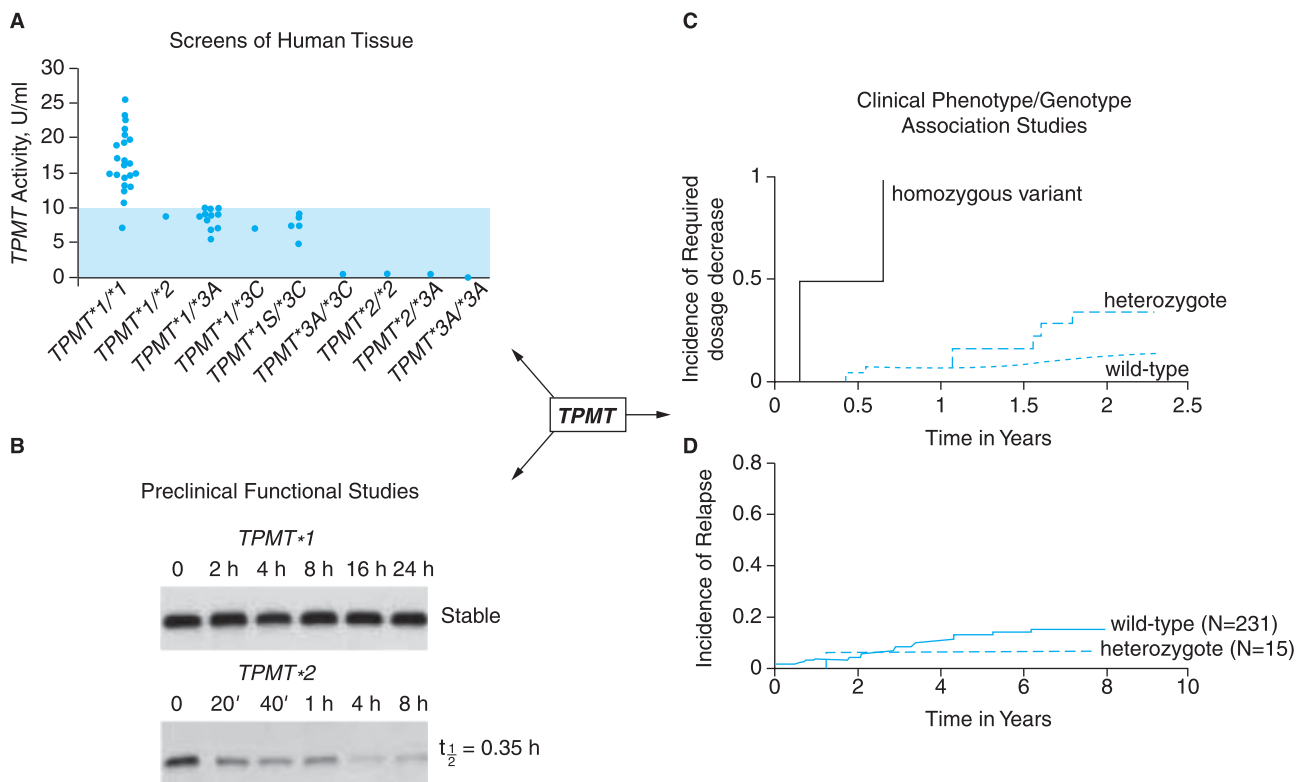

Figure 4-14. Three primary types of evidence in pharmacogenetics. Screens of human tissue (A) link phenotype (thiopurine methyltransferase activity in erythrocytes) with genotype (germline *TPMT* genotype). The two alleles are separated by a slash (/); the *1 and *1S alleles are wild-type, and the *2, *3A, and *3C are nonfunctional alleles. Shaded areas indicate low and intermediate levels of enzyme activity: those with the homozygous wild-type genotype have the highest activity, those heterozygous for at least one *1 allele have intermediate activity, and those homozygous for two inactive alleles have low or undetectable TPMT activity (Yates *et al.*, 1997). Directed preclinical functional studies (B) can provide biochemical data consistent with the *in vitro* screens of human tissue, and may offer further confirmatory evidence. Here, the heterologous expression of the *TPMT**1 wild-type and the *TPMT**2 variant alleles indicate that the former produces a more stable protein, as assessed by Western blot (Tai *et al.*, 1997). The third type of evidence comes from clinical phenotype/genotype association studies (C and D). The incidence of required dosage decrease for thiopurine in children with leukemia (C) differs by *TPMT* genotype: 100%, 35%, and 7% of patients with homozygous variant, heterozygous, or homozygous wild-type, respectively, require a dosage decrease (Relling *et al.*, 1999). When dosages of thiopurine are adjusted based on *TPMT* genotype in the successor study (D), leukemic relapse is not compromised, as indicated by comparable relapse rates in children who were wild-type vs. heterozygous for *TPMT*. Taken together, these three data sets indicate that the polymorphism should be accounted for in dosing of thiopurines. (Reproduced with permission from Relling *et al.*, 1999.)

of such adjustments has not been studied. Even though there are many examples of significant effects of polymorphisms on drug disposition (*e.g.*, Table 4-3), there is much more hesitation from clinicians to adjust doses based on genetic testing than on indirect clinical measures of renal and liver function. Whether this hesitation reflects resistance to abandon the “trial-and-error” approach that has defined most drug dosing, distrust of the genetic tests (which are constantly being refined), or unfamiliarity with the principles of genetics is not clear. Nonetheless, broad public initiatives, such as the NIH-funded Pharmacogenetics and Pharmacogenomics

Knowledge Base (www.pharmGKB.org), provide useful resources to permit clinicians to access information on pharmacogenetics (*see* Table 4-1).

The fact that functionally important polymorphisms are so common means that complexity of dosing will be likely to increase substantially in the postgenomic era. Even if every drug has only one important polymorphism to consider when dosing, the scale of complexity could be large. Many individuals take multiple drugs simultaneously for different diseases, and many therapeutic regimens for a single disease consist of multiple agents. This situation translates into a large number of possible drug-dose combina-

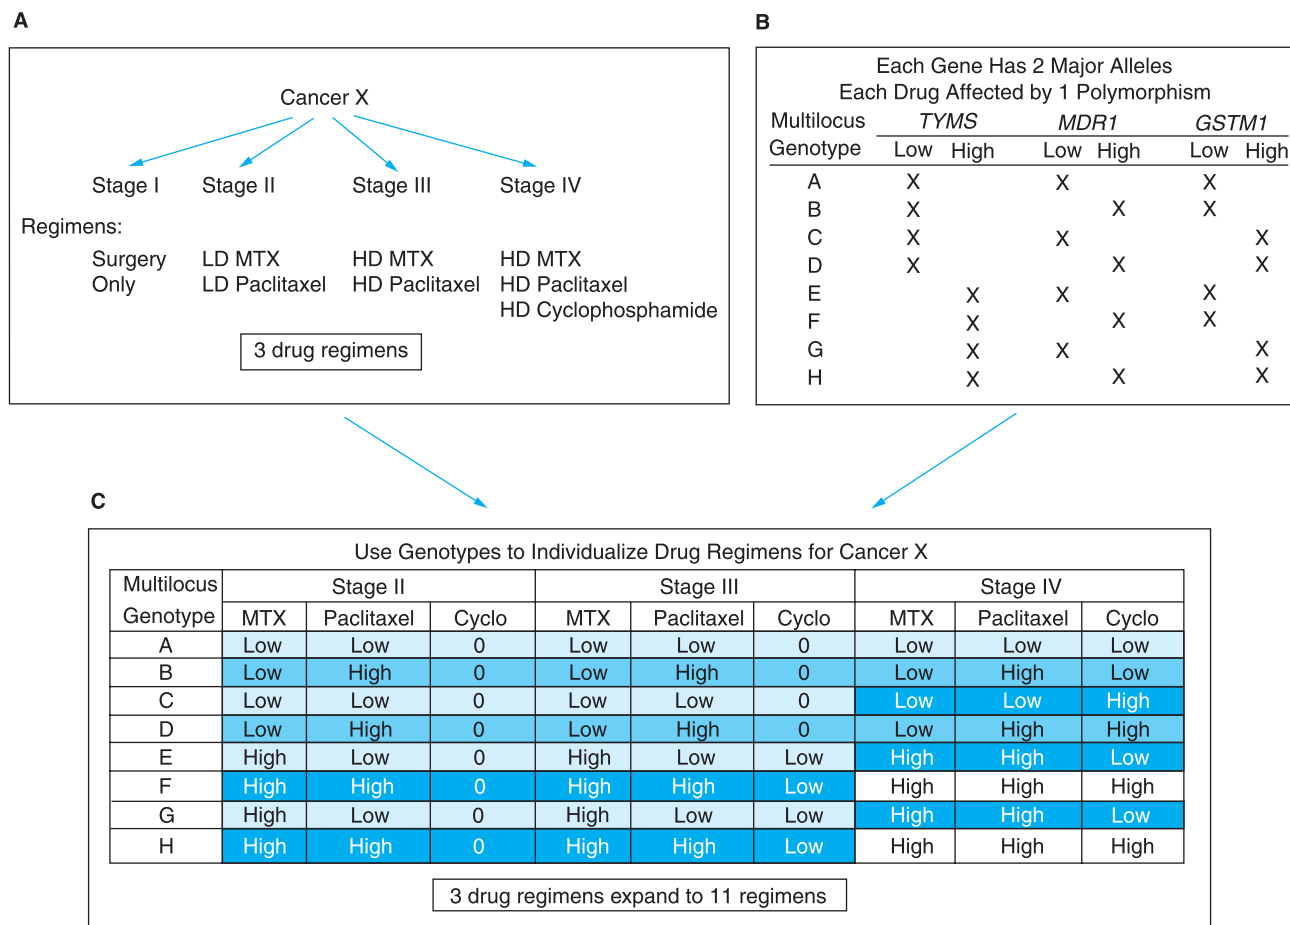

Figure 4–15. Potential impact of incorporation of pharmacogenetics into dosing of drugs for a relatively simple therapeutic regimen. The traditional approach to treatment for a disease (A), in this case a cancer, is based purely on stage of the cancer. Up to three different drugs are used in combination, with intensity of dosing dependent on the stage of the cancer. With this strategy, some with stage II disease are not receiving as much drug as they could tolerate; some patients with stage III or IV disease are undertreated and some are overtreated. B illustrates a hypothetical patient population with eight different multilocus genotypes. It is assumed that each of the three drugs is affected by just one genetic polymorphism (*TYMS* for methotrexate [MTX], *MDR1* for paclitaxel, and *GSTM1* for cyclophosphamide), and each polymorphism has just two important genotypes (one coding for low and one for high activity). The possible multilocus genotypes are designated by the letters A to H, and the combinations of *TYMS*, *MDR1* and *GSTM1* genotypes giving rise to those multilocus genotypes are indicated in the table. If these three genotypes, along with stage of cancer, are used to individualize dosages (C), so that those with low activity receive lower doses (LD) and those with higher activity receive higher doses (HD) of the relevant drug, what began as a total of three drug regimens in the absence of pharmacogenetics becomes 11 regimens by using pharmacogenetics for dosage individualization.

tions. Much of the excitement regarding the promise of human genomics has emphasized the hope of discovering individualized “magic bullets,” and ignored the reality of the added complexity of additional testing and need for interpretation of results to capitalize on individualized dosing. This is illustrated in a potential pharmacogenetic example in Figure 4–15. In this case, a traditional anticancer treatment approach is replaced with one that incorpo-

rates pharmacogenetic information with the stage of the cancer determined by a variety of standardized pathological criteria. Assuming just one important genetic polymorphism for each of the three different anticancer drugs, 11 individual drug regimens can easily be generated.

Nonetheless, the potential utility of pharmacogenetics to optimize drug therapy is great. Once adequate genotype/phenotype studies have been conducted, molecular

diagnostic tests will be developed that detect >95% of the important genetic variants for the majority of polymorphisms, and genetic tests have the advantage that they need only be conducted once during an individual's lifetime. With continued incorporation of pharmacogenetics into clinical trials, the important genes and polymorphisms will be identified, and data will demonstrate whether dosage individualization can improve outcomes and decrease short- and long-term adverse effects. Significant covariates will be identified to allow refinement of dosing in the context of drug interactions and disease influences. Although the challenges are substantial, accounting for the genetic basis of variability in response to medications is likely to become a fundamental component of diagnosing any illness and guiding the choice and dosage of medications.

THE SCIENCE OF DRUG THERAPY

John A. Oates

Drug therapy affords an expanding opportunity for preventing and treating disease and for alleviating symptoms. Pharmacologic agents also expose patients to risk. Basic principles of drug therapy provide a conceptual framework for deploying drugs with maximal efficacy while minimizing the risk of adverse effects.

Optimal therapeutic decisions are based on an evaluation of the individual patient in concert with assessment of the evidence for efficacy and safety of the treatment under consideration. An understanding of the pharmacokinetics and pharmacodynamics of the drug should be integrated with this patient-focused information to guide implementation of therapy.

EVALUATION OF THE EVIDENCE

Initial determination of the effectiveness and safety of drugs is based predominantly on evaluation of experimental interventions in *clinical trials*. Well-designed and effectively executed clinical trials provide the scientific evidence that informs most therapeutic decisions. Evidence from clinical trials may be supplemented by *observational studies*, particularly in assessing adverse effects that elude detection in clinical trials designed to determine efficacy and that do not occur frequently or rapidly enough.

Clinical Trials

Similarity of the control group with the group receiving the intervention is key to obtaining valid information in all experimental science. In clinical trials, this similarity is best achieved by random assignment of patients or volunteers to the control group or the group receiving the

experimental therapy. Such randomization is the optimal method for distributing between the treatment and control groups the known and unknown variables that could affect outcome. Recognizing that a randomized clinical trial is the “gold standard” of clinical trials, it nonetheless may be impossible to use this design to study all disorders; for patients who cannot—by regulation, ethics, or both—be studied with this design (*e.g.*, children, fetuses, or some patients with psychiatric disease) or for disorders with a typically fatal outcome (*e.g.*, rabies), it may be necessary to resort to historical controls.

A second important element of study design is *concealment* of the outcome of randomization from the study participants and investigators. Concealing whether participants are assigned to the control or the treatment group is referred to as *blinding* or *masking* the study. In therapeutic investigations, participants in the control group will receive an inactive replica of the drug, *e.g.*, a tablet or capsule containing inert ingredients that is identical in appearance to the active agent. This inert replica of the drug is designated as a *placebo*. When only the study participants are blinded to treatment assignment but investigators know whether the active agent is being given, this is designated as a *single-blind study*. In a *double-blind study*, neither the study participants nor the investigators knows whether the active agent is being given. Blinding the investigators not only removes bias in interpreting the outcomes and in decisions regarding management of the patient but also eliminates selectivity in the enthusiasm for therapy typically conveyed by clinicians. By eliminating participant and observer bias, the randomized, double-blind, placebo-controlled trial provides the highest likelihood of revealing the truth about the effects of a drug (Temple, 1997). The double-blind, placebo-controlled design permits evaluation of subjective end points, such as pain, that are powerfully influenced by the administration of placebo. Striking

instances in which placebo effects are observed include pain in labor, where a placebo produces approximately 40% of the relief provided by the opioid analgesic *meperidine* with a remarkably similar time course, and angina pectoris, where as much as a 60% improvement in symptoms is achieved with placebo. The response to placebo in patients with depression is often 60% to 70% as great as that of an active antidepressant drug; as described below, this complicates clinical trials of efficacy.

Benjamin Franklin pioneered the blinded study design. The king of France appointed him to a commission to evaluate the claims of the flamboyant healer Friedrich Anton Mesmer, who employed magnetized iron rods to heal illnesses. Franklin and the commission conducted an experiment in which patients were blindfolded to conceal whether or not they received Mesmer's treatment and found that the healing effects were independent of exposure to the magnetized rods.

The existence of a therapy already known to improve disease outcome may provide an ethical basis for comparing a new drug with the established treatment rather than placebo (Passamani, 1991). If the aim is to show that the new drug is as effective as the comparator, then the size of the trial must be sufficiently large to have the statistical power to demonstrate a meaningful difference between the two groups if such a difference were to exist. Trials conducted against comparators as controls can be misleading if they claim equal effectiveness based on the lack of a statistical difference between the drugs in a trial that was too small to demonstrate such a difference. When trials against comparator drugs examine the relative incidence of side effects, it also is important that the doses of the drugs are equally effective.

A clear hypothesis for the trial should guide the selection of a *primary end point*, which should be specified before the trial is initiated. Ideally, this primary end point should measure a clinical outcome, either a disease-related outcome, such as improvement of survival or reduction of myocardial infarction, or a symptomatic outcome, such as pain relief or quality of life. Examination of a single, prospectively selected end point is most likely to yield a valid result from the study. A few additional (secondary) end points also may be designated in advance; the greater the number of end points that are examined, the greater is the likelihood that apparently significant changes in one of them will occur by chance. The least rigorous examination of trial results comes from retrospective selection of end points after viewing the data. Because this introduces a selection bias and increases the probability of a chance result, retrospective selection should be used only as the basis to generate hypotheses that then can be tested prospectively.

In some instances, therapeutic decisions must be based on trials evaluating surrogate end points—measures such as clinical signs or laboratory findings that are correlated with but do not directly measure clinical outcome. Such surrogate end points include measurements of blood pressure (for antihypertensive drugs), plasma glucose (for diabetic drugs), and levels of viral RNA in plasma (for antiretroviral drugs). The extent to which surrogate end points predict clinical outcomes varies, and two drugs with the same effect on a surrogate end point may have different effects on clinical outcome. Of greater concern, the effect of a drug on a surrogate end point may lead to erroneous conclusions about the clinical consequences of drug administration. One compelling example of the danger of reliance on surrogate end points emerged from the Cardiac Arrhythmia Suppression Trial (CAST). Based on their ability to suppress the surrogate markers of ventricular premature contractions and nonsustained ventricular tachycardia, antiarrhythmic drugs such as *encainide*, *flecainide*, and *morizizine* frequently were used in patients with ventricular ectopy after myocardial infarction (see Chapter 33). The CAST study showed that despite their ability to suppress ventricular ectopy, the drugs actually increased the frequency of sudden cardiac death (Echt *et al.*, 1991). Thus, the ultimate test of a drug's efficacy must arise from actual clinical outcomes rather than surrogate markers (Bucher *et al.*, 1999).

The *sample* of patients selected for a clinical trial may not be representative of the entire *population* of patients with that disease who may receive the drug. The patients entered into a trial usually are selected according to the severity of their disease and other characteristics (*inclusion criteria*) or are excluded because of coexisting disease, concurrent therapy, or specific features of the disease itself (*exclusion criteria*). It always is important to ascertain that the clinical characteristics of an individual patient correspond with those of patients in the trial (Feinstein, 1994). For example, the Randomized Aldactone Evaluation Study (RALES) showed that treatment with the mineralocorticoid-receptor antagonist *spironolactone* was associated with a 30% reduction in death in patients with severe congestive heart failure (Pitt *et al.*, 1999). The potential adverse effect of hyperkalemia was seen only rarely in this study, which excluded patients with serum creatinine levels of greater than 2.5 mg/dl. With the expanded use of spironolactone after the RALES results were published, numerous patients, many of whom did not meet the criteria for inclusion that minimized the risk in the RALES trial, have developed severe hyperkalemia on spironolactone (Jurlink *et al.*, 2004). Knowledge of the criteria for selecting the patients in a trial must inform the application of study results to an individual patient.

Determination of efficacy and safety is an ongoing process that usually is based on the results of more than one randomized, double-blind, controlled trial. Because the trials may not all provide the same results, and some may show an apparent effect that does not achieve statistical significance, it may be useful to aggregate the results of several similarly designed drug trials that examined the same clinical end point into an overview termed a *meta-analysis*. The larger numbers of patients and controls in such a meta-analysis can yield narrower confidence limits and strengthen the likelihood that an apparent effect is (or is not) due to the drug rather than chance. In one example, a meta-analysis of 65 randomized trials involving nearly 60,000 patients strongly supported the current use of low-dose aspirin to prevent death, myocardial infarction, and stroke in high-risk patients (Antiplatelet Trialists' Collaboration, 2002).

Observational Studies

Important but infrequent adverse drug effects may escape detection in the randomized, controlled trials that demonstrate efficacy. In controlled trials that form the basis for approval of drugs for marketing, the number of patient-years of exposure to a drug is small relative to exposure after it is marketed. Also, some adverse effects may have a long latency or may affect patients excluded from the controlled trials. Therefore, nonexperimental or observational studies are used to examine those adverse effects that only become apparent with widespread, prolonged use of the drug in the practice of medicine. For example, such observational studies identified peptic ulcers and gastritis as serious adverse effects of nonsteroidal anti-inflammatory drugs and aspirin.

The quality of information derived from observational studies varies with the design and depends highly on the selection of controls and the accuracy of the information on medication use (Ray, 2004; Sackett, 1991). Automated prescription databases provide a relatively reliable measure of drug exposure for such studies. *Cohort studies* compare the occurrence of events in users and nonusers of a drug; this is the more powerful of the observational study designs. *Case-control studies* compare drug exposure among patients with an adverse outcome with that in control patients. Because the control and treatment groups in an observational study are not selected randomly, there may be unknown differences between the groups that determine outcome independent of drug use. Because of the limitations of observational studies, their validity cannot be equated with that of randomized, controlled trials (Table 5-1). Rather, the role of observational studies is to raise questions and pose hypotheses about adverse reactions. Howev-

er, if it is not feasible to test these hypotheses in controlled clinical trials, then replicated findings from observational studies may form the basis for clinical decisions.

PATIENT-CENTERED THERAPEUTICS

Optimal treatment decisions are based on an understanding of the characteristics of the individual patient that will determine the response to the drug. Interindividual differences in drug delivery to its site(s) of action can profoundly influence therapeutic effectiveness and adverse effects. Pharmacodynamic differences in the response to a drug may result from alterations in the effect on the target organ or from differences in the body's adaptation to the target-organ response owing to disease or other drugs. Moreover, precision in diagnosis and prognosis governs the type of therapy and the therapeutic regimen, as well as the urgency and intensity of treatment. Some of the determinants of interindividual variation are indicated in Figure 5-1. Thus, therapeutic success and safety are determined by integration of evidence of efficacy and safety with knowledge of the individual factors that determine response in a particular patient.

Drug History

A thorough drug history is a key element in individualizing therapy, and information on concurrent therapy must be accessible at each encounter to guide safe and effective treatment. Documentation of current prescription drug use is a starting point in the drug history. Despite increasing use of computerized drug lists, it often is very helpful for patients to bring all current medications with them to the clinical encounter. Specific prompting is required to elicit the use of over-the-counter drugs and herbal medications, both of

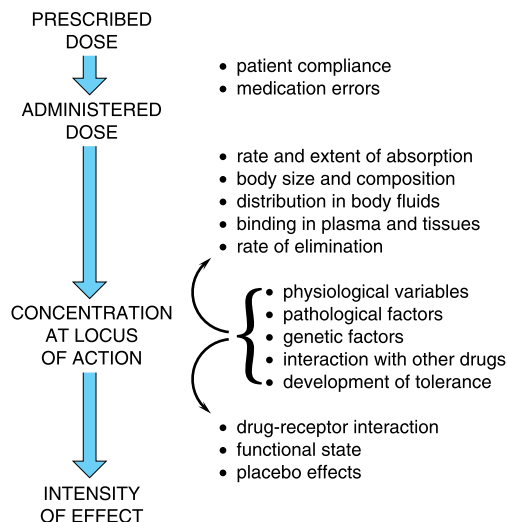

Figure 5–1. Factors that determine the relationship between prescribed drug dosage and drug effect. (Modified from Koch-Weser, 1972.)

which may affect therapeutic decisions. Information about medications that are used only sporadically (e.g., *sildenafil* for erectile dysfunction) may not be volunteered without a specific query. With cognitively impaired patients, it may be necessary to go beyond the interview to include caregivers and pharmacy records; as noted earlier, requests to examine the actual medications also can be invaluable.

Adverse reactions to drugs, allergic or otherwise, should be documented with specifics regarding severity. Full elucidation of adverse effects is aided by asking whether patients or their physicians have discontinued any medications in the past.

An accessible current drug profile and list of adverse effects are required for each patient encounter. Review of the medication list on hospital rounds and during outpatient visits is essential to maximize effectiveness and safety of treatment. With electronic medical records, the medication list can be printed for the patient to optimize communication about therapy and adherence to the regimen.

DETERMINANTS OF INTERINDIVIDUAL VARIATION IN RESPONSE TO DRUGS

Disease-Induced Alterations in Pharmacokinetics

Knowledge of the pathway of a drug's disposition is key to predicting how a disease process will alter delivery of the drug to its site of action.

Impaired Renal Clearance of Drugs. If a drug is cleared primarily by the kidney, and if adverse effects result from elevated levels of the drug, then dose modification should be considered in patients with renal dysfunction. There are many such drugs, including *vancomycin*, *aminoglycoside antibiotics*, and *digoxin*. When renal clearance of a drug is diminished, the desired pharmacological effect can be maintained either by decreasing the dose or lengthening the interval between doses. Estimation of the glomerular filtration rate (GFR) provides an approximation of the extent to which renal drug clearance is impaired; this index of renal function is applicable to assessing decreases in elimination of drugs cleared by either glomerular filtration or tubular secretion. GFR can be measured by the iothalamate clearance method. Alternatively, creatinine clearance can be used, as estimated from serum creatinine by the formula of Cockcroft and Gault:

$$\text{creatinine clearance} = \frac{(140 - \text{age}) \times \left(\frac{\text{ideal body weight in kg}}{\text{weight in kg}} \right) \times 0.85 \text{ for women}}{72 \times \text{serum creatinine (mg/dl)}}$$

Ideal body weight for men = 50 kg + 2.3 kg/in over 5 ft in height. Ideal body weight for women = 45.5 kg + 2.3 kg/in over 5 feet in height. The 0.85 multiplier for women accounts for their reduced muscle mass. The serum creatinine concentration may be a misleading indicator of renal impairment because it does not reflect GFR in states where the GFR is changing or in elderly or emaciated patients whose decreased muscle mass is associated with decreased creatinine formation.

With knowledge of the GFR, initial dosing reductions can be estimated from tables provided in the package insert or from other published tables (e.g., Aronoff, 1999). The accuracy of the estimated initial dosing regimen should be monitored by clinical assessment and by analysis of plasma drug concentration where feasible.

Drug metabolites that may accumulate with impaired renal function may be pharmacologically active or toxic. Although *meperidine* is metabolized extensively and is not dependent on renal function for elimination, its metabolite, *normeperidine*, is cleared by the kidney and accumulates when renal function is impaired. Because normeperidine has greater convulsant activity than meperidine, its high levels in renal failure probably account for the central nervous system (CNS) excitation with irritability, twitching, and seizures that can occur when multiple doses of meperidine are given to patients with impaired renal function (see Chapter 21).

Impaired Hepatic Clearance of Drugs. The effect of liver disease on the hepatic biotransformation of drugs cannot be predicted from any measure of hepatic function.

Thus, even though the metabolism of some drugs is decreased with impaired hepatic function, there is no quantitative basis for dose adjustment other than assessment of the clinical response and plasma concentration. The oral bioavailability of drugs may be increased in liver disease, and a marked increase may occur with drugs that normally have high first-pass hepatic clearance. In patients with cirrhosis, the oral availability of drugs that have high first-pass clearance (e.g., *morphine*, *meperidine*, *midazolam*, and *nifedipine*) is almost doubled. Portosystemic shunting will further reduce first-pass clearance and lead to high plasma drug levels with the potential for adverse effects.

Circulatory Insufficiency Owing to Cardiac Failure or Shock. In circulatory failure, neuroendocrine compensation can reduce renal and hepatic blood flow substantially. Accordingly, elimination of many drugs is reduced. Particularly affected are drugs with high hepatic extraction ratios, such as *lidocaine*, whose clearance is a function of hepatic blood flow; in this setting, only half the usual infusion rate of lidocaine is required to achieve therapeutic plasma levels.

Altered Drug Binding to Plasma Proteins. When a drug is highly bound to plasma proteins, its egress from the vascular compartment is limited largely to the unbound (free) drug. Thus, the therapeutic response should be related to the level of unbound drug in plasma rather than to the total drug concentration. Hypoalbuminemia owing to renal insufficiency, hepatic disease, or other causes can reduce the extent of binding of acidic and neutral drugs; in these conditions, measurement of free drug provides a more accurate guide to therapy than does analysis of total drug. Because a small change in the extent of binding produces a large change in the level of free drug, drugs for which changes in protein binding are particularly important are those that are more than 90% bound to plasma protein. *Phenytoin* is one such drug, and measurement of unbound phenytoin is used to guide dosing in patients with renal failure or other conditions that reduce protein binding (see Chapter 19).

Metabolic clearance of such highly bound drugs also is a function of the unbound fraction of drug. Thus, clearance is increased in those conditions that reduce protein binding; shorter dosing intervals therefore must be employed to maintain therapeutic plasma levels.

INTERACTIONS BETWEEN DRUGS

Marked alterations in the effects of some drugs can result from coadministration with another agent. Such interac-

tions can increase the drug effect to the level of toxicity, or they can inhibit the drug effect and deprive the patient of therapeutic benefit. Drug interactions always should be considered when unexpected responses to drugs occur. Whereas the sheer number of drug interactions defies memorization, understanding their mechanisms provides a conceptual framework for preventing them.

Drug interactions may be *pharmacokinetic* (i.e., the delivery of a drug to its site of action is altered by a second drug) or *pharmacodynamic* (i.e., the response of the drug target is modified by a second drug).

Pharmacokinetic Interactions Caused by Diminished Drug Delivery to the Site of Action

A number of mechanisms may affect drug delivery to the site of action. Impaired gastrointestinal absorption is an important consideration for drugs administered orally. For example, aluminum ions in certain antacids or ferrous ions in oral iron supplements form insoluble chelates of the *tetracycline antibiotics*, thereby preventing their absorption. The antifungal *ketoconazole* is a weak base that is only soluble at acid pH. Drugs that raise gastric pH, such as the protein pump inhibitors and histamine H₂-receptor antagonists, impair the dissolution and absorption of ketoconazole.

An especially prominent form of drug interaction involves the cytochrome P450 enzymes (CYPs). As described in detail in Chapter 3, the hepatic CYPs play a key role in the metabolism of a large number of drugs, and their expression can be induced or their activity inhibited by a diverse array of drugs. Examples of drugs that induce these enzymes include antibiotics (e.g., *rifampin*), anticonvulsants (e.g., *phenobarbital*, *phenytoin*, and *carbamazepine*), nonnucleoside reverse transcriptase inhibitors (e.g., *efavirenz* and *nevirapine*), and herbal drugs (e.g., *St. John's wort*). Although these drugs most potently induce CYP3A4, the expression of CYPs in the 1A, 2B, and 2C families also can be increased. Induction of these enzymes accelerates the metabolism of drugs that are their substrates and notably decreases oral bioavailability by increasing first-pass metabolism in the liver. The inducing drugs lower the plasma levels of drugs that are metabolized predominantly by these enzymes, including *cyclosporine*, *tacrolimus*, *warfarin*, *verapamil*, *methadone*, *dexamethasone*, *methylprednisolone*, *low-dose oral contraceptives*, and the *HIV protease inhibitors*. Loss of efficacy is the unfortunate but predictable consequence of these interactions.

Pharmacokinetic Interactions That Increase Drug Delivery to the Site of Action

Inhibition of Drug-Metabolizing Enzymes. For drugs whose clearance depends primarily on biotransformation, inhibition of a metabolizing enzyme leads to reduced clearance, prolonged half-life, and drug accumulation during maintenance therapy, sometimes with severe adverse effects. The prominent role of CYPs in drug metabolism makes them key effectors of such interactions, and knowledge of the CYP isoforms that catalyze the principal pathways of drug metabolism provides a basis for understanding and even predicting drug interactions (*see* Chapter 3).

Hepatic CYP3A isozymes catalyze the metabolism of many drugs that are subject to significant drug interactions owing to inhibition of metabolism. Drugs metabolized predominantly by CYP3A isozymes include immunosuppressants (*e.g.*, cyclosporine and tacrolimus), HMG-CoA reductase inhibitors (*e.g.*, *lovastatin*, *simvastatin*, and *atorvastatin*), HIV protease inhibitors (*e.g.*, *indinavir*, *nelfinavir*, *saquinavir*, *amprinavir*, and *ritonavir*), Ca²⁺ channel antagonists (*e.g.*, *felodipine*, *nifedipine*, *nisoldipine*, and *diltiazem*), glucocorticoids (*e.g.*, dexamethasone and *methylprednisolone*), benzodiazepines (*e.g.*, *alprazolam*, *midazolam*, and *triazolam*), and lidocaine.

The inhibition of CYP3A isoforms may vary even among structurally related members of a given drug class. For example, the antifungal azoles ketoconazole and *itraconazole* potently inhibit CYP3A enzymes, whereas the related *fluconazole* inhibits minimally except at high doses or in the setting of renal insufficiency. Similarly, certain macrolide antibiotics (*e.g.*, *erythromycin* and *clarithromycin*) potently inhibit CYP3A isoforms, but *azithromycin* does not. In one instance, the inhibition of CYP3A4 activity is turned to therapeutic advantage. The HIV protease inhibitor ritonavir inhibits CYP3A4 activity; when administered in combination with other protease inhibitors metabolized by this pathway, it increases their half-lives and permits less frequent dosing.

Drug interactions mediated by inhibition of CYP3A can be severe. Examples include nephrotoxicity induced by cyclosporine and tacrolimus and severe myopathy and rhabdomyolysis resulting from increased levels of HMG-CoA reductase inhibitors. Whenever an inhibitor of the CYP3A isoforms is administered, the clinician must be cognizant of the potential for serious interactions with drugs metabolized by CYP3A.

Drug interactions also can result from inhibition of other CYPs. *Amiodarone* and its active metabolite *desethylamiodarone* promiscuously inhibit several CYPs, including CYP2C9, the principal enzyme that eliminates the

active *S*-enantiomer of warfarin. Because many patients treated with amiodarone are also receiving warfarin (*e.g.*, subjects with atrial fibrillation), the potential exists for major bleeding complications.

Knowledge of the specific pathways of metabolism of a drug and the molecular mechanisms of enzyme induction can help to identify potential interactions; thus the pathways of drug metabolism often are determined during preclinical drug development (Yuan *et al.*, 1999; Peck, 1993). If *in vitro* studies indicate that a compound is metabolized by CYP3A4, for example, studies can focus on commonly used drugs that either inhibit (*e.g.*, ketoconazole) or induce (*e.g.*, rifampin) this enzyme. Other probes for the evaluation of potential drug interactions targeted at CYPs in human beings include midazolam or erythromycin for CYP3A4 and *dextromethorphan* for CYP2D6.

Inhibition of Drug Transport. Drug transporters are key determinants of the availability of certain drugs to their site(s) of action, and clinically significant drug interactions can result from inhibition of drug transporters (*see* Chapter 2). The best-studied drug transporter is the P-glycoprotein, which initially was defined as a factor that actively transported multiple chemotherapeutic drugs out of cancer cells, thereby rendering them resistant to drug action. P-glycoprotein is expressed on the luminal aspect of intestinal epithelial cells (where it functions to inhibit xenobiotic absorption), on the luminal surface of renal tubular cells, and on the canalicular aspect of hepatocytes; inhibition of P-glycoprotein-mediated transport at these sites results in increased plasma levels of drug at steady state. Digoxin is largely dependent on transport by P-glycoprotein for elimination, and drugs that inhibit the transporter can elevate plasma digoxin levels to the toxic range. Inhibitors of P-glycoprotein include verapamil, diltiazem, amiodarone, *quinidine*, ketoconazole, itraconazole, and erythromycin; as discussed earlier, many of these drugs also inhibit CYP3A4 (Kim *et al.*, 1999). P-glycoprotein on the capillary endothelium that forms the blood-brain barrier exports drugs from the brain, and inhibition of P-glycoprotein enhances CNS distribution of some of these drugs (*e.g.*, some HIV protease inhibitors).

Pharmacodynamic Interactions

Combinations of drugs often are employed to therapeutic advantage either because their beneficial effects are additive or synergistic or because therapeutic effects can be achieved with fewer drug-specific adverse effects by using submaximal doses of drugs in concert. As discussed

in more detail in specific chapters, combination therapy constitutes optimal treatment for many conditions, including heart failure (see Chapter 33), severe hypertension (see Chapter 32), and cancer (see Chapter 51). This section addresses pharmacodynamic interactions that produce adverse effects.

Nitroglycerin, related *nitrates*, and *nitroprusside* produce vasodilation by nitric oxide–dependent elevation of cyclic GMP in vascular smooth muscle. The pharmacologic effects of *sildenafil*, *tadalafil*, and *vardenafil* result from inhibition of the type 5 isoform of phosphodiesterase that inactivates cyclic GMP in the vasculature. Thus, coadministration of a nitric oxide donor such as nitroglycerin with a phosphodiesterase 5 inhibitor can cause profound and potentially catastrophic hypotension.

The oral anticoagulant warfarin has a narrow margin between therapeutic inhibition of clot formation and bleeding complications and is subject to several important drug interactions (see Chapter 54). Nonsteroidal anti-inflammatory drugs cause gastric and duodenal ulcers (see Chapter 36), and their concurrent administration with warfarin increases the risk of gastrointestinal bleeding almost fourfold compared with warfarin alone. By inhibiting platelet aggregation, *aspirin* increases the incidence of bleeding in warfarin-treated patients. Finally, antibiotics that alter the intestinal flora reduce the bacterial synthesis of vitamin K, thereby enhancing the effect of warfarin.

A subset of nonsteroidal antiinflammatory drugs, including *indomethacin*, *ibuprofen*, *piroxicam*, and the *cyclooxygenase-2 inhibitors*, can antagonize antihypertensive therapy, especially with regimens employing angiotensin-converting enzyme inhibitors, angiotensin-receptor antagonists, and β adrenergic receptor antagonists. The effect on arterial pressure ranges from trivial to severe. Interestingly, these cyclooxygenase inhibitors do not reverse the hypotensive effect of Ca^{2+} channel blockers. Aspirin and *sulindac*, in contrast, produce little, if any, elevation of blood pressure when used concurrently with these antihypertensive drugs.

Antiarrhythmic drugs that block potassium channels, such as *sotalol* and quinidine, can cause the polymorphic ventricular tachycardia known as *torsades de pointes* (see Chapter 34). The abnormal repolarization that leads to polymorphic ventricular tachycardia is potentiated by hypokalemia, and diuretics that produce potassium loss increase the risk of this drug-induced arrhythmia.

Age as a Determinant of Response to Drugs. Most drugs initially are evaluated in young and middle-aged adults, and data on their use in children and the elderly frequently are sparse and become available only belatedly.

At the extremes of age, individuals differ in the way that they handle drugs (pharmacokinetics) and in their response to drugs (pharmacodynamics). These differences may require substantial alteration in the dose or dosing regimen to produce the desired clinical effect in children (Kearns *et al.*, 2003) or in the very old.

Children. Drug disposition in childhood does not vary linearly with either body weight or body surface area, and there are no reliable, broadly applicable principles or formulas for converting doses of drugs used in adults to doses that are safe and effective in children. An important generality is that variability in pharmacokinetics is likely to be greatest at times of physiological change (*e.g.*, the newborn or premature baby or at puberty) such that dosing adjustment, often aided by therapeutic drug monitoring for drugs with narrow therapeutic indices, becomes critical for safe, effective therapeutics.

Most drug-metabolizing enzymes are expressed at low levels at birth, followed by an isozyme-specific postnatal induction of CYP expression. CYP2E1 and CYP2D6 appear in the first day, followed within 1 week by CYP3A4 and the CYP2C subfamily. CYP2A1 is not expressed until 1 to 3 months after birth. Some glucuronidation pathways are decreased in the newborn, and an inability of newborns to glucuronidate *chloramphenicol* was responsible for the “gray baby syndrome” characterized by vomiting, neonatal hypothermia, flaccidity, cyanosis, and cardiovascular collapse (see Chapter 46). When adjusted for body weight or surface area, hepatic drug metabolism in children after the neonatal period often exceeds that of adults. Studies using *caffeine* as a model substrate illustrate the developmental changes in CYP1A2 that occur during childhood (Figure 5–2). The mechanisms regulating such developmental changes are uncertain, and other pathways of drug metabolism probably mature with different patterns (deWildt *et al.*, 1999).

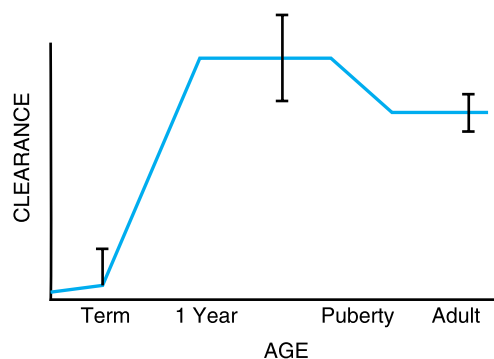

Figure 5–2. Developmental changes in CYP1A2 activity, assessed as caffeine clearance. (See Lambert *et al.*, 1986.)

Renal elimination of drugs also is reduced in the neonatal period. Neonates at term have markedly reduced GFRs (2 to 4 ml/min/1.73 m²), and prematurity reduces renal function even further. As a result, neonatal dosing regimens for a number of drugs (e.g., aminoglycosides) must be reduced to avoid toxic drug accumulation. GFR (corrected for body surface area) increases progressively to adult levels by 8 to 12 months of age.

Based on these nonlinear changes in drug disposition that differ depending on the mode of elimination, dosing guidelines for children—where they exist—are drug- and age-specific, as detailed in drug labeling and in handbooks (Taketomo *et al.*, 2000). The need for attention to dosing guidelines is not eliminated by topical drug administration; severe hypoadrenal crisis in children has resulted from the use of adult doses of inhaled glucocorticoids.

Drug pharmacodynamics in children also may differ from those in adults. *Antihistamines* and *barbiturates* that generally sedate adults may cause children to become “hyperactive.” The enhanced sensitivity to the sedating effects of *propofol* in children has led to the administration of excessive doses that produced a syndrome of myocardial failure, metabolic acidosis, and multiorgan failure. Unique features of childhood development also may provide special vulnerabilities to drug toxicity; for example, tetracyclines can permanently stain developing teeth, and glucocorticoids can attenuate linear growth of bones.

The Elderly. As adults age, gradual changes in pharmacokinetics and pharmacodynamics increase the interindividual variability of doses required for a given effect. Pharmacokinetic changes result from changes in body composition and the function of drug-eliminating organs. The reduction in lean body mass, serum albumin, and total-body water, coupled with the increase in percentage of body fat, alters distribution of drugs in a manner dependent on their lipid solubility and protein binding. The clearance of many drugs is reduced in the elderly. Renal function declines at a variable rate to about 50% of that in young adults. Hepatic blood flow and drug metabolism also are reduced in the elderly, but the variability of these changes is great. In general, the activities of hepatic CYPs are reduced, but conjugation mechanisms are relatively preserved. Frequently, the elimination half-lives of drugs are increased as a consequence of larger apparent volumes of distribution of lipid-soluble drugs and/or reductions in the renal or metabolic clearance.

Changes in pharmacodynamics also are important factors in treating the elderly. Drugs that depress the CNS produce increased effects at any given plasma concentration. Even if the dosage is decreased appropriately to

account for age-related pharmacokinetic changes, physiological changes and loss of homeostatic resilience can result in increased sensitivity to unwanted effects of drugs (e.g., hypotension from psychotropic medications and hemorrhage from anticoagulants).

The proportion of the elderly and very old in the population of developed nations is increasing rapidly. These individuals have more illnesses than younger people and consume a disproportionate share of prescription and over-the-counter drugs. These factors, combined with age-related changes in pharmacokinetics and pharmacodynamics, make the elderly a population in whom drug use is especially likely to be marred by serious adverse effects and drug interactions. They therefore should receive drugs only when absolutely necessary for well-defined indications and at the lowest effective doses. Prospectively defined end points, appropriate monitoring of drug levels, and frequent reviews of the patient’s drug history, with discontinuation of those drugs that did not achieve the desired end point or are no longer required, would greatly improve the health of the elderly population. On the other hand, *appropriate* therapy should not be withheld because of these concerns; outcomes data with several drug interventions for chronic conditions (e.g., hypertension and dyslipidemia) have proven that the elderly benefit at least as much as, and often more than, the young (LaRosa *et al.*, 1999). Furthermore, several chronic diseases that predominantly affect the elderly, such as osteoporosis and prostatic hypertrophy, can be halted or reduced by appropriate drug therapy.

GENETIC DETERMINANTS OF THE RESPONSE TO DRUGS

Allelic variations in the genes encoding drug-metabolizing enzymes, drug transporters, and receptors can be responsible for striking differences in pharmacological activity. A variation in DNA sequence that occurs with a frequency of more than 1% is termed a *polymorphism*. Polymorphisms in the enzymes responsible for drug disposition can produce major alterations in the delivery of a drug or its active metabolite to the pharmacologic target.

Mercaptopurine, an antileukemia drug, also is the active metabolite of the immunosuppressant *azathioprine*. Mercaptopurine is inactivated by thiopurine *S*-methyltransferase (TPMT). Genetic polymorphisms in this enzyme lead to differences in inactivation of mercaptopurine and to vast interindividual differences in toxic and therapeutic responses. Homozygotes for alleles encoding inactive

TPMT (0.3% to 1% of patients) experience severe pancytopenia on the “usual” dose of mercaptopurine or azathiopurine, and even heterozygotes experience more bone marrow suppression. Importantly, the occurrence of bone marrow toxicity in heterozygotes has resulted in the selection of a standard dose of the drugs that probably undertreats patients homozygous for TPMT alleles with full catalytic activity. The genotype for TPMT polymorphisms is highly concordant with phenotype, providing a basis for genotyping patients to direct safer and more effective therapy with these drugs (see Chapter 4).

The proton pump inhibitor *omeprazole* is metabolized almost entirely by CYP2C19, and polymorphisms of this isoform determine the rate of omeprazole elimination. After the recommended drug doses, patients homozygous for the polymorphism that confers the highest rate of elimination (*extensive metabolizers*) have drug levels that are too low to inhibit gastric acid secretion, whereas those homozygous for the poor metabolizer polymorphism respond with suppression of acid secretion. Predictably, the efficacy of omeprazole in eradication of *Helicobacter pylori* infection is markedly reduced in the extensive metabolizer phenotype.

Activity of the CYP2D6 isoform is polymorphically distributed in the population, and 8% to 10% of Caucasians are deficient in the enzyme (*poor metabolizers*). CYP2D6 is the principal pathway for the metabolism of many drugs, including selective serotonin-reuptake inhibitors (e.g., *fluoxetine* and *paroxetine*), tricyclic antidepressants (e.g., *nortriptyline*, *desipramine*, *imipramine*, and *clomipramine*), and certain opiates (e.g., *codeine* and *dextromethorphan*). Because the analgesic effect of codeine depends on its metabolism to morphine by CYP2D6, patients who are poor metabolizers respond poorly to the analgesic effect of codeine. At the other extreme, patients who have a gene duplication of CYP2D6 exhibit an exaggerated response to codeine. Poor metabolizers and extensive metabolizers differ substantially in their therapeutic and adverse responses to many of the CYP2D6 substrates; as a consequence, there is an active attempt in drug development programs to avoid candidate drug molecules that depend on CYP2D6 for metabolism.

CYP2C9 catalyzes the major pathway of metabolism of warfarin and phenytoin. Certain allelic variants of CYP2C9 are devoid of catalytic function, and the required doses of warfarin and phenytoin are much reduced in these patients. Initiation of therapy with the usual dose of warfarin in such CYP2C9-deficient patients puts them at risk of bleeding complications.

Genetic polymorphisms also influence the response of the target organs to drugs. The antiarrhythmic drugs that

act by prolonging repolarization (e.g., quinidine and sotalol) can prolong repolarization markedly in some patients and induce polymorphic ventricular tachycardia. Allelic variants of genes encoding ion channels also are associated with prolonged repolarization, and patients with these polymorphisms are highly susceptible to arrhythmias when treated with these drugs (see Chapter 34).

Altered drug response has been associated with allelic variants of genes encoding the molecular targets of drugs or of key proteins in the pathophysiologic system affected by the drug. For example, the effect of β -adrenergic receptor antagonists on blood pressure has been shown to be associated with β_1 -receptor polymorphisms, and the action of β adrenergic receptor agonists in asthma has been related to variants in the β_2 adrenergic receptor gene. With the availability of the human genomic database and the identification of multiple single-nucleotide polymorphisms, associations between drug effect and genetic polymorphisms will be reported increasingly. The initial reports undoubtedly will yield a number of false-positive associations and will require confirmation in prospective studies. Even if an association between a polymorphism and drug response is confirmed, it may reflect a haplotype effect or linkage of the polymorphism with another genetic determinant.

Some general principles of pharmacogenetics and additional examples are presented in Chapter 4.

THE PHARMACODYNAMIC CHARACTERISTICS OF A DRUG THAT DETERMINE ITS USE IN THERAPY

When drugs are administered to patients, there is no single characteristic relationship between the drug concentration in plasma and the measured effect; the concentration–effect curve may be concave upward, concave downward, linear, sigmoid, or an inverted-U shape. Moreover, the concentration–effect relationship may be distorted if the response being measured is a composite of several effects, such as the change in blood pressure produced by a combination of cardiac, vascular, and reflex effects. However, such a composite concentration–effect curve often can be resolved into simpler curves for each of its components. These simplified concentration–effect relationships, regardless of their exact shape, can be viewed as having four characteristic variables: *potency*, *maximal efficacy*, *slope*, and *individual variation*. These are illustrated in Figure 5–3 for the common sigmoidal log dose–effect curve.

Figure 5–3. The log concentration–effect relationship. Representative log concentration–effect curve illustrating its four characterizing variables. Here, the effect is measured as a function of increasing drug concentration in the plasma. Similar relationships also can be plotted as a function of the dose of drug administered. These plots are referred to as dose–effect curves. (See text for further discussion.)

Potency. The location of the concentration–effect curve along the *concentration axis* is an expression of the potency of a drug. Although often related to the dose of a drug required to produce an effect, potency is more properly related to the concentration of the drug in plasma to approximate more closely the situation in isolated systems *in vitro* and to avoid the complicating factors of pharmacokinetic variables. Although potency obviously affects drug dosage, potency *per se* is relatively unimportant in the clinical use of drugs, provided that the required dose can be given conveniently and that there is no toxicity related to the chemical structure of the drug rather than to its mechanism. There is no justification for the view that more potent drugs are superior therapeutic agents. However, if the drug is to be administered by transdermal absorption, a highly potent drug is required because the capacity of the skin to absorb drugs is limited (see Chapter 62).

Maximal Efficacy. The maximal effect that can be produced by a drug is its *maximal*, or *clinical*, *efficacy* (which is related to, but not precisely the same as, the term *efficacy* as discussed in Chapter 1). Maximal efficacy is determined principally by the properties of the drug and its receptor–effector system and is reflected in the plateau of the concentration–effect curve. In clinical use, however, undesired effects may limit a drug’s dosage such that its true maximal efficacy may not be achievable. The maximal efficacy of a drug is clearly a major characteristic—of much greater clinical importance than its potency. Furthermore, the two properties are not related and should not be confused. For instance, although some thiazide diuretics have similar or

greater potency than the loop diuretic *furosemide*, the maximal efficacy of *furosemide* is considerably greater.

Slope. The *slope* of the concentration–effect curve reflects the mechanism of action of a drug, including the shape of the curve that describes drug binding to its receptor (see Chapter 1). The steepness of the curve dictates the range of doses that are useful for achieving a clinical effect. Aside from this fact, the slope of the concentration–effect curve has more theoretical than practical usefulness.

Pharmacodynamic Variability

Individuals vary in the magnitude of their response to the same concentration of a single drug or to similar drugs when the appropriate correction has been made for differences in potency, maximal efficacy, and slope. In fact, a single individual may not always respond in the same way to the same concentration of drug. A concentration–effect curve applies only to a single individual at one time or to an average individual. The intersecting brackets in Figure 5–3 indicate that an effect of varying intensity will occur in different individuals at a specified concentration of a drug or that a range of concentrations is required to produce an effect of specified intensity in all of the patients.

Attempts have been made to define and measure individual “sensitivity” to drugs in the clinical setting, and progress has been made in understanding some of the determinants of sensitivity to drugs that act at specific receptors. For example, responsiveness to β adrenergic receptor agonists may change because of disease (e.g., thyrotoxicosis or heart failure) or because of previous administration of either β adrenergic receptor agonists or antagonists that can cause changes in the concentration of the β adrenergic receptor and/or coupling of the receptor to its effector systems (Iaccarino *et al.*, 1999) (see Chapter 10). Receptors are not static components of the cell; rather, they are in a dynamic state, and their concentration and function may be up-regulated and down-regulated by endogenous and exogenous factors.

Data on the association of drug levels with efficacy and toxicity must be interpreted in the context of the pharmacodynamic variability in the population. The plasma concentration of phenobarbital required to control seizures, for example, is higher in children than in adults. Variability in pharmacodynamic response can result from any of the factors responsible for altering drug effect that include genetics, age, disease, and other drugs. The variability in pharmacodynamic response in the population may be analyzed by constructing a quantal concentration–effect curve (Figure 5–4A). The concentration of a drug that produces a specified effect in a single patient is called

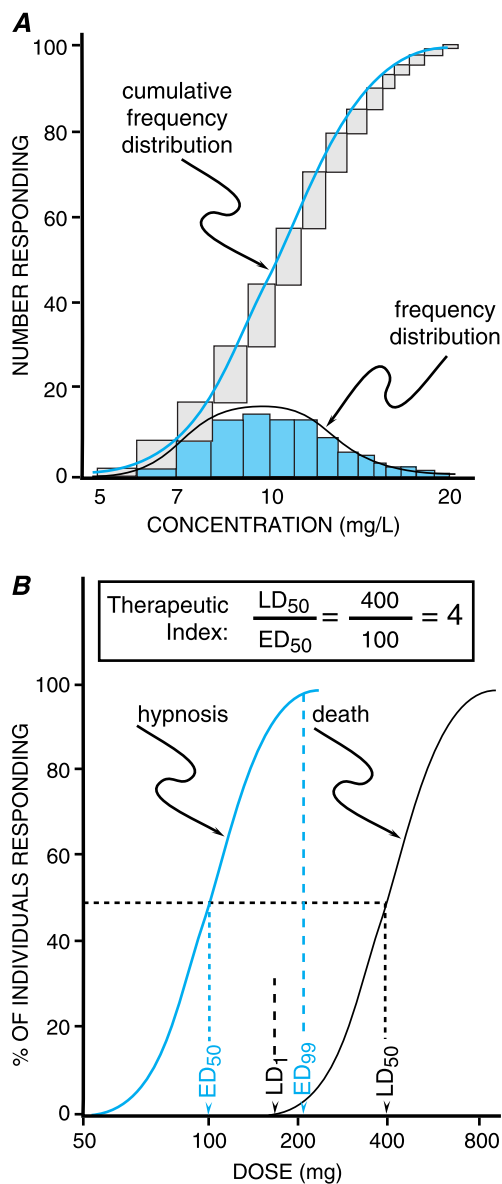

Figure 5-4. Frequency distribution curves and quantal concentration-effect and dose-effect curves. **A.** Frequency distribution curves. An experiment was performed on 100 subjects, and the effective plasma concentration that produced a quantal response was determined for each individual. The number of subjects who required each dose is plotted, giving a log-normal frequency distribution (colored bars). The gray bars demonstrate that the normal frequency distribution, when summated, yields the cumulative frequency distribution—a sigmoidal curve that is a quantal concentration-effect curve. **B.** Quantal dose-effect curves. Animals were injected with varying doses of sedative-hypnotic, and the responses were determined and plotted. The calculation of the therapeutic index, the ratio of the LD₅₀ to the ED₅₀, is an indication of how selective a drug is in producing its desired effects relative to its toxicity. (See text for additional explanation.)

the *individual effective concentration*. This is a quantal response because the defined effect is either present or absent. Individual effective concentrations usually are log normally distributed, which means that a normal variation curve is the result of plotting the logarithms of the concentration against the frequency of patients achieving the defined effect. A cumulative frequency distribution of individuals achieving the defined effect as a function of drug concentration is the concentration-percent curve or the quantal concentration-effect curve. The slope of the concentration-percent curve is an expression of the pharmacodynamic variability in the population.

The Therapeutic Index

The dose of a drug required to produce a specified effect in 50% of the population is the *median effective dose*, abbreviated as the ED₅₀ (Figure 5-4B). In preclinical studies of drugs, the *median lethal dose*, as determined in experimental animals, is abbreviated as LD₅₀. The ratio of the LD₅₀ to the ED₅₀ is an indication of the *therapeutic index*, which is a statement of how selective the drug is in producing its desired *versus* its adverse effects. In clinical studies, the dose, or preferably the concentration, of a drug required to produce toxic effects can be compared with the concentration required for the therapeutic effects in the population to evaluate the *clinical therapeutic index*. However, since pharmacodynamic variation in the population may be marked, the concentration or dose of drug required to produce a therapeutic effect in most of the population usually will overlap the concentration required to produce toxicity in some of the population, even though the drug's therapeutic index in an individual patient may be large. Also, the concentration-percent curves for efficacy and toxicity need not be parallel, adding yet another complexity to determination of the therapeutic index in patients. Finally, no drug produces a single effect, and depending on the effect being measured, the therapeutic index for a drug will vary. For example, much less codeine is required for cough suppression than for control of pain in 50% of the population, and thus the margin of safety, selectivity, or therapeutic index of codeine are much greater as an antitussive than as an analgesic.

ADVERSE DRUG REACTIONS AND DRUG TOXICITY

Any drug, no matter how trivial its therapeutic actions, has the potential to do harm. Adverse reactions are a cost

of modern medical therapy. Although the mandate of the Food and Drug Administration (FDA) is to ensure that drugs are safe and effective, these terms are relative. The anticipated benefit from any therapeutic decision must be balanced by the potential risks.

The magnitude of the problem of adverse reactions to marketed drugs is difficult to quantify. It has been estimated that 3% to 5% of all hospitalizations can be attributed to adverse drug reactions, resulting in 300,000 hospitalizations annually in the United States. Once hospitalized, patients have about a 30% chance of an untoward event related to drug therapy, and the risk attributable to each course of drug therapy is about 5%. The chance of a life-threatening drug reaction is about 3% per patient in the hospital and about 0.4% per each course of therapy (Jick, 1984). *Adverse reactions to drugs are the most common cause of iatrogenic disease* (Leape *et al.*, 1991).

Mechanism-based adverse drug reactions are extensions of the principal pharmacological action of the drug. These would be expected to occur with all members of a class of drugs having the same mechanism of action. Hyperkalemia, for example, is a mechanism-based adverse effect of all mineralocorticoid-receptor antagonists. Adverse effects that are not a consequence of the drug's primary mechanism of action are considered to be *off-target reactions* and are a consequence of the particular drug molecule. The hepatotoxicity of *acetaminophen* is an off-target toxicity.

When an adverse effect is encountered infrequently, it may be referred to as *idiosyncratic*, meaning that it results from an interaction of the drug with unique host factors and does not occur in the population at large. Idiosyncratic adverse effects may be mechanism-based (*e.g.*, angioedema on angiotensin-converting enzyme inhibitors) or off-target reactions (*e.g.*, anaphylaxis to *penicillin*). Investigations of idiosyncratic reactions often have identified a genetic or environmental basis for the unique host factors leading to the unusual effects.

THERAPEUTIC DRUG MONITORING

Given the multiple factors that alter drug disposition, measurement of the concentration in body fluids can assist in individualizing therapy with selected drugs. Determination of the concentration of a drug in blood, serum, or plasma is particularly useful when well-defined criteria are fulfilled:

1. A demonstrated relationship exists between the concentration of drug in plasma and the desired therapeutic effect or the toxic effect to be avoided. The range of plasma levels between that required for efficacy and that at which toxicity occurs for a given individual is designated the *therapeutic window* (Figure 5–5).
2. There is sufficient variability in plasma level that the level cannot be predicted from the dose alone.
3. The drug produces effects, intended or unwanted, that are difficult to monitor.
4. The concentration required to produce the therapeutic effect is close to the level that causes toxicity (*i.e.*, there is a low therapeutic index).

A clear demonstration of the relation of drug concentration to efficacy or toxicity is not achievable for many drugs; even when such a relationship can be determined, it usually predicts a probability of efficacy or toxicity. In trials of antidepressant drugs, for example, such a high proportion of patients respond to placebo that it is difficult to determine the plasma level associated with efficacy. The end points defining drug effect may not prove to be relevant. A digoxin level of 2 ng/ml initially was selected as the threshold of toxicity based on the surrogate marker of electrocardiographic evidence of ventricular arrhythmias at higher concentrations. A subsequent retrospective examination of the data from a clinical trial of the effect of digoxin *versus* placebo on clinical outcome in patients with heart failure revealed that patients with digoxin levels exceeding 1.1 ng/ml had a higher risk of cardiac mortality. Like most data that link plasma levels with effect, this was not a randomized, controlled evaluation of the consequences of drug level but rather a retrospective examination of trial data, and an alternative explanation is that impaired clearance of digoxin *via* P-glycoprotein is an indicator of a poor prognosis in cardiac failure. Nonetheless, these data provide evidence based on clinical outcome that will guide the adjustment of digoxin dosing until controlled data become available.

There is a quantal concentration–response curve for efficacy and adverse effects (Figure 5–5), and for many drugs, the concentration that achieves efficacy in all the population may produce adverse effects in some individuals. Thus, a *population therapeutic window* expresses a range of concentrations in which the likelihood of efficacy is high and the probability of adverse effects is low. It is not a guarantee of either efficacy or safety. *Therefore, use of the population therapeutic window to adjust dosage of a drug should be complemented by monitoring appropriate clinical and surrogate markers for drug effect.*

Figure 5-5. The relation of the therapeutic window of drug concentrations to the therapeutic and adverse effects in the population. Ordinate is linear; abscissa is logarithmic.

Intravenous Administration of Drugs

Rapid intravenous administration produces an abrupt rise in the concentration of drug in the plasma compartment (Figure 5-6). The concentration then falls rapidly as the drug distributes to the extravascular compartments, after which the plasma and extravascular compartments are in equilibrium during the phase of drug elimination. By contrast, when the same dose is infused more slowly (*e.g.*, over 1 hour), as illustrated in Figure 5-6, distribution takes place concurrently with delivery of drug into the plasma compartment, and concentrations of drug in plasma do not rise much above the level achieved at equilibrium. Thus the slower intravenous administration never produces the high plasma concentration that follows the intravenous bolus. The shaded area in Figure 5-6 indicates the excess exposure to drug in the plasma compartment during the distribution phase after intravenous bolus compared with the peak level after the slower infusion. The excessive levels after intravenous bolus could yield either therapeutic advantage or a catastrophic outcome depending on the drug and the target organs that are immediately affected by the concentration of drug in plasma.

If the drug in the plasma compartment is immediately available to an organ to which the higher levels are toxic, then an adverse outcome rapidly ensues. Thus bolus or even very rapid intravenous administration of drugs such as *procainamide*, *phenytoin*, or *potassium* can produce cardiovascular collapse. However, if the same intravenous doses were given slowly, the continuous distribution of the infused drug would prevent the excessively high plasma levels and would be safe. Thus, the rate of intravenous

Figure 5-6. High concentrations of drug in the plasma after rapid (bolus) intravenous administration. The plasma levels achieved after intravenous administration of procainamide (500 mg) as a rapid bolus compared with an infusion over 1 hour. The shaded area depicts the excess exposure to the drug in the plasma compartment when a rapid bolus instead of an infusion is administered. Scale on ordinate is logarithmic.

administration is of crucial importance for drugs that could produce toxicity from high plasma levels.

By contrast, some sedative drugs are distributed rapidly from plasma to the brain, and relatively rapid intravenous administration will produce prompt sedation as the brain extracts the drug from plasma. In this case, the high concentration of drug in plasma during the distribution phase after rapid intravenous administration is therapeutically advantageous for use in anesthesiology.

When considering administration of a drug by intravenous bolus, a full understanding of the safety of this mode of administration is required.

THE DYNAMIC INFORMATION BASE

With the development of new drugs, the accrual of new information on marketed agents, the findings emerging from clinical trials, ongoing regulatory decisions, and the updated guidelines for disease management, the information base available to guide drug therapy is in a state of constant and brisk evolution. Among the available sources are textbooks of pharmacology and therapeutics, medical journals, published guidelines for treatment of spe-

cific diseases, analytical evaluations of drugs, drug compendia, professional seminars and meetings, and advertising. Developing a strategy to extract objective and unbiased data is required for the practice of rational therapeutics. As is the case with all continuing medical education, patient-centered acquisition of the relevant information is a centerpiece of such a strategy. This requires access to the information in the practice setting and increasingly is facilitated by electronic availability of information resources. Facile online access to the primary medical literature that forms the basis for therapeutic decisions is available *via* PubMed, a search and retrieval system of the National Center for Biotechnology Information (www.ncbi.nlm.nih.gov/entrez/query.fcgi).

Depending on their aim and scope, textbooks of pharmacology may provide, in varying proportions, basic pharmacological principles, critical appraisal of useful categories of therapeutic agents, and detailed descriptions of individual drugs or prototypes that serve as standards of reference for assessing new drugs. In addition, pharmacodynamics and pathophysiology are correlated. Therapeutics is considered in virtually all textbooks of medicine, but often superficially.

A source of information often used by physicians is the *Physicians' Desk Reference* (PDR), available in printed form and online (www.pdr.net). The brand-name manufacturers whose products appear support this book. No comparative data on efficacy, safety, or cost are included. The information is identical to that contained in drug package inserts, which are largely based on the results of phase 3 testing; its value includes designation of the FDA-approved indications for use of a drug and summaries of pharmacokinetics, contraindications, adverse reactions, and recommended doses; some of this information is not available in the scientific literature. Many commonly used drugs that are no longer patent-protected are not covered by the PDR.

Several unbiased sources of information on the clinical uses of drugs provide balanced and comparative data. All recognize that the clinician's legitimate use of a drug in a particular patient is not limited by FDA-approved labeling in the package insert. The *Medical Letter* (www.medletter.com) provides objective summaries in a biweekly newsletter of scientific reports and consultants' evaluations of the safety, efficacy, and rationale for use of drugs. The "Drug Therapy" section of the *New England Journal of Medicine* provides timely evaluations of specific drugs and areas of therapeutics. The *United States Pharmacopeia Dispensing Information* (USPDI) comes in two volumes. One, *Drug Information for the Health Care Professional*, consists of drug monographs that contain clinically

significant information aimed at minimizing the risks and enhancing the benefits of drugs. Monographs are developed by USP staff and are reviewed by advisory panels and other reviewers. The *Advice for the Patient* volume is intended to reinforce, in lay language, the oral consultation with the physician and may be provided to the patient in written form. *Drug Facts and Comparisons* also is organized by pharmacological classes and is updated monthly (online at www.factsandcomparisons.com). Information in monographs is presented in a standard format and incorporates FDA-approved information, which is supplemented with current data obtained from the biomedical literature. A useful feature is the comprehensive list of preparations with a "Cost Index," an index of the average wholesale price for equivalent quantities of similar or identical drugs. Other online resources that can bring data to the practice setting include *Epocrates* (www2.epocrates.com) and *UpToDate* (www.uptodateonline.com).

Particularly helpful in obtaining a comprehensive overview of therapy for specific diseases are the guidelines published by a number of professional organizations. These can be accessed by judicious use of a search engine; for example, a search for *heart failure guidelines* on Google will yield the Web address for the American College of Cardiology/American Heart Association Guidelines for the Evaluation and Management of Chronic Heart Failure in the Adult.

Industry promotion—in the form of direct-mail brochures, journal advertising, displays, professional courtesies, or the detail person or pharmaceutical representative—is intended to be persuasive rather than educational. The pharmaceutical industry cannot, should not, and indeed does not purport to be responsible for the education of physicians in the use of drugs.

More than 1500 medical journals are published regularly in the United States. However, of the two to three dozen medical publications with circulations in excess of 70,000 copies, the great majority are sent to physicians free of charge and paid for by the industry. In addition, special supplements of some peer-reviewed journals are entirely supported by a single drug manufacturer whose product is featured prominently and described favorably. Objective journals that are not supported by drug manufacturers include *Clinical Pharmacology and Therapeutics*, which is devoted to original articles that evaluate the actions and effects of drugs in human beings, and *Drugs*, which publishes timely reviews of individual drugs and drug classes. The *New England Journal of Medicine*, *Annals of Internal Medicine*, *Journal of the American Medical Association*, *Archives of Internal Medicine*, *British Medical Journal*,

Lancet, and *Postgraduate Medicine* offer timely therapeutic reports and reviews.

DRUG NOMENCLATURE

The existence of many names for each drug, even when the names are reduced to a minimum, has led to a lamentable and confusing situation in drug nomenclature. In addition to its formal *chemical* name, a new drug is usually assigned a *code* name by the pharmaceutical manufacturer. If the drug appears promising and the manufacturer wishes to place it on the market, a *U.S. adopted name* (USAN) is selected by the USAN Council, which is jointly sponsored by the American Medical Association, the American Pharmaceutical Association, and the United States Pharmacopeial Convention, Inc. This *nonproprietary* name often is referred to as the *generic name*. If the drug is eventually admitted to the *United States Pharmacopeia* (see below), the USAN becomes the *official name*. However, the nonproprietary and official names of an older drug may differ. Subsequently, the drug also will be assigned a *proprietary name*, or *trade-mark*, by the manufacturer. If more than one company markets the drug, then it may have several proprietary names. If mixtures of the drug with other agents are marketed, each such mixture also may have a separate proprietary name.

There is increasing worldwide adoption of the same *nonproprietary name* for each therapeutic substance. For newer drugs, the USAN is usually adopted for the nonproprietary name in other countries, but this is not true for older drugs. International agreement on drug names is mediated through the World Health Organization and the pertinent health agencies of the cooperating countries.

One area of continued confusion and ambiguity is the designation of the stereochemical composition in the name of a drug. The nonproprietary names usually give no indication of the drug's stereochemistry except for a few drugs such as *levodopa* and *dextroamphetamine*. Even the chemical names cited by the USAN Council often are ambiguous. Physicians and other medical scientists frequently are ignorant about drug stereoisomerism and are likely to remain so until the system of nonproprietary nomenclature incorporates stereoisomeric information (Gal, 1988). This issue becomes especially important when a drug's different diastereomers produce different pharmacologic effects, as is the case with *labetalol*, for instance (see Chapters 10 and 32).

The nonproprietary or official name of a drug should be used whenever possible, and such a practice has been adopted in this textbook. The use of the nonproprietary

name is clearly less confusing when the drug is available under multiple proprietary names and when the nonproprietary name more readily identifies the drug with its pharmacological class. The facile argument for the proprietary name is that it is frequently more easily pronounced and remembered as a result of advertising. *For purposes of identification, representative proprietary names, designated by SMALLCAP TYPE, appear throughout the text and in the index.* Not all proprietary names for drugs are included because the number of proprietary names for a single drug may be large and because proprietary names differ from country to country.

The Drug Price Competition and Patent Term Restoration Act of 1984 allows more generic versions of brand-name drugs to be approved for marketing. When the physician prescribes drugs, the question arises as to whether the nonproprietary name or a proprietary name should be employed. A pharmacist may substitute a preparation that is equivalent unless the physician indicates "no substitution" or specifies the manufacturer on the prescription. In view of the preceding discussion on the individualization of drug therapy, it is understandable why a physician who has carefully adjusted the dose of a drug to a patient's individual requirements for chronic therapy may be reluctant to surrender control over the source of the drug that the patient receives (Burns, 1999). In the past, there was concern that prescribing by nonproprietary name could result in the patient's receiving a preparation of inferior quality or uncertain bioavailability; indeed, such therapeutic failures owing to decreased bioavailability have been reported (Hendeles *et al.*, 1993). To address this issue, the FDA has established standards for bioavailability and compiled information about the interchangeability of drug products, which are published annually (*Approved Drug Products with Therapeutic Equivalence Evaluations*). Because of potential cost savings to the individual patient and simplification of communication about drugs, nonproprietary names should be used when prescribing except for drugs with a low therapeutic index and known differences in bioavailability among marketed products (Hendeles *et al.*, 1993).

DRUG DEVELOPMENT AND ITS REGULATION

Drug Regulation

The history of drug regulation in the United States reflects the growing involvement of governments in most coun-

tries to ensure some degree of efficacy and safety in marketed medicinal agents. The first legislation, the Federal Food and Drug Act of 1906, was concerned with the interstate transport of adulterated or misbranded foods and drugs. There were no obligations to establish drug efficacy and safety. This act was amended in 1938, after the deaths of 105 children that resulted from the marketing of a solution of *sulfanilamide* in diethylene glycol, an excellent but highly toxic solvent. The amended act, the enforcement of which was entrusted to the FDA, was concerned primarily with the truthful labeling and safety of drugs. Toxicity studies, as well as approval of a new drug application (NDA), were required before a drug could be promoted and distributed. However, no proof of efficacy was required, and extravagant claims for therapeutic indications were made commonly (Wax, 1995).

In this relatively relaxed atmosphere, research in basic and clinical pharmacology burgeoned in industrial and academic laboratories. The result was a flow of new drugs, called “wonder drugs” by the lay press. Because efficacy was not rigorously defined, a number of therapeutic claims could not be supported by data. The risk-to-benefit ratio was seldom mentioned, but it emerged in dramatic fashion early in the 1960s. At that time, *thalidomide*, a hypnotic with no obvious advantage over other drugs in its class, was introduced in Europe. After a short period, it became apparent that the incidence of a relatively rare birth defect, phocomelia, was increasing. It soon reached epidemic proportions, and retrospective epidemiological research firmly established the causative agent to be thalidomide taken early in the course of pregnancy. The reaction to the dramatic demonstration of the teratogenicity of a needless drug was worldwide. In the United States, it resulted in the Harris-Kefauver Amendments to the Food, Drug, and Cosmetic Act in 1962.

The Harris-Kefauver Amendments require sufficient pharmacological and toxicological research in animals before a drug can be tested in human beings. The data from such studies must be submitted to the FDA in the form of an application for an investigational new drug (IND) before clinical studies can begin. Three phases of clinical testing (*see* below) have evolved to provide the data that are used to support an NDA. Proof of efficacy is required, as is documentation of relative safety in terms of the risk-to-benefit ratio for the disease entity to be treated.

To demonstrate efficacy, “adequate and well-controlled investigations” must be performed. This generally has been interpreted to mean two replicate clinical trials that are usually, but not always, randomized, double-blind, and placebo-controlled. Safety is demonstrated by having a sufficiently large database of patients/subjects who have received the drug at the time of filing an NDA with the

FDA for approval. As a result of these requirements, the number of patients on the drug, the number of studies, the development cost, and the time required for the clinical studies to complete the NDA increased. The regulatory review time also increased as a result of the mass and complexity of the data so that by 1990 the average review time was approaching 3 years. This increased the inherent tension that exists between the FDA, which is motivated to protect the public health, and the drug developers, who are motivated to market effective and profitable drugs. Competing pressures also exist in the community, where medical practitioners and patient activist groups have criticized the FDA for delaying approval, whereas some “watchdog” groups criticize the FDA for allowing drugs on the market that occasionally cause unexpected problems after they are marketed. The FDA has the difficult task of balancing the requirement that drugs be safe and effective and yet allowing useful medications to be made available in a timely manner.

Beginning in the late 1980s with pressure from AIDS activists, the FDA undertook a number of initiatives that have had profound effects in streamlining the process of regulatory approval. These initiatives have all but eliminated the concern about the “drug lag,” where drugs were available in other countries significantly sooner than in the United States (Kessler *et al.*, 1996). First, the FDA initiated new “treatment” IND regulations that allow patients with life-threatening diseases for which there is no satisfactory alternative treatment to receive drugs for therapy prior to general marketing if there is limited evidence of drug efficacy without unreasonable toxicity (Figure 5–5). Second, the agency has established expedited reviews for drugs used to treat life-threatening diseases. Congress has enacted the Prescription Drug User Fee Act, whereby the FDA collects a fee from drug manufacturers that is to be used to help fund the personnel required to speed the review process (Shulman and Kaitin, 1996). Finally, the FDA is becoming involved more actively in the drug development process in order to facilitate the approval of drugs. A priority review system has been established for drugs in new therapeutic classes and drugs for the treatment of life-threatening or debilitating diseases. By working with the pharmaceutical industry throughout the period of clinical drug development, the FDA attempts to reduce the time from submission of an IND application to approval of an NDA. This streamlining process is accomplished by the interactive design of well-planned, focused clinical studies using validated surrogate markers or clinical end points other than survival or irreversible morbidity. Sufficient data then will be available earlier in the development process to allow a risk-benefit analysis and a possible decision for approval. In some cases, this system may reduce or obviate the need for phase 3 testing prior to approval. Coupled with this expedited development process is the requirement, when appropriate, for restricted distribution to certain specialists or facilities and for postmarketing studies to answer remaining issues of risks, benefits, and optimal uses of the drug. If postmarketing studies are inadequate or demonstrate lack of safety or clinical benefit, approval for the new drug may be withdrawn. In 1997, these changes were codified in the FDA Modernization Act (Suydam and Elder, 1999). As a result of these initiatives, the review time at the FDA has been reduced dramatically to a period of less than 1 year, with an ultimate goal of 10 months. Details of this act, which includes a variety of other initiatives, such as those discussed earlier for pediatric drug development, are available on the Internet at www.fda.gov/opacom/7modact.html. These new initiatives by the FDA are based on the assumption that society is willing to accept unknown risks from drugs used to treat life-threatening or debilitating diseases. Some worry that such shortcuts

in the drug approval process will result in the release of drugs without sufficient information to determine their utility and proper use. A seemingly contradictory directive to the FDA also is contained in the Food, Drug, and Cosmetic Act: The FDA cannot interfere with the practice of medicine. Thus, once the efficacy of a new agent has been proven in the context of acceptable toxicity, the drug can be marketed. The physician then is allowed to determine its most appropriate use. Physicians must realize that new drugs are inherently more risky because of the relatively small amount of data about their effects, yet there is no practical way to increase knowledge about a drug before it is marketed. Thus, a systematic method for postmarketing surveillance is an indispensable requirement for early optimization of drug use.

Before a drug can be marketed, a package insert for use by physicians must be prepared. This is a cooperative effort between the FDA and the pharmaceutical company. The insert usually contains basic pharmacological information, as well as essential clinical information in regard to approved indications, contraindications, precautions, warnings, adverse reactions, usual dosage, and available preparations. Promotional materials cannot deviate from information contained in the insert.

One area in which the FDA does not have clear authority is in the regulation of “dietary supplements,” including vitamins, minerals, proteins, and herbal preparations. Until 1994, the FDA regulated such supplements as either food additives or drugs depending on the substance and the indications that were claimed. However, in 1994, Congress passed the Dietary Supplement Health and Education Act (DSHEA), which weakened the authority of the FDA. The act defined *dietary supplement* as a product intended to supplement the diet that contains “(a) a vitamin; (b) a mineral; (c) an herb or other botanical; (d) an amino acid; (e) a dietary substance for use by humans to supplement the diet by increasing the total daily intake; or (f) a concentrate, metabolite, constituent, extract or combination of an ingredient described in clause (a), (b), (c), (d), or (e).” Such products must be labeled as *dietary supplement*. The FDA does not have the authority to require approval prior to marketing of such supplements unless the supplements make specific claims relating to the diagnosis, treatment, prevention, or cure of a disease. However, the common conditions associated with natural states, such as pregnancy, menopause, aging, and adolescence, will not be treated as diseases by the FDA. Treatment of hot flashes, symptoms of the menstrual cycle, morning sickness associated with pregnancy, mild memory problems associated with aging, hair loss, and noncystic acne are examples of claims that can be made without prior FDA approval. Also, health maintenance and other “nondisease” claims such as “helps you relax” or “maintains a healthy circulation” are allowed without approval. Many supplements with such claims are labeled as follows: “*This statement has not been evaluated by the FDA. This product is not intended to diagnose, treat, cure, or prevent any disease.*” The FDA cannot remove such products from the market unless it can prove that there is a “significant or unreasonable risk of illness or injury” when the product is used as directed or under normal conditions of use. It is the manufacturer’s responsibility to ensure that its products are safe.

As a result of the DSHEA legislation, a large number of unregulated products that have not been demonstrated to be safe or effective are widely available. There have been several occasions where such products have been associated with serious adverse effects or have been shown to interact with prescription drugs (see Fugh-Berman, 2000). Under these circumstances, the FDA can act, but the burden is on the FDA to prove that the supplements are not safe.

The presence of *ephedrine* in weight-loss supplements is a recent case in point (see Chapter 10). In many ways, this situation is analogous to the lack of regulation of drugs that existed before the 1938 disaster involving elixir of sulfanilamide (described earlier). Physicians and patients alike should be aware of the lack of regulation of dietary supplements. Adverse reactions or suspected interactions with such substances should be reported to the FDA using the same mechanisms as for adverse drug reactions (see below).

Drug Development

Understanding the process of drug development and realizing the type and limitations of the data that support the efficacy and safety of a marketed product are necessary in estimating the risk-to-benefit ratio of a new drug.

By the time an investigational new drug (IND) application has been initiated and a drug reaches the stage of testing in humans, its pharmacokinetic, pharmacodynamic, and toxic properties have been evaluated *in vivo* in several species of animals in accordance with regulations and guidelines published by the FDA. Although the value of many requirements for preclinical testing is self-evident, such as those that screen for direct toxicity to organs and characterize dose-related effects, the value of others is controversial, particularly because of the well-known interspecies variation in the effects of drugs.

Trials of drugs in human beings in the United States generally are conducted in three phases, which must be completed before an NDA can be submitted to the FDA for review; these are outlined in Figure 5–7. Although assessment of risk is a major objective of such testing, this is far more difficult than is the determination of whether a drug is efficacious for a selected clinical condition. Usually about 2000 to 3000 carefully selected patients receive a new drug during phase 3 clinical trials. At most, only a few hundred are treated for more than 3 to 6 months regardless of the likely duration of therapy that will be required in practice. Thus, the most profound and overt risks that occur almost immediately after the drug is given can be detected in a phase 3 study if they occur more often than once per 100 administrations. Risks that are medically important but delayed or less frequent than 1 in 1000 administrations may not be revealed prior to marketing. Consequently, a number of unanticipated adverse and beneficial effects of drugs are detectable only after the drug is used broadly. The same can be more convincingly stated about most of the effects of drugs on children or the fetus, where premarketing experimental studies are restricted. For these reasons, many countries, including the United States, have established systematic methods for the surveillance of the effects of drugs after they have been approved for distribution (Brewer and Colditz, 1999; see below).

Postmarketing Surveillance for Adverse Reactions

Because of the limitations in the capacity of the premarketing phase of drug development to define uncommon but significant risks of new drugs, postmarketing surveillance of drug usage is imperative to detect such adverse effects.

Mechanism-based adverse drug reactions are relatively easily predicted by preclinical and clinical pharmacology studies. For idiosyncratic adverse reactions, current approaches to “safety assessment,” preclinically and in clinical trials, are problematic.

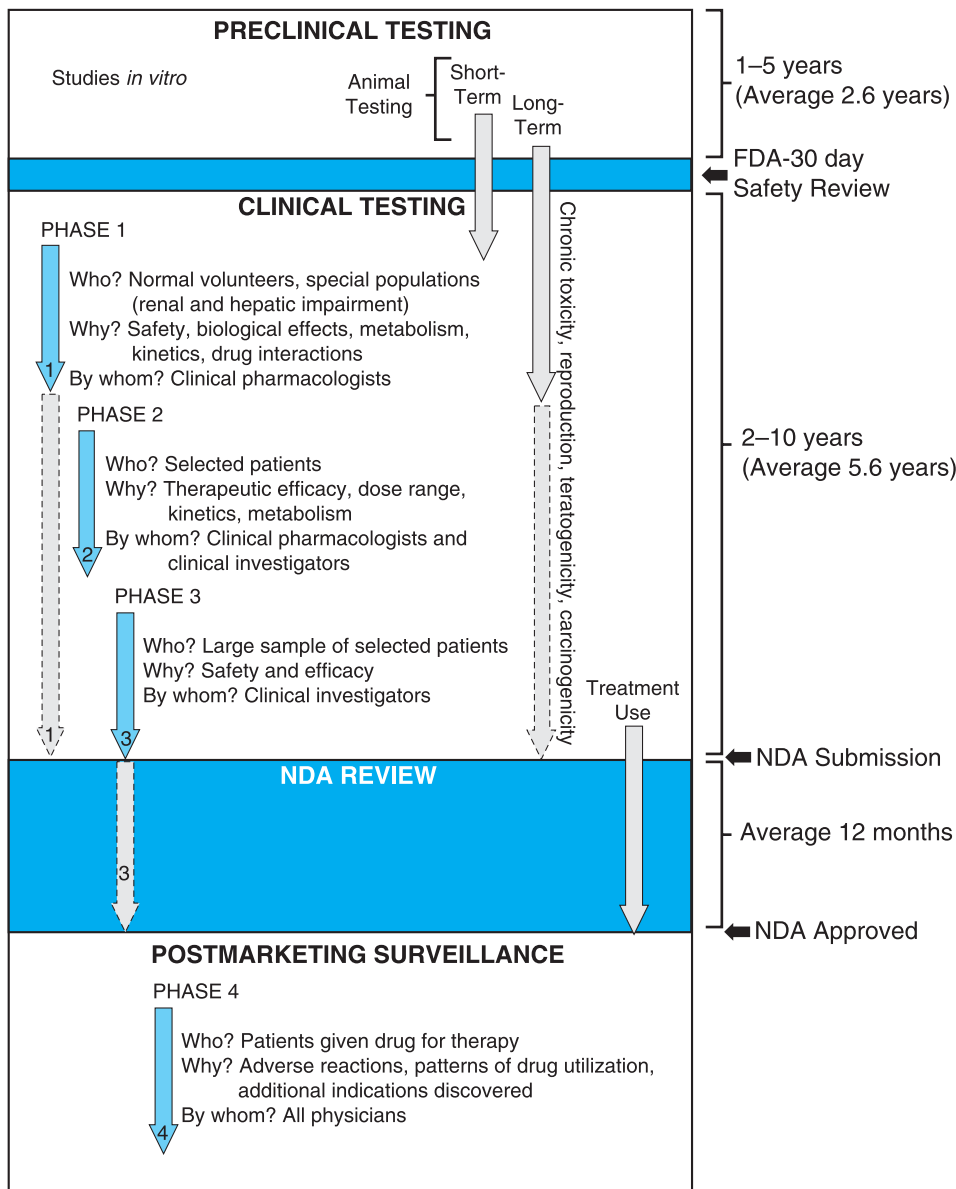

Figure 5–7. The phases of drug development in the United States.

The relative rarity of severe idiosyncratic reactions (*e.g.*, severe dermatological, hematological, or hepatological toxicities) presents epidemiological ascertainment issues. In addition, it is clear that a risk of 1 in 1000 is not distributed evenly across the population; some patients, because of unique genetic or environmental factors, are at an extremely high risk, whereas the remainder of the population may be at low or no risk. In contrast to the human heterogeneity underlying idiosyncratic risk, the standard process of drug development, particularly the preclinical safety assessment using inbred healthy animals maintained in a defined environment on a defined diet and manifesting predictable habits, limits the identification of risk for idiosyncratic adverse drug reactions in the human population. Understanding the genetic and environmental bases of

idiosyncratic adverse events holds the promise of assessing individual rather than population risk, thereby improving the overall safety of pharmacotherapy.

Several strategies exist to detect adverse reactions after marketing of a drug, but debate continues about the most efficient and effective method. Formal approaches for estimation of the magnitude of an adverse drug effect are the *follow-up* or *cohort* study of patients who are receiving a particular drug, the *case-control* study, where the frequency of drug use in cases of adverse reactions is compared with controls, and *meta-analyses* of pre- and postmarketing studies. Cohort studies can estimate the incidence of an adverse reaction but cannot, for practical reasons, discover rare events. To have any significant advantage over the premarketing studies, a

cohort study must follow at least 10,000 patients who are receiving the drug to detect with 95% confidence one event that occurs at a rate of 1 in 3300, and the event can be attributed to the drug only if it does not occur spontaneously in the control population. If the adverse event occurs spontaneously in the control population, substantially more patients and controls must be followed to establish the drug as the cause of the event (Strom and Tugwell, 1990). Meta-analyses combine the data from several studies in an attempt to discern benefits or risks that are sufficiently uncommon that an individual study lacks the power to discover them (Temple, 1999). Case-control studies also can discover rare drug-induced events. However, it may be difficult to establish the appropriate control group (Feinstein and Horwitz, 1988), and a case-control study cannot establish the incidence of an adverse drug effect. Furthermore, the suspicion of a drug as a causative factor in a disease must be the impetus for the initiation of such case-control studies.

The Key Role of the Clinician in Surveillance for Adverse Reactions

Because of the shortcomings of cohort and case-control studies and meta-analyses, additional approaches must be used. Spontaneous reporting of adverse reactions has proven to be an effective way to generate an early signal that a drug may be causing an adverse event. It is the only practical way to detect rare events, events that occur after prolonged use of drug, adverse effects that are delayed in appearance, and many drug–drug interactions. In the past few years, considerable effort has gone into improving the reporting system in the United States, which is now called MEDWATCH (Brewer and Colditz, 1999). Still, the voluntary reporting system in the United States is deficient compared with the legally mandated systems of the United Kingdom, Canada, New Zealand, Denmark, and Sweden. Most physicians feel that detecting adverse reactions is a professional obligation, but relatively few actually report such reactions. Many physicians are not aware that the FDA has a reporting system for adverse drug reactions, even though the system has been repeatedly publicized in major medical journals.

The most important spontaneous reports are those that describe serious reactions, whether they have been described previously or not. Reports on newly marketed drugs (within the past 5 years) are the most significant, even though the physician may not be able to attribute a causal role to a particular drug. The major use of this system is to provide early warning signals of unexpected adverse effects that can then be investigated by more formal techniques. However, the system also serves to monitor changes in the nature or frequency of adverse drug reactions owing to aging of the population, changes in the disease itself, or the introduction of new, concurrent therapies. *The primary sources for the reports are responsible, alert physicians; other potentially useful sources are*

nurses, pharmacists, and students in these disciplines. In addition, hospital-based pharmacy and therapeutics committees and quality assurance committees frequently are charged with monitoring adverse drug reactions in hospitalized patients, and reports from these committees should be forwarded to the FDA. *The simple forms for reporting may be obtained 24 hours a day 7 days a week by calling (800)-FDA-1088; alternatively, adverse reactions can be reported directly on the Internet (www.fda.gov/med-watch).* Additionally, health professionals may contact the pharmaceutical manufacturer, who is legally obligated to file reports with the FDA. With this facile reporting system, the clinician can serve as a vital sentinel in the detection of unexpected adverse reactions to drugs.

SECTION II

Drugs Acting at Synaptic and Neuroeffector Junctional Sites

CHAPTER 6

NEUROTRANSMISSION

The Autonomic and Somatic Motor Nervous Systems

Thomas C. Westfall and David P. Westfall

ANATOMY AND GENERAL FUNCTIONS OF THE AUTONOMIC AND SOMATIC MOTOR NERVOUS SYSTEMS

The autonomic nervous system, also called the *visceral*, *vegetative*, or *involuntary nervous system*, is distributed widely throughout the body and regulates autonomic functions that occur without conscious control. In the periphery, it consists of nerves, ganglia, and plexuses that innervate the heart, blood vessels, glands, other visceral organs, and smooth muscle in various tissues.

Differences between Autonomic and Somatic Nerves. The efferent nerves of the involuntary system supply all innervated structures of the body except skeletal muscle, which is served by somatic nerves. The most distal synaptic junctions in the autonomic reflex arc occur in ganglia that are entirely outside the cerebrospinal axis. These ganglia are small but complex structures that contain axodendritic synapses between preganglionic and postganglionic neurons. Somatic nerves contain no peripheral ganglia, and the synapses are located entirely within the cerebrospinal axis. Many autonomic nerves form extensive peripheral

plexuses, but such networks are absent from the somatic system. Whereas motor nerves to skeletal muscles are myelinated, postganglionic autonomic nerves generally are nonmyelinated. When the spinal efferent nerves are interrupted, the denervated skeletal muscles lack myogenic tone, are paralyzed, and atrophy, whereas smooth muscles and glands generally retain some level of spontaneous activity independent of intact innervation.

Visceral Afferent Fibers. The afferent fibers from visceral structures are the first link in the reflex arcs of the autonomic system. With certain exceptions, such as local axon reflexes, most visceral reflexes are mediated through the central nervous system (CNS).

Information on the status of the visceral organs is transmitted to the CNS through two main sensory systems: the cranial nerve (parasympathetic) visceral sensory system and the spinal (sympathetic) visceral afferent system (Saper, 2002). The cranial visceral sensory system carries mainly mechanoreceptor and chemosensory information, whereas the afferents of the spinal visceral system principally convey sensations related to temperature and tissue injury of mechanical, chemical, or thermal origin. Cranial visceral sensory information enters the CNS *via* four cranial nerves: the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagus (X). These four cranial nerves transmit visceral sensory information from the internal face and head (V), tongue (taste, VII), hard palate and upper part of the oropharynx (IX), and carotid body, lower part of the oropharynx, larynx, trachea, esophagus, and thoracic and abdominal organs, with the exception of the pelvic viscera

(X). The pelvic viscera are innervated by nerves from the second through fourth sacral spinal segments.

The visceral afferents from these four cranial nerves terminate topographically in the solitary tract nucleus (STN) (Altschuler *et al.*, 1989). The most massive site for termination of the fibers from the STN is the parabrachial nucleus, which is thus the major relay station. The parabrachial nucleus consists of at least 13 separate subnuclei, which in turn project extensively to a wide range of sites in the brainstem, hypothalamus, basal forebrain, thalamus, and cerebral cortex. Other direct projections from the STN also innervate these brain structures.

Sensory afferents from visceral organs also enter the CNS *via* the spinal nerves. Those concerned with muscle chemosensation may arise at all spinal levels, whereas sympathetic visceral sensory afferents generally arise at the thoracic levels where sympathetic preganglionic neurons are found. Pelvic sensory afferents from spinal segments S2–S4 enter at that level and are important for the regulation of sacral parasympathetic outflow. In general, visceral afferents that enter the spinal nerves convey information concerned with temperature as well as nociceptive visceral inputs related to mechanical, chemical, and thermal stimulation. The primary pathways taken by ascending spinal visceral afferents are complex and controversial (Saper, 2002). Most probably converge with musculoskeletal and cutaneous afferents and ascend *via* the spinothalamic and spinoreticular tracts. Others ascend *via* the dorsal column. An important feature of the ascending pathways is that they provide collaterals that converge with the cranial visceral sensory pathway at virtually every level (Saper, 2000). At the brainstem level, collaterals from the spinal system converge with the cranial nerve sensory system in the STN, the ventrolateral medulla, and the parabrachial nucleus. At the level of the forebrain, the spinal system appears to form a posterolateral continuation of the cranial nerve visceral sensory thalamus and cortex (Saper, 2000).

The neurotransmitters that mediate transmission from sensory fibers have not been characterized unequivocally. Substance P and calcitonin gene-related peptide, which are present in afferent sensory fibers, in the dorsal root ganglia, and in the dorsal horn of the spinal cord, are leading candidates for neurotransmitters that communicate nociceptive stimuli from the periphery to the spinal cord and higher structures. Other neuroactive peptides, including somatostatin, vasoactive intestinal polypeptide (VIP), and cholecystokinin, also have been found in sensory neurons (Lundburg, 1996; Hökfelt *et al.*, 2000), and one or more such peptides may play a role in the transmission of afferent impulses from autonomic structures. Adenosine triphosphate (ATP) appears to be a neurotransmitter in certain sensory neurons, including those that innervate the urinary bladder. Enkephalins, present in interneurons in the dorsal spinal cord (within an area termed the *substantia gelatinosa*), have antinociceptive effects that appear to arise from presynaptic and postsynaptic actions to inhibit the release of substance P and diminish the activity of cells that project from the spinal cord to higher centers in the CNS. The excitatory amino acids glutamate and aspartate also play major roles in transmission of sensory responses to the spinal cord.

Central Autonomic Connections. There probably are no purely autonomic or somatic centers of integration, and extensive overlap occurs. Somatic responses always are accompanied by visceral responses, and *vice versa*. Autonomic reflexes can be elicited at the level of the spinal cord. They clearly are demonstrable in experimental animals or humans with spinal cord transection and are manifested by sweating, blood pressure alterations, vasomotor responses

to temperature changes, and reflex emptying of the urinary bladder, rectum, and seminal vesicles. Extensive central ramifications of the autonomic nervous system exist above the level of the spinal cord. For example, integration of the control of respiration in the medulla oblongata is well known. The hypothalamus and the STN generally are regarded as principal loci of integration of autonomic nervous system functions, which include regulation of body temperature, water balance, carbohydrate and fat metabolism, blood pressure, emotions, sleep, respiration, and reproduction. Signals are received through ascending spinobulbar pathways, the limbic system, neostriatum, cortex, and to a lesser extent other higher brain centers. Stimulation of the STN and the hypothalamus activates bulbospinal pathways and hormonal output to mediate autonomic and motor responses (Andresen and Kunze, 1994) (*see* Chapter 12). The hypothalamic nuclei that lie posteriorly and laterally are sympathetic in their main connections, whereas parasympathetic functions evidently are integrated by the midline nuclei in the region of the tuber cinereum and by nuclei lying anteriorly.

The CNS can produce a wide range of patterned autonomic and somatic responses from discrete activation of sympathetic or parasympathetic neurons to more generalized activation of these nerves with highly integrated patterns of response. There are highly differentiated patterns of activity during a wide range of physiological conditions consistent with the need for modulation of different organ functions. There is evidence for organotropical organization of neuronal pools at multiple levels of the CNS that generate these various patterns of sympathetic and parasympathetic responses. The pattern generators at these different levels of the neuroaxis are often organized in a hierarchical manner that allows individual response or larger responses made up of multiple individual units.

As mentioned earlier, highly integrated patterns of response generally are organized at a hypothalamic level. These integrated patterns of response involve autonomic, endocrine, and behavioral components. On the other hand, more limited patterned responses are organized at other levels of basal forebrain, brainstem, and spinal cord.

Divisions of the Peripheral Autonomic System. On the efferent side, the autonomic nervous system consists of two large divisions: (1) the sympathetic or thoracolumbar outflow and (2) the parasympathetic or craniosacral outflow. A brief outline of those anatomical features is necessary for an understanding of the actions of autonomic drugs.

The arrangement of the principal parts of the peripheral autonomic nervous system is presented schematically in Figure 6–1. The neurotransmitter of all preganglionic autonomic fibers, all postganglionic parasympathetic fibers, and a few postganglionic sympathetic fibers is *acetylcholine* (ACh). The adrenergic fibers comprise the majority of the postganglionic sympathetic fibers; here the transmitter is *norepinephrine* (*noradrenaline*, *levarterenol*). The terms *cholinergic* and *adrenergic* were proposed originally by Dale to describe neurons that liberate ACh or norepinephrine, respectively. As noted earlier, not all the transmitter(s) of the primary afferent fibers, such as those from the mechano- and chemo-receptors of

the carotid body and aortic arch, have been identified conclusively. Substance P and glutamate are thought to mediate many afferent impulses; both are present in high concentrations in the dorsal spinal cord.

Sympathetic Nervous System. The cells that give rise to the preganglionic fibers of this division lie mainly in the intermediolateral columns of the spinal cord and extend from the first thoracic to the second or third lumbar segment. The axons from these cells are carried in the anterior (ventral) nerve roots and synapse, with neurons lying in sympathetic ganglia outside the cerebrospinal axis. Sympathetic ganglia are found in three locations: paravertebral, prevertebral, and terminal.

The 22 pairs of paravertebral sympathetic ganglia form the lateral chains on either side of the vertebral column. The ganglia are connected to each other by nerve trunks and to the spinal nerves by *rami communicantes*. The white rami are restricted to the segments of the thoracolumbar outflow; they carry the preganglionic myelinated fibers that exit the spinal cord *via* the anterior spinal roots. The gray rami arise from the ganglia and carry postganglionic fibers back to the spinal nerves for distribution to sweat glands and pilomotor muscles and to blood vessels of skeletal muscle and skin. The prevertebral ganglia lie in the abdomen and the pelvis near the ventral surface of the bony vertebral column and consist mainly of the celiac (solar), superior mesenteric, aorticorenal, and inferior mesenteric ganglia. The terminal ganglia are few in number, lie near the organs they innervate, and include ganglia connected with the urinary bladder and rectum and the cervical ganglia in the region of the neck. In addition, small intermediate ganglia lie outside the conventional vertebral chain, especially in the thoracolumbar region. They are variable in number and location but usually are in close proximity to the communicating rami and the anterior spinal nerve roots.

Preganglionic fibers issuing from the spinal cord may synapse with the neurons of more than one sympathetic ganglion. Their principal ganglia of termination need not correspond to the original level from which the preganglionic fiber exits the spinal cord. Many of the preganglionic fibers from the fifth to the last thoracic segment pass through the paravertebral ganglia to form the splanchnic nerves. Most of the splanchnic nerve fibers do not synapse until they reach the celiac ganglion; others directly innervate the adrenal medulla (*see below*).

Postganglionic fibers arising from sympathetic ganglia innervate visceral structures of the thorax, abdomen, head, and neck. The trunk and the limbs are supplied by the sympathetic fibers in spinal nerves, as described earlier. The prevertebral ganglia contain cell bodies whose axons innervate the glands and smooth muscles of the abdominal and the pelvic viscera. Many of the upper thoracic sympathetic fibers from the vertebral ganglia form terminal plexuses, such as the cardiac, esophageal, and pulmonary plexuses. The sympathetic distribution to the head and the neck (vasomotor, pupillodilator, secretory, and pilomotor) is *via* the cervical sympathetic chain and its three ganglia. All postganglionic fibers in this chain arise from cell bodies located in these three ganglia; all preganglionic fibers arise from the upper thoracic segments of the spinal cord, there being no sympathetic fibers that leave the CNS above the first thoracic level.

The adrenal medulla and other chromaffin tissue are embryologically and anatomically similar to sympathetic ganglia; all are derived from the neural crest. The adrenal medulla in humans and

many other species differs from sympathetic ganglia in that its principal catecholamine is *epinephrine* (*adrenaline*), whereas norepinephrine is released from postganglionic sympathetic fibers. The chromaffin cells in the adrenal medulla are innervated by typical preganglionic fibers that release ACh.

Parasympathetic Nervous System. The parasympathetic nervous system consists of preganglionic fibers that originate in the CNS and their postganglionic connections. The regions of central origin are the midbrain, the medulla oblongata, and the sacral part of the spinal cord. The midbrain, or tectal, outflow consists of fibers arising from the Edinger–Westphal nucleus of the third cranial nerve and going to the ciliary ganglion in the orbit. The medullary outflow consists of the parasympathetic components of the seventh, ninth, and tenth cranial nerves. The fibers in the seventh (facial) cranial nerve form the chorda tympani, which innervates the ganglia lying on the submaxillary and sublingual glands. They also form the greater superficial petrosal nerve, which innervates the sphenopalatine ganglion. The autonomic components of the ninth (glossopharyngeal) cranial nerve innervate the otic ganglia. Postganglionic parasympathetic fibers from these ganglia supply the sphincter of the iris (pupillary constrictor muscle), the ciliary muscle, the salivary and lacrimal glands, and the mucous glands of the nose, mouth, and pharynx. These fibers also include vasodilator nerves to these same organs. The tenth (vagus) cranial nerve arises in the medulla and contains preganglionic fibers, most of which do not synapse until they reach the many small ganglia lying directly on or in the viscera of the thorax and abdomen. In the intestinal wall, the vagal fibers terminate around ganglion cells in the myenteric and submucosal plexuses. Thus, preganglionic fibers are very long, whereas postganglionic fibers are very short. The vagus nerve also carries a far greater number of afferent fibers (but apparently no pain fibers) from the viscera into the medulla; the cell bodies of these fibers lie mainly in the nodose ganglion.

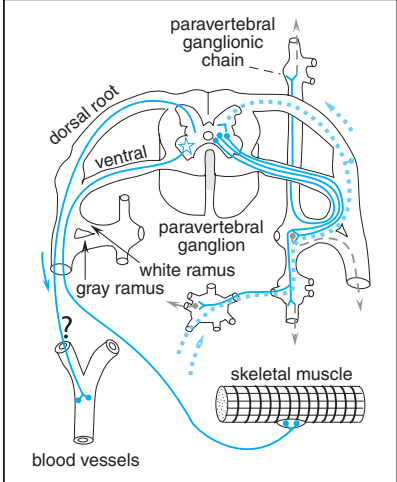

The parasympathetic sacral outflow consists of axons that arise from cells in the second, third, and fourth segments of the sacral cord and proceed as preganglionic fibers to form the pelvic nerves (*nervi erigentes*). They synapse in terminal ganglia lying near or within the bladder, rectum, and sexual organs. The vagal and sacral outflows provide motor and secretory fibers to thoracic, abdominal, and pelvic organs, as indicated in Figure 6–1.

Enteric Nervous System. The processes of mixing, propulsion, and absorption of nutrients in the GI tract are controlled locally through a restricted part of the peripheral nervous system called the *enteric nervous system* (ENS). The ENS is involved in sensorimotor control and thus consists of both afferent sensory neurons and a number of motor nerves and interneurons that are organized principally into two nerve plexuses: the myenteric (Auerbach's) plexus and the submucosal (Meissner's) plexus. The myenteric plexus, located between the longitudinal and circular muscle layers, plays an important role in the contraction and relaxation of gastrointestinal smooth muscle (Kunze and Furness, 1999). The submucosal plexus is involved with secretory and absorptive functions of the gastrointestinal epithelium, local blood flow, and neuroimmune activities (Cooke, 1998). Although originally classified by Langley in the 1920s as a third division of the autonomic nervous system, the ENS is actually comprised of components of the sympathetic and parasympathetic nervous systems and has sensory nerve connections through the spinal and nodose ganglia (*see Chapter 37*).

Segmental postganglionic adrenergic fibers from paravertebral ganglia to blood vessels and hair follicles via gray rami and spinal nerves

Segmental postganglionic cholinergic fibers from paravertebral ganglia to sweat glands and certain blood vessels via gray rami and spinal nerves

Parasympathetic input to the GI tract is excitatory; preganglionic neurons in the vagus innervate the parasympathetic ganglia of the enteric plexuses. Postganglionic sympathetic nerves also synapse with the intramural enteric parasympathetic ganglia. Sympathetic nerve activity induces relaxation primarily by inhibiting the release of ACh from the preganglionic ganglia (Broadley, 1996).

The intrinsic primary afferent neurons are present in both the myenteric and submucosal plexuses. They respond to luminal chemical stimuli, to mechanical deformation of the mucosa, and to stretch (Costa *et al.*, 2000). The nerve endings of the primary afferent neurons can be activated by a number of endogenous substances (*e.g.*, serotonin) arising from enterochromaffin cells in the wall of the gut or possibly from serotonergic nerves.

The muscle layers of the GI tract are dually innervated by excitatory and inhibitory motor neurons whose cell bodies are in the gut wall (Kunze and Furness, 1999). ACh, in addition to being the transmitter of parasympathetic nerves to the ENS, is the primary excitatory transmitter acting on nicotinic acetylcholine receptors (nAChRs) in ascending intramural pathways. Pharmacological blockade of cholinergic neurotransmission, however, does not completely abolish this excitatory transmission because tachykinin cotransmitters, such as substance P and neurokinin A, are coreleased with ACh and contribute to the excitatory response (Costa *et al.*, 1996). Although ACh also may play a role in descending motor pathways, another important excitatory neurotransmitter in such pathways is ATP acting through P2X receptors (Galligan, 2002).

Figure 6–1. The autonomic nervous system. Schematic representation of the autonomic nerves and effector organs based on chemical mediation of nerve impulses. Blue, cholinergic; gray, adrenergic; dotted blue, visceral afferent; solid lines, preganglionic; broken lines, postganglionic. In the upper rectangle at the right are shown the finer details of the ramifications of adrenergic fibers at any one segment of the spinal cord, the path of the visceral afferent nerves, the cholinergic nature of somatic motor nerves to skeletal muscle, and the presumed cholinergic nature of the vasodilator fibers in the dorsal roots of the spinal nerves. The asterisk (*) indicates that it is not known whether these vasodilator fibers are motor or sensory or where their cell bodies are situated. In the lower rectangle on the right, vagal preganglionic (*solid blue*) nerves from the brainstem synapse on both excitatory and inhibitory neurons found in the myenteric plexus. A synapse with a postganglionic cholinergic neuron (*blue with varicosities*) gives rise to excitation, whereas synapses with purinergic, peptide (VIP), or an NO-generating neuron (*black with varicosities*) lead to relaxation. Sensory nerves (*dotted blue lines*) originating primarily in the mucosal layer send afferent signals to the CNS but often branch and synapse with ganglia in the plexus. Their transmitter is substance P or other tachykinins. Other interneurons (*white*) contain serotonin and will modulate intrinsic activity through synapses with other neurons eliciting excitation or relaxation (*black*). Cholinergic, adrenergic, and some peptidergic neurons pass through the circular smooth muscle to synapse in the submucosal plexus or terminate in the mucosal layer, where their transmitter may stimulate or inhibit gastrointestinal secretion.

Similar to excitatory intramural neurons, inhibitory neurons of the ENS exhibit a variety of transmitters and cotransmitters, including nitric oxide (NO), ATP acting on P2Y receptors, VIP, and pituitary adenylyl cyclase-activating peptide (PACAP) (Kunze and Furness, 1999). NO seems to be the primary inhibitory transmitter (Stark and Szurszewski, 1992).

The interstitial cells of Cajal (ICC) are one component of the excitatory and inhibitory pathways in the GI tract. These cells appear to relay signals from the nerves to the smooth muscle cells to which they are electrically coupled. The ICC have receptors for both the inhibitory transmitter NO and the excitatory tachykinins. Disruption of the ICC impairs excitatory and inhibitory neurotransmission (Horowitz *et al.*, 1999).

Differences among Sympathetic, Parasympathetic, and Motor Nerves. The sympathetic system is distributed to effectors throughout the body, whereas parasympathetic distribution is much more limited. Furthermore, the sympathetic fibers ramify to a much greater extent. A preganglionic sympathetic fiber may traverse a considerable distance of the sympathetic chain and pass through several ganglia before it finally synapses with a postganglionic neuron; also, its terminals make contact with a large number of postganglionic neurons. In some ganglia, the ratio of preganglionic axons to ganglion cells may be 1:20 or more. This organization permits a diffuse discharge of the sympathetic system. In addition, synaptic innervation overlaps, so one ganglion cell may be supplied by several preganglionic fibers.

The parasympathetic system, in contrast, has terminal ganglia very near or within the organs innervated and thus is more circumscribed in its influences. In some organs, a 1:1 relationship between the number of preganglionic and postganglionic fibers has been suggested, but the ratio of preganglionic vagal fibers to ganglion cells in the myenteric plexus has been estimated as 1:8000. Hence this distinction between the two systems does not apply to all sites.

The cell bodies of somatic motor neurons reside in the ventral horn of the spinal cord; the axon divides into many branches, each of which innervates a single muscle fiber, so more than 100 muscle fibers may be supplied by one motor neuron to form a motor unit. At each neuromuscular junction, the axonal terminal loses its myelin sheath and forms a terminal arborization that lies in apposition to a specialized surface of the muscle membrane, termed the *motor end plate*. Mitochondria and a collection of synaptic vesicles are concentrated at the nerve terminal. Through trophic influences of the nerve, those cell nuclei in the multinucleated skeletal muscle cell lying in close apposition to the synapse acquire the capacity to activate specific genes that express synapse-localized proteins (Hall and Sanes, 1993; Sanes and Lichtman, 1999).

Details of Innervation. The terminations of the postganglionic autonomic fibers in smooth muscle and glands form a rich plexus, or terminal reticulum. The terminal reticulum (sometimes called the *autonomic ground plexus*) consists of the final ramifications of the postganglionic sympathetic, parasympathetic, and visceral afferent fibers, all of which are enclosed within a frequently interrupted sheath of satellite or Schwann cells. At these interruptions, varicosities packed with vesicles are seen in the efferent fibers. Such varicosities occur repeatedly but at variable distances along the course of the ramifications of the axon.

“Protoplasmic bridges” occur between the smooth muscle fibers themselves at points of contact between their plasma membranes. They are believed to permit the direct conduction of impulses from cell to cell without the need for chemical transmission. These structures have been termed *nexuses*, or *tight junctions*, and they enable the smooth muscle fibers to function as a syncytial unit.

Sympathetic ganglia are extremely complex anatomically and pharmacologically (see Chapter 9). The preganglionic fibers lose their myelin sheaths and divide repeatedly into a vast number of end fibers with diameters ranging from 0.1 to 0.3 μm ; except at points of synaptic contact, they retain their satellite cell sheaths. The vast majority of synapses are axodendritic. Apparently, a given axonal terminal may synapse with one or more dendritic processes.

Responses of Effector Organs to Autonomic Nerve Impulses. From the responses of the various effector organs to autonomic nerve impulses and the knowledge of the intrinsic autonomic tone, one can predict the actions of drugs that mimic or inhibit the actions of these nerves. In most instances, the sympathetic and parasympathetic neurotransmitters can be viewed as physiological or functional antagonists. If one neurotransmitter inhibits a certain function, the other usually augments that function. Most viscera are innervated by both divisions of the autonomic nervous system, and the level of activity at any moment represents the integration of influences of the two components. Despite the conventional concept of antagonism between the two portions of the autonomic nervous system, their activities on specific structures may be either discrete and independent or integrated and interdependent. For example, the effects of sympathetic and parasympathetic stimulation of the heart and the iris show a pattern of functional antagonism in controlling heart rate and pupillary aperture, respectively, whereas their actions on male sexual organs are complementary and are integrated to promote sexual function. The control of peripheral vascular resistance is primarily, but not exclusively, due to sympathetic control of arteriolar resistance. The effects of stimulating the sympathetic and parasympathetic nerves to various organs, visceral structures, and effector cells are summarized in Table 6–1.

General Functions of the Autonomic Nervous System. The integrating action of the autonomic nervous system is of vital importance for the well-being of the

organism. In general, the autonomic nervous system regulates the activities of structures that are not under voluntary control and that function below the level of consciousness. Thus, respiration, circulation, digestion, body temperature, metabolism, sweating, and the secretions of certain endocrine glands are regulated, in part or entirely, by the autonomic nervous system. Thus, the autonomic nervous system is the primary regulator of the constancy of the internal environment of the organism.

The sympathetic system and its associated adrenal medulla are not essential to life in a controlled environment, but the lack of sympatho-adrenal functions becomes evident under circumstances of stress. Body temperature cannot be regulated when environmental temperature varies; the concentration of glucose in blood does not rise in response to urgent need; compensatory vascular responses to hemorrhage, oxygen deprivation, excitement, and exercise are lacking; resistance to fatigue is lessened; sympathetic components of instinctive reactions to the external environment are lost; and other serious deficiencies in the protective forces of the body are discernible.

The sympathetic system normally is continuously active; the degree of activity varies from moment to moment and from organ to organ. In this manner, adjustments to a constantly changing environment are accomplished. The sympathoadrenal system also can discharge as a unit. This occurs particularly during rage and fright, when sympathetically innervated structures over the entire body are affected simultaneously. Heart rate is accelerated; blood pressure rises; red blood cells are poured into the circulation from the spleen (in certain species); blood flow is shifted from the skin and splanchnic region to the skeletal muscles; blood glucose rises; the bronchioles and pupils dilate; and the organism is better prepared for “fight or flight.” Many of these effects result primarily from or are reinforced by the actions of epinephrine secreted by the adrenal medulla (see below). In addition, signals are received in higher brain centers to facilitate purposeful responses or to imprint the event in memory.

The parasympathetic system is organized mainly for discrete and localized discharge. Although it is concerned primarily with conservation of energy and maintenance of organ function during periods of minimal activity, its elimination is not compatible with life. Sectioning the vagus, for example, soon gives rise to pulmonary infection because of the inability of cilia to remove irritant substances from the respiratory tract. The parasympathetic system slows the heart rate, lowers the blood pressure, stimulates gastrointestinal movements

Table 6-1

Responses of Effector Organs to Autonomic Nerve Impulses

ORGAN SYSTEM	SYMPATHETIC EFFECT ^a	ADRENERGIC RECEPTOR TYPE ^b	PARASYMPATHETIC EFFECT ^a	CHOLINERGIC RECEPTOR TYPE ^b
<i>Eye</i>				
Radial muscle, iris	Contraction (mydriasis)++	α_1

^aResponses are designated + to +++ to provide an approximate indication of the importance of sympathetic and parasympathetic nerve activity in the control of the various organs and functions listed. ^bAdrenergic receptors: α_1 , α_2 and subtypes thereof; β_1 , β_2 , β_3 . Cholinergic receptors: nicotinic (N); muscarinic (M), with subtypes 1–4. The receptor subtypes are described more fully in Chapters 7 and 10 and in Tables 6–2, 6–3 and 6–8. When a designation of subtype is not provided, the nature of the subtype has not been determined, unequivocally. Only the principal receptor subtypes are shown. Transmitters other than acetylcholine and norepinephrine contribute to many of the responses. ^cIn the human heart, the ratio of β_1 to β_2 is about 3:2 in atria and 4:1 in ventricles. While M₂ receptors predominate, M₃ receptors are also present (Wang *et al.*, 2004). ^dThe predominant α_1 receptor subtype in most blood vessels (both arteries and veins) is α_{1A} (see Table 6–8), although other α_1 subtypes are present in specific blood vessels. The α_{1D} is the predominant subtype in the aorta (Michelotti *et al.*, 2000). ^eDilation predominates *in situ* owing to metabolic autoregulatory mechanisms. ^fOver the usual concentration range of physiologically released circulating epinephrine, the β -receptor response (vasodilation) predominates in blood vessels of skeletal muscle and liver; α -receptor response (vasoconstriction) in blood vessels of other abdominal viscera. The renal and mesenteric vessels also contain specific dopaminergic receptors whose activation causes dilation (see review by Goldberg *et al.*, 1978). ^gSympathetic cholinergic neurons cause vasodilation in skeletal muscle beds, but this is not involved in most physiological responses. ^hThe endothelium of most blood vessels releases NO, which causes vasodilation in response to muscarinic stimuli. However, unlike the receptors innervated by sympathetic cholinergic fibers in skeletal muscle blood vessels, these muscarinic receptors are not innervated and respond only to exogenously added muscarinic agonists in the circulation. ⁱWhile adrenergic fibers terminate at inhibitory β -receptors on smooth muscle fibers and at inhibitory α -receptors on parasympathetic (cholinergic) excitatory ganglion cells of the myenteric plexus, the primary inhibitory response is mediated *via* enteric neurons through NO, P2Y receptors, and peptide receptors. ^jUterine responses depend on stages of menstrual cycle, amount of circulating estrogen and progesterone, and other factors. ^kPalms of hands and some other sites (“adrenergic sweating”). ^lThere is significant variation among species in the receptor types that mediate certain metabolic responses. All three β adrenergic receptors have been found in human fat cells. Activation of β_3 adrenergic receptors produces a vigorous thermogenic response as well as lipolysis. The significance is unclear. Activation of β adrenergic receptors also inhibits leptin release from adipose tissue.

and secretions, aids absorption of nutrients, protects the retina from excessive light, and empties the urinary bladder and rectum. Many parasympathetic responses are rapid and reflexive in nature.

NEUROTRANSMISSION

Nerve impulses elicit responses in smooth, cardiac, and skeletal muscles, exocrine glands, and postsynaptic neurons by liberating specific chemical neurotransmitters. The processes are presented in some detail because an understanding of the chemical mediation of nerve impulses

provides the framework for our knowledge of the mechanism of action of drugs at these sites.

Historical Aspects

The earliest concrete proposal of a neurohumoral mechanism was made shortly after the turn of the twentieth century. Lewandowsky and Langley independently noted the similarity between the effects of injection of extracts of the adrenal gland and stimulation of sympathetic nerves. A few years later, in 1905, T. R. Elliott, while a student with Langley at Cambridge, England, postulated that sympathetic nerve impulses release minute amounts of an epinephrine-like substance in immediate contact with effector cells. He considered this substance to be the chemical step in the process of transmission. He also noted that long after sympathetic nerves had degenerated, the effector organs still responded characteristically to the hormone

of the adrenal medulla. In 1905, Langley suggested that effector cells have excitatory and inhibitory “receptive substances” and that the response to epinephrine depended on which type of substance was present. In 1907, Dixon, impressed by the correspondence between the effects of the alkaloid *muscarine* and the responses to vagal stimulation, advanced the concept that the vagus nerve liberated a muscarine-like substance that acted as a chemical transmitter of its impulses. In the same year, Reid Hunt described the actions of ACh and other choline esters. In 1914, Dale investigated the pharmacological properties of ACh and other choline esters and distinguished its nicotine-like and muscarine-like actions. Intrigued with the remarkable fidelity with which this drug reproduced the responses to stimulation of parasympathetic nerves, he introduced the term *parasympathomimetic* to characterize its effects. Dale also noted the brief duration of action of this chemical and proposed that an esterase in the tissues rapidly splits ACh to acetic acid and choline, thereby terminating its action.

The studies of Loewi, begun in 1921, provided the first direct evidence for the chemical mediation of nerve impulses by the release of specific chemical agents. Loewi stimulated the vagus nerve of a perfused (donor) frog heart and allowed the perfusion fluid to come in contact with a second (recipient) frog heart used as a test object. The recipient frog heart was found to respond, after a short lag, in the same way as the donor heart. It thus was evident that a substance was liberated from the first organ that slowed the rate of the second. Loewi referred to this chemical substance as *Vagusstoff* (“vagus substance,” “parasympathin”); subsequently, Loewi and Navratil presented evidence to identify it as ACh. Loewi also discovered that an accelerator substance similar to epinephrine and called *Acceleranstoff* was liberated into the perfusion fluid in summer, when the action of the sympathetic fibers in the frog’s vagus, a mixed nerve, predominated over that of the inhibitory fibers. Feldberg and Krayner demonstrated in 1933 that the cardiac “vagus substance” also is ACh in mammals.

In addition to its role as the transmitter of all postganglionic parasympathetic fibers and of a few postganglionic sympathetic fibers, ACh has been shown to function as a neurotransmitter in three additional classes of nerves: preganglionic fibers of both the sympathetic and the parasympathetic systems, motor nerves to skeletal muscle, and certain neurons within the CNS.

In the same year as Loewi’s discovery, Cannon and Uridil reported that stimulation of the sympathetic hepatic nerves resulted in the release of an epinephrine-like substance that increased blood pressure and heart rate. Subsequent experiments firmly established that this substance is the chemical mediator liberated by sympathetic nerve impulses at neuroeffector junctions. Cannon called this substance “sympathin.” In many of its pharmacological and chemical properties, “sympathin” closely resembled epinephrine but also differed in certain important respects. As early as 1910, Barger and Dale noted that the effects of sympathetic nerve stimulation were reproduced more closely by the injection of sympathomimetic primary amines than by that of epinephrine or other secondary amines. The possibility that demethylated epinephrine (norepinephrine) might be “sympathin” had been advanced repeatedly, but definitive evidence for its being the sympathetic nerve mediator was not obtained until specific assays were developed for the determination of sympathomimetic amines in extracts of tissues and body fluids. In 1946, von Euler found that the sympathomimetic substance in highly purified extracts of bovine splenic nerve resembled norepinephrine by all criteria used. Norepinephrine is the predominant sympathomimetic substance in the postganglionic sympathetic

nerves of mammals and is the adrenergic mediator liberated by their stimulation. Norepinephrine, its immediate precursor *dopamine*, and epinephrine also are neurotransmitters in the CNS (see Chapter 12).

Evidence for Neurohumoral Transmission

The concept of neurohumoral transmission or chemical neurotransmission was developed primarily to explain observations relating to the transmission of impulses from postganglionic autonomic fibers to effector cells. Evidence supporting this concept includes (1) demonstration of the presence of a physiologically active compound and its biosynthetic enzymes at appropriate sites; (2) recovery of the compound from the perfusate of an innervated structure during periods of nerve stimulation but not (or in greatly reduced amounts) in the absence of stimulation; (3) demonstration that the compound is capable of producing responses identical to responses to nerve stimulation; and (4) demonstration that the responses to nerve stimulation and to the administered compound are modified in the same manner by various drugs, usually competitive antagonists.

While these criteria are applicable for most neurotransmitters, including norepinephrine and ACh, there now are exceptions to these general rules. For instance, NO has been found to be a neurotransmitter in nonadrenergic, noncholinergic neurons in the periphery, in the ENS, and in the CNS. However, NO is not stored in neurons and released by exocytosis. Rather, it is synthesized when needed and readily diffuses across membranes.

Chemical rather than electrogenic transmission at autonomic ganglia and the neuromuscular junction of skeletal muscle was not generally accepted for a considerable period because techniques were limited in time and chemical resolution. Techniques of intracellular recording and microiontophoretic application of drugs, as well as sensitive analytical assays, have overcome these limitations.

Neurotransmission in the peripheral and central nervous systems once was believed to conform to the hypothesis that each neuron contains only one transmitter substance. However, peptides such as enkephalin, substance P, neuropeptide Y, VIP, and somatostatin; purines such as ATP and adenosine; and small molecules such as NO have been found in nerve endings. These substances can depolarize or hyperpolarize nerve terminals or postsynaptic cells. Furthermore, results of histochemical, immunocytochemical, and autoradiographic studies have demonstrated that one or more of these substances is present in the same neurons that contain one of the classical biogenic amine neurotransmitters (Bartfai *et al.*, 1988; Lundberg *et al.*, 1996). For example, enkephalins are found in postganglionic sympathetic neurons and adrenal medullary chromaffin cells. VIP is localized selectively in peripheral cholinergic neurons that innervate exocrine glands, and neuropeptide Y is found in sympathetic nerve endings. These observations suggest that synaptic transmission in many instances may be mediated by the release of more than one neurotransmitter (see below).

Steps Involved in Neurotransmission

The sequence of events involved in neurotransmission is of particular importance because pharmacologically active agents modulate the individual steps.

The term *conduction* is reserved for the passage of an impulse along an axon or muscle fiber; *transmission* refers to the passage of an impulse across a synaptic or neuroeffector junction. With the

exception of the local anesthetics, very few drugs modify axonal conduction in the doses employed therapeutically. Hence this process is described only briefly.

Axonal Conduction. Current knowledge of axonal conduction stems largely from the work of Hodgkin and Huxley.

At rest, the interior of the typical mammalian axon is approximately 70 mV negative to the exterior. The resting potential is essentially a diffusion potential based chiefly on the 40 times higher concentration of K^+ in the axoplasm as compared with the extracellular fluid and the relatively high permeability of the resting axonal membrane to K^+ . Na^+ and Cl^- are present in higher concentrations in the extracellular fluid than in the axoplasm, but the axonal membrane at rest is considerably less permeable to these ions; hence their contribution to the resting potential is small. These ionic gradients are maintained by an energy-dependent active transport mechanism, the Na^+K^+ -ATPase (*see* Hille, 1992; Hille *et al.*, 1999).

In response to depolarization to a threshold level, an action potential or nerve impulse is initiated at a local region of the membrane. The action potential consists of two phases. Following a small gating current resulting from depolarization inducing an open conformation of the channel, the initial phase is caused by a rapid increase in the permeability of Na^+ through voltage-sensitive Na^+ channels. The result is inward movement of Na^+ and a rapid depolarization from the resting potential, which continues to a positive overshoot. The second phase results from the rapid inactivation of the Na^+ channel and the delayed opening of a K^+ channel, which permits outward movement of K^+ to terminate the depolarization. Inactivation appears to involve a voltage-sensitive conformational change in which a hydrophobic peptide loop physically occludes the open channel at the cytoplasmic side. Although not important in axonal conduction, Ca^{2+} channels in other tissues (*e.g.*, L-type Ca^{2+} channels in heart) contribute to the action potential by prolonging depolarization by an inward movement of Ca^{2+} . This influx of Ca^{2+} also serves as a stimulus to initiate intracellular events (Hille, 1992; Catterall, 2000).

The transmembrane ionic currents produce local circuit currents around the axon. As a result of such localized changes in membrane potential, adjacent resting channels in the axon are activated, and excitation of an adjacent portion of the axonal membrane occurs. This brings about propagation of the action potential without decrement along the axon. The region that has undergone depolarization remains momentarily in a refractory state. In myelinated fibers, permeability changes occur only at the nodes of Ranvier, thus causing a rapidly progressing type of jumping, or saltatory, conduction. The puffer fish poison *tetrodotoxin* and a close congener found in some shellfish, *saxitoxin*, selectively block axonal conduction; they do so by blocking the voltage-sensitive Na^+ channel and preventing the increase in Na^+ permeability associated with the rising phase of the action potential. In contrast, *batrachotoxin*, an extremely potent steroidal alkaloid secreted by a South American frog, produces paralysis through a selective increase in permeability of the Na^+ channel, which induces a persistent depolarization. Scorpion toxins are peptides that also cause persistent depolarization, but they do so by inhibiting the inactivation process (*see* Catterall, 2000). Na^+ and Ca^{2+} channels are discussed in more detail in Chapters 14, 31, and 34.

Junctional Transmission. The arrival of the action potential at the axonal terminals initiates a series of events that

trigger transmission of an excitatory or inhibitory impulse across the synapse or neuroeffector junction. These events, diagrammed in Figure 6–2, are:

1. *Storage and release of the transmitter.* The non-peptide (small molecule) neurotransmitters are largely synthesized in the region of the axonal terminals and stored there in synaptic vesicles. Peptide neurotransmitters (or precursor peptides) are found in large dense-core vesicles that are transported down the axon from their site of synthesis in the cell body. During the resting state, there is a continual slow release of isolated quanta of the transmitter; this produces electrical responses at the postjunctional membrane [miniature end-plate potentials (*mepps*)] that are associated with the maintenance of physiological responsiveness of the effector organ. A low level of spontaneous activity within the motor units of skeletal muscle is particularly important because skeletal muscle lacks inherent tone. The action potential causes the synchronous release of several hundred quanta of neurotransmitter. Depolarization of the axonal terminal triggers this process; a critical step in most but not all nerve endings is the influx of Ca^{2+} , which enters the axonal cytoplasm and promotes fusion between the axoplasmic membrane and those vesicles in close proximity to it (*see* Meir *et al.*, 1999; Hille *et al.*, 1999). The contents of the vesicles, including enzymes and other proteins, then are discharged to the exterior by a process termed *exocytosis*. Synaptic vesicles may either fully exocytose with complete fusion and subsequent endocytosis or form a transient pore that closes after transmitter has escaped (Murthy and Stevens, 1998).

Synaptic vesicles are clustered in discrete areas underlying the presynaptic plasma membrane, termed *active zones*; they often are aligned with the tips of postsynaptic folds. Some 20 to 40 proteins, playing distinct roles as transporter or trafficking proteins, are found in the vesicle. Neurotransmitter transport into the vesicle is driven by an electrochemical gradient generated by the vacuolar proton pump.

The function of the trafficking proteins is less well understood, but the vesicle protein synaptobrevin (VAMP) assembles with the plasma membrane proteins SNAP-25 and syntaxin 1 to form a core complex that initiates or drives the vesicle–plasma membrane fusion process (Jahn *et al.*, 2003). The submillisecond triggering of exocytosis by Ca^{2+} appears to be mediated by a separate family of proteins, the synaptotagmins. GTP-binding proteins of the Rab 3 family regulate the fusion process and cycle on and off the vesicle through GTP hydrolysis. Several other regulatory proteins of less well-defined function—synapsin, synaptophysin, and synaptogyrin—also play a role in fusion and exocytosis, as do proteins such as RIM and neuexin that are found on the active zones of the plasma membrane. Many of the trafficking proteins are homologous to those used in vesicular transport in yeast.

Figure 6–2. Steps involved in excitatory and inhibitory neurotransmission. **1.** The nerve action potential (AP) consists of a transient self-propagated reversal of charge on the axonal membrane. (The internal potential E_i goes from a negative value, through zero potential, to a slightly positive value primarily through increases in Na⁺ permeability and then returns to resting values by an increase in K⁺ permeability.) When the AP arrives at the presynaptic terminal, it initiates release of the excitatory or inhibitory transmitter. Depolarization at the nerve ending and entry of Ca²⁺ initiate docking and then fusion of the synaptic vesicle with the membrane of the nerve ending. Docked and fused vesicles are shown. **2.** Combination of the excitatory transmitter with postsynaptic receptors produces a localized depolarization, the excitatory postsynaptic potential (EPSP), through an increase in permeability to cations, most notably Na⁺. The inhibitory transmitter causes a selective increase in permeability to K⁺ or Cl⁻, resulting in a localized hyperpolarization, the inhibitory postsynaptic potential (IPSP). **3.** The EPSP initiates a conducted AP in the postsynaptic neuron; this can be prevented, however, by the hyperpolarization induced by a concurrent IPSP. The transmitter is dissipated by enzymatic destruction, by reuptake into the presynaptic terminal or adjacent glial cells, or by diffusion. (Modified from Eccles, 1964, 1973; Katz, 1966; Catterall, 1992; Jahn and Südhof, 1994.)

Over the past 30 years an extensive variety of receptors has been identified on soma, dendrites, and axons of neurons, where they respond to neurotransmitters or modulators released from the same neuron or from adjacent neurons or cells (Langer, 1997; Miller, 1998; Westfall, 2004). Soma–dendritic receptors are those receptors located on or near the cell body and dendrites; when activated, they primarily modify functions of the soma–dendritic region such as protein synthesis and generation of action potentials. Presynaptic receptors are those presumed to be located on, in, or near axon terminals or varicosities; when activated, they modify functions of the terminal region such as synthesis and release of transmitters. Two main classes of presynaptic receptors have been identified on most neurons, including sympathetic and parasympathetic terminals. Heteroreceptors are presynaptic receptors that respond to neurotransmitters, neuro-modulators, or neurohormones released from adjacent neurons or

cells. For example, norepinephrine can influence the release of ACh from parasympathetic neurons by acting on α_{2A} , α_{2B} , and α_{2C} receptors, whereas ACh can influence the release of norepinephrine from sympathetic neurons by acting on M₂ and M₄ receptors (*see below*). The other class of presynaptic receptors consists of autoreceptors, which are receptors located on or close to those axon terminals of a neuron through which the neuron's own transmitter can modify transmitter synthesis and release. For example, norepinephrine released from sympathetic neurons may interact with α_{2A} and α_{2C} receptors to inhibit neurally released norepinephrine. Similarly, ACh released from parasympathetic neurons may interact with M₂ and M₄ receptors to inhibit neurally released ACh.

Presynaptic nicotinic receptors enhance transmitter release in motor neurons (Bowman *et al.*, 1990) and in a variety of other central and peripheral synapses (MacDermott *et al.*, 1999).

Adenosine, dopamine, *glutamate*, γ -aminobutyric acid (GABA), *prostaglandins*, and *enkephalins* have been shown to influence neurally mediated release of various neurotransmitters. The receptors for these agents exert their modulatory effects in part by altering the function of prejunctional ion channels (Tsien *et al.*, 1988; Miller, 1998). A number of ion channels that directly control transmitter release are found in presynaptic terminals (Meir *et al.*, 1999).

2. Combination of the transmitter with postjunctional receptors and production of the postjunctional potential.

The transmitter diffuses across the synaptic or junctional cleft and combines with specialized receptors on the postjunctional membrane; this often results in a localized increase in the ionic permeability, or conductance, of the membrane. With certain exceptions (noted below), one of three types of permeability change can occur: (a) a generalized increase in the permeability to cations (notably Na^+ but occasionally Ca^{2+}), resulting in a localized depolarization of the membrane, *i.e.*, an excitatory postsynaptic potential (EPSP); (b) a selective increase in permeability to anions, usually Cl^- , resulting in stabilization or actual hyperpolarization of the membrane, which constitutes an inhibitory postsynaptic potential (IPSP); or (c) an increased permeability to K^+ . Because the K^+ gradient is directed out of the cell, hyperpolarization and stabilization of the membrane potential occur (an IPSP).

It should be emphasized that the potential changes associated with the EPSP and IPSP at most sites are the results of passive fluxes of ions down their concentration gradients. The changes in channel permeability that cause these potential changes are specifically regulated by the specialized postjunctional receptors for the neurotransmitter that initiates the response (*see* Chapter 12 and below). These receptors may be clustered on the effector cell surface, as seen at the neuromuscular junctions of skeletal muscle and other discrete synapses, or distributed more uniformly, as observed in smooth muscle.

By using microelectrodes that form high-resistance seals on the surface of cells, electrical events associated with a single neurotransmitter-gated channel can be recorded (*see* Hille, 1992). In the presence of an appropriate neurotransmitter, the channel opens rapidly to a high-conductance state, remains open for about a millisecond, and then closes. A short squarewave pulse of current is observed as a result of the channel's opening and closing. The summation of these microscopic events gives rise to the EPSP. The graded response to a neurotransmitter usually is related to the frequency of opening events rather than to the extent of opening or the duration of opening. High-conductance ligand-gated ion channels usually permit passage of Na^+ or Cl^- ; K^+ and Ca^{2+} are involved less frequently. The preceding ligand-gated channels belong to a large superfamily of ionotropic receptor proteins that includes the nicotinic, glutamate, and certain serotonin (5-HT₃) and purine receptors, which conduct primarily Na^+ , cause depolarization, and are excitatory, and GABA and glycine receptors, which conduct Cl^- , cause hyperpolarization, and are inhibitory. The nicotinic, GABA, gly-

cine, and 5-HT₃ receptors are closely related, whereas the glutamate and purinergic ionotropic receptors have distinct structures (Karlin and Akabas, 1995). Neurotransmitters also can modulate the permeability of K^+ and Ca^{2+} channels indirectly. In these cases, the receptor and channel are separate proteins, and information is conveyed between them by G proteins (*see* Chapter 1). Other receptors for neurotransmitters act by influencing the synthesis of intracellular second messengers and do not necessarily cause a change in membrane potential. The most widely documented examples of receptor regulation of second-messenger systems are the activation or inhibition of adenylyl cyclase and the increase in intracellular concentrations of Ca^{2+} that results from release of the ion from internal stores by *inositol trisphosphate* (*see* Chapter 1).

3. Initiation of postjunctional activity.

If an EPSP exceeds a certain threshold value, it initiates a propagated action potential in a postsynaptic neuron or a muscle action potential in skeletal or cardiac muscle by activating voltage-sensitive channels in the immediate vicinity. In certain smooth muscle types in which propagated impulses are minimal, an EPSP may increase the rate of spontaneous depolarization, cause Ca^{2+} release, and enhance muscle tone; in gland cells, the EPSP initiates secretion through Ca^{2+} mobilization. An IPSP, which is found in neurons and smooth muscle but not in skeletal muscle, will tend to oppose excitatory potentials simultaneously initiated by other neuronal sources. Whether a propagated impulse or other response ensues depends on the summation of all the potentials.

4. Destruction or dissipation of the transmitter.

When impulses can be transmitted across junctions at frequencies up to several hundred per second, it is obvious that there should be an efficient means of disposing of the transmitter following each impulse. At cholinergic synapses involved in rapid neurotransmission, high and localized concentrations of *acetylcholinesterase* (AChE) are available for this purpose. On inhibition of AChE, removal of the transmitter is accomplished principally by diffusion. Under these circumstances, the effects of released ACh are potentiated and prolonged (*see* Chapter 8).

Rapid termination of norepinephrine occurs by a combination of simple diffusion and reuptake by the axonal terminals of most of the released norepinephrine. Termination of the action of amino acid transmitters results from their active transport into neurons and surrounding glia. Peptide neurotransmitters are hydrolyzed by various peptidases and dissipated by diffusion; specific uptake mechanisms have not been demonstrated for these substances.

5. Nonelectrogenic functions.

The continual quantal release of neurotransmitters in amounts insufficient to elicit a postjunctional response probably is important in

the transjunctional control of neurotransmitter action. The activity and turnover of enzymes involved in the synthesis and inactivation of neurotransmitters, the density of presynaptic and postsynaptic receptors, and other characteristics of synapses probably are controlled by trophic actions of neurotransmitters or other trophic factors released by the neuron or the target cells (Sanes and Lichtman, 1999).

Cholinergic Transmission

The synthesis, storage, and release of ACh follow a similar life cycle in all cholinergic synapses, including those at skeletal neuromuscular junctions, preganglionic sympathetic and parasympathetic terminals, postganglionic parasympathetic varicosities, postganglionic sympathetic varicosities innervating sweat glands in the skin, and in the CNS. The neurochemical events that underlie cholinergic neurotransmission are summarized in Figure 6–3 (see Whittaker, 1988, for review). Two enzymes, choline acetyltransferase and AChE, are involved in ACh synthesis and degradation, respectively.

Choline Acetyltransferase. Choline acetyltransferase catalyzes the final step in the synthesis of ACh—the acetylation of choline with acetyl coenzyme A (CoA) (see Wu and Hersh, 1994). The primary structure of choline acetyltransferase is known from molecular cloning, and its immunocytochemical localization has proven useful for identification of cholinergic axons and nerve cell bodies.

Acetyl CoA for this reaction is derived from pyruvate *via* the multistep pyruvate dehydrogenase reaction or is synthesized by acetate thiokinase, which catalyzes the reaction of acetate with ATP to form an enzyme-bound acyladenylate (acetyl AMP). In the presence of CoA, transacetylation and synthesis of acetyl CoA proceed.

Choline acetyltransferase, like other protein constituents of the neuron, is synthesized within the perikaryon and then is transported along the length of the axon to its terminal. Axonal terminals contain a large number of mitochondria, where acetyl CoA is synthesized. Choline is taken up from the extracellular fluid into the axoplasm by active transport. The final step in the synthesis occurs within the cytoplasm, following which most of the ACh is sequestered within synaptic vesicles. Although moderately potent inhibitors of choline acetyltransferase exist, they have no therapeutic utility in part because the uptake of choline is the rate-limiting step in ACh biosynthesis.

Choline Transport. Transport of choline from the plasma into neurons is accomplished by distinct high- and low-affinity transport systems. The high-affinity system ($K_m = 1$ to $5 \mu\text{M}$) is unique to cholinergic neurons, is

dependent on extracellular Na^+ , and is inhibited by *hemicholinium*. Plasma concentrations of choline approximate $10 \mu\text{M}$; thus, the concentration of choline does not limit its availability to cholinergic neurons. Much of the choline formed from AChE-catalyzed hydrolysis of ACh is recycled into the nerve terminal. The cloning of the high-affinity choline transporter found in presynaptic terminals reveals a sequence and structure differing from those of other neurotransmitter transporters but similar to that of the Na^+ -dependent glucose transporter family (Ferguson and Blakely, 2004).

Storage of ACh. After its synthesis from choline, ACh is taken up by the storage vesicles principally at the nerve terminals. The vesicles are transported anterogradely from the cell body *via* the microtubules, with little ACh incorporation taking place during this process.

There appear to be two types of vesicles in cholinergic terminals: electron-lucent vesicles (40 to 50 nm in diameter) and dense-cored vesicles (80 to 150 nm). The core of the vesicles contains both ACh and ATP, at an estimated ratio of 10:1, which are dissolved in the fluid phase with metal ions (Ca^{2+} and Mg^{2+}) and a proteoglycan called *vesiculin*. Vesiculin is negatively charged and is thought to sequester the Ca^{2+} or ACh. It is bound within the vesicle, with the protein moiety anchoring it to the vesicular membrane. In some cholinergic terminals there are peptides, such as VIP, that act as cotransmitters at some junctions. The peptides usually are located in the dense-cored vesicles. Vesicular membranes are rich in lipids, primarily cholesterol and phospholipids, as well as protein. The proteins include ATPase, which is ouabain-sensitive and thought to be involved in proton pumping and in vesicular inward transport of Ca^{2+} . Other proteins include protein kinase (involved in phosphorylation mechanisms of Ca^{2+} uptake), calmodulin, atractyloside-binding protein (which acts as an ATP carrier), and synapsin (which is thought to be involved with exocytosis).

The vesicular transporter allows for the uptake of ACh into the vesicle, has considerable concentrating power, is saturable, and is ATPase-dependent. The process is inhibited by vesamicol (Figure 6–3). Inhibition by *vesamicol* is noncompetitive and reversible and does not affect the vesicular ATPase. The gene for choline acetyltransferase and the vesicular transporter are found at the same locus, with the transporter gene positioned in the first intron of the transferase gene. Hence a common promoter regulates the expression of both genes (Eiden, 1998).

Estimates of the ACh content of synaptic vesicles range from 1000 to over 50,000 molecules per vesicle, and it has been calculated that a single motor nerve terminal contains 300,000 or more vesicles. In addition, an uncertain but possibly significant amount of ACh is present in the extravesicular cytoplasm. Recording the electrical events associated with the opening of single channels at the motor end plate during continuous application of ACh has permitted estimation of the potential change induced by a single molecule of ACh (3×10^{-7} V); from such calculations it is evident that even the lower estimate of the ACh content per vesicle (1000 molecules) is sufficient to account for the magnitude of the mepps.

Figure 6–3. Schematic representations of a cholinergic neuroeffector junction showing features of the synthesis, storage, and release of acetylcholine (ACh) and receptors on which ACh acts. The synthesis of ACh in the varicosity depends on the uptake of choline via a sodium-dependent carrier. This uptake can be blocked by hemicholinium. Choline and the acetyl moiety of acetyl coenzyme A, derived from mitochondria, form ACh, a process catalyzed by the enzyme choline acetyltransferase (ChAT). ACh is transported into the storage vesicle by another carrier that can be inhibited by vesamicol. ACh is stored in vesicles along with other potential cotransmitters (Co-T) such as ATP and VIP at certain neuroeffector junctions. Release of ACh and the Co-T occurs on depolarization of the varicosity, which allows the entry of Ca²⁺ through voltage-dependent Ca²⁺ channels. Elevated [Ca²⁺]_{in} promotes fusion of the vesicular membrane with the cell membrane, and exocytosis of the transmitters occurs. This fusion process involves the interaction of specialized proteins associated with the vesicular membrane (VAMPs, vesicle-associated membrane proteins) and the membrane of the varicosity (SNAPS, synaptosome-associated proteins). The exocytotic release of ACh can be blocked by botulinum toxin. Once released, ACh can interact with the muscarinic receptors (mAChR), which are GPCRs, or nicotinic receptors (nAChR), which are ligand-gated ion channels, to produce the characteristic response of the effector. ACh also can act on presynaptic mAChRs or nAChRs to modify its own release. The action of ACh is terminated by metabolism to choline and acetate by acetylcholinesterase (AChE), which is associated with synaptic membranes.

Release of Acetylcholine. Fatt and Katz recorded at the motor end plate of skeletal muscle and observed the random occurrence of small (0.1 to 3.0 mV) spontaneous depolarizations at a frequency of approximately 1 Hz. The magnitude of these mepps is considerably below the threshold required to fire a muscle action potential (AP); that they are due to the release of ACh is indicated by their enhancement by *neostigmine* (an anti-ChE agent) and their block-

ade by *D-tubocurarine* (a competitive antagonist that acts at nicotinic receptors). These results led to the hypothesis that ACh is released from motor nerve endings in constant amounts, or quanta. The likely morphological counterpart of quantal release was discovered shortly thereafter in the form of synaptic vesicles by De Robertis and Bennett. Most of the storage and release properties of ACh originally investigated in motor end plates apply to other

fast-responding synapses. When an AP arrives at the motor nerve terminal, there is a synchronous release of 100 or more quanta (or vesicles) of ACh.

The release of ACh and other neurotransmitters by exocytosis through the prejunctional membrane is inhibited by botulinum and tetanus toxins from *Clostridium*. The *Clostridium* toxins, consisting of disulfide-linked heavy and light chains, bind to an as-yet-unidentified receptor on the membrane of the cholinergic nerve terminal. Through endocytosis, they are transported into the cytosol. The light chain is a Zn²⁺-dependent protease that becomes activated and hydrolyzes components of the core or SNARE complex involved in exocytosis. The various serotypes of botulinum toxin digest select proteins in the plasma membrane (syntaxin and SNAP-25) and the synaptic vesicle (synaptobrevin). Therapeutic uses of botulinum toxin are described in Chapters 9 and 63.

By contrast, tetanus toxin primarily has a central action because it is transported in retrograde fashion up the motor neuron to its soma in the spinal cord. From there the toxin migrates to inhibitory neurons that synapse with the motor neuron and blocks exocytosis in the inhibitory neuron. The block of release of inhibitory transmitter gives rise to tetanus or spastic paralysis. The toxin from the venom of black widow spiders (α -latrotoxin) binds to neurexins, transmembrane proteins that reside on the nerve terminal membrane, resulting in massive synaptic vesicle exocytosis (Schiavo *et al.*, 2000).

Acetylcholinesterase (AChE). For ACh to serve as a neurotransmitter in the motor system and at other neuronal synapses, it must be removed or inactivated within the time limits imposed by the response characteristics of the synapse. At the neuromuscular junction, immediate removal is required to prevent lateral diffusion and sequential activation of adjacent receptors. Modern biophysical methods have revealed that the time required for hydrolysis of ACh at the neuromuscular junction is less than a millisecond. The K_m of AChE for ACh is approximately 50 to 100 μ M. Choline has only 10^{-3} to 10^{-5} the potency of ACh at the neuromuscular junction.

While AChE is found in cholinergic neurons (dendrites, perikarya, and axons), it is distributed more widely than cholinergic synapses. It is highly concentrated at the postsynaptic end plate of the neuromuscular junction. Butyrylcholinesterase (BuChE; also known as *pseudocholinesterase*) is present in low abundance in glial or satellite cells but is virtually absent in neuronal elements of the central and peripheral nervous systems. BuChE is synthesized primarily in the liver and is found in liver and plasma; its likely vestigial physiological function is the hydrolysis of ingested esters from plant sources. AChE and BuChE typically are distinguished by the relative rates of ACh and butyrylcholine hydrolysis and by effects of selective inhibitors (*see* Chapter 8). Almost all pharmacological effects of the anti-ChE agents are due to the inhibition of AChE, with the consequent accumulation of endogenous ACh in the vicinity of the nerve terminal. Distinct but single genes encode AChE and BuChE in mammals; the diversity

of molecular structure of AChE arises from alternative mRNA processing (Taylor *et al.*, 2000).

AChE also has been proposed to have multiple nonclassical biological functions that are not obvious and that remain controversial (Soreg and Seidman, 2001). These nonclassical functions include neuritogenesis, cell adhesion, synaptogenesis, amyloid fiber assembly, activation of dopamine receptors, hematopoiesis, and thrombopoiesis.

Characteristics of Cholinergic Transmission at Various Sites. There are marked differences among various sites of cholinergic transmission with respect to architecture and fine structure, the distributions of AChE and receptors, and the temporal factors involved in normal function. In skeletal muscle, for example, the junctional sites occupy a small, discrete portion of the surface of the individual fibers and are relatively isolated from those of adjacent fibers; in the superior cervical ganglion, approximately 100,000 ganglion cells are packed within a volume of a few cubic millimeters, and both the presynaptic and postsynaptic neuronal processes form complex networks.

Skeletal Muscle. Stimulation of a motor nerve results in the release of ACh from perfused muscle; close intra-arterial injection of ACh produces muscular contraction similar to that elicited by stimulation of the motor nerve. The amount of ACh (10^{-17} mol) required to elicit an end-plate potential (EPP) following its microiontophoretic application to the motor end plate of a rat diaphragm muscle fiber is equivalent to that recovered from each fiber following stimulation of the phrenic nerve.

The combination of ACh with nicotinic ACh receptors at the external surface of the postjunctional membrane induces an immediate, marked increase in cation permeability. On receptor activation by ACh, its intrinsic channel opens for about 1 ms; during this interval, about 50,000 Na⁺ ions traverse the channel. The channel-opening process is the basis for the localized depolarizing EPP within the end plate, which triggers the muscle AP. The latter, in turn, leads to contraction.

Following section and degeneration of the motor nerve to skeletal muscle or of the postganglionic fibers to autonomic effectors, there is a marked reduction in the threshold doses of the transmitters and of certain other drugs required to elicit a response; *i.e.*, denervation supersensitivity occurs. In skeletal muscle, this change is accompanied by a spread of the receptor molecules from the end-plate region to the adjacent portions of the sarcoplasmic membrane, which eventually involves the entire muscle surface. Embryonic muscle also exhibits this uniform sensitivity to ACh prior to innervation. Hence, innervation represses the expression of the receptor gene by the nuclei that lie in extrajunctional regions of the muscle fiber and directs the subsynaptic nuclei to express the structural and functional proteins of the synapse (Sanes and Lichtman, 1999).

Autonomic Effectors. Stimulation or inhibition of autonomic effector cells occurs on activation of muscarinic acetylcholine receptors (*see* below). In this case, the effector is coupled to the receptor by a G protein (*see* Chapter 1). In contrast to skeletal mus-

cle and neurons, smooth muscle and the cardiac conduction system [sinoatrial (SA) node, atrium, atrioventricular (AV) node, and the His–Purkinje system] normally exhibit intrinsic activity, both electrical and mechanical, that is modulated but not initiated by nerve impulses.

In the basal condition, unitary smooth muscle exhibits waves of depolarization and/or spikes that are propagated from cell to cell at rates considerably slower than the AP of axons or skeletal muscle. The spikes apparently are initiated by rhythmic fluctuations in the membrane resting potential. Application of ACh (0.1 to 1 μM) to isolated intestinal muscle causes a decrease in the resting potential (*i.e.*, the membrane potential becomes less negative) and an increase in the frequency of spike production, accompanied by a rise in tension. A primary action of ACh in initiating these effects through muscarinic receptors is probably partial depolarization of the cell membrane brought about by an increase in Na^+ and, in some instances, Ca^{2+} conductance. ACh also can produce contraction of some smooth muscles when the membrane has been depolarized completely by high concentrations of K^+ , provided that Ca^{2+} is present. Hence, ACh stimulates ion fluxes across membranes and/or mobilizes intracellular Ca^{2+} to cause contraction.

In the heart, spontaneous depolarizations normally arise from the SA node. In the cardiac conduction system, particularly in the SA and AV nodes, stimulation of the cholinergic innervation or the direct application of ACh causes inhibition, associated with hyperpolarization of the membrane and a marked decrease in the rate of depolarization. These effects are due, at least in part, to a selective increase in permeability to K^+ (Hille, 1992).

Autonomic Ganglia. The primary pathway of cholinergic transmission in autonomic ganglia is similar to that at the neuromuscular junction of skeletal muscle. Ganglion cells can be discharged by injecting very small amounts of ACh into the ganglion. The initial depolarization is the result of activation of nicotinic ACh receptors, which are ligand-gated cation channels with properties similar to those found at the neuromuscular junction. Several secondary transmitters or modulators either enhance or diminish the sensitivity of the postganglionic cell to ACh. This sensitivity appears to be related to the membrane potential of the postsynaptic nerve cell body or its dendritic branches. Ganglionic transmission is discussed in more detail in Chapter 9.

Actions of Acetylcholine at Prejunctional Sites. As described earlier, both cholinergic and adrenergic nerve terminal varicosities contain autoreceptors and heteroreceptors. ACh release therefore is subject to complex regulation by mediators, including ACh itself acting on M_2 and M_4 autoreceptors, and other transmitters (*e.g.*, norepinephrine acting on α_{2A} - and α_{2C} adrenergic receptors) (Philipp and Hein, 2004; Wess, 2004) or substances produced locally in tissues (*e.g.*, NO). ACh-mediated inhibition of ACh release following activation of M_2 and M_4 autoreceptors is thought to represent a physiological negative-feedback control mechanism. At some neuroeffector junctions such as the myenteric plexus in the GI tract or the SA node in the heart, sympathetic and parasympathetic nerve terminals often lie juxtaposed to each other. The opposing effects of norepinephrine and ACh, therefore, result not only from the opposite effects of the two transmitters on the smooth muscle or cardiac cells but also from the inhibition of ACh release by norepinephrine or inhibition of norepinephrine release by ACh acting on heteroreceptors on para-

sympathetic or sympathetic terminals. The muscarinic autoreceptors and heteroreceptors also represent drug targets for both agonists and antagonists. Muscarinic agonists can inhibit the electrically induced release of ACh, whereas antagonists will enhance the evoked release of transmitter. The parasympathetic nerve terminal varicosities also may contain additional heteroreceptors that could respond by inhibition or enhancement of ACh release by locally formed autacoids, hormones, or administered drugs. In addition to α_{2A} and α_{2C} adrenergic receptors, other inhibitory heteroreceptors on parasympathetic terminals include adenosine A_1 receptors, histamine H_3 receptors, and opioid receptors. Evidence also exists for β_2 -adrenoceptive facilitatory receptors (for review, *see* Broadly, 1996).

Extraneuronal Cholinergic Systems. ACh is present in the vast majority of human cells and organs, including epithelial cells (airways, alimentary tract, epidermis, glandular tissue), mesothelial and endothelial cells, circulating cells (platelets), and immune cells (mononuclear cells, macrophages). Although the exact function of non-neuronal ACh is not known precisely, proposed roles include the regulation of elementary cell functions such as mitosis, locomotion, automaticity, ciliary activity, cell–cell contact, barrier function, respiration and secretion, and regulation of lymphocyte function (Wessler *et al.*, 1998; Kawashima and Fujii, 2000).

Cholinergic Receptors and Signal Transduction. Sir Henry Dale noted that the various esters of choline elicited responses that were similar to those of either *nicotine* or *muscarine* depending on the pharmacological preparation. A similarity in response also was noted between muscarine and nerve stimulation in those organs innervated by the craniosacral divisions of the autonomic nervous system. Thus, Dale suggested that ACh or another ester of choline was a neurotransmitter in the autonomic nervous system; he also stated that the compound had dual actions, which he termed a “nicotine action” (*nicotinic*) and a “muscarine action” (*muscarinic*).

The capacities of *tubocurarine* and *atropine* to block nicotinic and muscarinic effects of ACh, respectively, provided further support for the proposal of two distinct types of cholinergic receptors. Although Dale had access only to crude plant alkaloids of then unknown structure from *Amanita muscaria* and *Nicotiana tabacum*, this classification remains as the primary subdivision of cholinergic receptors. Its utility has survived the discovery of several distinct subtypes of nicotinic and muscarinic receptors.

Although ACh and certain other compounds stimulate both muscarinic and nicotinic cholinergic receptors, several other agonists

and antagonists are selective for one of the two major types of receptors. ACh is a flexible molecule, and indirect evidence suggests that the conformations of the neurotransmitter are distinct when it is bound to nicotinic or muscarinic cholinergic receptors.

Nicotinic receptors are ligand-gated ion channels whose activation always causes a rapid (millisecond) increase in cellular permeability to Na^+ and Ca^{2+} , depolarization, and excitation. By contrast, muscarinic receptors are G protein-coupled receptors (GPCRs). Responses to muscarinic agonists are slower; they may be either excitatory or inhibitory, and they are not necessarily linked to changes in ion permeability.

The primary structures of various species of nicotinic receptors (Numa *et al.*, 1983; Changeux and Edelman, 1998) and muscarinic receptors (Bonner, 1989; Caulfield and Birdsall, 1998) have been deduced from the sequences of their respective genes. That these two types of receptors belong to distinct families of proteins is not surprising, retrospectively, in view of their distinct differences in chemical specificity and function.

Subtypes of Nicotinic Acetylcholine Receptors

The nicotinic ACh receptors (nAChRs) are members of a superfamily of ligand-gated ion channels. The receptors exist at the skeletal neuromuscular junction, autonomic ganglia, and adrenal medulla and in the CNS. They are the natural targets for ACh as well as pharmacologically administered drugs, including nicotine. The receptor forms a pentameric structure consisting of homomeric α and β subunits. In humans, eight α subunits (α_2 through α_7 , α_9 , and α_{10}) and three β subunits (β_2 through β_4) have been cloned. A further α_8 subunit has been cloned in chickens but is not present in mammals. Both the muscle and neuronal nAChRs share structural and functional properties with other ligand-gated channels such as the GABA_A, 5-HT₃, and glycine receptors. The muscle nAChR is the best-characterized ligand-gated ion channel both because large quantities of receptors have been purified from *Torpedo* electrical organs and because of the existence of highly specific agonists and antagonists (Picciotto *et al.*, 2001).

The muscle nicotinic receptor contains four distinct subunits in a pentameric complex ($\alpha\beta\delta\gamma$ or $\alpha_2\beta\delta\epsilon$). Receptors in embryonic or denervated muscle contain a γ subunit, whereas an ϵ subunit replaces the γ in adult innervated muscle (Table 6–2). This change in expression of the genes encoding the γ and ϵ subunits gives rise to small differences in ligand selectivity but may be more important for dictating rates of turnover of the receptors or their tissue localization.

The muscle and neuronal subunits share the basic topography of a large extracellular N-terminal domain that contributes to agonist binding, four hydrophobic transmembrane domains (TM₁ through TM₄), a large

cytoplasmic loop between TM₃ and TM₄, and a short extracellular C terminus. The M₂ transmembrane region is thought to form the ion pore of the nAChR (Picciotto *et al.*, 2001).

Functional neuronal nAChRs also exist as pentamers composed of two α and three β subunits with “duplex” (α/β) or “triplex” (α_x , $\alpha_y\beta$, or $\alpha\beta_x\beta_y$) conformation (De Biasi, 2002). The *in vivo* composition and functional role of most of the nAChRs is unclear. Autonomic ganglia form homomeric α_7 and heteromeric $\alpha_3\beta_4$, with $(\alpha_3)_2(\beta_4)_3$ being the most prevalent.

The pentameric structure of the neuronal nAChR and the considerable molecular diversity of its subunits offer the possibility of a large number of nAChRs with different physiological properties. These receptors may subserve a variety of discrete functions and thus represent novel drug targets for a wide variety of therapeutic agents. The stoichiometry of most nAChRs in brain is still uncertain, although an abundant nAChR $\alpha_4\beta_3$ is proposed to have two α_4 and three β_3 subunits (Lindstrom, 2000). More complex combinations with three ($\alpha_3\beta_4\alpha_5$) or four ($\alpha_3\beta_2\beta_3\alpha_5$) different subunits have been identified. Until recently, few selective ligands were available that affect nAChR function, but the list of selective agents is expanding considerably (Lloyd and Williams, 2000). For example, the neuronal nAChR subunits on presynaptic terminals of dopamine neurons projecting to the striatum have been fully defined (Luetje, 2004), as has the complete subunit composition of four major presynaptic nAChR subtypes in the striatum (Salminen *et al.*, 2004). The α conotoxin MII-sensitive class of receptors consists of $\alpha_6\beta_2\beta_3$ and $\alpha_3\alpha_6\beta_2\beta_3$, whereas the α conotoxin MII-resistant class consists of $\alpha_4\beta_2$ and $\alpha_4\alpha_5\beta_2$ subunits. It can be expected that similar advances soon will be made with other neuronal nAChRs.

Owing to the large number of permutations of α and β subunits, it is not possible to make a pharmacological classification of all the subtypes at this time. Distinctions between nAChRs are listed in Table 6–2. The structure, function, distribution, and subtypes of nicotinic receptors are described in more detail in Chapter 9.

Subtypes of Muscarinic Receptors. In mammals, five distinct subtypes of muscarinic ACh receptors (mAChRs) have been identified, each produced by a different gene. Like the different forms of nicotinic receptors, these variants have distinct anatomical locations in the periphery and CNS and differing chemical specificities. The mAChRs are GPCRs (see Table 6–3 for characteristics of the mAChRs).

Different experimental approaches including immunohistochemical and mRNA hybridization studies have shown that mAChRs are present in virtually all organs, tissues, and cell types (Table 6–3), although certain subtypes often predominate specific sites. For example, the M₂ receptor is the predominant subtype in the heart, whereas the M₃ receptor is the predominant subtype in the bladder (Dhein *et al.*, 2001; Fetscher *et al.*, 2002). In the periphery, mAChRs mediate the classical muscarinic actions of

Table 6–2
Characteristics of Subtypes of Nicotinic Acetylcholine Receptors (nAChRs)

RECEPTOR (PRIMARY RECEPTOR SUBTYPE)*	MAIN SYNAPTIC LOCATION	MEMBRANE RESPONSE	MOLECULAR MECHANISM	AGONISTS	ANTAGONISTS
Skeletal muscle (N_M) (α_1) ₂ (β_1) $\epsilon\delta$ adult (α_1) ₂ (β_1) $\gamma\delta$ fetal	Skeletal neuro-muscular junction (postjunctional)	Excitatory; end-plate depolarization; skeletal muscle contraction	Increased cation permeability (Na^+ ; K^+)	ACh Nicotine Succinylcholine	Atracurium Vecuronium <i>d</i> -Tubocurarine Pancuronium α -Conotoxin α -Bungarotoxin
Peripheral neuronal (N_N) (α_3) ₂ (β_4) ₃	Autonomic ganglia; adrenal medulla	Excitatory; depolarization; firing of postganglion neuron; depolarization and secretion of catecholamines	Increased cation permeability (Na^+ ; K^+)	ACh Nicotine Epibatidine Dimethylphenylpiperazinium	Trimethaphan Mecamylamine
Central neuronal (CNS) (α_4) ₂ (β_4) ₃ (α -btox-insensitive)	CNS; pre- and postjunctional	Pre- and postsynaptic excitation Prejunctional control of transmitter release	Increased cation permeability (Na^+ ; K^+)	Cytisine, epibatidine Anatoxin A	Mecamylamine Dihydro- β -erythrodine Erysodine Lophotoxin
(α_7) ₅ (α -btox-sensitive)	CNS; Pre- and postsynaptic	Pre- and postsynaptic excitation Prejunctional control of transmitter release	Increased permeability (Ca^{2+})	Anatoxin A	Methyllycaconitine α -Bungarotoxin α -Conotoxin IMI

*Nine individual subunits have been identified and cloned in human brain, which combine in various conformations to form individual receptor subtypes. The structure of individual receptors and the subtype composition are incompletely understood. Only a finite number of naturally occurring functional nAChR constructs have been identified. α -btox, α -bungarotoxin.

ACh in organs and tissues innervated by parasympathetic nerves, although receptors may be present at sites that lack parasympathetic innervation (*e.g.*, most blood vessels). In the CNS, mAChRs are involved in regulating a large number of cognitive, behavior, sensory, motor, and autonomic functions. Owing to the lack of specific muscarinic agonists and antagonists that demonstrate selectivity for individual mAChRs and the fact that most organs and tissues express multiple mAChRs, it has been a challenge to assign specific pharmacological functions to distinct mAChRs. The development of gene-targeting techniques in mice has been very helpful in defining specific functions (Table 6–3) (*see* Wess, 2004).

The basic functions of muscarinic cholinergic receptors are mediated by interactions with G proteins and thus by G protein-induced changes in the function of distinct member-bound effector molecules. The M_1 , M_3 , and M_5 subtypes couple through the pertussis toxin-insensitive G_{11} and G_{13} that are responsible for stimulation of phospholipase C activity. The immediate result is hydrolysis of

membrane phosphatidylinositol 4,5 diphosphate to form inositol polyphosphates. Inositol trisphosphate (IP_3) causes release of intracellular Ca^{2+} from the endoplasmic reticulum, with activation of Ca^{2+} -dependent phenomena such as contraction of smooth muscle and secretion (Berridge, 1993) (*see* Chapter 1). The second product of the phospholipase C reaction, diacylglycerol, activates protein kinase C (in conjunction with Ca^{2+}). This arm of the pathway plays a role in the phosphorylation of numerous proteins, leading to various physiological responses. Activation of M_1 , M_3 , and M_5 receptors can also cause the activation of phospholipase A_2 , leading to the release of arachidonic acid and consequent eicosanoid synthesis, resulting in autocrine/paracrine stimulation of adenylyl cyclase and an increase in cyclic AMP.

Stimulation of M_2 and M_4 cholinergic receptors leads to interaction with other G proteins, (*e.g.*, G_i and G_o) with a resulting inhibition of adenylyl cyclase leading to a decrease in cyclic AMP, activation of inwardly rectifying K^+ channels, and inhibition of voltage-gated Ca^{2+} channels (van Koppen and Kaiser, 2003). The

*Most organs, tissues, and cells express multiple mAChRs. †M₁, M₃, and M₅ mAChRs appear to couple to the same G proteins and signal through similar pathways. Likewise, M₂ and M₄ mAChRs couple through similar G proteins and signal through similar pathways. ‡Despite the fact that in many tissues, organs, and cells multiple subtypes of mAChRs coexist, one subtype may predominate in producing a particular function; in others, there may be equal predominance. ABBREVIATIONS: PLC, phospholipase C; IP₃, inositol-1,4,5-triphosphate; DAG, diacylglycerol; PLD₂, phospholipase D; AA, arachidonic acid; PLA, phospholipase A; cAMP, cyclic AMP; SA node, sinoatrial node; AV node, atrioventricular node; HR, heart rate; PTX, pertussis toxin; VTA, ventral tegmentum area.

functional consequences of these effects are hyperpolarization and inhibition of excitable membranes. These are most clear in myocardium, where inhibition of adenylyl cyclase and activation of K^+ conductances account for the negative chronotropic and inotropic effects of ACh.

Following activation by classical or allosteric agonists, mAChRs can be phosphorylated by a variety of receptor kinases and second-messenger regulated kinases; the phosphorylated mAChR subtypes then can interact with β -arrestin and presumably other adaptor proteins. As a result, the various mAChR signaling pathways may be differentially altered, leading to short- or long-term desensitization of a particular signaling pathway, receptor-mediated activation of the MAP kinase pathway downstream of mAChR phosphorylation, and long-term potentiation of mAChR-mediated phospholipase C stimulation. Agonist activation of mAChRs also may induce receptor internalization and down-regulation (van Koppen and Kaiser, 2003).

Adrenergic Transmission

Under this general heading are norepinephrine (NE), the principal transmitter of most sympathetic postganglionic fibers and of certain tracts in the CNS, dopamine, the predominant transmitter of the mammalian extrapyramidal system and of several mesocortical and mesolimbic neuronal pathways, and epinephrine, the major hormone of the adrenal medulla. Collectively, these three amines are called *catecholamines*.

A tremendous amount of information about catecholamines and related compounds has accumulated in recent years partly because of the importance of interactions between the endogenous catecholamines and many of the drugs used in the treatment of hypertension, mental disorders, and a variety of other conditions. The details of these interactions and of the pharmacology of the sympathomimetic amines themselves will be found in subsequent chapters. The basic physiological, biochemical, and pharmacological features are presented here.

Synthesis, Storage, and Release of Catecholamines. *Synthesis.* The steps in the synthesis of dopamine, norepinephrine (noradrenaline), and epinephrine (adrenaline) are shown in Figure 6–4. Tyrosine is sequentially 3-hydroxylated and decarboxylated to form dopamine. Dopamine is β -hydroxylated to yield norepinephrine, which is N-methylated in chromaffin tissue to give epinephrine. The enzymes involved have been identified, cloned, and characterized (Nagatsu, 1991). Table 6–4 summarizes some of the important characteristics of the four enzymes. These enzymes are not completely specific; consequently, other endogenous substances, as well as certain drugs, are also substrates. For example, 5-hydroxytryptamine (5-HT, sero-

Figure 6–4. Steps in the enzymatic synthesis of dopamine, norepinephrine, and epinephrine. The enzymes involved are shown in blue; essential cofactors in italics. The final step occurs only in the adrenal medulla and in a few epinephrine-containing neuronal pathways in the brainstem.

tonin) can be produced from 5-hydroxy-L-tryptophan by aromatic L-amino acid decarboxylase (or dopa decarboxylase). Dopa decarboxylase also converts dopa into dopamine, and methyl dopa to α -methyl dopamine, which, in turn, is converted by dopamine β -hydroxylase (D β H) to methyl norepinephrine.

The hydroxylation of tyrosine by tyrosine hydroxylase generally is regarded as the rate-limiting step in the biosynthesis of catecholamines (Zigmond *et al.*, 1989); this enzyme is activated following stimulation of sympathetic nerves or the adrenal medulla. The enzyme is a substrate for PKA, PKC, and CaM kinase; kinase-catalyzed phosphorylation may be associated with increased hydroxylase activity (Zigmond *et al.*, 1989; Daubner *et al.*, 1992). This is an important acute mechanism for increasing catecholamine synthesis in response to elevated nerve stimulation. In addition, there is a delayed increase in tyrosine hydroxylase gene expression after nerve stimulation. This increased expression can occur at multiple levels of regulation, including transcription, RNA processing, regulation of RNA stability, translation, and enzyme stability (Kumer and Vrana, 1996). These mechanisms serve to maintain the content of catecholamines in response to increased transmitter release. In addition, tyrosine hydroxylase is subject to feedback

Table 6-4
Enzymes for Synthesis of Catecholamines

ENZYME	OCCURRENCE	SUBCELLULAR DISTRIBUTION	COFACTOR REQUIREMENT	SUBSTRATE SPECIFICITY	COMMENTS
Tyrosine hydroxylase	Widespread; sympathetic nerves	Cytoplasmic	Tetrahydrobiopterin, O ₂ , Fe ²⁺	Specific for L-tyrosine	Rate limiting step. Inhibition can lead to depletion of NE
Aromatic L-amino acid decarboxylase	Widespread; sympathetic nerves	Cytoplasmic	Pyridoxal phosphate	Nonspecific	Inhibition does not alter tissue NE and Epi appreciably
Dopamine β-hydroxylase	Widespread; sympathetic nerves	Synaptic vesicles	Ascorbic acid, O ₂ (contains copper)	Nonspecific	Inhibition can decrease NE and Epi levels
Phenylethanolamine N-methyltransferase	Largely in adrenal gland	Cytoplasmic	S-Adenosyl methionine (CH ₃ donor)	Nonspecific	Inhibition leads to decrease in adrenal catecholamines; under control of glucocorticoids

inhibition by catechol compounds, which allosterically modulate enzyme activity.

Tyrosine hydroxylase deficiency has been reported in humans and is characterized by generalized rigidity, hypokinesia, and low cerebrospinal fluid (CSF) levels of norepinephrine and dopamine metabolites homovanillic acid and 3-methoxy-4-hydroxyphenylethylene glycol (Wevers *et al.*, 1999). Tyrosine hydroxylase knockout is embryonically lethal in mice, presumably because the loss of catecholamines results in altered cardiac function. Interestingly, residual levels of dopamine are present in these mice. It has been suggested that tyrosinase may be an alternate source for catecholamines, although tyrosinase-derived catecholamines are clearly not sufficient for survival (Carson and Robertson, 2002).

DβH deficiency in humans is characterized by orthostatic hypotension, ptosis of the eyelids, retrograde ejaculation, and elevated plasma levels of dopamine. In the case of DH-deficient mice, there is about 90% embryonic mortality (Carson and Robertson, 2002).

Our understanding of the cellular sites and mechanisms of synthesis, storage, and release of catecholamines derives from studies of sympathetically innervated organs and the adrenal medulla. Nearly all the norepinephrine content of the former is confined to the postganglionic sympathetic fibers; it disappears within a few days after section of the nerves. In the adrenal medulla, catecholamines are stored in chromaffin granules (Aunis, 1998). These vesicles contain extremely high concentrations of catecholamines (approximately 21% dry weight), ascorbic acid, and ATP, as well as specific proteins such as chromogranins, DβH, and peptides including enkephalin and neuropeptide Y. Interestingly, vasostatin-1, the N-terminal fragment of chromogranin A, has been found to have antibacterial and antifungal

activity (Lugardon *et al.*, 2000), as have other chromogranin A fragments such as chromofungin, vasostatin II, prochromacin, and chromacin I and II (Taupenot *et al.*, 2003). Two types of storage vesicles are found in sympathetic nerve terminals: large dense-core vesicles corresponding to chromaffin granules and small dense-core vesicles containing norepinephrine, ATP, and membrane-bound DβH.

The main features of the mechanisms of synthesis, storage, and release of catecholamines and their modifications by drugs are summarized in Figure 6-5. In the case of adrenergic neurons, the enzymes that participate in the formation of norepinephrine are synthesized in the cell bodies of the neurons and then are transported along the axons to their terminals. In the course of synthesis (Figure 6-5), the hydroxylation of tyrosine to dopa and the decarboxylation of dopa to dopamine take place in the cytoplasm. About half the dopamine formed in the cytoplasm then is actively transported into the DβH-containing storage vesicles, where it is converted to norepinephrine; the remainder, which escapes capture by the vesicles, is deaminated to 3,4-dihydroxyphenylacetic acid (DOPAC) and subsequently *O*-methylated to homovanillic acid (HVA). The adrenal medulla has two distinct catecholamine-containing cell types: those with norepinephrine and those with primarily epinephrine. The latter cell population contains the enzyme phenylethanolamine-*N*-methyltransferase (PNMT). In these cells, the norepinephrine formed in the granules leaves these structures, presumably by diffusion, and is methylated in the cytoplasm to epinephrine. Epinephrine then reenters the chromaffin granules, where it is stored until released. In adults, epinephrine accounts for approximately 80% of the catecholamines of the adrenal medulla, with norepinephrine making up most of the remainder (von Euler, 1972).

A major factor that controls the rate of synthesis of epinephrine, and hence the size of the store available for release from the adrenal medulla, is the level of glucocorticoids secreted by the

Figure 6–5. Schematic representation of an adrenergic neuroeffector junction showing features of the synthesis, storage, release, and receptors for norepinephrine (NE), the cotransmitters neuropeptide Y (NPY), and ATP. Tyrosine is transported into the varicosity and is converted to DOPA by tyrosine hydroxylase (TH) and DOPA to dopamine via the action of aromatic L-amino acid decarboxylase (AAADC). Dopamine is taken up into the vesicles of the varicosity by a transporter that can be blocked by reserpine. Cytoplasmic NE also can be taken up by this transporter. Dopamine is converted to NE within the vesicle via the action of dopamine-β-hydroxylase (DβH). NE is stored in vesicles along with other cotransmitters, NPY and ATP, depending on the particular neuroeffector junction. Release of the transmitters occurs upon depolarization of the varicosity, which allows entry of Ca²⁺ through voltage-dependent Ca²⁺ channels. Elevated levels of Ca²⁺ promote the fusion of the vesicular membrane with the membrane of the varicosity, with subsequent exocytosis of transmitters. This fusion process involves the interaction of specialized proteins associated with the vesicular membrane (VAMPs, vesicle-associated membrane proteins) and the membrane of the varicosity (SNAPS, synaptosome-associated proteins). In this schematic representation, NE, NPY, and ATP are stored in the same vesicles. Different populations of vesicles, however, may preferentially store different proportions of the cotransmitters. Once in the synapse, NE can interact with α and β adrenergic receptors to produce the characteristic response of the effector. The adrenergic receptors are GPCRs. α and β receptors also can be located presynaptically where NE can either diminish (α₂), or facilitate (β) its own release and that of the cotransmitters. The principal mechanism by which NE is cleared from the synapse is via a cocaine-sensitive neuronal uptake transporter. Once transported into the cytosol, NE can be restored in the vesicle or metabolized by monoamine oxidase (MAO). NPY produces its effects by activating NPY receptors, of which there are at least five types (Y₁ through Y₅). NPY receptors are GPCRs. NPY can modify its own release and that of the other transmitters via presynaptic receptors of the Y₂ type. NPY is removed from the synapse by metabolic breakdown by peptidases. ATP produces its effects by activating P₂X receptors or P₂Y receptors. P₂X receptors are ligand-gated ion channels; P₂Y receptors are GPCRs. There are multiple subtypes of both P₂X and P₂Y receptors. As with the other cotransmitters, ATP can act presynaptically to modify its own release via receptors for ATP or via its metabolic breakdown to adenosine that acts on P₁ (adenosine) receptors. ATP is cleared from the synapse primarily by releasable nucleotidases (rNTPase) and by cell-fixed ectonucleotidases.

adrenal cortex. The intra-adrenal portal vascular system carries the corticosteroids directly to the adrenal medullary chromaffin cells, where they induce the synthesis of PNMT (Figure 6–4). The activities of both tyrosine hydroxylase and D β H also are increased in the adrenal medulla when the secretion of glucocorticoids is stimulated (Carroll *et al.*, 1991; Viskupic *et al.*, 1994). Thus, any stress that persists sufficiently to evoke an enhanced secretion of corticotropin mobilizes the appropriate hormones of both the adrenal cortex (predominantly cortisol in humans) and medulla (epinephrine). This remarkable relationship is present only in certain mammals, including humans, in which the adrenal chromaffin cells are enveloped entirely by steroid-secreting cortical cells. In the dogfish, for example, where the chromaffin cells and steroid-secreting cells are located in independent, noncontiguous glands, epinephrine is not formed. Nonetheless, there is evidence indicating that PMNT is expressed in mammalian tissues such as brain, heart, and lung, leading to extra-adrenal epinephrine synthesis (Kennedy *et al.*, 1993).

In addition to its *de novo* synthesis, norepinephrine stores in the terminal portions of the adrenergic fibers are also replenished by active transport of norepinephrine previously released to the extracellular fluid by the norepinephrine transporter (NET, originally named *uptake 1*) (see below). To effect the reuptake of norepinephrine into adrenergic nerve terminals and to maintain the concentration gradient of norepinephrine within the vesicles, at least two distinct carrier-mediated transport systems are involved: one across the axoplasmic membrane from the extracellular fluid to the cytoplasm mentioned earlier and the other from the cytoplasm into the storage vesicles, the vesicular monoamine transporter (VMAT-2).

Uptake by the NET is more important than extraneuronal uptake and metabolism of norepinephrine released by neurons. It has been estimated that the sympathetic nerves as a whole remove approximately 87% of released norepinephrine by NET compared with 5% by extraneuronal uptake (ENT, *uptake 2*; see below) and 8% diffusion to the circulation. In contrast, clearance of circulating catecholamines is primarily by nonneuronal mechanisms, with liver and kidney accounting for over 60% of the clearance of circulating catecholamines. Because the VMAT-2 has a much higher affinity for norepinephrine than does monoamine oxidase (MAO), over 70% of recaptured norepinephrine is sequestered into storage vesicles (Eisenhofer, 2001).

Storage of Catecholamines. Catecholamines are stored in vesicles, ensuring their regulated release; this storage decreases intraneuronal metabolism of these transmitters and their leakage outside the cell. The vesicular amine transporter (VMAT-2) extensively appears to be driven by pH and potential gradients that are established by an ATP-dependent proton translocase. For every molecule of amine taken up, two H⁺ ions are extruded (Brownstein and Hoffman, 1994). Monoamine transporters are relatively promiscuous and transport dopamine, norepinephrine, epinephrine, and serotonin, for example, as well as *meta-iodobenzylguanidine*, can be used to image chromaffin cell tumors (Schuldiner, 1994). *Reserpine* inhibits monoamine transport into storage vesicles and ultimately leads to depletion of catecholamine from sympathetic

nerve endings and in the brain. Several vesicular transport cDNAs have been cloned; these cDNAs reveal open reading frames predictive of proteins with 12 transmembrane domains (see Chapter 2). Regulation of the expression of these various transporters may be important in the regulation of synaptic transmission (Varoqui and Erickson, 1997).

There are two neuronal membrane transporters for catecholamines, the norepinephrine transporter (NET) mentioned earlier and the dopamine transporter (DAT); their characteristics are depicted in Table 6–5. The NET is also present in the adrenal medulla, the liver, and the placenta, whereas the DAT is present in the stomach, pancreas, and kidney (Eisenhofer, 2001).

NET is Na⁺-dependent and is blocked selectively by a number of drugs, including *cocaine* and tricyclic antidepressants such as *imipramine*. This transporter has a high affinity for norepinephrine and a somewhat lower affinity for epinephrine (Table 6–5); the synthetic β adrenergic receptor agonist *isoproterenol* is not a substrate for this system. A number of highly specific neurotransmitter transporters have been identified. High-affinity transporters include those for dopamine, norepinephrine, serotonin, and a variety of amino acid transmitters (Amara and Kuhar, 1993; Brownstein and Hoffman, 1994; Masson *et al.*, 1999). These transporters are members of an extended family sharing common structural motifs, particularly the putative 12-transmembrane helices. These plasma membrane transporters appear to have greater substrate specificity than do vesicular transporters and may be viewed as targets (“receptors”) for specific drugs such as cocaine (dopamine transporter) or *fluoxetine* (serotonin transporter).

Certain sympathomimetic drugs (*e.g.*, *ephedrine* and *tyramine*) produce some of their effects indirectly by displacing norepinephrine from the nerve terminals to the extracellular fluid, where it then acts at receptor sites of the effector cells. The mechanisms by which these drugs release norepinephrine from nerve endings are complex. All such agents are substrates for NET. As a result of their transport across the neuronal membrane and release into the axoplasm, they make carrier available at the inner surface of the membrane for the outward transport of norepinephrine (“facilitated exchange diffusion”). In addition, these amines are able to mobilize norepinephrine stored in the vesicles by competing for the vesicular uptake process. Reserpine, which depletes vesicular stores of norepinephrine, also inhibits this uptake mechanism, but in contrast with the indirect-acting sympathomimetic amines, it enters the adrenergic nerve ending by passive diffusion across the axonal membrane.

Table 6-5
 Characteristics of Transporters for Endogenous Catecholamines

TYPE OF TRANSPORTER	SUBSTRATE SPECIFICITY	TISSUE	REGION/CELL TYPE	INHIBITORS
<i>Neuronal</i>				
NET	DA > NE > Epi	All sympathetically innervated tissue Adrenal medulla Liver Placenta	Sympathetic nerves Chromaffin cells Capillary endothelial cells Syncytiotrophoblast	Desipramine, cocaine, nisoxetine
DAT	DA >> NE > Epi	Kidney Stomach Pancreas	Endothelium Parietal and endothelial cells Pancreatic duct	Cocaine, imazindol
<i>Nonneuronal:</i>				
OCT 1	DA ≈ Epi >> NE	Liver Intestine Kidney (not human)	Hepatocytes Epithelial cells Distal tubule	Isocyanines; corticosterone
OCT 2	DA >> NE > Epi	Kidney Brain	Medullary proximal and distal tubules Glial cells of DA-rich regions, some non-adrenergic neurons	Isocyanines; corticosterone
ENT (OCT 3)	Epi >> NE > DA	Liver Brain Heart Blood vessels Kidney Placenta Retina	Hepatocytes Glial cells, others Myocytes Endothelial cells Cortex, proximal and distal tubules Syncytiotrophoblasts (basal membrane) Photoreceptors, ganglion amacrine cells	Isocyanines; corticosterone; <i>O</i> -methyl-isoproterenol

ABBREVIATIONS: NET, norepinephrine transporter, originally known as uptake 1; DAT, dopamine transporter; ENT (OCT3), extraneuronal transporter, originally known as uptake 2; OCT 1, OCT 2, organic cation transporters; Epi, epinephrine; NE, norepinephrine; DA, dopamine.

The actions of indirect-acting sympathomimetic amines are subject to *tachyphylaxis*. For example, repeated administration of tyramine results in rapidly decreasing effectiveness, whereas repeated administration of norepinephrine does not reduce effectiveness and, in fact, reverses the tachyphylaxis to tyramine. Although these phenomena have not been explained fully, several hypotheses have been proposed. One possible explanation is that the pool of neurotransmitter available for displacement by these drugs is small relative to the total amount stored in the sympathetic nerve ending. This pool is presumed to reside in close proximity to the plasma membrane, and the norepinephrine of such vesicles may be replaced by the less potent amine following repeated administration of the latter substance. In any case, neurotransmitter release by displacement is not associated with the release of

D β H and does not require extracellular Ca²⁺; thus, it is presumed not to involve exocytosis.

There are also three extraneuronal transporters that handle a wide range of endogenous and exogenous substrates. The extraneuronal amine transporter (ENT), originally named *uptake-2* and also designated *OCT3*, is an organic cation transporter. Relative to NET, ENT exhibits lower affinity for catecholamines, favors epinephrine over norepinephrine or dopamine, and shows a higher maximum rate of catecholamine uptake. The ENT is not Na⁺-dependent and displays a completely different profile of

pharmacological inhibition. Other members of this family are the organic cation transporters OCT1 and OCT2 (*see* Chapter 2). All three can transport catecholamines in addition to a wide variety of other organic acids, including serotonin, histamine, choline, spermine, guanidine, and creatinine (Eisenhofer, 2001). The characteristics and location of the nonneuronal transporters are summarized in Table 6–5.

Release of Catecholamines. The full sequence of steps by which the nerve impulse effects the release of norepinephrine from sympathetic neurons is not known. In the adrenal medulla, the triggering event is the liberation of ACh by the preganglionic fibers and its interaction with nicotinic receptors on chromaffin cells to produce a localized depolarization; a subsequent step is the entrance of Ca^{2+} into these cells, which results in the extrusion by exocytosis of the granular contents, including epinephrine, ATP, some neuroactive peptides or their precursors, chromogranins, and $\text{D}\beta\text{H}$. Influx of Ca^{2+} likewise plays an essential role in coupling the nerve impulse, membrane depolarization, and opening of voltage-gated Ca^{2+} channels with the release of norepinephrine at sympathetic nerve terminals. Blockade of N-type Ca^{2+} channels leads to hypotension likely owing to inhibition of norepinephrine release. Ca^{2+} -triggered secretion involves interaction of highly conserved molecular scaffolding proteins leading to docking of granules at the plasma membrane and ultimately leading to secretion (Aunis, 1998).

Reminiscent of the release of ACh at cholinergic terminals, various synaptic proteins, including the plasma membrane proteins syntaxin and synaptosomal protein 25kDa (SNAP-25), and the vesicle membrane protein synaptobrevin form a complex that interacts in an ATP-dependent manner with the soluble proteins *N*-ethylmaleimide-sensitive fusion protein (NSF) and soluble NSF attachment proteins (SNAPs). The ability of synaptobrevin, syntaxin, and SNAP-25 to bind SNAPs has led to their designation as *SNAP receptors* (SNAREs). It has been hypothesized that most, if not all, intracellular fusion events are mediated by SNARE interactions (Boehm and Kubista, 2002). As with cholinergic neurotransmission, important evidence supporting the involvement of SNARE proteins (*e.g.*, SNAP-25, syntaxin, and synaptobrevin) in transmitter release comes from the fact that botulinum neurotoxins and tetanus toxin, which potently block neurotransmitter release, proteolyse these proteins.

Enhanced activity of the sympathetic nervous system is accompanied by an increased concentration of both $\text{D}\beta\text{H}$ and chromogranins in the circulation, supporting the argument that the process of release following adrenergic nerve stimulation also involves exocytosis.

Adrenergic fibers can sustain the output of norepinephrine during prolonged periods of stimulation without exhausting their

reserve supply, provided that synthesis and uptake of the transmitter are unimpaired. To meet increased needs for norepinephrine, acute regulatory mechanisms are evoked involving activation of tyrosine hydroxylase and $\text{D}\beta\text{H}$ (*see above*).

Prejunctional Regulation of Norepinephrine Release

The release of the three sympathetic cotransmitters can be modulated by prejunctional autoreceptors and heteroreceptors. Following their release from sympathetic terminals, all three cotransmitters—norepinephrine, neuropeptide Y (NPY), and ATP—can feedback on prejunctional receptors to inhibit the release of each other (Westfall, *et al.*, 2002; Westfall, 2004). The most thoroughly studied have been prejunctional α_2 adrenergic receptors. The α_{2A} and α_{2C} adrenergic receptors are the principal prejunctional receptors that inhibit sympathetic neurotransmitter release, whereas the α_{2B} adrenergic receptors also may inhibit transmitter release at selected sites. Antagonists of this receptor, in turn, can enhance the electrically evoked release of sympathetic neurotransmitter. NPY, acting on Y_2 receptors, and ATP-derived adenosine, acting on P1 receptors, also can inhibit sympathetic neurotransmitter release. Numerous heteroreceptors on sympathetic nerve varicosities also inhibit the release of sympathetic neurotransmitters; these include: M_2 and M_4 muscarinic, serotonin, PGE_2 , histamine, enkephalin, and dopamine receptors. Enhancement of sympathetic neurotransmitter release can be produced by activation of β_2 adrenergic receptors, angiotensin II receptors, and nACh receptors. All these receptors can be targets for agonists and antagonists.

Termination of the Actions of Catecholamines.

The actions of norepinephrine and epinephrine are terminated by (1) reuptake into nerve terminals by NET; (2) dilution by diffusion out of the junctional cleft and uptake at extraneuronal sites by ENT, OCT 1, and OCT 2; and (3) metabolic transformation. Two enzymes are important in the initial steps of metabolic transformation of catecholamines—monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT). In addition, catecholamines are metabolized by sulfotransferases (Dooley, 1998) (*see* Chapter 3). However, termination of action by a powerful degradative enzymatic pathway, such as that provided by AChE at sites of cholinergic transmission, is absent from the adrenergic nervous system. The importance of neuronal reuptake of catecholamines is shown by observations that inhibitors of this process (*e.g.*, cocaine and imipramine) potentiate the

effects of the neurotransmitter; inhibitors of MAO and COMT have relatively little effect. However, MAO metabolizes transmitter that is released within the nerve terminal. COMT, particularly in the liver, plays a major role in the metabolism of endogenous circulating and administered catecholamines.

Both MAO and COMT are distributed widely throughout the body, including the brain; the highest concentrations of each are in the liver and the kidney. However, little or no COMT is found in sympathetic neurons. In the brain, there is also no significant COMT in presynaptic terminals, but it is found in some postsynaptic neurons and glial cells. In the kidney, COMT is localized in proximal tubular epithelial cells, where dopamine is synthesized, and is thought to exert local diuretic and natriuretic effects. The physiological substrates for COMT include L-dopa, all three endogenous catecholamines (dopamine, norepinephrine, and epinephrine), their hydroxylated metabolites, catecholestrogens, ascorbic acid, and dihydroxyindolic intermediates of melanin (*see* review by Männistö and Kaakkola, 1999). There are distinct differences in the cytological locations of the two enzymes; MAO is associated chiefly with the outer surface of mitochondria, including those within the terminals of sympathetic or central noradrenergic neuronal fibers, whereas COMT is largely cytoplasmic. These factors are of importance both in determining the primary metabolic pathways followed by catecholamines in various circumstances and in explaining the effects of certain drugs. Two different isozymes of MAO (MAO-A and MAO-B) are found in widely varying proportions in different cells in the CNS and in peripheral tissues. In the periphery, MAO-A is located in the syncytiotrophoblast layer of term placenta and liver, whereas MAO-B is located in platelets, lymphocytes, and liver. In the brain, MAO-A is located in all regions containing catecholamines, with the highest abundance in the locus ceruleus. MAO-B, on the other hand, is found primarily in regions that are known to synthesize and store serotonin. MAO-B is most prominent in the nucleus raphe dorsalis but also in the posterior hypothalamus and in glial cells in regions known to contain nerve terminals. MAO-B is also present in osteocytes around blood vessels (Abell and Kwan, 2001). Selective inhibitors of these two isozymes are available (*see* Chapter 17). Irreversible antagonists of MAO-A (*e.g.*, *phenelzine*, *tranylcypromine*, and *isocarboxazid*) enhance the bioavailability of tyramine contained in many foods; tyramine-induced norepinephrine release from sympathetic neurons may lead to markedly increased blood pressure (hypertensive crisis). Selective MAO-B inhibitors (*e.g.*, *selegiline*) or reversible MAO-A-selective inhibitors (*e.g.*, *moclobemide*) are less likely to cause this potential interaction (Volz and Geiter, 1998; Wouters, 1998). MAO inhibitors are useful in the treatment of Parkinson's disease and mental depression (*see* Chapters 17 and 20).

Most of the epinephrine and norepinephrine that enters the circulation—from the adrenal medulla or following administration or that is released by exocytosis from sympathetic fibers—is methylated by COMT to metanephrine or normetanephrine, respectively (Figure 6–6). Norepinephrine that is released intraneuronally by drugs such as reserpine is deaminated initially by MAO to 3,4-dihydroxyphenylglycolaldehyde (DOPGAL) (Figure 6–6). The aldehyde is reduced by aldehyde reductase to 3,4-dihydroxyphenylethylene glycol (DOPEG) or is oxidized by aldehyde dehydrogenase to form

3,4-dihydroxymandelic acid (DOMA). 3-Methoxy-4-hydroxymandelic acid [generally but incorrectly called *vanillylmandelic acid* (VMA)] is the major metabolite of catecholamines excreted in the urine. The corresponding product of the metabolic degradation of dopamine, which contains no hydroxyl group in the side chain, is homovanillic acid (HVA). Other metabolic reactions are described in Figure 6–6. Measurement of the concentrations of catecholamines and their metabolites in blood and urine is useful in the diagnosis of pheochromocytoma, a catecholamine-secreting tumor of the adrenal medulla.

Inhibitors of MAO (*e.g.*, *pargyline* and *nialamide*) can cause an increase in the concentration of norepinephrine, dopamine, and 5-HT in the brain and other tissues accompanied by a variety of pharmacological effects. No striking pharmacological action in the periphery can be attributed to the inhibition of COMT. However, the COMT inhibitors *entacapone* and *tocapone* have been found to be efficacious in the therapy of Parkinson's disease (Chong and Mersfelder, 2000) (*see* Chapter 20).

Classification of Adrenergic Receptors. Crucial to understanding the remarkably diverse effects of the catecholamines and related sympathomimetic agents is an understanding of the classification and properties of the different types of adrenergic receptors (or adrenoceptors). Elucidation of the characteristics of these receptors and the biochemical and physiological pathways they regulate has increased our understanding of the seemingly contradictory and variable effects of catecholamines on various organ systems. Although structurally related (*see* below), different receptors regulate distinct physiological processes by controlling the synthesis or release of a variety of second messengers (Tables 6–6 and 6–7).

Based on studies of the abilities of epinephrine, norepinephrine, and other related agonists to regulate various physiological processes, Ahlquist first proposed the existence of more than one adrenergic receptor. It was known that these drugs could cause either contraction or relaxation of smooth muscle depending on the site, the dose, and the agent chosen. For example, norepinephrine was known to have potent excitatory effects on smooth muscle and correspondingly low activity as an inhibitor; isoproterenol displayed the opposite pattern of activity. Epinephrine could both excite and inhibit smooth muscle. Thus, Ahlquist proposed the designations α and β for receptors on smooth muscle where catecholamines produce excitatory and inhibitory responses, respectively. An exception is the gut, which generally is relaxed by activation of either α or β receptors. The rank order of potency of agonists is isoproterenol > epinephrine \geq norepinephrine for β adrenergic receptors and epinephrine \geq norepinephrine \gg isoproterenol for α adrenergic receptors (Table 6–3). This initial classification was corroborated by the finding that certain antagonists produce selective blockade of the effects of adrenergic nerve impulses and sympathomimetic agents at α receptors (*e.g.*, *phenoxymethamine*), whereas others produce selective β receptor blockade (*e.g.*, *propranolol*).

β Receptors later were subdivided into β_1 (*e.g.*, those in the myocardium) and β_2 (smooth muscle and most other sites) because

Figure 6–6. Steps in the metabolic disposition of catecholamines. Norepinephrine and epinephrine are first oxidatively deaminated by monoamine oxidase (MAO) to 3,4-dihydroxyphenylglycoaldehyde (DOPGAL) and then either reduced to 3,4-dihydroxyphenylethylene glycol (DOPEG) or oxidized to 3,4-dihydroxymandelic acid (DOMA). Alternatively, they can be methylated initially by catechol-*O*-methyltransferase (COMT) to normetanephrine and metanephrine, respectively. Most of the products of either type of reaction then are metabolized by the other enzyme to form the major excretory products in blood and urine, 3-methoxy-4-hydroxyphenylethylene glycol (MOPEG or MHPG) and 3-methoxy-4-hydroxymandelic acid (VMA). Free MOPEG is largely converted to VMA. The glycol and, to some extent, the *O*-methylated amines and the catecholamines may be conjugated to the corresponding sulfates or glucuronides. (Modified from Axelrod, 1966, and others.)

epinephrine and norepinephrine essentially are equipotent at the former sites, whereas epinephrine is 10 to 50 times more potent than norepinephrine at the latter. Antagonists that discriminate between β_1 and β_2 receptors subsequently were developed (*see* Chapter 10). A human gene that encodes a third β receptor (designated β_3) has been isolated (Emorine *et al.*, 1989; Granneman *et al.*, 1993). Since the β_3 receptor is about tenfold more sensitive to norepinephrine than to epinephrine and is relatively resistant to blockade by antagonists such as propranolol, it may mediate responses to catecholamine at sites with “atypical” pharmacological characteristics (*e.g.*,

adipose tissue). Although the adipocytes are a major site of β_3 adrenergic receptors, all three β adrenergic receptors are present in both white adipose tissue (WAT) and brown adipose tissue (BAT). Animals treated with β_3 receptor agonists exhibit a vigorous thermogenic response as well as lipolysis (Robidoux *et al.*, 2004). Polymorphisms in the β_3 receptor gene may be related to risk of obesity or type 2 diabetes in some populations (Arner and Hoffstedt, 1999). Also, there has been interest in the possibility that β_3 -receptor-selective agonists may be beneficial in treating these disorders (Weyer *et al.*, 1999).

Table 6-6
Characteristics of Subtypes of Adrenergic Receptors*

RECEPTOR	AGONISTS	ANTAGONISTS	TISSUE	RESPONSES
α_1^\dagger	Epi \geq NE \gg Iso Phenylephrine	Prazosin	Vascular smooth muscle GU smooth muscle Liver [‡] Intestinal smooth muscle Heart	Contraction Contraction Glycogenolysis; gluconeogenesis Hyperpolarization and relaxation Increased contractile force; arrhythmias
α_2^\dagger	Epi \geq NE \gg Iso Clonidine	Yohimbine	Pancreatic islets (β cells) Platelets Nerve terminals Vascular smooth muscle	Decreased insulin secretion Aggregation Decreased release of NE Contraction
β_1	Iso $>$ Epi = NE Dobutamine	Metoprolol CGP 20712A	Juxtaglomerular cells Heart	Increased renin secretion Increased force and rate of contraction and AV nodal conduction velocity
β_2	Iso $>$ Epi \gg NE Terbutaline	ICI 118551	Smooth muscle (vascular, bronchial, GI, and GU) Skeletal muscle Liver [‡]	Relaxation Glycogenolysis; uptake of K ⁺ Glycogenolysis; gluconeogenesis
β_3^{\S}	Iso = NE $>$ Epi BRL 37344	ICI 118551 CGP 20712A	Adipose tissue	Lipolysis

ABBREVIATIONS: Epi, epinephrine; NE, norepinephrine; Iso, isoproterenol; GI, gastrointestinal; GU, genitourinary. *This table provides examples of drugs that act on adrenergic receptors and of the location of subtypes of adrenergic receptors. [†]At least three subtypes each of α_1 and α_2 adrenergic receptors are known, but distinctions in their mechanisms of action have not been clearly defined. [‡]In some species (*e.g.*, rat), metabolic responses in the liver are mediated by α_1 adrenergic receptors, whereas in others (*e.g.*, dog) β_2 adrenergic receptors are predominantly involved. Both types of receptors appear to contribute to responses in human beings. [§]Metabolic responses in adipocytes and certain other tissues with atypical pharmacological characteristics may be mediated by this subtype of receptor. Most β adrenergic receptor antagonists (including propranolol) do not block these responses.

The heterogeneity of α adrenergic receptors also is now appreciated. The initial distinction was based on functional and anatomical considerations when it was realized that norepinephrine and other α -adrenergic receptors could profoundly inhibit the release of norepinephrine from neurons (Westfall, 1977) (Figure 6-5). Indeed, when sympathetic nerves are stimulated in the presence of certain α receptor antagonists, the amount of norepinephrine liberated by each nerve impulse increases markedly. This feedback-inhibitory effect of norepinephrine on its release from nerve terminals is mediated by α receptors that are pharmacologically distinct from the classical postsynaptic α receptors. Accordingly, these presynaptic α adrenergic receptors were designated α_2 , whereas the postsynaptic "excitatory" α receptors were designated α_1 (*see* Langer, 1997). Compounds such as *clonidine* are more potent agonists at α_2 than at α_1 receptors; by contrast, *phenylephrine* and *methoxamine* selectively activate postsynaptic α_1 receptors. Although there is little evidence to suggest that α_1 adrenergic receptors function presynaptically in the autonomic nervous system, it now is clear that α_2 receptors

also are present at postjunctional or nonjunctional sites in several tissues. For example, stimulation of postjunctional α_2 receptors in the brain is associated with reduced sympathetic outflow from the CNS and appears to be responsible for a significant component of the antihypertensive effect of drugs such as *clonidine* (*see* Chapter 10). Thus, the anatomical concept of prejunctional α_2 and postjunctional α_1 adrenergic receptors has been abandoned in favor of a pharmacological and functional classification (Table 6-6 and 6-8).

Cloning revealed additional heterogeneity of both α_1 and α_2 adrenergic receptors (Bylund, 1992). There are three pharmacologically defined α_1 receptors (α_{1A} , α_{1B} , and α_{1D}) with distinct sequences and tissue distributions (Tables 6-6 and 6-8). There are also three cloned subtypes of α_2 receptors (α_{2A} , α_{2B} , and α_{2C}) (Table 6-8). Distinct patterns of distribution of these subtypes exist.

Owing to the lack of sufficiently subtype-selective ligands, the precise physiological function and therapeutic potential of the subtypes of adrenergic receptors have not been elucidated fully. Great

Table 6–7
Adrenergic Receptors and Their Effector Systems

ADRENERGIC RECEPTOR	G PROTEIN	EXAMPLES OF SOME BIOCHEMICAL EFFECTORS
β_1	G_s	↑ adenylyl cyclase, ↑ L-type Ca^{2+} channels
β_2	G_s	↑ adenylyl cyclase
β_3	G_s	↑ adenylyl cyclase
α_1 Subtypes	G_q	↑ phospholipase C
	G_q	↑ phospholipase D
	$G_q, G_i/G_o$	↑ phospholipase A_2
α_2 Subtypes	G_q	? ↑ Ca^{2+} channels
	G_i 1, 2, or 3	↓ adenylyl cyclase
	G_i ($\beta\gamma$ subunits)	↑ K^+ channels
	G_o	↓ Ca^{2+} channels (L- and N-type)
	?	↑ PLC, PLA_2

advances in our understanding have been made through the use of genetic approaches using transgenic and receptor knockout experiments in mice (discussed below). These mouse models have been used to identify the particular receptor subtypes and pathophysiological relevance of individual adrenergic receptors subtypes (Steinberg, 2002; Tanoue *et al.*, 2002a, 2002b, 2002c; Hein and Schmitt, 2003; Philipp and Hein, 2004).

Molecular Basis of Adrenergic Receptor Function. All of the adrenergic receptors are GPCRs that link to heterotrimeric G proteins. Each major type shows preference for a particular class of G proteins, *i.e.*, α_1 to G_q , α_2 to G_i , and β to G_s (Table 6–7). The responses that follow activation of all types of adrenergic receptors result from G protein–mediated effects on the generation of second messengers and on the activity of ion channels. As discussed in Chapter 1, these systems involve three interacting proteins—the GPCR, the coupling G protein, and effector enzymes or ion channels. The pathways overlap broadly with those discussed for muscarinic acetylcholine receptors and are summarized in Table 6–7.

Structure of Adrenergic Receptors. Adrenergic receptors constitute a family of closely related proteins that are related both structurally and functionally to GPCRs for a wide variety of other hormones and neurotransmitters (Lefkowitz, 2000). The GPCR family includes the muscarinic ACh receptors and the visual “photon receptor”

rhodopsin (*see* Chapter 1). Ligand binding, site-directed labeling, and mutagenesis have revealed that the conserved membrane-spanning regions are crucially involved in ligand binding (Strader *et al.*, 1994; Hutchins, 1994). These regions appear to create a ligand-binding pocket analogous to that formed by the membrane-spanning regions of rhodopsin to accommodate the covalently attached chromophore, retinal, with molecular models placing catecholamines either horizontally (Strader *et al.*, 1994) or perpendicularly (Hutchins, 1994) in the bilayer. The crystal structure of mammalian rhodopsin confirms a number of predictions about the structure of GPCRs (Palczewski *et al.*, 2000).

β Adrenergic Receptors. The three β receptors share approximately 60% amino acid sequence identity within the presumed membrane-spanning domains where the ligand-binding pocket for epinephrine and norepinephrine is found. Based on results of site-directed mutagenesis, individual amino acids in the β_2 receptor that interact with each of the functional groups on the catecholamine agonist molecule have been identified.

β Receptors regulate numerous functional responses, including heart rate and contractility, smooth muscle relaxation, and multiple metabolic events (Table 6–1). All three of the β receptor subtypes (β_1 , β_2 , and β_3) couple to G_s and activate adenylyl cyclase (Table 6–7). However, recent data suggest differences in downstream signals and events activated by the three β receptors (Lefkowitz, 2000; Ma and Huang, 2002). Catecholamines promote β receptor feedback regulation, *i.e.*, desensitization and receptor down-regulation (Kohout and Lefkowitz, 2003). β Receptors differ in the extent to which they undergo such regulation, with the β_2 receptor being the most susceptible. Stimulation of β adrenergic receptors leads to the accumulation of cyclic AMP, activation of the PKA, and altered function of numerous cellular proteins as a result of their phosphorylation (*see* Chapter 1). In addition, G_s can enhance directly the activation of voltage-sensitive Ca^{2+} channels in the plasma membrane of skeletal and cardiac muscle.

Several reports demonstrate that β_1 , β_2 , and β_3 receptors differ in their intracellular signaling pathways and subcellular location. While the positive chronotropic effects of β_1 receptor activation are clearly mediated *via* G_s in myocytes, dual coupling of β_2 receptors to G_s and G_i occurs in myocytes from newborn mice. Stimulation of β_2 receptors caused a transient increase in heart rate that is followed by a prolonged decrease. Following pretreatment with pertussis toxin, which prevents activation of G_i , the negative chronotropic effect of β_2 activation is abolished. It is thought that these specific signaling properties of β receptor subtypes are linked to subtype-selective association with intracellular scaffolding and signaling proteins (Baillie and Houslay, 2005).

Table 6-8

Subtypes of Adrenergic Receptors

SUBTYPE	GENE LOCATION IN HUMAN CHROMOSOME	TISSUE LOCALIZATION	SUBTYPE DOMINANT EFFECTS
α_{1A}	8	Heart, liver, cerebellum cerebral cortex, prostate, lung, vas deferens, blood vessels	Predominant receptor causing contraction of smooth muscle including vasoconstriction in numerous arteries and veins. With α_{1B} promotes cardiac growth and structure
α_{1B}	5	Kidney, spleen, lung, cerebral cortex, blood vessels	Most abundant subtype in heart; with α_{1A} promotes cardiac growth and structure
α_{1D}	20	Platelets, cerebral cortex, prostate, hippocampus, aorta, coronary arteries	Predominant receptor causing vasoconstriction in the aorta and coronary arteries
α_{2A}	10	Platelets, cerebral cortex, locus ceruleus, spinal cord, sympathetic neurons; autonomic ganglia	Predominant inhibitory autoreceptor in sympathetic nerve varicosities Predominant receptor mediating α_2 agonist-induced antinociception, sedation, hypotension, and hypothermia
α_{2B}	2	Liver, kidney, blood vessels	Predominant receptor mediating α_2 -induced vasoconstriction
α_{2C}	4	Cerebral cortex	Predominant receptor modulating dopamine neurotransmission Predominant inhibitory receptor on adrenal medulla
β_1	10 _{q24q26}	Heart, kidney, adipocytes, other tissues	Predominant receptor in heart producing + inotropic and chronotropic effects
β_2	5 _{q32-q32}	Heart; vascular, bronchial, and GI smooth muscle; glands; leukocytes; hepatocytes	Prominent receptor in smooth muscle producing relaxation; highly polymorphic
β_3	8 _{p12-p11.2}	Adipose tissue, GI tract, other tissue	Prominent adrenergic receptor producing metabolic effects

β_2 Receptors normally are confined to caveolae in cardiac myocyte membranes. The activation of PKA by AMP and the importance of compartmentation of components of the cyclic AMP pathway are discussed in Chapter 1.

α Adrenergic Receptors. The deduced amino acid sequences from the three α_1 receptor genes (α_{1A} , α_{1B} , and α_{1D}) and three α_2 receptor genes (α_{2A} , α_{2B} , and α_{2C}) conform to the well-established GPCR paradigm (Zhong and Minneman, 1999; Bylund, 1992). While not as thoroughly investigated as β receptors, the general structural features and their relation to the functions of ligand binding and G protein activation appear to agree with those set forth in Chapter 1 and above for the β

receptors. Within the membrane-spanning domains, the three α_1 adrenergic receptors share approximately 75% identity in amino acid residues, as do the three α_2 receptors, but the α_1 and α_2 subtypes are no more similar than are the α and β subtypes (approximately 30% to 40%).

α_2 Adrenergic Receptors. As shown in Table 6-7, α_2 receptors couple to a variety of effectors (Aantaa *et al.*, 1995; Bylund, 1992). Inhibition of adenylyl cyclase activity was the first effect observed, but in some systems the enzyme actually is stimulated by α_2 adrenergic receptors, either by $G_i \beta\gamma$ subunits or by weak direct stimulation of G_s . The physiological significance of these latter processes is not currently clear. α_2 Receptors activate G protein-gated K^+ channels, resulting in membrane hyperpolarization.

In some cases (*e.g.*, cholinergic neurons in the myenteric plexus) this may be Ca^{2+} -dependent, whereas in others (*e.g.*, muscarinic ACh receptors in atrial myocytes) it results from direct interaction of $\beta\gamma$ subunits with K^+ channels. α_2 Receptors also can inhibit voltage-gated Ca^{2+} channels; this is mediated by G_o . Other second-messenger systems linked to α_2 receptor activation include acceleration of Na^+/H^+ exchange, stimulation of phospholipase $\text{C}_{\beta 2}$ activity and arachidonic acid mobilization, increased phosphoinositide hydrolysis, and increased intracellular availability of Ca^{2+} . The latter is involved in the smooth muscle–contracting effect of α_2 adrenergic receptor agonists. In addition, the α_2 receptors activate mitogen-activated protein kinases (MAPKs) likely via $\beta\gamma$ subunits released from pertussis toxin–sensitive G proteins (Della Rocca *et al.*, 1997; Richman and Regan, 1998). This and related pathways lead to activation of a variety of tyrosine kinase–mediated downstream events. These pathways are reminiscent of pathways activated by tyrosine kinase activities of growth factor receptors. Although α_2 receptors may activate several different signaling pathways, the exact contribution of each to many physiological processes is not clear. The α_{2A} receptor plays a major role in inhibiting norepinephrine release from sympathetic nerve endings and suppressing sympathetic outflow from the brain, leading to hypotension (MacMillan *et al.*, 1996; Docherty, 1998; Kable *et al.*, 2000).

In the CNS, α_{2A} receptors, which appear to be the most dominant adrenergic receptor, probably produce the antinociceptive effects, sedation, hypothermia, hypotension, and behavioral actions of α_2 agonists (Lakhlani *et al.*, 1997). The α_{2C} receptor occurs in the ventral and dorsal striatum and hippocampus. It appears to modulate dopamine neurotransmission and various behavioral responses. The α_{2B} receptor is the main receptor mediating α_2 -induced vasoconstriction, whereas the α_{2C} receptor is the predominant receptor inhibiting the release of catecholamines from the adrenal medulla and modulating dopamine neurotransmission in the brain.

α_1 Adrenergic Receptors. Stimulation of α_1 receptors results in the regulation of multiple effector systems. A primary mode of signal transduction involves activation of the G_q -PLC β -IP $_3$ - Ca^{2+} pathway and the activation of other Ca^{2+} and calmodulin sensitive pathways such as CaM kinases (*see* Chapter 1). For example, α_1 receptors regulate hepatic glycogenolysis in some animal species; this effect results from the activation of phosphorylase kinase by the mobilized Ca^{2+} , aided by the inhibition of glycogen synthase caused by PKC-mediated phosphorylation. PKC phosphorylates many substrates, including membrane proteins such as channels, pumps, and ion-exchange proteins (*e.g.*, Ca^{2+} -transport ATPase). These effects presumably lead to regulation of various ion conductances.

α_1 Receptor stimulation of phospholipase A_2 leads to the release of free arachidonate, which is then metabolized *via* the cyclooxygenase and lipoxygenase pathways to the bioactive prostaglandins and leukotrienes, respectively (*see* Chapter 25). Stimulation of phospholipase A_2 activity by various agonists (including epinephrine acting at α_1 receptors) is found in many tissues and cell lines, suggesting that this effector is physiologically important. Phospholipase D hydrolyzes phosphatidylcholine to yield phosphatidic acid (PA). Although PA itself may act as a second messenger by releasing Ca^{2+} from intracellular stores, it also is metabolized to the second messenger DAG. Phospholipase D is an effector for ADP-ribosylating factor (ARF), suggesting that phospholipase D may play a role in membrane trafficking. Finally, some evidence in vascular

smooth muscle suggests that α_1 receptors are capable of regulating a Ca^{2+} channel *via* a G protein.

In most smooth muscles, the increased concentration of intracellular Ca^{2+} ultimately causes contraction as a result of activation of Ca^{2+} -sensitive protein kinases such as the calmodulin-dependent myosin light-chain kinase; phosphorylation of the light chain of myosin is associated with the development of tension (Stull *et al.*, 1990). In contrast, the increased concentration of intracellular Ca^{2+} that result from stimulation of α_1 receptors in gastrointestinal smooth muscle causes hyperpolarization and relaxation by activation of Ca^{2+} -dependent K^+ channels (McDonald *et al.*, 1994).

As with α_2 receptors, there is considerable evidence demonstrating that α_1 receptors activate MAPKs and other kinases such as PI3 kinase leading to important effects on cell growth and proliferation (Dorn and Brown, 1999; Gutkind, 1998). For example, prolonged stimulation of α_1 receptors promotes growth of cardiac myocytes and vascular smooth muscle cells. The α_{1A} receptor is the predominant receptor causing vasoconstriction in many vascular beds, including the following arteries: mammary, mesenteric, splenic, hepatic, omental, renal, pulmonary, and epicardial coronary. It is also the predominant subtype in the vena cava and the saphenous and pulmonary veins (Michelotti *et al.*, 2001). Together with the α_{1B} receptor subtype, it promotes cardiac growth and structure. The α_{1B} receptor subtype is the most abundant subtype in the heart, whereas the α_{1D} receptor subtype is the predominant receptor causing vasoconstriction in the aorta. There is evidence to support the idea that α_{1B} receptors mediate behaviors such as reaction to novelty and exploration and are involved in behavioral sensitizations and in the vulnerability to addiction (*see* Chapter 23).

Localization of Adrenergic Receptors. Presynaptically located α_2 and β_2 receptors fulfill important roles in the regulation of neurotransmitter release from sympathetic nerve endings. Presynaptic α_2 receptors also may mediate inhibition of release of neurotransmitters other than norepinephrine in the central and peripheral nervous systems. Both α_2 and β_2 receptors are located at postsynaptic sites, *e.g.*, on many types of neurons in the brain. In peripheral tissues, postsynaptic α_2 receptors are found in vascular and other smooth muscle cells (where they mediate contraction), adipocytes, and many types of secretory epithelial cells (intestinal, renal, endocrine). Postsynaptic β_2 receptors can be found in the myocardium (where they mediate contraction) as well as on vascular and other smooth muscle cells (where they mediate relaxation). Both α_2 and β_2 receptors may be situated at sites that are relatively remote from nerve terminals releasing norepinephrine. Such extrajunctional receptors typically are found on vascular smooth muscle cells and blood elements (platelets and leukocytes) and may be activated preferentially by circulating catecholamines, particularly epinephrine.

In contrast, α_1 and β_1 receptors appear to be located mainly in the immediate vicinity of sympathetic adrenergic nerve terminals in peripheral target organs, strategically placed to be activated during stimulation of these nerves. These receptors also are distributed widely in the mammalian brain.

The cellular distributions of the three α_1 and three α_2 receptor subtypes still are incompletely understood. *In situ* hybridization of receptor mRNA and receptor subtype-specific antibodies indicates that α_{2A} receptors in the brain may be both pre- and postsynaptic. These findings and other studies indicate that this receptor subtype functions as a presynaptic autoreceptor in cen-

tral noradrenergic neurons (Aantaa *et al.*, 1995; Lakhani *et al.*, 1997). Using similar approaches, α_{1A} mRNA was found to be the dominant subtype message expressed in prostatic smooth muscle (Walden *et al.*, 1997).

Refractoriness to Catecholamines. Exposure of catecholamine-sensitive cells and tissues to adrenergic agonists causes a progressive diminution in their capacity to respond to such agents. This phenomenon, variously termed *refractoriness*, *desensitization*, or *tachyphylaxis*, can limit the therapeutic efficacy and duration of action of catecholamines and other agents (*see* Chapter 1). Although descriptions of such adaptive changes are common, the mechanisms are incompletely understood. They have been studied most extensively in cells that synthesize cyclic AMP in response to β receptor agonists.

Multiple mechanisms are involved in desensitization, including rapid events such as receptor phosphorylation by both G-protein receptor kinases (GRKs) and by signaling kinases such as PKA and PKC and receptor sequestration and uncoupling from G proteins. More slowly occurring events also are seen, such as receptor endocytosis, which decreases receptor number. An understanding of the mechanisms involved in regulation of GPCR desensitization has developed over the last few years (Perry and Lefkowitz, 2002; Lefkowitz *et al.*, 2002; Kohout and Lefkowitz, 2003). Such regulation is very complex and exceeds the simplistic model of GPCR phosphorylation by GRKs followed by arrestin binding and uncoupling of G protein signaling. It is known that GRK activities are extensively regulated by numerous interactions with and modifications by other proteins. β -Arrestin, now recognized as a scaffolding protein, can physically interrupt signaling to the G proteins as well as to further enhance GPCR desensitization by causing translocation of cytosolic proteins to the receptor (*e.g.*, phosphodiesterase and c-Src). These, in turn, can turn off signaling at its source by degrading cyclic AMP or phosphorylating GRK2 to enhance its activity to the receptor.

RELATIONSHIP BETWEEN THE NERVOUS AND THE ENDOCRINE SYSTEMS

The theory of neurohumoral transmission by its very designation implies at least a superficial resemblance between the nervous and endocrine systems. It is now clear that the similarities extend considerably deeper, particularly with respect to the autonomic nervous system. In the regulation of homeostasis, the autonomic nervous system is responsible for rapid adjustments to changes in the environment, which it effects at both its ganglionic synapses and its postganglionic terminals by the liberation of chemical agents that act transiently at their immediate sites of release. The endocrine system, in contrast, regu-

lates slower, more generalized adaptations by releasing hormones into the systemic circulation to act at distant, widespread sites over periods of minutes to hours or days. Both systems have major central representations in the hypothalamus, where they are integrated with each other and with subcortical, cortical, and spinal influences. The neurohumoral theory provides a unitary concept of the functioning of the nervous and endocrine systems in which the differences largely relate to the distances over which the released mediators travel.

PHARMACOLOGICAL CONSIDERATIONS

The foregoing sections contain numerous references to the actions of drugs considered primarily as tools for the dissection and elucidation of physiological mechanisms. This section presents a classification of drugs that act on the peripheral nervous system and its effector organs at some stage of neurotransmission. In the subsequent four chapters, the systematic pharmacology of the important members of each of these classes is described.

Each step involved in neurotransmission (Figures 6–2, 6–3, and 6–5) represents a potential point of therapeutic intervention. This is depicted in the diagrams of the cholinergic and adrenergic terminals and their postjunctional sites (Figure 6–3 and 6–5). Drugs that affect processes involved in each step of transmission at both cholinergic and adrenergic junctions are summarized in Table 6–9, which lists representative agents that act *via* the mechanisms described below.

Interference with the Synthesis or Release of the Transmitter. Cholinergic. *Hemicholinium* (HC-3), a synthetic compound, blocks the transport system by which choline accumulates in the terminals of cholinergic fibers, thus limiting the synthesis of the ACh store available for release. *Vesamicol* blocks the transport of ACh into its storage vesicles, preventing its release. The site on the presynaptic nerve terminal for block of ACh release by botulinum toxin was discussed previously; death usually results from respiratory paralysis unless patients with respiratory failure receive artificial ventilation. Injected locally, *botulinum toxin type A* is used in the treatment of certain ophthalmological conditions associated with spasms of ocular muscles (*e.g.*, strabismus and blepharospasm) (*see* Chapter 63) and for a wide variety of unlabeled

Table 6–9

Representative Agents Acting at Peripheral Cholinergic and Adrenergic Neuroeffector Junctions

MECHANISM OF ACTION	SYSTEM	AGENTS	EFFECT
1. Interference with synthesis of transmitter	Cholinergic	Choline acetyl transferase inhibitors	Minimal depletion of ACh
	Adrenergic	α -Methyltyrosine (inhibition of tyrosine hydroxylase)	Depletion of NE
2. Metabolic transformation by same pathway as precursor of transmitter	Adrenergic	Methyldopa	Displacement of NE by α -methyl-NE, which is an α_2 agonist, similar to clonidine, that reduces sympathetic outflow from CNS.
3. Blockade of transport system at nerve terminal membrane	Cholinergic	Hemicholinium	Block of choline uptake with consequent depletion of ACh
	Adrenergic	Cocaine, imipramine	Accumulation of NE at receptors
4. Blockade of transport system of storage vesicle	Cholinergic	Vesamicol	Block of ACh storage
	Adrenergic	Reserpine	Destruction of NE by mitochondrial MAO, and depletion from adrenergic terminals
5. Promotion of exocytosis or displacement of transmitter from axonal terminal	Cholinergic	Latrotoxins	Cholinomimetic followed by anticholinergic
	Adrenergic	Amphetamine, tyramine	Adrenomimetic
6. Prevention of release of transmitter	Cholinergic	Botulinum toxin	Anticholinergic
	Adrenergic	Bretylium, guanadrel	Antiadrenergic
7. Mimicry of transmitter at postjunctional sites	Cholinergic		
	Muscarinic*	Methacholine, bethanachol	Cholinomimetic
	Nicotinic [†]	Nicotine, epibatidine, cytisine	Cholinomimetic
	Adrenergic		
	α_1	Phenylephrine	Selective α_1 adrenomimetic
	α_2	Clonidine	Adrenomimetic (periphery); reduced sympathetic outflow (CNS)
	α_1, α_2	Oxymetazoline	Non-selective α adrenomimetic
	β_1	Dobutamine	Selective cardiac stimulation (also activates α_1 receptors)
β_2	Terbutaline, albuterol metaproterenol	Selective β_2 receptor agonist (selective inhibition of smooth muscle contraction)	
β_1, β_2	Isoproterenol	Nonselective β adrenomimetic	

(Continued)

Table 6–9

Representative Agents Acting at Peripheral Cholinergic and Adrenergic Neuroeffector Junctions (Continued)

MECHANISM OF ACTION	SYSTEM	AGENTS	EFFECT
8. Blockade of postsynaptic receptor	Cholinergic		
	Muscarinic*	Atropine	Muscarinic blockade
	Nicotinic (N _M) [†]	<i>d</i> -tubocurarine, atracurium	Neuromuscular blockade
	Nicotinic (N _N) [†]	trimethaphan	Ganglionic blockade
	Adrenergic		
	α ₁ , α ₂	Phenoxybenzamine	Nonselective α receptor blockade (irreversible)
	α ₁ , α ₂	Phentolamine	Nonselective α receptor blockade (reversible)
	α ₁	Prazosin, terazosin, doxazosin	Selective α ₁ receptor blockade (reversible)
	α ₂	Yohimbine	Selective α ₂ receptor blockade
	β ₁ , β ₂	Propranolol	Nonselective β receptor blockade
9. Inhibition of enzymatic breakdown of transmitter	Cholinergic	AChE inhibitors (edrophonium, neostigmine, pyridostigmine)	Cholinomimetic (muscarinic sites) Depolarization blockade (nicotinic sites)
	Adrenergic	Nonselective MAO inhibitors (paraglyline, nialamide)	Little direct effect on NE or sympathetic response; potentiation of tyramine
		Selective MAO-B inhibitor (selegiline)	Adjunct in Parkinson's disease
		Peripheral COMT inhibitor (entacapone)	Adjunct in Parkinson's disease
		Peripheral and central COMT inhibitor (tolcapone)	

ABBREVIATIONS: ACh, acetylcholine; AChE, acetylcholine esterase; COMT, catechol-*O*-methyl transferase; MAO, monoamine oxidase; NE, norepinephrine. *At least five subtypes of muscarinic receptors exist. Agonists show little selectivity for subtypes whereas several antagonists show partial subtype selectivity (see Table 6–3). [†]Two subtypes of muscle acetylcholine nicotinic receptors and several subtypes of neuronal receptors have been identified (see Table 6–2).

uses ranging from treatment of muscle dystonias and palsy (see Chapter 9) to cosmetic erasure of facial lines and wrinkles (see Chapter 62).

Adrenergic. *α-Methyltyrosine (metyrosine)* blocks the synthesis of norepinephrine by inhibiting tyrosine hydroxylase, the enzyme that catalyzes the rate-limiting step in catecholamine synthesis. This drug occasionally may be useful in treating selected patients with pheochromocytoma. On the other hand, *methyl dopa*, an inhibitor of aromatic L-amino acid decarboxylase, is—like dopa itself—successively decarboxylated and hydroxylated in its side chain to form the putative “false neurotransmitter” *α-methylnorepinephrine*. The use of methyl dopa in the treatment of hypertension is discussed in Chapter 32. *Bretylium*, *guanadrel*, and *guanethidine* act by preventing the release of norepinephrine by the nerve impulse. However, such agents can transiently stimulate the release of norepinephrine because of their capacity to displace the amine from storage sites.

Promotion of the Release of the Transmitter. Cholinergic. The ability of cholinergic agents to promote the release of ACh is limited presumably because ACh and other cholinomimetic agents are quaternary amines and do not readily cross the axonal membrane into the nerve ending. The *latrotoxins* from black widow spider venom and stonefish are known to promote neuroexocytosis by binding to receptors on the neuronal membrane.

Adrenergic. Several drugs that promote the release of the adrenergic mediator already have been discussed. On the basis of the rate and duration of the drug-induced release of norepinephrine from adrenergic terminals, one of two opposing effects can predominate. Thus tyramine, *ephedrine*, *amphetamine*, and related drugs cause a relatively rapid, brief liberation of the transmitter and produce a sympathomimetic effect. On the other hand, reserpine, by blocking the vesicular amine transporter (VAMT 2) uptake of amines, produces a slow, prolonged depletion of the adrenergic transmitter from adrenergic storage vesicles, where it is largely metabolized by intraneuronal MAO. The resulting depletion of transmitter produces the equivalent of adrenergic blockade. Reserpine also causes the depletion of serotonin, dopamine, and possibly other, unidentified amines from central and peripheral sites, and many of its major effects may be a consequence of the depletion of transmitters other than norepinephrine.

As discussed earlier, deficiencies of tyrosine hydroxylase in humans cause a neurologic disorder (Carson and Robertson, 2002) that can be treated by supplementation with the dopamine precursor *levodopa*.

A syndrome caused by congenital DβH deficiency has been described; this syndrome is characterized by the absence of norepinephrine and epinephrine, elevated concentrations of dopamine, intact baroreflex afferent fibers and cholinergic innervation, and undetectable concentrations of plasma DβH activity (Carson and Robertson, 2002). Patients have severe orthostatic hypotension, ptosis of the eyelids, and retrograde ejaculations. *Dihydroxyphenylserine* (L-DOPS) has been shown to improve postural hypotension in this rare disorder. This therapeutic approach cleverly takes advantage of the nonspecificity of aromatic L-amino acid decarboxylase, which synthesizes norepinephrine directly from this drug in the absence of DβH (Man in't Veld *et al.*, 1988; Robertson *et al.*, 1991). Despite the restoration of plasma norepinephrine in humans with L-DOPS, epinephrine levels are not restored, leading to speculations that PNMT may require DβH for appropriate functioning (Carson and Robertson, 2002).

Agonist and Antagonist Actions at Receptors. Cholinergic. The nicotinic receptors of autonomic ganglia and skeletal muscle are not identical; they respond differently to certain stimulating and blocking agents, and their pentameric structures contain different combinations of homologous subunits (Table 6–2). *Dimethylphenylpiperazinium* (DMPP) and *phenyltrimethylammonium* (PTMA) show some selectivity for stimulation of autonomic ganglion cells and end plates of skeletal muscle, respectively. *Trimethaphan* and *hexamethonium* are relatively selective competitive and noncompetitive ganglionic blocking agents. Although tubocurarine effectively blocks transmission at both motor end plates and autonomic ganglia, its action at the former site predominates. *Succinylcholine*, a depolarizing agent, produces selective neuromuscular blockade. Transmission at autonomic ganglia and the adrenal medulla is complicated further by the presence of muscarinic receptors in addition to the principal nicotinic receptors (see Chapter 9).

Various toxins in snake venoms exhibit a high degree of specificity in the cholinergic nervous system. The *α*-neurotoxins from the Elapidae family interact with the agonist-binding site on the nicotinic receptor. *α-Bungarotoxin* is selective for the muscle receptor and interacts with only certain neuronal receptors, such as those containing *α₇* through *α₉* subunits. Neuronal bungarotoxin shows a wider range of inhibition of neuronal receptors. A second group of toxins, called the *fasciculins*, inhibits AChE. A third group of toxins, termed the *muscarinic toxins* (MT₁ through MT₄), includes partial agonists and antagonists for the muscarinic receptors. Venoms from the Viperidae family of snakes and the fish-hunting cone snails also have relatively selective toxins for nicotinic receptors.

Muscarinic ACh receptors, which mediate the effects of ACh at autonomic effector cells, now can be divided into five subclasses. Atropine blocks all the muscarinic

responses to injected ACh and related cholinomimetic drugs whether they are excitatory, as in the intestine, or inhibitory, as in the heart. Newer muscarinic agonists, *pirenzepine* for M_1 , *tripitramine* for M_2 , and *darifenacin* for M_3 , show selectivity as muscarinic blocking agents. Several muscarinic antagonists show sufficient selectivity in the clinical setting to minimize the bothersome side effects seen with the nonselective agents at therapeutic doses (see Chapter 7).

Adrenergic. A vast number of synthetic compounds that bear structural resemblance to the naturally occurring catecholamines can interact with α and β adrenergic receptors to produce sympathomimetic effects (see Chapter 10). Phenylephrine acts selectively at α_1 receptors, whereas clonidine is a selective α_2 adrenergic agonist. Isoproterenol exhibits agonist activity at both β_1 and β_2 receptors. Preferential stimulation of cardiac β_1 receptors follows the administration of *dobutamine*. *Terbutaline* is an example of a drug with relatively selective action on β_2 receptors; it produces effective bronchodilation with minimal effects on the heart. The main features of adrenergic blockade, including the selectivity of various blocking agents for α and β adrenergic receptors, have been mentioned (see Chapter 10). Again, partial dissociation of effects at β_1 and β_2 receptors has been achieved, as exemplified by the β_1 receptor antagonists *metoprolol* and *atenolol*, which antagonize the cardiac actions of catecholamines while causing somewhat less antagonism at bronchioles. *Prazosin* and *yohimbine* are representative of α_1 and α_2 receptor antagonists, respectively, although prazosin has a relatively high affinity at α_{2B} and α_{2C} subtypes compared with α_{2A} receptors. Several important drugs that promote the release of norepinephrine or deplete the transmitter resemble, in their effects, activators or blockers of postjunctional receptors (e.g., tyramine and reserpine, respectively).

Interference with the Destruction of the Transmitter. Cholinergic. The anti-ChE agents (see Chapter 8) constitute a chemically diverse group of compounds, the primary action of which is inhibition of AChE, with the consequent accumulation of endogenous ACh. At the neuromuscular junction, accumulation of ACh produces depolarization of end plates and flaccid paralysis. At postganglionic muscarinic effector sites, the response is either excessive stimulation resulting in contraction and secretion or an inhibitory response mediated by hyperpolarization. At ganglia, depolarization and enhanced transmission are observed.

Adrenergic. The reuptake of norepinephrine by the adrenergic nerve terminals *via* NET is the major mechanism for terminating its transmitter action. Interference with this process is the basis of the potentiating effect of cocaine on responses to adrenergic impulses and injected catecholamines. It also has been suggested that the antidepressant actions and some of the adverse effects of imipramine and related drugs are due to a similar action at adrenergic synapses in the CNS (see Chapter 17).

Entacapone and *tolcapone* are nitro catechol-type COMT inhibitors. Entacapone is a peripherally acting COMT inhibitor, whereas tolcapone also inhibits COMT activity in the brain. COMT inhibition has been shown to attenuate levodopa toxicity on dopamine neurons and enhance dopamine action in the brain of patients with Parkinson's disease (see Chapter 20). On the other hand, nonselective MAO inhibitors, such as tranylcypromine, potentiate the effects of tyramine and may potentiate effects of neurotransmitters. While most MAO inhibitors used as antidepressants inhibit both MAO-A and MAO-B, selective MAO-A and MAO-B inhibitors are available. Selegiline is a selective and irreversible MAO-B inhibitor that also has been used as an adjunct in the treatment of Parkinson's disease.

OTHER AUTONOMIC NEUROTRANSMITTERS

The vast majority of neurons in both the central and peripheral nervous systems contain more than one substance with potential or demonstrated activity at relevant postjunctional sites (see Chapter 12). In some cases, especially in peripheral structures, it has been possible to demonstrate that two or more such substances are contained within individual nerve terminals and are released simultaneously on nerve stimulation. Although the anatomical separation of the parasympathetic and sympathetic components of the autonomic nervous system and the actions of ACh and norepinephrine (their primary neurotransmitters) still provides the essential framework for studying autonomic function, a host of other chemical messengers such as purines, eicosanoids, NO, and peptides modulate or mediate responses that follow stimulation of the autonomic nervous system. An expanded view of autonomic neurotransmission has evolved to include instances where substances other than ACh or norepinephrine are released and may function as cotransmitters, neuromodulators, or even primary transmitters.

The evidence for cotransmission in the autonomic nervous system usually encompasses the following considerations: (1) A portion of responses to stimulation of preganglionic or postganglionic nerves or to field stimulation of target structures persists in the presence of concentrations of muscarinic or adrenergic antagonists that completely block their respective agonists. (2) The candidate substance can be detected within nerve fibers that course through target tissues. (3) The substance can be recovered on microdialysis or in the venous or perfusion effluent following electrical stimulation; such release often can be blocked by tetrodotoxin. (4) Effects of electrical stimulation are mimicked by the application of the substance and are inhibited in the presence of specific antagonists. When such antagonists are not available, reliance often is placed on neutralizing antibodies or selective desensitization produced by prior exposure to the substance. A more recent approach to this challenging problem is the use of knockout mice that do not express the putative cotransmitter.

A number of problems confound interpretation of such evidence. It is particularly difficult to establish that substances that fulfill all the listed criteria originate within the autonomic nervous system. In some instances, their origin can be traced to sensory fibers, to intrinsic neurons, or to nerves innervating blood vessels. Also, there may be marked synergism between the candidate substance and known or unknown transmitters (Lundberg, 1996). In knockout mice, compensatory mechanisms or transmitter redundancy may disguise even well-defined actions (Hökfelt *et al.*, 2000). Finally, it should be recognized that the putative cotransmitter may have primarily a trophic function in maintaining synaptic connectivity or in expressing a particular receptor.

It long has been known that ATP and ACh coexist in cholinergic vesicles (Dowdall *et al.*, 1974) and that ATP, NPY, and catecholamines are found within storage granules in nerves and the adrenal medulla (*see above*). ATP is released along with the transmitters, and either it or its metabolites have a significant function in synaptic transmission in some circumstances (*see below*). Recently, attention has focused on the growing list of peptides that are found in the adrenal medulla, nerve fibers, or ganglia of the autonomic nervous system or in the structures that are innervated by the autonomic nervous system. This list includes the enkephalins, substance P and other tachykinins, somatostatin, gonadotropin-releasing hormone, cholecystokinin, calcitonin gene-related peptide, galanin, pituitary adenylyl cyclase-activating pep-

tide, VIP, chromogranins, and NPY (Darlison and Richter, 1999; Lundberg, 1996; Bennett, 1997; Hökfelt *et al.*, 2000). Some of the orphan GPCRs discovered in the course of genome-sequencing projects may represent receptors for undiscovered peptides or other cotransmitters. The evidence for widespread transmitter function in the autonomic nervous system is substantial for VIP and NPY, and further discussion is confined to these peptides. The possibility that abnormalities in function of neuropeptide cotransmitters, in type 2 diabetes, for example, contribute to disease pathogenesis remains of interest (Ahren, 2000).

Cotransmission in the Autonomic Nervous System.

The evidence is substantial that ATP plays a role in sympathetic nerves as a cotransmitter with norepinephrine (Stjärne, 1989; Westfall *et al.*, 1991, 2002; Silinsky *et al.*, 1998; Burnstock, 1999). For example, the rodent vas deferens is supplied with a dense sympathetic innervation, and stimulation of the nerves results in a biphasic mechanical response that consists of an initial rapid twitch followed by a sustained contraction. The first phase of the response is mediated by ATP acting on postjunctional P2X receptors, whereas the second phase is mediated mainly by norepinephrine acting on α_1 receptors (Sneddon and Westfall, 1984). The cotransmitters apparently are released from the same types of nerves because pretreatment with *6-hydroxydopamine*, an agent that specifically destroys adrenergic nerves, abolished both phases of the neurogenically induced biphasic contraction. It has been assumed that the sympathetic nerves store ATP and norepinephrine in the same synaptic vesicles, and therefore, on release, the two cotransmitters are released together (Stjärne, 1989). This may not always be the case, and ATP and norepinephrine may be released from separate subsets of vesicles and subject to differential regulation.

While part of the metabolism of ATP, once released into the neuroeffector junction, is by extracellularly directed membrane-bound nucleotidases to ADP, AMP, and adenosine (Gordon, 1986), the majority of the metabolism occurs *via* the action of releasable nucleotidases. There is also evidence that ATP and its metabolites exert presynaptic modulatory effects on transmitter release *via* P2 receptors and receptors for adenosine. In addition to evidence showing that ATP is a cotransmitter with norepinephrine, there is also evidence that ATP may be a cotransmitter with ACh in certain postganglionic parasympathetic nerves, *e.g.*, in the urinary bladder.

The NPY family of peptides is distributed widely in the central and peripheral nervous systems and consists of

three members: NPY, pancreatic polypeptide, and peptide YY. NPY has been shown to be colocalized and coreleased with norepinephrine and ATP in most sympathetic nerves in the peripheral nervous system, especially those innervating blood vessels (*see* Westfall, 2004). There is also convincing evidence that NPY exerts prejunctional modulatory effects on transmitter release and synthesis. Moreover, there are numerous examples of postjunctional interactions that are consistent with a cotransmitter role for NPY at various sympathetic neuroeffector junctions. Thus, it seems that NPY, together with norepinephrine and ATP, is the third sympathetic cotransmitter. The functions of NPY include (1) direct postjunctional contractile effects; (2) potentiation of the contractile effects of the other sympathetic cotransmitters; and (3) inhibitory modulation of the nerve stimulation–induced release of all three sympathetic cotransmitters.

Studies with selective NPY- Y_1 antagonists provide evidence that the principal postjunctional receptor is of the Y_1 subtype, although other receptors are also present at some sites and may exert physiological actions. Studies with selective NPY- Y_2 antagonists suggest that the principal prejunctional receptor is of the Y_2 subtype both in the periphery and in the CNS. Again, there is evidence for a role for other NPY receptors, and clarification awaits the further development of selective antagonists. NPY also can act prejunctionally to inhibit the release of ACh, CGRP, and substance P. In the CNS, NPY exists as a cotransmitter with catecholamines in some neurons and with peptides and mediators in others. A prominent action of NPY is the presynaptic inhibition of the release of various neurotransmitters, including norepinephrine, dopamine, GABA, glutamate, and serotonin, as well as inhibition or stimulation of various neurohormones such as gonadotropin-releasing hormone, vasopressin, and oxytocin. Evidence also exists for stimulation of norepinephrine and dopamine release. NPY also acts on autoreceptors to inhibit its own release. NPY may use several mechanisms to produce its presynaptic effects, including: inhibition of Ca^{2+} channels, activation of K^+ channels, and perhaps regulation of the vesicle release complex at some point distal to calcium entry. NPY also may play a role in several pathophysiological conditions. The further development of selective NPY agonists and antagonists should enhance understanding about the physiological and pathophysiological roles of NPY.

The pioneering studies of Hökfelt and coworkers, which demonstrated the existence of VIP and ACh in peripheral autonomic neurons, initiated interest in the possibility of peptidergic cotransmission in the autonomic nervous system. Subsequent work has confirmed the frequent association of these two substances in autonomic fibers, including parasympathetic fibers that innervate smooth muscle and exocrine glands and cholinergic sympathetic neurons that innervate sweat glands (Hökfelt *et al.*, 2000).

The role of VIP in parasympathetic transmission has been studied most extensively in the regulation of salivary secretion. The evidence for cotransmission includes the release of VIP following stimulation of the chorda lingual nerve and the incomplete blockade by

atropine of vasodilation when the frequency of stimulation is raised; the latter observation may indicate independent release of the two substances, which is consistent with histochemical evidence for storage of ACh and VIP in separate populations of vesicles. Synergism between ACh and VIP in stimulating vasodilation and secretion also has been described. VIP may be involved in parasympathetic responses in the GI tract, where it may facilitate sphincter relaxation, and the trachea.

Nonadrenergic, Noncholinergic Transmission by Purines. The smooth muscle of many tissues that are innervated by the autonomic nervous system shows inhibitory junction potentials following stimulation by field electrodes (Bennett, 1997). Since such responses frequently are undiminished in the presence of adrenergic and muscarinic cholinergic antagonists, these observations have been taken as evidence for the existence of nonadrenergic, noncholinergic (NANC) transmission in the autonomic nervous system.

Burnstock (1996) and his colleagues have compiled compelling evidence for the existence of purinergic neurotransmission in the gastrointestinal tract, genitourinary tract, and certain blood vessels; ATP has fulfilled all the criteria for a neurotransmitter listed earlier. However, in at least some circumstances, primary sensory axons may be an important source of ATP (Burnstock, 2000). Although adenosine is generated from the released ATP by ectoenzymes and releasable nucleotidases, its primary function appears to be modulatory by causing feedback inhibition of release of the transmitter.

Adenosine can be transported from the cell cytoplasm to activate extracellular receptors on adjacent cells. The efficient uptake of adenosine by cellular transporters and its rapid rate of metabolism to inosine or to adenine nucleotides contribute to its rapid turnover. Several inhibitors of adenosine transport and metabolism are known to influence extracellular adenosine and ATP concentrations (Sneddon *et al.*, 1999).

The purinergic receptors found on the cell surface may be divided into the adenosine (P1) receptors and the receptors for ATP (P2X and P2Y receptors) (Fredholm *et al.*, 2000). Both of the P1 and P2 receptors have various subtypes. Methylxanthines such as *caffeine* and *theophylline* preferentially block adenosine receptors (*see* Chapter 27). There are four adenosine receptors (A1, A2A, A2B, and A3) and multiple subtypes of P2X and P2Y receptors throughout the body. The adenosine receptors and the P2Y receptors mediate their responses *via* G proteins, whereas the P2X receptors are a subfamily of ligand-gated ion channels (Burnstock, 2000).

Modulation of Vascular Responses by Endothelium-Derived Factors. Furchgott and colleagues demonstrated that an intact endothelium was necessary to achieve vascular relaxation in response to ACh (Furchgott, 1999). This inner cellular layer of the blood vessel now is known to modulate autonomic and hormonal effects on the contractility of blood vessels. In response to a variety of vasoactive agents and even physical stimuli, the endothelial cells release a short-lived vasodilator called *endothelium-derived relaxing factor* (EDRF), now known to be NO. Less commonly, an endothelium-derived hyperpolarizing factor (EDHF) and endothelium-derived contracting factor (EDCF) of as yet undefined compositions are released (Vanhoutte, 1996). EDCF formation depends on cyclooxygenase activity.

Products of inflammation and platelet aggregation (e.g., serotonin, histamine, bradykinin, purines, and thrombin) exert all or part of their action by stimulating the production of NO. Endothelial cell-dependent mechanisms of relaxation are important in a variety of vascular beds, including the coronary circulation (Hobbs *et al.*, 1999). Activation of specific GPCRs on endothelial cells promotes NO production. NO diffuses readily to the underlying smooth muscle and induces relaxation of vascular smooth muscle by activating the soluble form of guanylyl cyclase, which increases cyclic GMP concentrations. Nitrovasodilating drugs used to lower blood pressure or to treat ischemic heart disease probably act through conversion to or release of NO (*see* Chapter 31). NO also has been shown to be released from certain nerves (*nitrergic*) innervating blood vessels and smooth muscles of the gastrointestinal tract. NO has a negative inotropic action on the heart.

Alterations in the release or action of NO may affect a number of major clinical situations such as atherosclerosis (Hobbs *et al.*, 1999; Ignarro, 1999). Furthermore, there is evidence suggesting that the hypotension of endotoxemia or that induced by cytokines is mediated by induction of enhanced release of NO; consequently, increased release of NO may have pathological significance in septic shock. NO is synthesized from L-arginine and molecular oxygen by *nitric oxide synthase* (NOS). There are three known forms of this enzyme (Moncada *et al.*, 1997). One form (eNOS) is constitutive, residing in the endothelial cell and synthesizing NO over short periods in response to receptor-mediated increases in cellular Ca^{2+} . A second form (nNOS) is responsible for the Ca^{2+} -dependent NO synthesis neurons. The third form of NOS (iNOS) is induced after activation of cells by cytokines and bacterial endotoxins

and, once expressed, synthesizes NO for long periods of time. This Ca^{2+} -independent, high-output form is responsible for the above-mentioned toxic manifestations of NO. Glucocorticoids inhibit the expression of inducible, but not constitutive, forms of NOS in vascular endothelial cells. However, other endothelium-derived factors also may be involved in vasodilation and hyperpolarization of the smooth muscle cell. There has been considerable interest in the possibility that NOS inhibitors might have therapeutic benefit, for example, in septic shock and neurodegenerative diseases (Hobbs *et al.*, 1999). Conversely, diminished production of NO by the endothelial cell layer in atherosclerotic coronary arteries may contribute to the risk of myocardial infarction.

Full contractile responses of cerebral arteries also require an intact endothelium. A family of peptides, termed *endothelins*, is stored in vascular endothelial cells. Their release onto smooth muscle promotes contraction by stimulation of endothelin receptors. Endothelins contribute to the maintenance of vascular homeostasis by acting *via* multiple endothelin receptors (Sokolovsky, 1995) to reverse the response to NO (Rubanyi and Polokoff, 1994). In isolated cell systems, several G-protein-linked responses to endothelins are quasi-irreversible (Hilal-Dandan *et al.*, 1997).

MUSCARINIC RECEPTOR AGONISTS AND ANTAGONISTS

Joan Heller Brown and Palmer Taylor

ACETYLCHOLINE AND ITS MUSCARINIC RECEPTOR TARGET

Muscarinic acetylcholine receptors in the peripheral nervous system are found primarily on autonomic effector cells innervated by postganglionic parasympathetic nerves. Muscarinic receptors also are present in ganglia and on some cells, such as endothelial cells of blood vessels, that receive little or no cholinergic innervation. Within the central nervous system (CNS), the hippocampus, cortex, and thalamus have high densities of muscarinic receptors.

Acetylcholine (ACh), the naturally occurring neurotransmitter for these receptors, has virtually no systemic therapeutic applications because its actions are diffuse, and its hydrolysis, catalyzed by both acetylcholinesterase (AChE) and plasma butyrylcholinesterase, is rapid. Muscarinic agonists mimic the effects of ACh at these sites. These agonists typically are longer-acting congeners of ACh or natural alkaloids that display little selectivity for the various subtypes of muscarinic receptors. Several of these agents stimulate nicotinic as well as muscarinic receptors.

The mechanisms of action of endogenous ACh at the postjunctional membranes of the effector cells and neurons that correspond to the four classes of cholinergic synapses are discussed in Chapter 6. To recapitulate, these synapses are found at (1) autonomic effector sites, innervated by postganglionic parasympathetic fibers (and a small number of cholinergic sympathetic fibers); (2) sympathetic and parasympathetic ganglion cells and the adrenal medulla, innervated by preganglionic autonomic fibers; (3) motor endplates on skeletal muscle, innervated

by somatic motor nerves; and (4) certain synapses peripherally and within the CNS (Krnjević, 2004), where the actions can be either pre- or postsynaptic. When ACh is administered systemically, it potentially can act at all of these sites; however, as a quaternary ammonium compound, its CNS penetration is limited, and butyrylcholinesterase in the plasma reduces the concentrations of ACh that reach peripheral areas with low blood flow.

The actions of ACh and related drugs at autonomic effector sites are referred to as *muscarinic*, based on the original observation that muscarine acts selectively at those sites and produces the same qualitative effects as ACh. Accordingly, the muscarinic, or parasympathomimetic, actions of the drugs considered in this chapter are practically equivalent to the effects of postganglionic parasympathetic nerve impulses listed in Table 6–1; the differences between the actions of the classical muscarinic agonists are largely quantitative, as they show limited selectivity for one organ system or another. Muscarinic receptors also are present on autonomic ganglion cells and in the adrenal medulla. Muscarinic stimulation of ganglia and the adrenal medulla usually is thought to modulate nicotinic stimulation. All of the actions of ACh and its congeners at muscarinic receptors can be blocked by *atropine*. The *nicotinic* actions of cholinergic agonists refer to their initial stimulation, and often in high doses to subsequent blockade, of autonomic ganglion cells, the adrenal medulla, and the neuromuscular junction, actions comparable to those of nicotine.

Properties and Subtypes of Muscarinic Receptors

Muscarinic receptors were characterized initially by analysis of the responses of cells and tissues in the periphery and the CNS. Differential effects of two muscarinic agonists, *bethanechol* and McN-A-

343, on the tone of the lower esophageal sphincter led to the initial designation by Goyal and Rattan (1978) of muscarinic receptors as M_1 (ganglionic) and M_2 (effector cell) (see Chapter 6). The basis for the selectivity of these agonists is unclear, as there is limited evidence that agonists discriminate appreciably among the subtypes of muscarinic receptors (Eglen *et al.*, 1996; Caulfield and Birdsall, 1998). However, subsequent radioligand binding studies definitively revealed distinct populations of antagonist binding sites (Hammer *et al.*, 1980). In particular, the muscarinic antagonist *pirenzepine* was shown to bind with high affinity to sites in cerebral cortex and sympathetic ganglia (M_1) but to have lower affinity for sites in cardiac muscle, smooth muscle, and various glands. These data explain the ability of *pirenzepine* to block agonist-induced responses that are mediated by muscarinic receptors in sympathetic and myenteric ganglia at concentrations considerably lower than those required to block responses that result from direct stimulation of receptors in various effector organs. Antagonists that can further discriminate among various subtypes of muscarinic receptors are now available. For example, *tripitramine* displays selectivity for cardiac M_2 relative to M_3 muscarinic receptors, while *darifenacin* is relatively selective for antagonizing glandular and smooth muscle M_3 relative to M_2 receptors (Caulfield and Birdsall, 1998; Birdsall *et al.*, 1998; Levine *et al.*, 1999).

The cloning of the cDNAs that encode muscarinic receptors identified five distinct gene products (Bonner *et al.*, 1987), now designated as M_1 through M_5 (see Chapter 6). All of the known muscarinic receptor subtypes interact with members of a group of heterotrimeric guanine nucleotide-binding regulatory proteins (G proteins) that in turn are linked to various cellular effectors (see Chapter 1). Regions within the receptor responsible for the specificity of G protein coupling have been defined primarily by receptor mutants and chimeras formed between receptor subtypes. In particular, one region at the carboxyl-terminal end of the third intracellular loop of the receptor has been implicated in the specificity of G protein coupling and shows extensive homology within M_1 , M_3 , and M_5 receptors and between M_2 and M_4 receptors (Wess, 1996; Caulfield, 1993; Caulfield and Birdsall, 1998). Conserved regions in the second intracellular loop also confer specificity for proper G protein recognition. Although selectivity is not absolute, stimulation of M_1 or M_3 receptors causes hydrolysis of polyphosphoinositides and mobilization of intracellular Ca^{2+} as a consequence of activation of the G_q -PLC pathway (see Chapter 6); this effect in turn results in a variety of Ca^{2+} -mediated events, either directly or as a consequence of the phosphorylation of target proteins. In contrast, M_2 and M_4 muscarinic receptors inhibit adenylyl cyclase and regulate specific ion channels (*e.g.*, enhancement of K^+ conductance in cardiac atrial tissue) through subunits released from pertussis toxin-sensitive G proteins (G_i and G_o) that are distinct from the G proteins used by M_1 and M_3 receptors (see Chapter 1).

Studies using muscarinic receptor subtype-specific antibodies and ligands demonstrate discrete localization of the muscarinic receptor subtypes, for example within brain regions and in different populations of smooth muscle cells (Levey, 1993; Yasuda *et al.*, 1993; Eglen *et al.*, 1996; Caulfield and Birdsall, 1998). The M_1 through M_5 subtypes have been disrupted through gene targeting to create null alleles for each of these genes (Hamilton *et al.*, 1997; Gomeza *et al.*, 1999; Matsui *et al.*, 2000; Yamada *et al.*, 2001a; Yamada *et al.*, 2001b; Wess, 2004). All of the muscarinic receptor subtype deletions yield mice that are viable and fertile. Studies using these mice indicate that *pilocarpine*-induced seizures are mediated through M_1 , *oxotremorine*-induced tremors through M_2 ,

analgesia through M_2 and M_4 , and hypothermia through M_2 and other subtypes. *Carbachol* and vagally induced bradycardia are lost in M_2 receptor knockout mice, while mice lacking the M_3 receptor show loss of cholinergic bronchoconstriction and urinary bladder contraction (Fisher *et al.*, 2004; Wess, 2004). Full abolition of cholinergic bronchoconstriction, salivation, pupillary constriction, and bladder contraction generally requires deletion of more than a single receptor subtype. The minimal phenotypic alteration that accompanies deletion of a single receptor subtype suggests functional redundancy between receptor subtypes in various tissues.

Pharmacological Properties

Cardiovascular System. ACh has four primary effects on the cardiovascular system: vasodilation, a decrease in cardiac rate (the negative chronotropic effect), a decrease in the rate of conduction in the specialized tissues of the sinoatrial (SA) and atrioventricular (AV) nodes (the negative dromotropic effect), and a decrease in the force of cardiac contraction (the negative inotropic effect). The last effect is of lesser significance in ventricular than in atrial muscle. Certain of the above responses can be obscured by baroreceptor and other reflexes that dampen the direct responses to ACh.

Although ACh rarely is given systemically, its cardiac actions are important because of the involvement of cholinergic vagal impulses in the actions of the cardiac glycosides, antiarrhythmic agents, and many other drugs; afferent stimulation of the viscera during surgical interventions also stimulates vagal release of ACh.

The intravenous injection of a small dose of ACh produces a transient fall in blood pressure owing to generalized vasodilation, usually accompanied by reflex tachycardia. A considerably larger dose is required to elicit bradycardia or block of AV nodal conduction from a direct action of ACh on the heart. If large doses of ACh are injected after the administration of atropine, an increase in blood pressure is observed; the increase is caused by direct stimulation of the adrenal medulla and sympathetic ganglia to release catecholamines into the circulation and at postganglionic sympathetic nerve endings, respectively.

ACh produces dilation of essentially all vascular beds, including those of the pulmonary and coronary vasculature. Vasodilation of coronary beds is mediated by stimulation of local production of NO and may be elicited by baroreceptor or chemoreceptor reflexes or by direct electrical stimulation of the vagus (Feigl, 1998). However, neither parasympathetic vasodilator nor sympathetic vasoconstrictor tone plays a major role in the regulation of coronary blood flow relative to the effects of local oxygen tension and autoregulatory metabolic factors such as adenosine (Berne and Levy, 1997).

Dilation of vascular beds by exogenously administered ACh is due to muscarinic receptors, primarily of the M₃ subtype (Bruning *et al.*, 1994; Eglen *et al.*, 1996; Caulfield and Birdsall, 1998), despite the lack of apparent cholinergic innervation of most blood vessels. The muscarinic receptors responsible for relaxation are located on the endothelial cells of the vasculature; occupation of these receptors by agonist activates the G_q-PLC-IP₃ pathway of endothelial cells, leading to Ca²⁺-calmodulin-dependent activation of endothelial NO synthase (eNOS) and production of NO (endothelium-derived relaxing factor) (Moncada and Higgs, 1995), which diffuses to adjacent smooth muscle cells and causes them to relax (Furchgott, 1999; Ignarro *et al.*, 1999) (*see* Chapters 1 and 6). Vasodilation also may arise indirectly due to inhibition of norepinephrine release from adrenergic nerve endings by ACh. If the endothelium is damaged, as occurs under various pathophysiological conditions, ACh can stimulate receptors on vascular smooth muscle cells and cause vasoconstriction by activation of the G_q-PLC-IP₃ pathway. There is also evidence of NO-based (nitroergic) neurotransmission in peripheral blood vessels (Toda and Okamura, 2003).

Cholinergic stimulation affects cardiac function both directly and by inhibiting the effects of adrenergic activation. The latter depends on the level of sympathetic drive to the heart and results in part from inhibition of cyclic AMP formation and reduction in L-type Ca²⁺ channel activity, mediated through M₂ receptors (Brodde and Michel, 1999). The functional role of M₃ receptors in the human heart is unknown (Willmy-Matthes *et al.*, 2003). Inhibition of adrenergic stimulation of the heart arises not only from the capacity of ACh to modulate or depress the myocardial response to catecholamines, but also from a capacity to inhibit the release of norepinephrine from sympathetic nerve endings. There are also inhibitory M₂ receptors that regulate ACh release in the human heart (Oberhauser *et al.*, 2001). Cholinergic innervation of the ventricular myocardium is less dense, and the parasympathetic fibers terminate largely on specialized conduction tissue such as the Purkinje fibers but also on ventricular myocytes (Kent *et al.*, 1976; Levy and Schwartz, 1994).

In the SA node, each normal cardiac impulse is initiated by the spontaneous depolarization of the pacemaker cells (*see* Chapter 34). At a critical level—the threshold potential—this depolarization initiates an action potential. The action potential is conducted through the atrial muscle fibers to the AV node and thence through the Purkinje system to the ventricular muscle. ACh slows the heart rate by decreasing the rate of spontaneous diastolic depolarization (the pacemaker current) and by increasing the repolarizing K⁺ current at the SA node; attainment of the

threshold potential and the succeeding events in the cardiac cycle are therefore delayed (DiFrancesco, 1993).

In atrial muscle, ACh decreases the strength of contraction. This occurs largely indirectly, as a result of decreasing cyclic AMP and Ca²⁺ channel activity. Direct inhibitory effects are seen at higher ACh concentrations and result from M₂ receptor-mediated activation of G protein-regulated K⁺ channels (Wickman and Clapham, 1995). The rate of impulse conduction in the normal atrium is either unaffected or may increase in response to ACh. The increase is due to the activation of additional Na⁺ channels, possibly in response to the ACh-induced hyperpolarization. The combination of these factors is the basis for the perpetuation or exacerbation by vagal impulses of atrial flutter or fibrillation arising at an ectopic focus. In contrast, primarily in the AV node and to a much lesser extent in the Purkinje conducting system, ACh slows conduction and increases the refractory period. The decrement in AV nodal conduction usually is responsible for the complete heart block that may be observed when large quantities of cholinergic agonists are administered systemically. With an increase in vagal tone, such as is produced by the *digitalis* glycosides, the increased refractory period can contribute to the reduction in the frequency with which aberrant atrial impulses are transmitted to the ventricle, and thus decrease the ventricular rate during atrial flutter or fibrillation.

In the ventricle, ACh, whether released by vagal stimulation or applied directly, also has a negative inotropic effect, although it is smaller than that observed in the atrium. In humans and most mammals, inhibition is most apparent when there is concomitant adrenergic stimulation or underlying sympathetic tone (Levy and Schwartz, 1994; Brodde and Michel, 1999; Lewis *et al.*, 2001). Automaticity of Purkinje fibers is suppressed, and the threshold for ventricular fibrillation is increased (Kent and Epstein, 1976). Sympathetic and vagal nerve terminals lie in close proximity, and muscarinic receptors are believed to exist at presynaptic as well as postsynaptic sites (Wellstein and Pitschner, 1988).

Gastrointestinal and Urinary Tracts. Although stimulation of vagal input to the gastrointestinal tract increases tone, amplitude of contraction, and secretory activity of the stomach and intestine, such responses are inconsistently seen with administered ACh. Poor perfusion of visceral organs and rapid hydrolysis by plasma butyrylcholinesterase limit access of systemically administered ACh to visceral muscarinic receptors. Parasympathetic sacral innervation causes detrusor muscle contraction, increased voiding pressure, and ureter peristalsis, but for similar reasons these responses are not evident with administered ACh.

Table 7-1
Some Pharmacological Properties of Choline Esters and Natural Alkaloids

MUSCARINIC AGONIST	SUSCEPTIBILITY TO CHOLINESTERASES	MUSCARINIC ACTIVITY					NICOTINIC ACTIVITY
		Cardio-vascular	Gastro-intestinal	Urinary Bladder	Eye (Topical)	Antagonism by Atropine	
Acetylcholine	+++	++	++	++	+	+++	++
Methacholine	+	+++	++	++	+	+++	+
Carbachol	—	+	+++	+++	++	+	+++
Bethanechol	—	±	+++	+++	++	+++	—
Muscarine	—	++	+++	+++	++	+++	—
Pilocarpine	—	+	+++	+++	++	+++	—

Miscellaneous Effects. The influence of ACh and parasympathetic innervation on various organs and tissues is discussed in detail in Chapter 6. ACh and its analogs stimulate secretion by all glands that receive parasympathetic innervation, including the lacrimal, tracheobronchial, salivary, and digestive glands. The effects on the respiratory system, in addition to increased tracheobronchial secretion, include bronchoconstriction and stimulation of the chemoreceptors of the carotid and aortic bodies. When instilled into the eye, muscarinic agonists produce miosis (*see* Chapter 63).

Synergisms and Antagonisms. The muscarinic actions of ACh and all the drugs of this class are blocked by atropine, primarily through competitive occupation of muscarinic receptor sites on the autonomic effector cells and secondarily on autonomic ganglion cells. The nicotinic actions of ACh and its derivatives at autonomic ganglia are blocked by *hexamethonium* and *trimethaphan*; nicotinic actions at the neuromuscular junction of skeletal muscle are antagonized by *d-tubocurarine* and other competitive blocking agents (*see* Chapter 9).

CHOLINOMIMETIC CHOLINE ESTERS AND NATURAL ALKALOIDS

Muscarinic cholinergic receptor agonists can be divided into two groups: (1) ACh and several synthetic choline esters, and (2) the naturally occurring cholinomimetic alkaloids (particularly pilocarpine, *muscarine*, and *arecoline*) and their synthetic congeners.

Methacholine (acetyl- β -methylcholine) differs from ACh chiefly in its greater duration and selectivity of action. Its action is more prolonged because the added methyl group increases its resistance to hydrolysis by cholinesterases. Its selectivity is manifested by slight nicotinic and a predominance of muscarinic actions, the

latter being manifest in the cardiovascular system (Table 7-1).

Carbachol and bethanechol, which are unsubstituted carbamoyl esters, are completely resistant to hydrolysis by cholinesterases; their half-lives are thus sufficiently long that they become distributed to areas of low blood flow. Bethanechol has mainly muscarinic actions, showing some selectivity on gastrointestinal tract and urinary bladder motility. Carbachol retains substantial nicotinic activity, particularly on autonomic ganglia. It is likely that both its peripheral and its ganglionic actions are due, at least in part, to the release of endogenous ACh from the terminals of cholinergic fibers.

The three major natural alkaloids in this group—pilocarpine, muscarine, and arecoline—have the same principal sites of action as the choline esters discussed above. Muscarine acts almost exclusively at muscarinic receptor sites, and the classification of the receptors as such is derived from this fact. Arecoline also acts at nicotinic receptors. Pilocarpine has a dominant muscarinic action, but it causes anomalous cardiovascular responses; the sweat glands are particularly sensitive to the drug. Although these naturally occurring alkaloids are of great value as pharmacological tools, present clinical use is restricted largely to the employment of pilocarpine as a sialagogue and miotic agent (*see* Chapter 63).

History and Sources. Of the several hundred synthetic choline derivatives investigated, only methacholine, carbachol, and bethanechol have had clinical applications. The structures of these compounds are shown in Figure 7-1. Methacholine, the β -methyl analog of ACh, was studied by Hunt and Taveau as early as 1911. Carbachol and bethanechol, its β -methyl analog, were synthesized and investigated in the 1930s. Pilocarpine is the chief alkaloid obtained from the leaflets of South American shrubs of the genus *Pilocarpus*. Although it was long known by the natives that the chewing of leaves of *Pilocarpus* plants caused salivation, the first experiments were apparently

Figure 7–1. Structural formulas of acetylcholine, choline esters, and natural alkaloids that stimulate muscarinic receptors.

performed in 1874 by the Brazilian physician Coutinho. The alkaloid was isolated in 1875, and shortly thereafter the actions of pilocarpine on the pupil and on the sweat and salivary glands were described by Weber.

The poisonous effects of certain species of mushrooms have been known since ancient times, but it was not until Schmiedeberg isolated the alkaloid muscarine from *Amanita muscaria* in 1869 that its properties could be systematically investigated. Arecoline is the chief alkaloid of areca or betel nuts, the seeds of *Areca catechu*. The red-staining betel nut is consumed as a euphoric by the natives of the Indian subcontinent and East Indies in a masticatory mixture known as betel and composed of the nut, shell lime, and leaves of *Piper betle*, a climbing species of pepper.

Structure–Activity Relationships. The muscarinic alkaloids show marked differences as well as interesting relationships in structure when compared to the quaternary esters of choline (Figure 7–1). Arecoline and pilocarpine are tertiary amines. Muscarine, a quaternary ammonium compound, shows more limited absorption. McN-A-343 is an agonist that was originally proposed to stimulate M_1 receptors with some selectivity. While it is clear that McN-A-343 can stimulate sympathetic ganglia and inhibitory neurons in the myenteric plexus, this is a functional rather than a subtype-specific effect. Indeed, no therapeutically useful agonists with true M_1 or other subtype specificity are known (Caulfield and Birdsall, 1998; Eglen *et al.*, 2001).

Pharmacological Properties

Gastrointestinal Tract. All muscarinic agonists are capable of stimulating smooth muscle of the gastrointestinal tract, thereby increasing tone and motility; large doses will cause spasm and tenesmus. Unlike methacholine, carbachol, bethanechol, and pilocarpine stimulate the GI tract without significant cardiovascular effects.

Urinary Tract. The choline esters and pilocarpine contract the detrusor muscle of the bladder, increase voiding pressure, decrease bladder capacity, and increase ureteral peristalsis. In addition, the trigone and external sphincter muscles relax. Selectivity for bladder stimulation relative to cardiovascular activity is evident for bethanechol. In animals with experimental spinal cord lesions, muscarinic agonists promote evacuation of the bladder (Yoshimura *et al.*, 2000).

Exocrine Glands. The choline esters and muscarinic alkaloids stimulate secretion of glands that receive parasympathetic or sympathetic cholinergic innervation, including the lacrimal, salivary, digestive, tracheobronchial, and sweat glands. Pilocarpine in particular causes marked diaphoresis in human beings; 2 to 3 liters of sweat may be secreted. Salivation also is increased markedly. Oral administration of pilocarpine causes a more continuous production of saliva. Muscarine and arecoline also are potent diaphoretic agents. Accompanying side effects may include hiccough, salivation, nausea, vomiting, weakness, and occasionally collapse. These alkaloids also stimulate the lacrimal, gastric, pancreatic, and intestinal glands, and the mucous cells of the respiratory tract.

Respiratory System. In addition to tracheobronchial secretions, bronchial smooth muscle is stimulated by the muscarinic agonists. Asthmatic patients respond with intense bronchoconstriction, secretions, and a reduction in vital capacity. These actions form the basis of the methacholine challenge test used to diagnose airway hyperreactivity.

Cardiovascular System. Continuous intravenous infusion of methacholine elicits hypotension and bradycardia, just as ACh does but at 1/200 the dose. Muscarine, at small doses, also leads to a marked fall in blood pressure and a slowing or temporary cessation of the heartbeat. In contrast, carbachol and bethanechol generally cause only a transient fall in blood pressure at doses that affect the gastrointestinal and urinary tracts. Likewise, pilocarpine produces only a brief fall in blood pressure. However, if this is preceded by an appropriate dose of a nicotinic receptor antagonist, pilocarpine produces a marked rise in pressure. Both the vasodepressor and pressor responses are prevented by atropine; the latter effect also is abolished by α adrenergic receptor antagonists. These actions of pilocarpine have not been fully explained, but may arise from ganglionic and adrenomedullary stimulation.

Eye. Muscarinic agonists stimulate the pupillary constrictor and ciliary muscles when applied locally to the eye, causing pupil constriction and a loss of ability to accommodate to far vision.

Central Nervous System. The intravenous injection of relatively small doses of pilocarpine, muscarine, or arecoline evokes a characteristic cortical arousal or activation response in cats, similar to that produced by injection of anticholinesterase agents or by electrical stimulation of the brainstem reticular formation. The arousal response to all of these drugs is reduced or blocked by atropine and

related agents (Krnjević, 1974). Being quaternary, the choline esters do not cross the blood–brain barrier.

Therapeutic Uses

Acetylcholine (MIOCHOL-E) is available as an ophthalmic surgical aid for the rapid production of miosis. *Bethanechol chloride* (carbamylo- β -methylcholine chloride; URECHOLINE, others) is available in tablets and as an injection and is used as a stimulant of the smooth muscle of the gastrointestinal tract, and in particular, the urinary bladder. *Pilocarpine hydrochloride* (SALAGEN) is available as 5- or 7.5-mg oral doses for treatment of xerostomia or as ophthalmic solutions (PILOCAR, others) of varying strength. *Methacholine chloride* (acetyl- β -methylcholine chloride; PROVOCHOLINE) may be administered for diagnosis of bronchial hyperreactivity. The unpredictability of absorption and intensity of response has precluded its use as a vasodilator or cardiac vagomimetic agent. *Cevimeline* (EVOXAC) is a newer muscarinic agonist available orally for use in treatment of xerostomia.

Gastrointestinal Disorders. Bethanechol can be of value in certain cases of postoperative abdominal distention and in gastric atony or gastroparesis. The oral route is preferred; the usual dosage is 10 to 20 mg, three or four times daily. Bethanechol is given by mouth before each main meal in cases without complete retention; when gastric retention is complete and nothing passes into the duodenum, the subcutaneous route is necessary because of poor stomach absorption. Bethanechol likewise has been used to advantage in certain patients with congenital megacolon and with adynamic ileus secondary to toxic states. Prokinetic agents with combined cholinergic-agonist and dopamine-antagonist activity (e.g., *metoclopramide*) or serotonin-antagonist activity (see Chapter 37) have largely replaced bethanechol in gastroparesis or esophageal reflux disorders.

Urinary Bladder Disorders. Bethanechol may be useful in treating urinary retention and inadequate emptying of the bladder when organic obstruction is absent, as in postoperative and postpartum urinary retention and in certain cases of chronic hypotonic, myogenic, or neurogenic bladder (Wein, 1991). α Adrenergic receptor antagonists are useful adjuncts in reducing outlet resistance of the internal sphincter (see Chapter 10). Bethanechol may enhance contractions of the detrusor muscle after spinal injury if the vesical reflex is intact, and some benefit has been noted in partial sensory or motor paralysis of the bladder. Catheterization thus can be avoided. For acute retention, multiple subcutaneous doses of 2.5 mg of bethanechol may be administered. The stomach should be empty at the time the drug is injected. In chronic cases, 10 to 50 mg of the drug may be given orally two to four times daily with meals to avoid nausea and vomiting. When voluntary or spontaneous voiding begins, bethanechol is then slowly withdrawn.

Xerostomia. Pilocarpine is administered orally in 5- to 10-mg doses given three times daily for the treatment of xerostomia that follows head and neck radiation treatments or that is associated with Sjögren's syndrome (Wiseman and Faulds, 1995; Porter *et al.*, 2004). The latter is an autoimmune disorder occurring primarily in women in whom secretions, particularly salivary and lacrimal, are compromised (Anaya and Talal, 1999; Nusair and Rubinow, 1999). Provided salivary parenchyma maintains residual function, enhanced salivary secretion, ease of swallowing, and subjective improvement in hydration of the oral cavity are achieved. Side effects typify cholinergic

stimulation, with sweating being the most common complaint. Bethanechol is an oral alternative that produces less diaphoresis (Epstein *et al.*, 1994). Cevimeline (EVOXAC) is a newer agonist with activity at M_3 muscarinic receptors. These receptors are found on lacrimal and salivary gland epithelia. Cevimeline has a long-lasting sialagogic action and may have fewer side effects than pilocarpine (Anaya and Talal, 1999). It also enhances lacrimal secretions in Sjögren's syndrome (Ono *et al.*, 2004).

Ophthalmological. Pilocarpine also is used in the treatment of glaucoma, where it is instilled into the eye usually as a 0.5% to 4% solution. An ocular insert (OCUSERT PILO-20) that releases 20 μ g of pilocarpine per hour over 7 days also is marketed for the control of elevated intraocular pressure. Pilocarpine usually is better tolerated than are the anticholinesterases, and pilocarpine is the standard cholinergic agent in the treatment of open-angle glaucoma. Reduction of intraocular pressure occurs within a few minutes and lasts 4 to 8 hours. The ophthalmic use of pilocarpine alone and in combination with other agents is discussed in Chapter 63. The miotic action of pilocarpine is useful in reversing a narrow-angle glaucoma attack and overcoming the mydriasis produced by atropine; alternated with mydriatics, pilocarpine is employed to break adhesions between the iris and the lens.

CNS. Agonists that show functional selectivity for M_1 and M_2 receptors have been targets for drug development, and some have been in clinical trial for use in treating the cognitive impairment associated with Alzheimer's disease. The potential advantage of such agonists would arise from stimulating postsynaptic M_1 receptors in the CNS without concomitantly stimulating the presynaptic M_2 receptors that inhibit release of endogenous ACh. However, lack of efficacy in improvement of cognitive function has diminished enthusiasm for this approach (Eglen *et al.*, 1999).

Precautions, Toxicity, and Contraindications

Muscarinic agonists are administered subcutaneously to achieve an acute response and orally to treat more chronic conditions. Should serious toxic reactions to these drugs arise, *atropine sulfate* (0.5 to 1 mg in adults) should be given subcutaneously or intravenously. *Epinephrine* (0.3 to 1 mg, subcutaneously or intramuscularly) also is of value in overcoming severe cardiovascular or bronchoconstrictor responses.

Major contraindications to the use of the muscarinic agonists are asthma, hyperthyroidism, coronary insufficiency, and acid-peptic disease. Their bronchoconstrictor action is liable to precipitate an asthma attack, and hyperthyroid patients may develop atrial fibrillation. Hypotension induced by these agents can severely reduce coronary blood flow, especially if it is already compromised. Other possible undesirable effects of the cholinergic agents are flushing, sweating, abdominal cramps, belching, a sensation of tightness in the urinary bladder, difficulty in visual accommodation, headache, and salivation.

Toxicology

Poisoning from pilocarpine, muscarine, or arecoline is characterized chiefly by exaggeration of their various parasympathomimetic effects and resembles that produced by consumption of mushrooms of the genus *Inocybe* (see below). Treatment consists of the parental administration of atropine in doses sufficient to cross the

blood–brain barrier and measures to support the respiratory and cardiovascular systems and to counteract pulmonary edema.

Mushroom Poisoning (Mycetism). Mushroom poisoning has been known for centuries. The Greek poet Euripides (fifth century B.C.) is said to have lost his wife and three children from this cause. In recent years the number of cases of mushroom poisoning has been increasing as the result of the current popularity of the consumption of wild mushrooms. Various species of mushrooms contain many toxins, and species within the same genus may contain distinct toxins.

Although *Amanita muscaria* is the source from which muscarine was isolated, its content of the alkaloid is so low (approximately 0.003%) that muscarine cannot be responsible for the major toxic effects. Much higher concentrations of muscarine are present in various species of *Inocybe* and *Clitocybe*. The symptoms of intoxication attributable to muscarine develop within 30 to 60 minutes of ingestion; they include salivation, lacrimation, nausea, vomiting, headache, visual disturbances, abdominal colic, diarrhea, bronchospasm, bradycardia, hypotension, and shock. Treatment with atropine (1 to 2 mg intramuscularly every 30 minutes) effectively blocks these effects (Köppel, 1993; Goldfrank, 1998).

Intoxication produced by *A. muscaria* and related *Amanita* species arises from the neurologic and hallucinogenic properties of muscimol, ibotenic acid, and other isoxazole derivatives. These agents stimulate excitatory and inhibitory amino acid receptors. Symptoms range from irritability, restlessness, ataxia, hallucinations, and delirium to drowsiness and sedation. Treatment is mainly supportive; benzodiazepines are indicated when excitation predominates, whereas atropine often exacerbates the delirium.

Mushrooms from *Psilocybe* and *Panaeolus* species contain psilocybin and related derivatives of tryptamine. They also cause short-lasting hallucinations. *Gyromitra* species (false morels) produce gastrointestinal disorders and a delayed hepatotoxicity. The toxic substance, acetaldehyde methylformylhydrazine, is converted in the body to reactive hydrazines. Although fatalities from liver and kidney failure have been reported, they are far less frequent than with amatoxin-containing mushrooms.

The most serious form of mycetism is produced by *Amanita phalloides*, other *Amanita* species, *Lepiota*, and *Galerina* species (Goldfrank, 1998). These species account for more than 90% of all fatal cases. Ingestion of as little as 50 g of *A. phalloides* (deadly nightcap) can be fatal. The principal toxins are the amatoxins (α - and β -amanitin), a group of cyclic octapeptides that inhibit RNA polymerase II and hence block mRNA synthesis. This causes cell death, manifested particularly in the gastrointestinal mucosa, liver, and kidneys. Initial symptoms, which often are unnoticed, or when present are due to other toxins, include diarrhea and abdominal cramps. A symptom-free period lasting up to 24 hours is followed by hepatic and renal malfunction. Death occurs in 4 to 7 days from renal and hepatic failure (Goldfrank, 1998). Treatment is largely supportive; *penicillin*, *thioctic acid*, and *silibinin* may be effective antidotes, but the evidence is based largely on anecdotal studies (Köppel, 1993).

Because the severity of toxicity and treatment strategies for mushroom poisoning depend on the species ingested, their identification should be sought. Often symptomatology is delayed, limiting the value of gastric lavage and administration of activated charcoal. Regional poison control centers in the United States maintain up-to-

date information on the incidence of poisoning in the region and treatment procedures.

MUSCARINIC RECEPTOR ANTAGONISTS

The class of drugs referred to here as muscarinic receptor antagonists includes (1) the naturally occurring alkaloids, atropine and *scopolamine*; (2) semisynthetic derivatives of these alkaloids, which primarily differ from the parent compounds in their disposition in the body or their duration of action; and (3) synthetic congeners, some of which show selectivity for particular subtypes of muscarinic receptors. Noteworthy agents among the synthetic derivatives are *homatropine* and *tropicamide*, which have a shorter duration of action than atropine, and *methylatropine*, *ipratropium*, and *tiotropium*, which are quaternized and do not cross the blood–brain barrier or readily cross membranes. The latter two agents are given by inhalation in the treatment of chronic obstructive pulmonary disease and are pending approval for use in bronchial asthma. Ipratropium also has an FDA-approved indication for perennial- and common cold-associated rhinorrhea. The synthetic derivatives possessing partial receptor selectivity include pirenzepine, used in the treatment of acid-peptic disease in some countries, and *tolterodine*, *oxybutynin*, and several others, used in the treatment of urinary incontinence.

Muscarinic receptor antagonists prevent the effects of ACh by blocking its binding to muscarinic cholinergic receptors at neuroeffector sites on smooth muscle, cardiac muscle, and gland cells; in peripheral ganglia; and in the CNS. In general, muscarinic receptor antagonists cause little blockade at nicotinic receptor sites. However, the quaternary ammonium antagonists generally exhibit a greater degree of nicotinic blocking activity, and consequently are more likely to interfere with ganglionic or neuromuscular transmission.

Cholinergic transmission appears to be both muscarinic and nicotinic at spinal, subcortical, and cortical levels in the brain (*see* Chapter 12). At high or toxic doses, central effects of atropine and related drugs are observed, generally consisting of CNS stimulation followed by depression. Since quaternary compounds penetrate the blood–brain barrier poorly, they have little or no effect on the CNS.

Parasympathetic neuroeffector junctions in different organs vary in their sensitivity to muscarinic receptor antagonists (Table 7–2). Small doses of atropine depress salivary and bronchial secretion and sweating. With larger doses, the pupil dilates, accommodation of the lens to near vision is inhibited, and vagal effects on the heart are

Table 7-2
Effects of Atropine in Relation to Dose

DOSE	EFFECTS
0.5 mg	Slight cardiac slowing; some dryness of mouth; inhibition of sweating
1 mg	Definite dryness of mouth; thirst; acceleration of heart, sometimes preceded by slowing; mild dilation of pupils
2 mg	Rapid heart rate; palpitation; marked dryness of mouth; dilated pupils; some blurring of near vision
5 mg	All the above symptoms marked; difficulty in speaking and swallowing; restlessness and fatigue; headache; dry, hot skin; difficulty in micturition; reduced intestinal peristalsis
10 mg and more	Above symptoms more marked; pulse rapid and weak; iris practically obliterated; vision very blurred; skin flushed, hot, dry, and scarlet; ataxia, restlessness, and excitement; hallucinations and delirium; coma

blocked so that the heart rate is increased. Larger doses antagonize parasympathetic control of the urinary bladder and gastrointestinal tract, thereby inhibiting micturition and decreasing the tone and motility of the gut. Still larger doses are required to inhibit gastric motility and particularly secretion. Thus, doses of atropine and most related muscarinic receptor antagonists that depress gastric secretion also almost invariably affect salivary secretion, ocular accommodation, micturition, and gastrointestinal tone. This hierarchy of relative sensitivities is not a consequence of differences in the affinity of atropine for the muscarinic receptors at these sites because atropine lacks selectivity toward different muscarinic receptor subtypes. More likely determinants include the degree to which the functions of various end organs are regulated by parasympathetic tone and the involvement of intramural neurons and reflexes.

The actions of most clinically available muscarinic receptor antagonists differ only quantitatively from those of atropine, considered below as the prototype of the group. No antagonist in the receptor-selective category, including pirenzepine, is completely selective (*i.e.*, can be used to define a single receptor subtype relative to all other receptor subtypes). In fact, clinical efficacy of some

agents may arise from a balance of antagonistic actions on two or more receptor subtypes.

History. The naturally occurring muscarinic receptor antagonists atropine and scopolamine are alkaloids of the belladonna (*Solanaceae*) plants. Preparations of belladonna were known to the ancient Hindus and have been used by physicians for many centuries. During the time of the Roman Empire and in the Middle Ages, the deadly nightshade shrub was frequently used to produce obscure and often prolonged poisoning. This prompted Linnaeus to name the shrub *Atropa belladonna*, after Atropos, the oldest of the three Fates, who cuts the thread of life. The name *belladonna* derives from the alleged use of this preparation by Italian women to dilate their pupils; modern-day fashion models are known to use this same device for visual appeal. Atropine (*d,l*-hyoscyamine) also is found in *Datura stramonium*, also known as Jamestown or jimson weed. Scopolamine (*l*-hyoscine) is found chiefly in *Hyoscyamus niger* (henbane). In India, the root and leaves of the jimson weed plant were burned and the smoke inhaled to treat asthma. British colonists observed this ritual and introduced the belladonna alkaloids into western medicine in the early 1800s.

Accurate study of the actions of belladonna dates from the isolation of atropine in pure form by Mein in 1831. In 1867, Bezold and Bloebaum showed that atropine blocked the cardiac effects of vagal stimulation, and 5 years later Heidenhain found that it prevented salivary secretion produced by stimulation of the chorda tympani. Many semisynthetic congeners of the belladonna alkaloids and a large number of synthetic muscarinic receptor antagonists have been prepared, primarily with the objective of altering gastrointestinal or bladder activity without causing dry mouth or pupillary dilation.

Chemistry. Atropine and scopolamine are esters formed by combination of an aromatic acid, tropic acid, and complex organic bases, either tropine (tropanol) or scopine. Scopine differs from tropine only in having an oxygen bridge between the carbon atoms designated as 6 and 7 (Figure 7-2). Homatropine is a semisynthetic compound produced by combining the base tropine with mandelic acid. The corresponding quaternary ammonium derivatives, modified by the addition of a second methyl group to the nitrogen, are *methylatropine nitrate*, *methscopolamine bromide*, and *homatropine methylbromide*. Ipratropium and tiotropium also are quaternary tropine analogs esterified with synthetic aromatic acids.

Structure-Activity Relationships. An intact ester of tropine and tropic acid is essential for antimuscarinic action, since neither the free acid nor the basic alcohol exhibits significant antimuscarinic activity. The presence of a free OH group in the acyl portion of the ester also is important for activity. When given parenterally, quaternary ammonium derivatives of atropine and scopolamine are generally more potent than their parent compounds in both muscarinic receptor and ganglionic (nicotinic) blocking activities. The quaternary derivatives, when given orally, are poorly and unreliably absorbed.

Both tropic and mandelic acids have an enantiomeric center (boldface C in the formulas in Figure 7-2). Scopolamine is *l*-hyoscine and is much more active than *d*-hyoscine. Atropine is racemized during extraction and consists of *d,l*-hyoscyamine, but antimuscarinic activity is almost wholly due to the naturally occurring *l*

Figure 7-2. Structural formulas of the belladonna alkaloids and semisynthetic and synthetic analogs. The blue C identifies an asymmetric carbon atom.

isomer. Synthetic derivatives show a wide latitude of structures that spatially replicate the aromatic acid and the bridged nitrogen of the tropane.

Mechanism of Action. Atropine and related compounds compete with ACh and other muscarinic agonists for a common binding site on the muscarinic receptor. Based on the position of retinol in the mammalian rhodopsin structure (Palczewski *et al.*, 2000), the binding site for competitive antagonists and acetylcholine likely is in a cleft formed by several of the receptor's 7 transmembrane helices. An aspartic acid present in the *N*-terminal portion of the third transmembrane helix of all 5 muscarinic receptor subtypes is believed to form an ionic bond with the cationic quaternary nitrogen in acetylcholine and the tertiary or quaternary nitrogen of the antagonists (Wess, 1996; Caulfield and Birdsall, 1998).

Since antagonism by atropine is competitive, it can be overcome if the concentration of ACh at receptor sites of the effector organ is increased sufficiently. Muscarinic receptor antagonists inhibit responses to postganglionic cholinergic nerve stimulation less readily than they inhibit responses to injected choline esters. The difference may be due to release of ACh by cholinergic nerve terminals so close to receptors that very high concentrations of the transmitter gain access to the receptors in the neuroeffector junction.

Pharmacological Properties: The Prototypical Alkaloids Atropine and Scopolamine

Atropine and scopolamine differ quantitatively in anti-muscarinic actions, particularly in their ability to affect the CNS. Atropine has almost no detectable effect on the CNS in doses that are used clinically. In contrast, scopolamine has prominent central effects at low therapeutic doses. The basis for this difference is probably the greater permeation of scopolamine across the blood-brain barrier. Because atropine has limited CNS effects, it is preferred to scopolamine for most purposes.

Central Nervous System. Atropine in therapeutic doses (0.5 to 1 mg) causes only mild vagal excitation as a result of stimulation of the medulla and higher cerebral centers. With toxic doses of atropine, central excitation becomes more prominent, leading to restlessness, irritability, disorientation, hallucinations, or delirium (*see* discussion of atropine poisoning, below). With still larger doses, stimulation is followed by depression, leading to circulatory collapse and respiratory failure after a period of paralysis and coma.

Scopolamine in therapeutic doses normally causes CNS depression manifested as drowsiness, amnesia, fatigue, and dreamless sleep, with a reduction in rapid eye movement (REM) sleep. It also causes euphoria and is therefore sub-

ject to some abuse. The depressant and amnesic effects formerly were sought when scopolamine was used as an adjunct to anesthetic agents or for preanesthetic medication. However, in the presence of severe pain, the same doses of scopolamine can occasionally cause excitement, restlessness, hallucinations, or delirium. These excitatory effects resemble those of toxic doses of atropine. Scopolamine also is effective in preventing motion sickness. This action is probably either on the cortex or the vestibular apparatus.

The belladonna alkaloids and related muscarinic receptor antagonists have long been used in parkinsonism. These agents can be effective adjuncts to treatment with *levodopa* (see Chapter 20). Muscarinic receptor antagonists also are used to treat the extrapyramidal symptoms that commonly occur as side effects of conventional antipsychotic drug therapy (see Chapter 18). Certain antipsychotic drugs are relatively potent muscarinic-receptor antagonists (Richelson, 1999), and these cause fewer extrapyramidal side effects.

Ganglia and Autonomic Nerves. Cholinergic neurotransmission in autonomic ganglia is mediated primarily by activation of nicotinic ACh receptors, resulting in the generation of action potentials (see Chapters 6 and 9). ACh and other cholinergic agonists also cause the generation of slow excitatory postsynaptic potentials that are mediated by ganglionic M_1 muscarinic receptors. This response is particularly sensitive to blockade by pirenzepine. The extent to which the slow excitatory response can alter impulse transmission through the different sympathetic and parasympathetic ganglia is difficult to assess, but the effects of pirenzepine on responses of end organs suggest a physiological modulatory function for the ganglionic M_1 receptor (Caulfield, 1993; Eglen *et al.*, 1996; Birdsall *et al.*, 1998; Caulfield and Birdsall, 1998).

Pirenzepine inhibits gastric acid secretion at doses that have little effect on salivation or heart rate. Since the muscarinic receptors on the parietal cells do not appear to have a high affinity for pirenzepine, the M_1 receptor responsible for alterations in gastric acid secretion is postulated to be localized in intramural ganglia (Eglen *et al.*, 1996). Blockade of ganglionic muscarinic receptors (rather than those at the neuroeffector junction) also appears to underlie the ability of pirenzepine to inhibit the relaxation of the lower esophageal sphincter. Likewise, blockade of parasympathetic ganglia may contribute to the response to muscarinic antagonists in lung and heart (Wellstein and Pitschner, 1988).

Presynaptic muscarinic receptors also are present on terminals of sympathetic and parasympathetic neurons. Blockade of these presynaptic receptors, which are of variable subtype, generally augments neurotransmitter release. Nonselective muscarinic blocking agents may thus augment ACh release, partially counteracting their effective postsynaptic receptor blockade.

Since muscarinic receptor antagonists can alter autonomic activity at the ganglion and postganglionic neuron, the ultimate response of end

organs to blockade of muscarinic receptors is difficult to predict. Thus, while direct blockade at neuroeffector sites predictably reverses the usual effects of the parasympathetic nervous system, concomitant inhibition of ganglionic or presynaptic receptors may produce paradoxical responses.

Eye. Muscarinic receptor antagonists block the cholinergic responses of the pupillary sphincter muscle of the iris and the ciliary muscle controlling lens curvature (see Chapter 63). Thus, they dilate the pupil (mydriasis) and paralyze accommodation (cycloplegia). The wide pupillary dilation results in photophobia; the lens is fixed for far vision, near objects are blurred, and objects may appear smaller than they are. The normal pupillary reflex constriction to light or upon convergence of the eyes is abolished. These effects can occur after either local or systemic administration of the alkaloids. However, conventional systemic doses of atropine (0.6 mg) have little ocular effect, in contrast to equal doses of scopolamine, which cause definite mydriasis and loss of accommodation. Locally applied atropine or scopolamine produces ocular effects of considerable duration; accommodation and pupillary reflexes may not fully recover for 7 to 12 days. Other muscarinic receptor antagonists with shorter durations of action are therefore preferred as mydriatics in ophthalmological practice (see Chapter 63). Sympathomimetic agents also cause pupillary dilation but without loss of accommodation. Pilocarpine, choline esters, *physostigmine* (ophthalmic solution discontinued in the United States), and *isoflurophate* (DFP) in sufficient concentrations can partially or fully reverse the ocular effects of atropine.

Muscarinic receptor antagonists administered systemically have little effect on intraocular pressure except in patients predisposed to narrow-angle glaucoma, in whom the pressure may occasionally rise dangerously. The rise in pressure occurs when the anterior chamber is narrow and the iris obstructs outflow of aqueous humor into the trabeculae. Muscarinic antagonists may precipitate a first attack in unrecognized cases of this relatively rare condition. In patients with open-angle glaucoma, an acute rise in pressure is unusual. Atropinelike drugs generally can be used safely in this latter condition, particularly if the patient also is adequately treated with an appropriate miotic agent.

Cardiovascular System. Heart. The main effect of atropine on the heart is to alter the rate. Although the dominant response is tachycardia, the heart rate often decreases transiently with average clinical doses (0.4 to 0.6 mg). The slowing is rarely marked, about 4 to 8 beats per minute, and is usually absent after rapid intravenous injection. There are no accompanying changes in blood pressure or cardiac output. This unexpected effect once was thought to be due to central vagal stimulation; however, cardiac slowing also is seen with muscarinic receptor antagonists that do not readily enter the brain. Human studies show that pirenzepine is equipotent with atropine in decreasing heart rate and that its prior administration can prevent any further decrease by atropine (Wellstein and Pitschner, 1988).

Larger doses of atropine cause progressively increasing tachycardia by blocking vagal effects on M_2 receptors on the SA nodal pacemaker. The resting heart rate is increased by about 35 to 40 beats per minute in young men given 2 mg of atropine intramuscularly. The maximal heart rate (*e.g.*, in response to exercise) is not altered by atropine. The

influence of atropine is most noticeable in healthy young adults, in whom vagal tone is considerable. In infancy and old age, even large doses of atropine may fail to accelerate the heart. Atropine often produces cardiac arrhythmias, but without significant cardiovascular symptoms.

With low doses of scopolamine (0.1 or 0.2 mg), the cardiac slowing is greater than with atropine. With higher doses, a transient cardioacceleration may be observed.

Adequate doses of atropine can abolish many types of reflex vagal cardiac slowing or asystole—for example, from inhalation of irritant vapors, stimulation of the carotid sinus, pressure on the eyeballs, peritoneal stimulation, or injection of contrast dye during cardiac catheterization. It also prevents or abruptly abolishes bradycardia or asystole caused by choline esters, acetylcholinesterase inhibitors, or other parasympathomimetic drugs, as well as cardiac arrest from electrical stimulation of the vagus.

The removal of vagal influence on the heart by atropine also may facilitate AV conduction. Atropine shortens the functional refractory period of the AV node and can increase ventricular rate in patients who have atrial fibrillation or flutter. In certain cases of second-degree heart block (*e.g.*, Wenckebach AV block), in which vagal activity is an etiological factor (such as with digitalis toxicity), atropine may lessen the degree of block. In some patients with complete heart block, the idioventricular rate may be accelerated by atropine; in others it is stabilized. Atropine may improve the clinical condition of patients with inferior or posterior wall myocardial infarction by relieving severe sinus or nodal bradycardia or AV block.

Circulation. Atropine, in clinical doses, completely counteracts the peripheral vasodilation and sharp fall in blood pressure caused by choline esters. In contrast, when given alone, its effect on blood vessels and blood pressure is neither striking nor constant. This result is expected because most vascular beds lack significant cholinergic innervation. The presence of cholinergic sympathetic vasodilator fibers to vessels supplying skeletal muscle is not well documented in humans; they do not appear to be involved in the normal regulation of tone.

Atropine in toxic, and occasionally therapeutic, doses can dilate cutaneous blood vessels, especially those in the blush area (atropine flush). This may be a compensatory reaction permitting the radiation of heat to offset the atropine-induced rise in temperature that can accompany inhibition of sweating.

Respiratory Tract. The parasympathetic nervous system plays a major role in regulating bronchomotor tone. A diverse set of stimuli cause a reflex increase in parasympathetic activity that contributes to bronchoconstriction.

Vagal fibers synapse and activate nicotinic and M₁ muscarinic receptors in parasympathetic ganglia located in the airway wall; short postganglionic fibers release ACh, which acts on M₃ muscarinic receptors in airway smooth muscle. The submucosal glands also are innervated by parasympathetic neurons and also have predominantly M₃ receptors. Largely owing to the introduction of inhaled ipratropium and tiotropium, anticholinergic therapy of chronic obstructive pulmonary disease and asthma has been revived (Barnes and Hansel, 2004).

The belladonna alkaloids inhibit secretions of the nose, mouth, pharynx, and bronchi, and thus dry the mucous membranes of the respiratory tract. This action is especially marked if secretion is excessive and was the basis for the use of atropine and scopolamine to prevent irritating anesthetics such as diethyl ether from increasing bronchial secretion. Reduction of mucous secretion and mucociliary clearance resulting in mucus plugs are undesirable side effects of atropine in patients with airway disease.

Inhibition by atropine of bronchoconstriction caused by histamine, bradykinin, and the eicosanoids presumably reflects the participation of parasympathetic efferents in the bronchial reflexes elicited by these agents. The ability to block the indirect bronchoconstrictive effects of these mediators that are released during attacks of asthma forms the basis for the use of anticholinergic agents, along with β adrenergic receptor agonists, in the treatment of this disease (*see* Chapter 27).

Gastrointestinal Tract. Interest in the actions of muscarinic receptor antagonists on the stomach and intestine led to their use as antispasmodic agents for gastrointestinal disorders and in the treatment of peptic ulcer disease. Although atropine can completely abolish the effects of ACh (and other parasympathomimetic drugs) on the motility and secretions of the gastrointestinal tract, it inhibits only incompletely the effects of vagal impulses. This difference is particularly striking in the effects of atropine on gut motility. Preganglionic vagal fibers that innervate the GI synapse not only with postganglionic cholinergic fibers, but also with a network of noncholinergic intramural neurons. These neurons, which form the enteric plexus, utilize numerous neurotransmitters or neuromodulators including 5-hydroxytryptamine (5-HT), dopamine, and peptides. Since therapeutic doses of atropine do not block responses to gastrointestinal hormones or to noncholinergic neurohumoral transmitters, release of these substances from the intramural neurons can still effect changes in motility. Similarly, while vagal activity modulates gastrin-elicited histamine release and gastric acid secretion, the actions of gastrin can occur independent of vagal tone. Histamine H₂ receptor antago-

nists and proton pump inhibitors have replaced nonselective muscarinic antagonists as inhibitors of acid secretion (see Chapter 36).

Secretions. *Salivary secretion* appears to be mediated through M_3 receptors and is particularly sensitive to inhibition by muscarinic receptor antagonists, which can completely abolish the copious, watery, parasympathetically induced secretion. The mouth becomes dry, and swallowing and talking may become difficult. Gastric secretions during the cephalic and fasting phase are also reduced markedly by muscarinic receptor antagonists. In contrast, the intestinal phase of gastric secretion is only partially inhibited. The concentration of acid is not necessarily lowered because secretion of HCO_3^- as well as of H^+ is blocked. The gastric cells that secrete mucin and proteolytic enzymes are more directly under vagal influence than are the acid-secreting cells, and atropine decreases their secretory function.

Motility. The parasympathetic nerves enhance both tone and motility and relax sphincters, thereby favoring the passage of gastrointestinal contents. Both in normal subjects and in patients with gastrointestinal disease, muscarinic antagonists produce prolonged inhibitory effects on the motor activity of the stomach, duodenum, jejunum, ileum, and colon, characterized by a reduction in tone and in amplitude and frequency of peristaltic contractions. Relatively large doses are needed to produce such inhibition. The intestine has a complex system of intramural nerve plexuses that regulate motility independent of parasympathetic control; vagal impulses from the medulla serve to modulate the effects of the intrinsic reflexes (see Chapter 6).

Other Smooth Muscle. Urinary Tract. Muscarinic antagonists decrease the normal tone and amplitude of contractions of the ureter and bladder, and often eliminate drug-induced enhancement of ureteral tone. However, this inhibition is not achieved in the absence of inhibition of salivation and lacrimation and blurring of vision. Control of bladder contraction apparently is mediated by multiple muscarinic receptor subtypes. Receptors of the M_2 subtype appear most prevalent in the bladder, yet studies with selective antagonists suggest that the M_3 receptor mediates detrusor muscle contraction. The M_2 receptor may act to inhibit β adrenergic receptor-mediated relaxation of the bladder and may be involved primarily in the filling stages to diminish urge incontinence (Hegde and Eglen, 1999; Chapple, 2000). In addition, presynaptic M_1 receptors appear to facilitate the release of ACh from parasympathetic nerve terminals (Somogyi and de Groat, 1999).

Biliary Tract. Atropine exerts a mild antispasmodic action on the gallbladder and bile ducts in humans. However, this effect usually is not sufficient to overcome or prevent the marked spasm and increase in biliary duct pressure induced by opioids. The nitrites (see Chapter 31) are more effective than atropine in this respect.

Sweat Glands and Temperature. Small doses of atropine or scopolamine inhibit the activity of sweat glands innervated by sympathetic cholinergic fibers, and the skin becomes hot and dry. Sweating may be depressed enough to raise the body temperature, but only notably so after large doses or at high environmental temperatures.

Pharmacologic Properties: The Quaternary Derivatives Ipratropium and Tiotropium

Ipratropium bromide (ATROVENT, others) is a quaternary ammonium compound formed by the introduction of an

isopropyl group to the N atom of atropine. A similar agent, *oxitropium bromide*, an *N*-ethyl-substituted, quaternary derivative of scopolamine, is available in Europe. The most recently developed and bronchoselective member of this family is tiotropium bromide (SPIRIVA), which has a longer duration of action. Ipratropium appears to block all subtypes of muscarinic receptors and thus blocks presynaptic muscarinic inhibition of ACh release, whereas tiotropium shows some selectivity for M_1 and M_3 receptors. Tiotropium has a lower affinity for M_2 receptors, minimizing its presynaptic effect on ACh release.

Ipratropium produces bronchodilation, tachycardia, and inhibition of secretion similar to that of atropine when it is administered parenterally. Although somewhat more potent than atropine, ipratropium and tiotropium lack appreciable action on the CNS but have greater inhibitory effects on ganglionic transmission. An unexpected and therapeutically important property of ipratropium and tiotropium, evident upon either local or parenteral administration, is their minimal inhibitory effect on mucociliary clearance relative to atropine. Hence, the use of these agents in patients with airway disease minimizes the increased accumulation of lower airway secretions encountered with atropine.

When ipratropium or tiotropium is inhaled, its action is confined almost exclusively to the mouth and airways. Dry mouth is the only side effect reported frequently. Selectivity results from the very inefficient absorption of the drug from the lungs or the gastrointestinal tract. The degree of bronchodilation achieved by these agents is thought to reflect the level of basal parasympathetic tone, supplemented by reflex activation of cholinergic pathways brought about by various stimuli. In normal individuals, inhalation of the drugs can provide virtually complete protection against the bronchoconstriction produced by the subsequent inhalation of such irritants as sulfur dioxide, ozone, or cigarette smoke. However, atopic patients with asthma or patients with demonstrable bronchial hyperresponsiveness are less well protected. Although these drugs cause a marked reduction in sensitivity to methacholine in asthmatic subjects, more modest inhibition of responses to challenge with histamine, bradykinin, or $PGF_{2\alpha}$ is achieved, and little protection is afforded against the bronchoconstriction induced by serotonin or the leukotrienes.

The principal clinical use of ipratropium and tiotropium is in the treatment of chronic obstructive pulmonary disease; they are less effective in most asthmatic patients (Barnes and Hansel, 2004; Gross, 2004). Ipratropium is FDA approved for the treatment of perennial and common cold-associated rhinorrhea. The therapeutic use of ipratropium and tiotropium is discussed further in Chapter 27.

Absorption, Fate, and Excretion of Muscarinic Antagonists. The belladonna alkaloids and the tertiary synthetic and semisynthetic derivatives are absorbed rapidly

from the gastrointestinal tract. They also enter the circulation when applied locally to the mucosal surfaces of the body. Absorption from intact skin is limited, although efficient absorption does occur in the postauricular region for some agents, allowing delivery *via* transdermal patch. Systemic absorption of inhaled or orally ingested quaternary muscarinic receptor antagonists is minimal. The quaternary ammonium derivatives of the belladonna alkaloids also penetrate the conjunctiva of the eye less readily. Central effects are also lacking, because the quaternary agents do not cross the blood–brain barrier. Atropine has a half-life of ~4 hours; hepatic metabolism accounts for the elimination of about half of a dose; the remainder is excreted unchanged in the urine.

Ipratropium is administered as an aerosol or solution for inhalation whereas tiotropium is administered as a dry powder. As with most drugs administered by inhalation, about 90% of the dose is swallowed. Most of the swallowed drug appears in the feces. After inhalation, maximal responses usually develop over 30 to 90 minutes, with tiotropium having the slower onset. The effects of ipratropium last for 4 to 6 hours, while tiotropium's effects persist for 24 hours, and the drug is amenable to once-daily dosing (Barnes and Hansel, 2004).

THERAPEUTIC USES OF MUSCARINIC RECEPTOR ANTAGONISTS

Muscarinic receptor antagonists have been employed in a wide variety of clinical conditions, predominantly to inhibit effects of parasympathetic nervous system activity. The major limitation in the use of the nonselective drugs is often failure to obtain desired therapeutic responses without concomitant side effects. The latter usually are not serious but are sufficiently disturbing to decrease patient compliance, particularly during long-term administration. Selectivity has been achieved by local administration, either by pulmonary inhalation or instillation in the eye. Minimal systemic absorption and dilution from the site of action minimize systemic effects. Subtype-selective muscarinic receptor antagonists hold the most promise for treating specific clinical symptoms, but few show absolute selectivity.

Respiratory Tract. Atropine, related belladonna alkaloids, and synthetic analogs reduce secretion in both the upper and lower respiratory tracts. This effect in the nasopharynx may provide some symptomatic relief of acute rhinitis associated with coryza or hay fever,

although such therapy does not affect the natural course of the condition. It is probable that the contribution of antihistamines employed in “cold” mixtures is due primarily to their antimuscarinic properties, except in conditions with an allergic basis.

Systemic administration of belladonna alkaloids or their derivatives for bronchial asthma or chronic obstructive pulmonary disease carries the disadvantage of reducing bronchial secretions and inspissation of the residual secretions. This viscid material is difficult to remove from the respiratory tree, and its presence can dangerously obstruct airflow and predispose to infection.

Ipratropium and tiotropium, administered by inhalation, do not produce adverse effects on mucociliary clearance, in contrast to atropine and other muscarinic antagonists. Thus, their anticholinergic properties can be exploited safely in the treatment of airway disease. These agents often are used with inhalation of long-acting β adrenergic receptor agonists, although there is little evidence of true synergism. The muscarinic antagonists are more effective in chronic obstructive pulmonary disease, particularly when cholinergic tone is evident. β adrenergic receptor agonists control best the intermittent exacerbations of asthma (*see* Chapter 27).

Genitourinary Tract. Overactive urinary bladder disease can be successfully treated with muscarinic receptor antagonists. These agents can include synthetic substitutes of atropine, such as tolterodine and *trospium chloride*, which lower intravesicular pressure, increase capacity, and reduce the frequency of contractions by antagonizing parasympathetic control of the bladder. There is renewed interest in muscarinic antagonists as a modality for treating this increasingly common disorder, as well as for treating enuresis in children, particularly when a progressive increase in bladder capacity is the objective. These agents also are used to reduce urinary frequency in spastic paraplegia and to increase the capacity of the bladder (Chapple, 2000; Goessl *et al.*, 2000).

Oxybutynin (DITROPAN, others) and its more active enantiomer, (*S*)-oxybutynin, tolterodine (DETROL), trospium chloride (SANCTURA), darifenacin (ENABLEX), *solifenacin* (VESICARE), and *flavoxate* (URIS-PAS) are indicated for overactive bladder. Side effects of dry mouth and eyes limit the tolerability of these drugs with continued use, and patient acceptance declines. In an attempt to overcome this limitation, oxybutynin is marketed as a transdermal system (OXYTROL) that delivers 3.9 mg/day and is associated with a lower incidence of side effects than the oral immediate- or extended-release formulations. Tolterodine (DETROL) is a potent muscarinic antagonist that shows selectivity for the urinary bladder in animal models and in clinical studies. Its selectivity and greater patient acceptance is surprising, because studies on isolated receptors do not reveal a unique

subtype selectivity (Chapple, 2000; Abrams *et al.*, 1998; Abrams *et al.*, 1999). Inhibition of a particular complement of receptors in the bladder may give rise to synergism and clinical efficacy. Tolterodine is metabolized by CYP2D6 to a 5-hydroxymethyl metabolite. Since this metabolite possesses similar activity to the parent drug, variations in CYP2D6 levels do not affect the duration of action of the drug.

Trospium is a quaternary amine long used in Europe and approved recently for use in the United States for treatment of overactive bladder. It has been shown to be as effective as oxybutynin (*see below*) with better tolerability. Solifenacin is newly approved for overactive bladder with a favorable efficacy:side effect ratio (Chapple *et al.*, 2004). Stress urinary incontinence has been treated with some success with *duloxetine* (YENTREVE), that acts centrally to influence serotonin and norepinephrine levels (Millard *et al.*, 2004).

Triptiramine and darifenacin are selective antagonists for M₂ and M₃ muscarinic receptors, respectively. They are of potential utility in blocking cholinergic bradycardia (M₂) and smooth muscle activity or epithelial secretions (M₃).

Gastrointestinal Tract. Muscarinic receptor antagonists were once the most widely used drugs for the management of peptic ulcer. Although they can reduce gastric motility and the secretion of gastric acid, antisecretory doses produce pronounced side effects, such as dry mouth, loss of visual accommodation, photophobia, and difficulty in urination. As a consequence, patient compliance in the long-term management of symptoms of acid-peptic disease with these drugs is poor.

Pirenzepine is a tricyclic drug, similar in structure to *imipramine*. Pirenzepine has selectivity for M₁ over M₂ and M₃ receptors (Caulfield, 1993; Caulfield and Birdsall, 1998). However, pirenzepine's affinities for M₁ and M₄ receptors are comparable, so it does not possess total M₁ selectivity.

Telenzepine is an analog of pirenzepine that has higher potency and similar selectivity for M₁ muscarinic receptors. Both drugs are used in the treatment of acid-peptic disease in Europe, Japan, and Canada, but not currently in the United States. At therapeutic doses of pirenzepine, the incidence of dry mouth, blurred vision, and central muscarinic disturbances are relatively low. Central effects are not seen because of the drug's limited penetration into the CNS. Because of pirenzepine's relative selectivity for M₁ receptors, it clearly offers a marked improvement over atropine.

Most studies indicate that pirenzepine (100 to 150 mg per day) produces about the same rate of healing of duodenal and gastric ulcers as the H₂-receptor antagonists *cimetidine* or *ranitidine*; it also may be effective in preventing the recurrence of ulcers (Carmine and Brogden, 1985; Tryba and Cook, 1997). Side effects necessitate drug withdrawal in <1% of patients. Studies in human

subjects have shown pirenzepine to be more potent in inhibiting gastric acid secretion produced by neural stimuli than by muscarinic agonists, supporting the postulated localization of M₁ receptors at ganglionic sites. H₂-receptor antagonists and proton pump inhibitors generally are considered to be the current drugs of choice to reduce gastric acid secretion (*see* Chapter 36).

The belladonna alkaloids (atropine, *belladonna tincture*, l-hyoscyamine sulfate [ANASPAZ, LEVSIN, others], and scopolamine), and combinations with sedatives (*e.g.*, *phenobarbital* [DONNATAL, others] or *butabarbital* [BUTIBEL]), anti-anxiety agents (*e.g.*, *chlordiazepoxide* [LIBRAX, others], or *ergotamine* [BELLAMINE]) also have been used in a wide variety of conditions known or supposed to involve irritable bowel and increased tone (spasticity) or motility of the gastrointestinal tract. The belladonna alkaloids and their synthetic substitutes can reduce tone and motility when administered in maximal tolerated doses, and they might be expected to be efficacious if the condition simply involves excessive smooth muscle contraction, a point that is often in doubt. M₃-selective antagonists might achieve more selectivity, but M₃ receptors also exert a dominant influence on salivation, bronchiolar secretion and contraction, and bladder motility. Alternative agents for treatment of irritable bowel syndrome and its associated diarrhea are discussed in Chapter 38. Diarrhea sometimes associated with irritative conditions of the lower bowel, such as mild dysenteries and diverticulitis, may respond to atropine-like drugs. However, more severe conditions such as *Salmonella* dysentery, ulcerative colitis, and Crohn's disease respond poorly. The belladonna alkaloids and synthetic substitutes are very effective in reducing excessive salivation, such as drug-induced salivation and that associated with heavy-metal poisoning and parkinsonism.

Uses in Ophthalmology. Effects limited to the eye are obtained by local administration of muscarinic receptor antagonists to produce mydriasis and cycloplegia. Cycloplegia is not attainable without mydriasis and requires higher concentrations or more prolonged application of a given agent. Mydriasis often is necessary for thorough examination of the retina and optic disc and in the therapy of iridocyclitis and keratitis. The belladonna mydriatics may be alternated with miotics for breaking or preventing the development of adhesions between the iris and the lens. Complete cycloplegia may be necessary in the treatment of iridocyclitis and choroiditis and for accurate measurement of refractive errors. In instances in which complete cycloplegia is required, more effective agents such as atropine or scopolamine are preferred to drugs such as *cyclopentolate* and *tropicamide*.

Homatropine hydrobromide (ISOPTO HOMATROPINE, others), a semisynthetic derivative of atropine (Figure 7-2), *cyclopentolate hydrochloride* (CYCLOGYL, others), and *tropicamide* (MYDRIACYL, others) are agents used in ophthalmological practice. These agents are preferred to topical atropine or scopolamine because of their shorter duration of action. Additional information on the ophthalmology

logical properties and preparations of these and other drugs is provided in Chapter 63.

Cardiovascular System. The cardiovascular effects of muscarinic receptor antagonists are of limited clinical application. Generally, these agents are used in coronary care units for short-term interventions or in surgical settings.

Atropine may be considered in the initial treatment of patients with acute myocardial infarction in whom excessive vagal tone causes sinus or nodal bradycardia. Sinus bradycardia is the most common arrhythmia seen during acute myocardial infarction of the inferior or posterior wall. Atropine may prevent further clinical deterioration in cases of high vagal tone or AV block by restoring heart rate to a level sufficient to maintain adequate hemodynamic status and to eliminate AV nodal block. Dosing must be judicious; doses that are too low can cause a paradoxical bradycardia (see above), while excessive doses will cause tachycardia that may extend the infarct by increasing the demand for oxygen.

Atropine occasionally is useful in reducing the severe bradycardia and syncope associated with a hyperactive carotid sinus reflex. It has little effect on most ventricular rhythms. In some patients, atropine may eliminate premature ventricular contractions associated with a very slow atrial rate. It also may reduce the degree of AV block when increased vagal tone is a major factor in the conduction defect, such as the second-degree AV block that can be produced by digitalis.

Central Nervous System. For many years, the belladonna alkaloids and subsequently synthetic substitutes were the only agents helpful in the treatment of parkinsonism. Levodopa or levodopa along with *carbidopa* now is the treatment of choice, but alternative or concurrent therapy with muscarinic receptor antagonists may be required in some patients (see Chapter 20). Centrally acting agents such as benzotropine have been shown to be efficacious in preventing dystonias or parkinsonian symptoms in patients treated with antipsychotic drugs (Arana *et al.*, 1988) (see Chapter 20).

The belladonna alkaloids were among the first drugs to be used in the prevention of motion sickness. Scopolamine is the most effective prophylactic agent for short (4- to 6-hour) exposures to severe motion, and probably for exposures of up to several days. All agents used to combat motion sickness should be given prophylactically; they are much less effective after severe nausea or vomiting has developed. A transdermal preparation of scopolamine (TRANSDERM SCOP) has been shown to be highly effective when used prophylactically for the prevention of motion sickness. The drug, incorporated into a multilayered adhesive unit, is applied to the postauricular mastoid region, an area where transdermal absorption of the drug is especially efficient, and over a period of about 72 hours, approximately 0.5 mg of scopolamine is delivered. Dry mouth is common, drowsiness is not infrequent, and blurred vision occurs in some individuals. Mydriasis and cycloplegia can occur by inadvertent transfer of the drug to the eye from the fingers after handling the patch. Rare but severe psychotic episodes have been reported. The use of scopolamine to produce tranquilization and amnesia in a variety of circumstances, including labor, is declining and of questionable value. Given alone in the presence of pain or severe anxiety, scopolamine may induce outbursts of uncontrolled behavior.

Benzotropine mesylate (COGENTIN, others), *biperiden* (AKINETON), *procyclidine* (KEMADRIN), and *trihexphenidyl hydrochloride* (ARTANE, others) are tertiary-amine muscarinic receptor antagonists (together with the ethanolamine antihistamine *diphenhydramine* [BENADRYL, others]) that gain access to the CNS and can therefore

be used when anticholinergics are indicated to treat parkinsonism and the extrapyramidal side effects of antipsychotic drugs. These drugs are discussed in Chapter 20.

Uses in Anesthesia. The use of anesthetics that are relatively nonirritating to the bronchi has virtually eliminated the need for prophylactic use of muscarinic receptor antagonists. Atropine commonly is given to block responses to vagal reflexes induced by surgical manipulation of visceral organs. Atropine or glycopyrrolate is used with *neostigmine* to block its parasympathomimetic effects when the latter agent is used to reverse skeletal muscle relaxation after surgery (see Chapter 9). Serious cardiac arrhythmias have occasionally occurred, perhaps because of the initial bradycardia produced by atropine combined with the cholinomimetic effects of neostigmine.

Anticholinesterase Poisoning. The use of atropine in large doses for the treatment of poisoning by anticholinesterase organophosphorus insecticides is discussed in Chapter 8. Atropine also may be used to antagonize the parasympathomimetic effects of *pyridostigmine* or other anticholinesterase agents administered in the treatment of myasthenia gravis. It does not interfere with the salutary effects at the skeletal neuromuscular junction. It is most useful early in therapy, before tolerance to muscarinic side effects has developed.

Other Muscarinic Antagonists. **Methscopolamine.** Methscopolamine bromide (PAMINE) is a quaternary ammonium derivative of scopolamine and therefore lacks the central actions of scopolamine. Its use has been limited chiefly to gastrointestinal diseases. It is less potent than atropine and is poorly absorbed; however, its action is more prolonged, the usual oral dose (2.5 mg) acting for 6 to 8 hours.

Homatropine Methylbromide. Homatropine methylbromide is the quaternary derivative of homatropine. It is less potent than atropine in antimuscarinic activity, but it is four times more potent as a ganglionic blocking agent. It is available in combination with *hydrocodone* as an antitussive combination (HYCODAN) and has been used for relief of gastrointestinal spasms and as an adjunct in peptic ulcer disease.

Glycopyrrolate. *Glycopyrrolate* (ROBINUL, others) is employed orally to inhibit gastrointestinal motility and also is used parenterally to block the effects of vagal stimulation during anesthesia and surgery.

Dicyclomine hydrochloride (BENTYL, others), *flavoxate hydrochloride* (URISPAS, others), *oxybutynin chloride* (DITROPAN, others), and *tolterodine tartrate* (DETROL) are tertiary amines and *trospium chloride* (SANCTURA) is a quaternary amine; all are used for their antispasmodic properties. These agents appear to exert some non-specific direct relaxant effect on smooth muscle. In therapeutic doses they decrease spasm of the gastrointestinal tract, biliary tract, ureter, and uterus.

Mepenzolate Bromide. *Mepenzolate bromide* (CENTIL) is a quaternary amine with peripheral actions similar to those of atropine. It is indicated for adjunctive therapy of peptic ulcer disease and has been used as an antispasmodic for the relief of GI disorders.

Propantheline. *Propantheline bromide* (PRO-BANTHINE) is one of the more widely used of the synthetic nonselective muscarinic

receptor antagonists. High doses produce the symptoms of ganglionic blockade, and toxic doses block the skeletal neuromuscular junction. Its duration of action is comparable to that of atropine.

POISONING BY MUSCARINIC RECEPTOR ANTAGONISTS AND OTHER DRUGS WITH ANTICHOLINERGIC PROPERTIES

The deliberate or accidental ingestion of natural belladonna alkaloids is a major cause of poisonings. Many histamine H₁-receptor antagonists, phenothiazines, and tricyclic antidepressants also block muscarinic receptors, and in sufficient dosage, produce syndromes that include features of atropine intoxication.

Among the tricyclic antidepressants, *protriptyline* and *amitriptyline* are the most potent muscarinic receptor antagonists, with an affinity for the receptor that is approximately one-tenth that reported for atropine. Since these drugs are administered in therapeutic doses considerably higher than the effective dose of atropine, antimuscarinic effects often are observed clinically (*see* Chapter 17). In addition, overdose with suicidal intent is a danger in the population using antidepressants. Fortunately, most of the newer antidepressants and selective serotonin reuptake inhibitors are far less anticholinergic (Cusack *et al.*, 1994). In contrast, the newer antipsychotic drugs, classified as “atypical” and characterized by their low propensity for inducing extrapyramidal side effects, include agents that are potent muscarinic receptor antagonists. In particular, *clozapine* binds to human brain muscarinic receptors with one fifth the affinity of atropine; *olanzapine* also is a potent muscarinic receptor antagonist (Richelson, 1999). Accordingly, dry mouth is a prominent side effect of these drugs. A paradoxical side effect of clozapine is increased salivation and drooling, possibly the result of partial agonist properties of this drug (Richelson, 1999).

Infants and young children are especially susceptible to the toxic effects of muscarinic antagonists. Indeed, cases of intoxication in children have resulted from conjunctival instillation for ophthalmic refraction and other ocular effects. Systemic absorption occurs either from the nasal mucosa after the drug has traversed the nasolacrimal duct or from the GI tract if the drug is swallowed. Poisoning with *diphenoxylate-atropine* (LOMOTIL, others), used to treat diarrhea, has been extensively reported in the pediatric literature. Transdermal preparations of scopolamine used for motion sickness have been noted to cause toxic psychoses, especially in children and in the elderly. Serious intoxication may occur in

children who ingest berries or seeds containing belladonna alkaloids. Poisoning from ingestion and smoking of jimson weed, or thorn apple, is seen with some frequency today.

Table 7–2 shows the oral doses of atropine causing undesirable responses or symptoms of overdosage. These symptoms are predictable results of blockade of parasympathetic innervation. In cases of full-blown atropine poisoning, the syndrome may last 48 hours or longer. Intravenous injection of the anticholinesterase agent physostigmine may be used for confirmation. If physostigmine does not elicit the expected salivation, sweating, bradycardia, and intestinal hyperactivity, intoxication with atropine or a related agent is almost certain. Depression and circulatory collapse are evident only in cases of severe intoxication; the blood pressure declines, convulsions may ensue, respiration becomes inadequate, and death due to respiratory failure may follow after a period of paralysis and coma.

Measures to limit intestinal absorption should be initiated without delay if the poison has been taken orally (*see* Chapter 64). For symptomatic treatment, slow intravenous injection of physostigmine rapidly abolishes the delirium and coma caused by large doses of atropine, but carries some risk of overdose in mild atropine intoxication. Since physostigmine is metabolized rapidly, the patient may again lapse into coma within 1 to 2 hours, and repeated doses may be needed (*see* Chapter 8). If marked excitement is present and more specific treatment is not available, a benzodiazepine is the most suitable agent for sedation and for control of convulsions. Phenothiazines or agents with antimuscarinic activity should not be used, because their antimuscarinic action is likely to intensify toxicity. Support of respiration and control of hyperthermia may be necessary. Ice bags and alcohol sponges help to reduce fever, especially in children.

CLINICAL SUMMARY

The availability of cDNAs encoding five distinct muscarinic receptor subtypes has facilitated the development of subtype-selective agonists and antagonists. This approach has been more successful with antagonists; even here, a high degree of receptor subtype selectivity that eliminates unwanted side effects has been difficult to achieve. Subtype-selective muscarinic receptor antagonists show promise in certain therapeutic settings, for example, in the treatment of urinary incontinence and for management of irritable bowel syndrome. Therapeutic efficacy can be enhanced by targeting unique subsets of receptors that control muscarinic responses within a particular end organ. Local application by inhalation or instillation into the eye has resulted in organ selectivity of selected antagonists. Inhalation with quaternary antagonists has proved useful in the treatment of pulmonary conditions, particularly chronic obstructive pulmonary disease.

ANTICHOLINESTERASE AGENTS

Palmer Taylor

The function of acetylcholinesterase (AChE) in terminating the action of acetylcholine (ACh) at the junctions of the various cholinergic nerve endings with their effector organs or postsynaptic sites is considered in Chapter 6. Drugs that inhibit AChE are called *anticholinesterase* (anti-ChE) *agents*. They cause ACh to accumulate in the vicinity of cholinergic nerve terminals and thus are potentially capable of producing effects equivalent to excessive stimulation of cholinergic receptors throughout the central and peripheral nervous systems. In view of the widespread distribution of cholinergic neurons across animal species, it is not surprising that the anti-ChE agents have received extensive application as toxic agents, in the form of agricultural insecticides, pesticides, and potential chemical warfare “nerve gases.” Nevertheless, several compounds of this class are widely used therapeutically; others that cross the blood–brain barrier have been approved or are in clinical trials for the treatment of Alzheimer’s disease.

Prior to World War II, only the “reversible” anti-ChE agents were generally known, of which *physostigmine* is the prototype. Shortly before and during World War II, a new class of highly toxic chemicals, the organophosphates, was developed chiefly by Schrader at I.G. Farbenindustrie, first as agricultural insecticides and later as potential chemical warfare agents. The extreme toxicity of these compounds was found to be due to their “irreversible” inactivation of AChE, which resulted in prolonged enzyme inhibition. Since the pharmacological actions of both classes of anti-ChE agents are qualitatively similar, they are discussed here as a group. Interactions of anti-ChE agents with other drugs acting at peripheral autonomic synapses and the neuromuscular junction are described in Chapters 7 and 9.

History. Physostigmine, also called *eserine*, is an alkaloid obtained from the Calabar or ordeal bean, the dried, ripe seed of *Physostigma*

venenosum, Balfour, a perennial plant found in tropical West Africa. The Calabar bean once was used by native tribes of West Africa as an “ordeal poison” in trials for witchcraft. A pure alkaloid was isolated by Jobst and Hesse in 1864 and named physostigmine. The first therapeutic use of the drug was in 1877 by Laqueur, in the treatment of glaucoma, one of its clinical uses today. Interesting accounts of the history of physostigmine have been presented by Karczmar (1970) and Holmstedt (2000).

As a result of the basic research of Stedman and associates in elucidating the chemical basis of the activity of physostigmine, others began systematic investigations of a series of substituted aromatic esters of alkyl carbamic acids. *Neostigmine* was introduced into therapeutics in 1931 for its stimulant action on the GI tract and subsequently was reported to be effective in the symptomatic treatment of myasthenia gravis.

Remarkably, the first account of the synthesis of a highly potent organophosphorus anti-ChE, *tetraethyl pyrophosphate* (TEPP), was published by Clermont in 1854. It is even more remarkable that the investigator survived to report on the compound’s taste; a few drops should have been lethal. Modern investigations of the organophosphorus compounds date from the 1932 publication of Lange and Krueger on the synthesis of dimethyl and diethyl phosphorofluoridates. The authors’ statement that inhalation of these compounds caused a persistent choking sensation and blurred vision apparently was instrumental in leading Schrader to explore this class for insecticidal activity.

Upon synthesizing approximately 2000 compounds, Schrader defined the structural requirements for insecticidal (and, as learned subsequently, for anti-ChE) activity (*see below*) (Gallo and Lawryk, 1991). One compound in this early series, *parathion* (a phosphorothioate), later became the most widely used insecticide of this class. *Malathion*, which currently is used extensively, also contains the thionophosphorus bond found in parathion. Prior to and during World War II, the efforts of Schrader’s group were directed toward the development of chemical warfare agents. The synthesis of several compounds of much greater toxicity than parathion, such as *sarin*, *soman*, and *tabun*, were kept secret by the German government. Investigators in the Allied countries also followed Lange and Krueger’s lead in the search for potentially toxic compounds; diisopropyl phosphorofluoridate (*diisopropyl fluorophosphate*; DFP), synthesized by McCombie and Saunders, was studied most extensively by British and American scientists.

Figure 8–1. The active center gorge of mammalian acetylcholinesterase. Bound acetylcholine is shown by the dotted structure depicting its van der Waals radii. The crystal structure of mouse cholinesterase active center, which is virtually identical to human AChE, is shown (Bourne *et al.*, 1995). Included are the side chains of (a) the catalytic triad, Glu₃₃₄, His₄₄₇, Ser₂₀₃ (hydrogen bonds are denoted by the dotted lines); (b) acyl pocket, Phe₂₉₅ and Phe₂₉₇; (c) choline subsite, Trp₈₆, Glu₂₀₂, and Tyr₃₃₇; and (d) the peripheral site: Trp₂₈₆, Tyr₇₂, Tyr₁₂₄, and Asp₇₄. Tyrosines 337 and 449 are further removed from the active center but likely contribute to stabilization of certain ligands. The catalytic triad, choline subsite, and acyl pocket are located at the base of the gorge, while the peripheral site is at the lip of the gorge. The gorge is 18 to 20 Å deep, with its base centrosymmetric to the subunit.

In the 1950s, a series of aromatic carbamates was synthesized and found to have substantial selective toxicity against insects and to be potent anti-ChE agents (Ecobichon, 2000).

Structure of Acetylcholinesterase. AChE exists in two general classes of molecular forms: simple homomeric oligomers of catalytic subunits (*i.e.*, monomers, dimers, and tetramers) and heteromeric associations of catalytic subunits with structural subunits (Massoulié, 2000; Taylor *et al.*, 2000). The homomeric forms are found as soluble species in the cell, presumably destined for export or for association with the outer membrane of the cell, typically through an attached glycopospholipid. One heteromeric form, largely found in neuronal synapses, is a tetramer of catalytic subunits disulfide-linked to a 20,000-dalton lipid-linked subunit. Similar to the glycopospholipid-attached form, it is found in the outer surface of the cell membrane. The other heteromeric form consists of tetramers of catalytic subunits, disulfide linked to each of three strands of a collagen-like structural subunit. This molecular species, whose molecular mass approaches 10^6 daltons, is associated with the basal lamina of junctional areas of skeletal muscle.

Molecular cloning revealed that a single gene encodes vertebrate AChEs (Schumacher *et al.*, 1986; Taylor *et al.*, 2000). However, multiple gene products arise from alternative processing of the mRNA that differ only in their carboxyl-termini; the portion of the

gene encoding the catalytic core of the enzyme is invariant. Hence, the individual AChE species can be expected to show identical substrate and inhibitor specificities.

A separate, structurally related gene encodes butyrylcholinesterase, which is synthesized in the liver and is primarily found in plasma (Lockridge *et al.*, 1987). The cholinesterases define a superfamily of proteins whose structural motif is the α , β hydrolase-fold (Cygler *et al.*, 1993). The family includes several esterases, other hydrolases not found in the nervous system, and surprisingly, proteins without hydrolase activity such as thyroglobulin and members of the tactin and neuroligin families of proteins (Taylor *et al.*, 2000).

The three-dimensional structures of AChEs show the active center to be nearly centrosymmetric to each subunit, residing at the base of a narrow gorge about 20 Å in depth (Sussman *et al.*, 1991; Bourne *et al.*, 1995). At the base of the gorge lie the residues of the catalytic triad: serine 203, histidine 447, and glutamate 334 in mammals (Figure 8–1). The catalytic mechanism resembles that of other hydrolases; the serine hydroxyl group is rendered highly nucleophilic through a charge-relay system involving the carboxylate anion from glutamate, the imidazole of histidine, and the hydroxyl of serine (Figure 8–2A).

During enzymatic attack of ACh, an ester with trigonal geometry, a tetrahedral intermediate between enzyme and substrate is

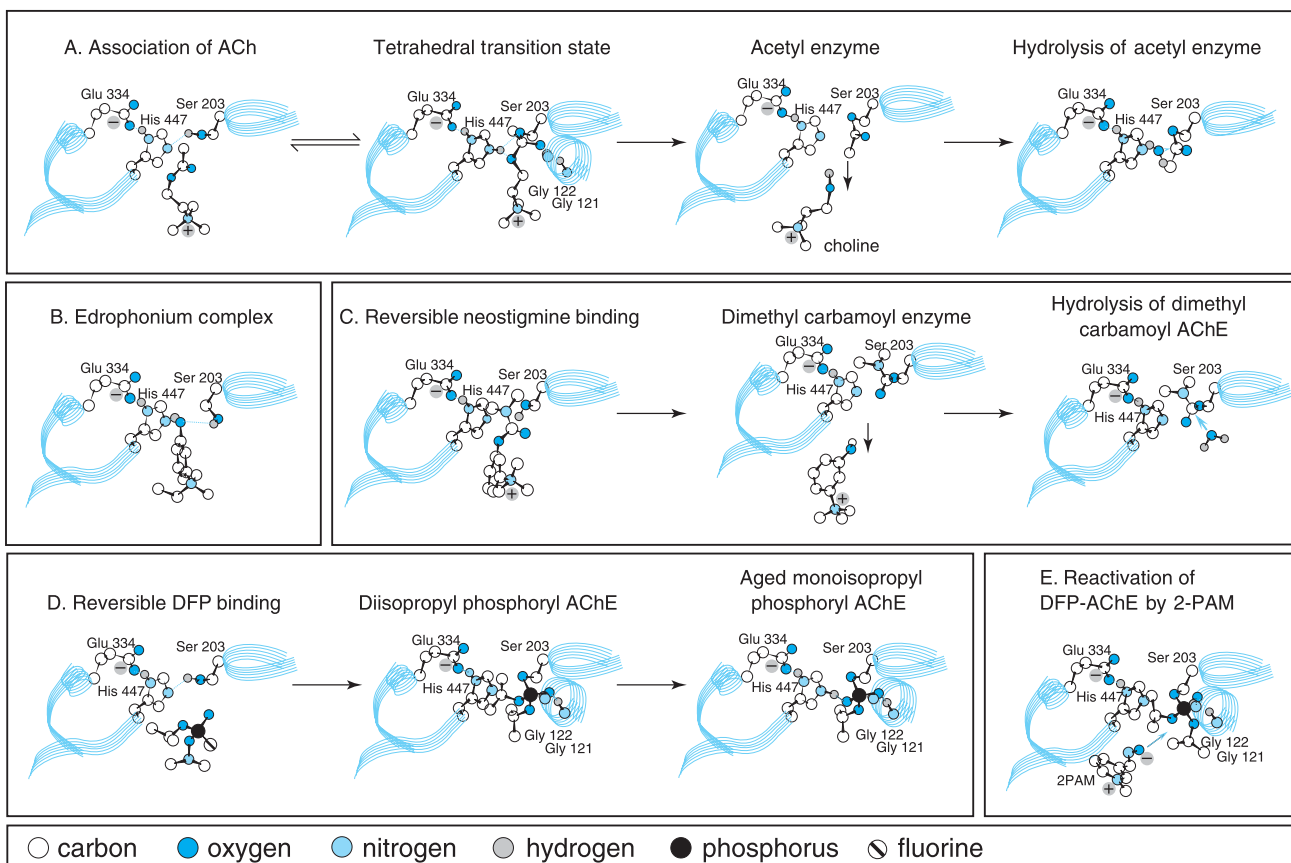

Figure 8–2. Steps involved in the hydrolysis of acetylcholine by acetylcholinesterase and in the inhibition and reactivation of the enzyme. Only the three residues of the catalytic triad shown in Figure 8–1 are depicted. The associations and reactions shown are: **A.** Acetylcholine (ACh) catalysis: binding of ACh, formation of a tetrahedral transition state, formation of the acetyl enzyme with liberation of choline, rapid hydrolysis of the acetyl enzyme with return to the original state. **B.** Reversible binding and inhibition by edrophonium. **C.** Neostigmine reaction with and inhibition of AChE: reversible binding of neostigmine, formation of the dimethyl carbamoyl enzyme, slow hydrolysis of the dimethyl carbamoyl enzyme. **D.** Diisopropyl fluorophosphate (DFP) reaction and inhibition of AChE: reversible binding of DFP, formation of the diisopropyl phosphoryl enzyme, formation of the aged monoisopropyl phosphoryl enzyme. Hydrolysis of the diisopropyl enzyme is very slow and is not shown. The aged monoisopropyl phosphoryl enzyme is virtually resistant to hydrolysis and reactivation. The tetrahedral transition state of ACh hydrolysis resembles the conjugates formed by the tetrahedral phosphate inhibitors and accounts for their potency. Amide bond hydrogens from Gly 121 and 122 stabilize the carbonyl and phosphoryl oxygens. **E.** Reactivation of the diisopropyl phosphoryl enzyme by pralidoxime (2-PAM). 2-PAM attack of the phosphorus on the phosphorylated enzyme will form a phospho-oxime with regeneration of active enzyme. The individual steps of phosphorylation reaction and oxime reaction have been characterized by mass spectrometry (Jennings *et al.*, 2004).

formed (Figure 8–2A) that collapses to an acetyl enzyme conjugate with the concomitant release of choline. The acetyl enzyme is very labile to hydrolysis, which results in the formation of acetate and active enzyme (Froede and Wilson, 1971; Rosenberry, 1975). AChE is one of the most efficient enzymes known: one molecule of AChE can hydrolyze 6×10^5 ACh molecules per minute; this yields a turnover time of 150 microseconds.

Mechanism of Action of AChE Inhibitors. The mechanisms of the action of compounds that typify the three classes of anti-ChE agents are also shown in Figure 8–2.

Three distinct domains on AChE constitute binding sites for inhibitory ligands and form the basis for specificity differences between AChE and butyrylcholinesterase: the acyl pocket of the active center, the choline subsite of the active center, and the peripheral anionic site (Taylor and Radic', 1994; Reiner and Radic', 2000). Reversible inhibitors, such as *edrophonium* and *tacrine*, bind to the choline subsite in the vicinity of tryptophan 86 and glutamate 202 (Silman and Sussman, 2000) (Figure 8–2B). Edrophonium has a brief duration of action because its quaternary structure facilitates renal elimination and it binds reversibly to the AChE active center. Additional reversible inhibitors, such as *donepezil*, bind with higher affinity to the active center.

Other reversible inhibitors, such as *propidium* and the snake peptidic toxin *fasciculin*, bind to the peripheral anionic site on AChE. This site resides at the rim of the gorge and is defined by tryptophan 286 and tyrosines 72 and 124 (Figure 8–1).

Drugs that have a carbamoyl ester linkage, such as physostigmine and neostigmine, are hydrolyzed by AChE, but much more slowly than is ACh. The quaternary amine neostigmine and the tertiary amine physostigmine exist as cations at physiological pH. By serving as alternate substrates to ACh (Figure 8–2C), attack by the active center serine generates the carbamoylated enzyme. The carbamoyl moiety resides in the acyl pocket outlined by phenylalanines 295 and 297. In contrast to the acetyl enzyme, methylcarbamoyl AChE and dimethylcarbamoyl AChE are far more stable (the half-life for hydrolysis of the dimethylcarbamoyl enzyme is 15 to 30 minutes). Sequestration of the enzyme in its carbamoylated form thus precludes the enzyme-catalyzed hydrolysis of ACh for extended periods of time. *In vivo*, the duration of inhibition by the carbamoylating agents is 3 to 4 hours.

The organophosphorus inhibitors, such as diisopropyl fluorophosphate (DFP), serve as true hemisubstrates, since the resultant conjugate with the active center serine phosphorylated or phosphonylated is extremely stable (Figure 8–2D). The organophosphorus inhibitors are tetrahedral in configuration, a configuration that resembles the transition state formed in carboxyl ester hydrolysis. Similar to the carboxyl esters, the phosphoryl oxygen binds within the oxyanion hole of the active center. If the alkyl groups in the phosphorylated enzyme are ethyl or methyl, spontaneous regeneration of active enzyme requires several hours. Secondary (as in DFP) or tertiary alkyl groups further enhance the stability of the phosphorylated enzyme, and significant regeneration of active enzyme usually is not observed. Hence, the return of AChE activity depends on synthesis of a new enzyme. The stability of the phosphorylated enzyme is enhanced through “aging,” which results from the loss of one of the alkyl groups.

From the foregoing account, it is apparent that the terms *reversible* and *irreversible* as applied to the carbamoyl ester and organophosphorate anti-ChE agents, respectively, reflect only quantitative differences in rates of decarbamylation or dephosphorylation of the conjugated enzyme. Both chemical classes react covalently with the enzyme serine in essentially the same manner as does ACh.

Action at Effector Organs. The characteristic pharmacological effects of the anti-ChE agents are due primarily to the prevention of hydrolysis of ACh by AChE at sites of cholinergic transmission. Transmitter thus accumulates, enhancing the response to ACh that is liberated by cholinergic impulses or that is spontaneously released from the nerve ending. Virtually all acute effects of moderate doses of organophosphates are attributable to this action. For example, the characteristic miosis that follows local application of DFP to the eye is not observed after chronic postganglionic denervation of the eye because there is no source from which to release endogenous ACh. The consequences of enhanced concentrations of ACh at motor endplates are unique to these sites and are discussed below.

The tertiary amine and particularly the quaternary ammonium anti-ChE compounds may have additional

direct actions at certain cholinergic receptor sites. For example, the effects of neostigmine on the spinal cord and neuromuscular junction are based on a combination of its anti-ChE activity and direct cholinergic stimulation.

Chemistry and Structure–Activity Relationships. The structure–activity relationships of anti-ChE agents are reviewed in previous editions of this book. Only agents of general therapeutic or toxicological interest are considered here.

Noncovalent Inhibitors. While these agents interact by reversible and noncovalent association with the active site in AChE, they differ in their disposition in the body and their affinity for the enzyme. Edrophonium, a quaternary drug whose activity is limited to peripheral nervous system synapses, has a moderate affinity for AChE. Its volume of distribution is limited and renal elimination is rapid, accounting for its short duration of action. By contrast, tacrine and donepezil (Figure 8–3) have higher affinities for AChE, are more hydrophobic, and readily cross the blood–brain barrier to inhibit AChE in the central nervous system (CNS). Their partitioning into lipid and their higher affinities for AChE account for their longer durations of action.

“Reversible” Carbamate Inhibitors. Drugs of this class that are of therapeutic interest are shown in Figure 8–3. Early studies showed that the essential moiety of the physostigmine molecule was the methylcarbamate of an amine-substituted phenol. The quaternary ammonium derivative neostigmine is a compound of equal or greater potency. *Pyridostigmine* is a close congener that also is used to treat myasthenia gravis.

An increase in anti-ChE potency and duration of action can result from the linking of two quaternary ammonium moieties. One such example is the miotic agent *demecarium*, which consists of two neostigmine molecules connected by a series of ten methylene groups. The second quaternary group confers additional stability to the interaction by associating with a negatively charged amino side chain, Asp74, near the rim of the gorge. Carbamoylating inhibitors with high lipid solubilities (*e.g.*, *rivastigmine*), which readily cross the blood–brain barrier and have longer durations of action, are approved or in clinical trial for the treatment of Alzheimer’s disease (Giacobini, 2000; Cummings, 2004) (*see* Chapter 20).

The carbamate insecticides *carbaryl* (SEVIN), *propoxur* (BAYGON), and *aldicarb* (TEMIK), which are used extensively as garden insecticides, inhibit ChE in a fashion identical with other carbamoylating inhibitors. The symptoms of poisoning closely resemble those of the organophosphates (Baron, 1991; Ecobichon, 2000). Carbaryl has a particularly low toxicity from dermal absorption. It is used topically for control of head lice in some countries. Not all carbamates in garden formulations are ChE inhibitors; the dithiocarbamates are fungicidal.

Organophosphorus Compounds. The general formula for this class of ChE inhibitors is presented in Table 8–1. A great variety of substituents is possible: R₁ and R₂ may be alkyl, alkoxy, aryloxy, amido, mercaptan, or other groups, and X, the leaving group, typically a conjugate base of a weak acid, is a halide, cyanide, thiocyanate, phenoxy, thiophenoxy, phosphate, thiocholine, or carboxylate group. For a compilation of the organophosphorus compounds and their toxicity, *see* Gallo and Lawryk (1991).

DFP produces virtually irreversible inactivation of AChE and other esterases by alkylphosphorylation. Its high lipid solubility, low molecular weight, and volatility facilitate inhalation, transdermal absorption, and penetration into the CNS. After desulfuration, the insecticides in current use form the dimethoxy or diethoxyphosphoryl enzyme.

Figure 8–3. Representative “reversible” anticholinesterase agents employed clinically.

The “nerve gases”—tabun, sarin, and soman—are among the most potent synthetic toxins known; they are lethal to laboratory animals in nanogram doses. Insidious employment of these agents has occurred in warfare and terrorism attacks (Nozaki and Aikawa, 1995).

Because of their low volatility and stability in aqueous solution, parathion and *methylparathion* were widely used as insecticides. Acute and chronic toxicity has limited their use, and potentially less hazardous compounds have replaced them for home and garden use. These compounds are inactive in inhibiting AChE *in vitro*; *paraoxon* is the active metabolite. The phosphoryl oxygen for sulfur substitution is carried out predominantly by hepatic CYPs. This reaction also occurs in the insect, typically with more efficiency. Other insecticides possessing the phosphorothioate structure have been widely employed for home, garden, and agricultural use. These include *diazinon* (SPECTRACIDE, others) and *chlorpyrifos* (DURSBAN, LORSBAN). Chlorpyrifos recently has been placed under restricted use because of evidence of chronic toxicity in the newborn animal. For the same reason, diazinon was banned for indoor use in the United States in 2001 and will be phased out of all outdoor residential use by 2005.

Malathion (CHEMATHION, MALA-SPRAY) also requires replacement of a sulfur atom with oxygen *in vivo*, conferring resistance to mammalian species. Also, this insecticide can be detoxified by hydrolysis of the carboxyl ester linkage by plasma carboxylesterases, and plasma carboxylesterase activity dictates species resistance to malathion. The detoxification reaction is much more rapid in mammals and birds than in insects (Costa *et al.*, 1987). In recent years, malathion has been employed in aerial spraying of relatively populous areas for control of citrus orchard-destructive Mediterranean fruit flies and mosquitoes that harbor and transmit

viruses harmful to human beings, such as the West Nile encephalitis virus.

Evidence of acute toxicity from malathion arises only with suicide attempts or deliberate poisoning (Bardin *et al.*, 1994). The lethal dose in mammals is about 1 g/kg. Exposure to the skin results in a small fraction (<10%) of systemic absorption. Malathion is used topically in the treatment of pediculosis (lice) infestations.

Among the quaternary ammonium organophosphorus compounds (group E in Table 8–1), only *echothiophate* is useful clinically and is limited to ophthalmic administration. Being positively charged, it is not volatile and does not readily penetrate the skin.

Metrifonate is a low-molecular-weight organophosphate that is spontaneously converted to the active phosphoryl ester, *dimethyl 2,2-dichlorovinyl phosphate* (DDVP, *dichlorvos*). Both metrifonate and DDVP readily cross the blood–brain barrier to inhibit AChE in the CNS. Metrifonate originally was developed for the treatment of schistosomiasis (*see* Chapter 41). Its capacity to inhibit AChE in the CNS and its reported low toxicity led to its clinical trial in treatment of Alzheimer’s disease (Cummings *et al.*, 1999; Cummings, 2004); a low incidence of skeletal muscle paralysis may limit its acceptance.

PHARMACOLOGICAL PROPERTIES

Generally, the pharmacological properties of anti-ChE agents can be predicted by knowing those loci where ACh is released physiologically by nerve impulses, the degree of nerve impulse activity, and the responses of the corresponding effector organs to ACh (*see* Chapter 6). The

Table 8-1

Chemical Classification of Representative Organophosphorus Compounds of Particular Pharmacological or Toxicological Interest (Continued)

GROUP	STRUCTURAL FORMULA	COMMON, CHEMICAL, AND OTHER NAMES	COMMENTS
		Chlorpyrifos <i>O,O</i> -Diethyl <i>O</i> -(3,5,6-trichloro-2-pyridyl) phosphorothioate	Insecticide with restricted use in consumer products and limited to nonresidential settings
		Malathion <i>O,O</i> -Dimethyl <i>S</i> -(1,2-dicarboethoxyethyl) phosphorodithioate	Widely employed insecticide of greater safety than parathion or other agents because of rapid detoxification by higher organisms
D		TEPP Tetraethyl pyrophosphate	Early insecticide
E		Echothiophate (PHOSPHOLINE IODIDE), MI-217 Diethoxyphosphinyllthiocholine iodide	Extremely potent choline derivative; employed in treatment of glaucoma; relatively stable in aqueous solution

anti-ChE agents potentially can produce all the following effects: (1) stimulation of muscarinic receptor responses at autonomic effector organs; (2) stimulation, followed by depression or paralysis, of all autonomic ganglia and skeletal muscle (nicotinic actions); and (3) stimulation, with occasional subsequent depression, of cholinergic receptor sites in the CNS. Following toxic or lethal doses of anti-ChE agents, most of these effects can be noted (*see* below). However, with smaller doses, particularly those used therapeutically, several modifying factors are significant. In general, compounds containing a quaternary ammonium group do not penetrate cell membranes readily; hence, anti-ChE agents in this category are absorbed poorly from the GI tract or across the skin and are excluded from the CNS by the blood-brain barrier after moderate doses. On the other hand, such compounds act preferentially at the neuromuscular junctions of skeletal muscle, exerting their action both as anti-ChE agents and as direct agonists. They have comparatively less effect at autonomic effector sites and ganglia. In contrast, the more lipid-soluble agents are well absorbed after oral administration, have ubiquitous effects at both peripheral and central cholinergic sites, and may be sequestered in lipids for long periods of time. Lipid-soluble organophosphorus agents

also are well absorbed through the skin, and the volatile agents are transferred readily across the alveolar membrane (Storm *et al.*, 2000).

The actions of anti-ChE agents on autonomic effector cells and on cortical and subcortical sites in the CNS, where the receptors are largely of the muscarinic type, are blocked by *atropine*. Likewise, *atropine* blocks some of the excitatory actions of anti-ChE agents on autonomic ganglia, since both nicotinic and muscarinic receptors are involved in ganglionic neurotransmission (*see* Chapter 9).

The sites of action of anti-ChE agents of therapeutic importance are the CNS, eye, intestine, and the neuromuscular junction of skeletal muscle; other actions are of toxicological consequence.

Eye. When applied locally to the conjunctiva, anti-ChE agents cause conjunctival hyperemia and constriction of the pupillary sphincter muscle around the pupillary margin of the iris (miosis) and the ciliary muscle (block of accommodation reflex with resultant focusing to near vision). Miosis is apparent in a few minutes and can last several hours to days. Although the pupil may be “pinpoint” in size, it generally contracts further when exposed to light. The block of accommodation is more transient

and generally disappears before termination of miosis. Intraocular pressure, when elevated, usually falls as the result of facilitation of outflow of the aqueous humor (*see* Chapter 63).

Gastrointestinal Tract. In humans, neostigmine enhances gastric contractions and increases the secretion of gastric acid. After bilateral vagotomy, the effects of neostigmine on gastric motility are greatly reduced. The lower portion of the esophagus is stimulated by neostigmine; in patients with marked achalasia and dilation of the esophagus, the drug can cause a salutary increase in tone and peristalsis.

Neostigmine also augments motor activity of the small and large bowel; the colon is particularly stimulated. Atony produced by muscarinic-receptor antagonists or prior surgical intervention may be overcome, propulsive waves are increased in amplitude and frequency, and movement of intestinal contents is thus promoted. The total effect of anti-ChE agents on intestinal motility probably represents a combination of actions at the ganglion cells of Auerbach's plexus and at the smooth muscle fibers, as a result of the preservation of ACh released by the cholinergic preganglionic and postganglionic fibers, respectively (*see* Chapter 37).

Neuromuscular Junction. Most of the effects of potent anti-ChE drugs on skeletal muscle can be explained adequately on the basis of their inhibition of AChE at neuromuscular junctions. However, there is good evidence for an accessory direct action of neostigmine and other quaternary ammonium anti-ChE agents on skeletal muscle. For example, the intra-arterial injection of neostigmine into chronically denervated muscle, or muscle in which AChE has been inactivated by prior administration of DFP, evokes an immediate contraction, whereas physostigmine does not.

Normally, a single nerve impulse in a terminal motor-axon branch liberates enough ACh to produce a localized depolarization (endplate potential) of sufficient magnitude to initiate a propagated muscle action potential. The ACh released is rapidly hydrolyzed by AChE, such that the lifetime of free ACh within the nerve-muscle synapse (~200 microseconds) is shorter than the decay of the endplate potential or the refractory period of the muscle. Therefore, each nerve impulse gives rise to a single wave of depolarization. After inhibition of AChE, the residence time of ACh in the synapse increases, allowing for lateral diffusion and rebinding of the transmitter to multiple receptors. Successive stimulation of neighboring receptors to the release site in the endplate results in a prolongation of the decay time of the endplate potential. Quanta

released by individual nerve impulses are no longer isolated. This action destroys the synchrony between endplate depolarizations and the development of the action potentials. Consequently, asynchronous excitation and fasciculations of muscle fibers occur. With sufficient inhibition of AChE, depolarization of the endplate predominates, and blockade owing to depolarization ensues (*see* Chapter 9). When ACh persists in the synapse, it also may depolarize the axon terminal, resulting in antidromic firing of the motoneuron; this effect contributes to fasciculations that involve the entire motor unit.

The anti-ChE agents will reverse the antagonism caused by competitive neuromuscular blocking agents (*see* Chapter 9). Neostigmine is not effective against the skeletal muscle paralysis caused by *succinylcholine*; this agent also produces neuromuscular blockade by depolarization, and depolarization will be enhanced by neostigmine.

Actions at Other Sites. Secretory glands that are innervated by postganglionic cholinergic fibers include the bronchial, lacrimal, sweat, salivary, gastric (antral G cells and parietal cells), intestinal, and pancreatic acinar glands. Low doses of anti-ChE agents augment secretory responses to nerve stimulation, and higher doses actually produce an increase in the resting rate of secretion.

Anti-ChE agents increase contraction of smooth muscle fibers of the bronchioles and ureters, and the ureters may show increased peristaltic activity.

The cardiovascular actions of anti-ChE agents are complex, since they reflect both ganglionic and postganglionic effects of accumulated ACh on the heart and blood vessels and actions in the CNS. The predominant effect on the heart from the peripheral action of accumulated ACh is bradycardia, resulting in a fall in cardiac output. Higher doses usually cause a fall in blood pressure, often as a consequence of effects of anti-ChE agents on the medullary vasomotor centers of the CNS.

Anti-ChE agents augment vagal influences on the heart. This shortens the effective refractory period of atrial muscle fibers and increases the refractory period and conduction time at the SA and AV nodes. At the ganglionic level, accumulating ACh initially is excitatory on nicotinic receptors, but at higher concentrations, ganglionic blockade ensues as a result of persistent depolarization of the cell membrane. The excitatory action on the parasympathetic ganglion cells would tend to reinforce the diminished cardiac output, whereas the opposite sequence would result from the action of ACh on sympathetic ganglion cells. Excitation followed by inhibition also is elicited by ACh at the central medullary vasomotor and cardiac centers. All of these effects are complicated further by the hypoxemia resulting from the bronchoconstrictor and secretory actions of increased ACh on the respiratory system; hypoxemia, in turn, can reinforce both sympathetic tone and ACh-induced discharge of epinephrine from the adrenal medulla. Hence, it is not surprising that an increase in heart rate is seen with severe ChE inhibitor poisoning. Hypoxemia probably is a major factor in the CNS depression that appears after large doses of anti-ChE agents. The CNS-stimulant effects are antagonized by atro-

pine, although not as completely as are the muscarinic effects at peripheral autonomic effector sites.

Absorption, Fate, and Excretion. Physostigmine is absorbed readily from the GI tract, subcutaneous tissues, and mucous membranes. The conjunctival instillation of solutions of the drug may result in systemic effects if measures (*e.g.*, pressure on the inner canthus) are not taken to prevent absorption from the nasal mucosa. Parenterally administered physostigmine is largely destroyed within 2 hours, mainly by hydrolytic cleavage by plasma esterases; renal excretion plays only a minor role in its elimination.

Neostigmine and pyridostigmine are absorbed poorly after oral administration, such that much larger doses are needed than by the parenteral route. Whereas the effective parenteral dose of neostigmine is 0.5 to 2 mg, the equivalent oral dose may be 15 to 30 mg or more. Neostigmine and pyridostigmine are destroyed by plasma esterases, and the quaternary aromatic alcohols and parent compounds are excreted in the urine; the half-lives of these drugs are only 1 to 2 hours (Cohan *et al.*, 1976).

Organophosphorus anti-ChE agents with the highest risk of toxicity are highly lipid-soluble liquids; many have high vapor pressures. The less volatile agents that are commonly used as agricultural insecticides (*e.g.*, diazinon, malathion) generally are dispersed as aerosols or as dusts adsorbed to an inert, finely particulate material. Consequently, the compounds are absorbed rapidly through the skin and mucous membranes following contact with moisture, by the lungs after inhalation, and by the GI tract after ingestion (Storm *et al.*, 2000).

Following their absorption, most organophosphorus compounds are excreted almost entirely as hydrolysis products in the urine. Plasma and liver esterases are responsible for hydrolysis to the corresponding phosphoric and phosphonic acids. However, the CYPs are responsible for converting the inactive phosphorothioates containing a phosphorus-sulfur (thiono) bond to phosphorates with a phosphorus-oxygen bond, resulting in their activation. These enzymes also play a role in the inactivation of certain organophosphorus agents.

The organophosphorus anti-ChE agents are hydrolyzed by two families of enzymes: the carboxylesterases and the paraoxonases (A-esterases). These enzymes are found in the plasma and liver and scavenge or hydrolyze a large number of organophosphorus compounds by cleaving the phosphoester, anhydride, PF, or PCN bonds. The paraoxonases are low-molecular-weight enzymes, requiring Ca^{2+} for catalysis, whose natural substrate is unclear. Some of the isozymes are associated with high density lipoproteins, and in addition to their capacity to hydrolyze organophosphates, they may control low density lipoprotein oxidation, thereby exerting a protective effect in athero-

sclerosis (Harel *et al.*, 2004; Mackness *et al.*, 2004). Genetic polymorphisms that govern organophosphate substrate specificity and possible susceptibility to atherosclerosis have been found (Costa *et al.*, 2003; Mackness *et al.*, 2004). Wide variations in paraoxonase activity exist among animal species. Young animals are deficient in carboxylesterases and paraoxonases, which may account for age-related toxicities seen in newborn animals and suspected to be a basis for toxicity in human beings (Padilla *et al.*, 2004).

Plasma and hepatic carboxylesterases (aliesterases) and plasma butyrylcholinesterase are inhibited irreversibly by organophosphorus compounds (Lockridge and Masson, 2000); their scavenging capacity for organophosphates can afford partial protection against inhibition of AChE in the nervous system. The carboxylesterases also catalyze hydrolysis of malathion and other organophosphorus compounds that contain carboxyl-ester linkages, rendering them less active or inactive. Since carboxylesterases are inhibited by organophosphates, toxicity from exposure to two organophosphorus insecticides can be synergistic.

TOXICOLOGY

The toxicological aspects of the anti-ChE agents are of practical importance to clinicians. In addition to numerous cases of accidental intoxication from the use and manufacture of organophosphorus compounds as agricultural insecticides (over 40 have been approved for use in the United States), these agents have been used frequently for homicidal and suicidal purposes, largely because of their accessibility. Organophosphorus agents account for as much as 80% of pesticide-related hospital admissions. The World Health Organization documents pesticide toxicity as a widespread global problem; most poisonings occur in developing countries (Bardin *et al.*, 1994; Landrigan *et al.*, 2000). Occupational exposure occurs most commonly by the dermal and pulmonary routes, while oral ingestion is most common in cases of nonoccupational poisoning.

In the United States, the Environmental Protection Agency (EPA), by virtue of revised risk assessments and the Food Quality Protection Act of 1996, has placed several organophosphate insecticides on restricted use or phase-out status in consumer products for home and garden use. A primary concern relates to children, since the developing nervous system may be particularly susceptible to certain of these agents. The Office of Pesticide Programs of the EPA provides continuous reviews of the status of organophosphate pesticides, their tolerance reassessments, and revisions of risk assessments through their Web site (www.epa.gov/pesticides/op/). Public comment is sought prior to decisions on revisions.

Acute Intoxication. The effects of acute intoxication by anti-ChE agents are manifested by muscarinic and nicotinic signs and symptoms, and, except for compounds of extremely low lipid solubility,

by signs referable to the CNS. Systemic effects appear within minutes after inhalation of vapors or aerosols. In contrast, the onset of symptoms is delayed after gastrointestinal and percutaneous absorption. The duration of effects is determined largely by the properties of the compound: its lipid solubility, whether it must be activated to form the oxon, the stability of the organophosphorus-AChE bond, and whether "aging" of the phosphorylated enzyme has occurred.

After local exposure to vapors or aerosols or after their inhalation, ocular and respiratory effects generally appear first. Ocular manifestations include marked miosis, ocular pain, conjunctival congestion, diminished vision, ciliary spasm, and brow ache. With acute systemic absorption, miosis may not be evident due to sympathetic discharge in response to hypotension. In addition to rhinorrhea and hyperemia of the upper respiratory tract, respiratory effects consist of tightness in the chest and wheezing respiration, caused by the combination of bronchoconstriction and increased bronchial secretion. Gastrointestinal symptoms occur earliest after ingestion and include anorexia, nausea and vomiting, abdominal cramps, and diarrhea. With percutaneous absorption of liquid, localized sweating and muscle fasciculations in the immediate vicinity are generally the earliest symptoms. Severe intoxication is manifested by extreme salivation, involuntary defecation and urination, sweating, lacrimation, penile erection, bradycardia, and hypotension.

Nicotinic actions at the neuromuscular junctions of skeletal muscle usually consist of fatigability and generalized weakness, involuntary twitchings, scattered fasciculations, and eventually severe weakness and paralysis. The most serious consequence is paralysis of the respiratory muscles. Knockout mice lacking AChE can survive under highly supportive conditions and with a special diet, but they exhibit continuous tremors and are stunted in growth (Xie *et al.*, 2000). Mice that selectively lack AChE in skeletal muscle but have normal or near normal expression in brain and organs innervated by the autonomic nervous system grow normally and can reproduce, but have continuous tremors (Camp *et al.*, 2004). These studies show that cholinergic systems can partially adapt to chronically diminished hydrolytic capacity for AChE.

The broad spectrum of effects of acute AChE inhibition on the CNS includes confusion, ataxia, slurred speech, loss of reflexes, Cheyne-Stokes respiration, generalized convulsions, coma, and central respiratory paralysis. Actions on the vasomotor and other cardiovascular centers in the medulla oblongata lead to hypotension.

The time of death after a single acute exposure may range from less than 5 minutes to nearly 24 hours, depending on the dose, route, agent, and other factors. The cause of death primarily is respiratory failure, usually accompanied by a secondary cardiovascular component. Peripheral muscarinic and nicotinic as well as central actions all contribute to respiratory compromise; effects include laryngospasm, bronchoconstriction, increased tracheobronchial and salivary secretions, compromised voluntary control of the diaphragm and intercostal muscles, and central respiratory depression. Blood pressure may fall to alarmingly low levels and cardiac arrhythmias intervene. These effects usually result from hypoxemia and often are reversed by assisted pulmonary ventilation.

Delayed symptoms appearing after 1 to 4 days and marked by persistent low blood ChE and severe muscle weakness are termed the *intermediate syndrome* (Marrs, 1993; De Bleecker *et al.*, 1992; Lotti, 2002). A delayed neurotoxicity also may be evident after severe intoxication (*see below*).

Diagnosis and Treatment. The diagnosis of severe, acute anti-ChE intoxication is made readily from the history of exposure and the characteristic signs and symptoms. In suspected cases of milder

acute or chronic intoxication, determination of the ChE activities in erythrocytes and plasma generally will establish the diagnosis (Storm *et al.*, 2000). Although these values vary considerably in the normal population, they usually are depressed well below the normal range before symptoms are evident.

Atropine in sufficient dosage (*see below*) effectively antagonizes the actions at muscarinic receptor sites, including increased tracheobronchial and salivary secretion, bronchoconstriction, bradycardia, and to a moderate extent, peripheral ganglionic and central actions. Larger doses are required to get appreciable concentrations of atropine into the CNS. Atropine is virtually without effect against the peripheral neuromuscular compromise, which can be reversed by *pralidoxime* (2-PAM), a cholinesterase reactivator.

In moderate or severe intoxication with an organophosphorus anti-ChE agent, the recommended adult dose of pralidoxime is 1 to 2 g, infused intravenously over not less than 5 minutes. If weakness is not relieved or if it recurs after 20 to 60 minutes, the dose should be repeated. Early treatment is very important to assure that the oxime reaches the phosphorylated AChE while the latter still can be reactivated. Many of the alkylphosphates are extremely lipid soluble, and if extensive partitioning into body fat has occurred and desulfuration is required for inhibition of AChE, toxicity will persist and symptoms may recur after initial treatment. With severe toxicities from the lipid-soluble agents, it is necessary to continue treatment with atropine and pralidoxime for a week or longer.

General supportive measures also are important, including: (1) termination of exposure, by removal of the patient or application of a gas mask if the atmosphere remains contaminated, removal and destruction of contaminated clothing, copious washing of contaminated skin or mucous membranes with water, or gastric lavage; (2) maintenance of a patent airway, including endobronchial aspiration; (3) artificial respiration, if required; (4) administration of oxygen; (5) alleviation of persistent convulsions with *diazepam* (5 to 10 mg, intravenously); and (6) treatment of shock (Marrs, 1993; Bardin *et al.*, 1994).

Atropine should be given in doses sufficient to cross the blood-brain barrier. Following an initial injection of 2 to 4 mg, given intravenously if possible, otherwise intramuscularly, 2 mg should be given every 5 to 10 minutes until muscarinic symptoms disappear, if they reappear, or until signs of atropine toxicity appear. More than 200 mg may be required on the first day. A mild degree of atropine block then should be maintained for as long as symptoms are evident. Whereas the AChE reactivators can be of great benefit in the therapy of anti-ChE intoxication (*see below*), their use must be regarded as a supplement to the administration of atropine.

Cholinesterase Reactivators. Although the phosphorylated esteratic site of AChE undergoes hydrolytic regeneration at a slow or negligible rate, Wilson found that nucleophilic agents, such as hydroxylamine (NH_2OH), hydroxamic acids ($\text{RCONH}-\text{OH}$), and oximes ($\text{RCH}=\text{NOH}$), reactivate the enzyme more rapidly than does spontaneous hydrolysis. He reasoned that selective reactivation could be achieved by a site-directed nucleophile, wherein interaction of a quaternary nitrogen with the negative subsite of the active center would place the nucleophile in close apposition to the phosphorus. This goal was achieved to a remarkable degree by Wilson and Ginsburg with pyridine-2-aldoxime methyl chloride (pralidoxime) (Figure 8-2E);

reactivation with this compound occurs at a million times the rate of that with hydroxylamine. The oxime is oriented proximally to exert a nucleophilic attack on the phosphorus; a phosphoryloxime is formed, leaving the regenerated enzyme.

Several *bis*-quaternary oximes are even more potent as reactivators for insecticide and nerve gas poisoning (*see* below); an example is HI-6, which is used in Europe as an antidote. The structures of pralidoxime and HI-6 are:

The velocity of reactivation of phosphorylated AChE by oximes depends on their accessibility to the active center serine (Wong *et al.*, 2000). Furthermore, certain phosphorylated AChEs can undergo a fairly rapid process of “aging,” so that within the course of minutes or hours they become completely resistant to the reactivators. “Aging” is due to the loss of one alkoxy group, leaving a much more stable monoalkyl- or monoalkoxy-phosphoryl-AChE (Figure 8–2D and E). Organophosphorus compounds containing tertiary alkoxy groups are more prone to “aging” than are congeners containing the secondary or primary alkoxy groups. The oximes are not effective in antagonizing the toxicity of the more rapidly hydrolyzing carbamoyl ester inhibitors; since pralidoxime itself has weak anti-ChE activity, it is not recommended for the treatment of overdose with neostigmine or physostigmine or poisoning with carbamoylating insecticides such as carbaryl.

Pharmacology, Toxicology, and Disposition. The reactivating action of oximes *in vivo* is most marked at the skeletal neuromuscular junction. Following a dose of an organophosphorus compound that produces total blockade of transmission, the intravenous injection of an oxime can restore the response to stimulation of the motor nerve within a few minutes. Antidotal effects are less striking at autonomic effector sites, and the quaternary ammonium group restricts entry into the CNS.

Although high doses or accumulation of oximes can inhibit AChE and cause neuromuscular blockade, they should be given until one can be assured of clearance of the offending organophosphate. Many organophosphates partition into lipid and are released slowly as the active entity.

Current antidotal therapy for organophosphate exposure resulting from warfare or terrorism includes parenteral atropine, an oxime (2-PAM or HI-6), and a benzodiaz-

epine as an anticonvulsant. Parenterally administered human butyrylcholinesterase is under development as an antidote, to scavenge the inhibitor in the plasma before it reaches peripheral and central tissue sites (Doctor, 2003). Because this effect of butyrylcholinesterase is stoichiometric rather than catalytic, large quantities are required.

The oximes and their metabolites are readily eliminated by the kidney.

Delayed Neurotoxicity of Organophosphorus Compounds. Certain fluorine-containing organophosphorus anti-ChE agents (*e.g.*, DFP, *mipaflox*) have in common with the triarylphosphates, of which *tri-orthocresylphosphate* (TOCP) is the classical example, the property of inducing delayed neurotoxicity. This syndrome first received widespread attention following the demonstration that TOCP, an adulterant of Jamaica ginger, was responsible for an outbreak of thousands of cases of paralysis that occurred in the United States during Prohibition.

The clinical picture is that of a severe polyneuropathy manifested initially by mild sensory disturbances, ataxia, weakness, muscle fatigue and twitching, reduced tendon reflexes, and tenderness to palpation. In severe cases, the weakness may progress to flaccid paralysis and muscle wasting. Recovery may require several years and may be incomplete.

Toxicity from this organophosphate-induced delayed polyneuropathy is not dependent upon inhibition of cholinesterases; instead a distinct esterase, termed *neurotoxic esterase*, is linked to the lesions (Johnson, 1993). This enzyme has a substrate specificity for hydrophobic esters, but its natural substrate and function remain unknown (Glynn, 2000). Myopathies that result in generalized necrotic lesions and changes in endplate cytostructure also are found in experimental animals after long-term exposure to organophosphates (Dettbarn, 1984; De Bleecker *et al.*, 1992).

THERAPEUTIC USES

Current use of anti-AChE agents is limited to four conditions in the periphery: atony of the smooth muscle of the intestinal tract and urinary bladder, glaucoma, myasthenia gravis, and reversal of the paralysis of competitive neuromuscular blocking drugs (*see* Chapter 9). Long-acting and hydrophobic ChE inhibitors are the only inhibitors with well-documented efficacy, albeit limited, in the treatment of dementia symptoms of Alzheimer’s disease. Physostigmine, with its shorter duration of action, is useful in the treatment of intoxication by atropine and several drugs with anticholinergic side effects (*see* below); it also is indicated for the treatment of Friedreich’s or other inherited ataxias. Edrophonium has been used for terminating attacks of paroxysmal supraventricular tachycardia.

Available Therapeutic Agents. The compounds described here are those commonly used as anti-ChE drugs and ChE reactivators in the United States. Preparations used solely for ophthalmic purposes

es are described in Chapter 63. Conventional dosages and routes of administration are given in the discussion of therapeutic applications (*see below*).

Physostigmine salicylate (ANTILIRIUM) is available for injection. *Physostigmine sulfate ophthalmic ointment* and *physostigmine salicylate ophthalmic solution* also are available. *Pyridostigmine bromide* is available for oral (MESTINON) or parenteral (REGONOL, MESTINON) use. *Neostigmine bromide* (PROSTIGMIN) is available for oral use. *Neostigmine methylsulfate* (PROSTIGMIN) is marketed for parenteral injection. *Ambenonium chloride* (MYTELASE) is available for oral use. Tacrine (COGNEX), donepezil (ARICEPT), rivastigmine (EXELON), and *galantamine* (REMINYL) have been approved for the treatment of Alzheimer's disease.

Pralidoxime chloride (PROTOPAM CHLORIDE) is the only AChE reactivator currently available in the United States and can be obtained in a parenteral formulation. HI-6 is available in several European and Near Eastern countries.

Paralytic Ileus and Atony of the Urinary Bladder. In the treatment of both these conditions, neostigmine generally is preferred among the anti-ChE agents. The direct parasymphomimetic agents (Chapter 7) are employed for the same purposes.

Neostigmine is used for the relief of abdominal distension and acute colonic pseudo-obstruction from a variety of medical and surgical causes (Ponec *et al.*, 1999). The usual subcutaneous dose of neostigmine methylsulfate for postoperative paralytic ileus is 0.5 mg, given as needed. Peristaltic activity commences 10 to 30 minutes after parenteral administration, whereas 2 to 4 hours are required after oral administration of neostigmine bromide (15 to 30 mg). It may be necessary to assist evacuation with a small low enema or gas with a rectal tube.

When neostigmine is used for the treatment of atony of the detrusor muscle of the urinary bladder, postoperative dysuria is relieved, and the time interval between operation and spontaneous urination is shortened. The drug is used in a similar dose and manner as in the management of paralytic ileus. Neostigmine should not be used when the intestine or urinary bladder is obstructed, when peritonitis is present, when the viability of the bowel is doubtful, or when bowel dysfunction results from inflammatory bowel disease.

Glaucoma and Other Ophthalmologic Indications. Glaucoma is a complex disease characterized by an increase in intraocular pressure that, if sufficiently high and persistent, leads to damage to the optic disc at the juncture of the optic nerve and the retina; irreversible blindness can result. Of the three types of glaucoma—primary, secondary, and congenital—anti-AChE agents are of value in the management of the primary as well as of certain categories of the secondary type (*e.g.*, aphakic glaucoma, following cataract extraction); congenital glaucoma rarely responds to any therapy other than surgery. Primary glaucoma is subdivided into narrow-angle (acute congestive) and wide-angle (chronic simple) types, based on the configuration of the angle of the anterior chamber where the aqueous humor is reabsorbed.

Narrow-angle glaucoma is nearly always a medical emergency in which drugs are essential in controlling the acute attack, but the long-range management is often surgical (*e.g.*, peripheral or complete iridectomy). Wide-angle glaucoma, on the other hand, has a gradual, insidious onset and is not generally amenable to surgical improvement; in this type, control of intraocular pressure usually is dependent upon continuous drug therapy.

Since the cholinergic agonists and ChE inhibitors also block accommodation and induce myopia, these agents produce transient

blurring of far vision, limited visual acuity in low light, and loss of vision at the margin when instilled in the eye. With long-term administration of the cholinergic agonists and anti-ChE agents, the compromise of vision diminishes. Nevertheless, other agents without these side effects, such as β adrenergic receptor antagonists, prostaglandin analogs, or carbonic anhydrase inhibitors, have become the primary topical therapies for open-angle glaucoma (Alward, 1998) (*see Chapter 63*), with AChE inhibitors held in reserve for the chronic conditions when patients become refractory to the above agents. Topical treatment with long-acting ChE inhibitors such as echothiophate gives rise to symptoms characteristic of systemic ChE inhibition. Echothiophate treatment in advanced glaucoma may be associated with the production of cataracts (Alward, 1998).

Anti-ChE agents have been employed locally in the treatment of a variety of other less common ophthalmologic conditions, including accommodative esotropia and myasthenia gravis confined to the extraocular and eyelid muscles. Adie (or tonic pupil) syndrome results from dysfunction of the ciliary body, perhaps because of local nerve degeneration. Low concentrations of physostigmine are reported to decrease the blurred vision and pain associated with this condition. In alternation with a mydriatic drug such as atropine, short-acting anti-ChE agents have proven useful for breaking adhesions between the iris and the lens or cornea. (For a complete account of the use of anti-ChE agents in ocular therapy, *see Chapter 63*.)

Myasthenia Gravis. Myasthenia gravis is a neuromuscular disease characterized by weakness and marked fatigability of skeletal muscle (Drachman, 1994); exacerbations and partial remissions occur frequently. Jolly noted the similarity between the symptoms of myasthenia gravis and curare poisoning in animals and suggested that physostigmine, an agent then known to antagonize curare, might be of therapeutic value. Forty years elapsed before his suggestion was given systematic trial.

The defect in myasthenia gravis is in synaptic transmission at the neuromuscular junction. When a motor nerve of a normal subject is stimulated at 25 Hz, electrical and mechanical responses are well sustained. A suitable margin of safety exists for maintenance of neuromuscular transmission. Initial responses in the myasthenic patient may be normal, but they diminish rapidly, which explains the difficulty in maintaining voluntary muscle activity for more than brief periods.

The relative importance of prejunctional and postjunctional defects in myasthenia gravis was a matter of considerable debate until Patrick and Lindstrom found that rabbits immunized with the nicotinic receptor purified from electric eels slowly developed muscular weakness and respiratory difficulties that resembled the symptoms of myasthenia gravis. The rabbits also exhibited decremental responses following repetitive nerve stimulation, enhanced sensitivity to curare, and following the administration of anti-AChE agents, symptomatic and electrophysiological improvement of neuromuscular transmission. Although this experimental allergic myasthenia gravis and the naturally occurring disease differ somewhat, this animal model prompted intense investigation into whether the natural disease represented an autoimmune response directed toward the ACh receptor. Antireceptor antibodies are detectable in sera of 90% of patients with the disease, although the clinical status of the patient does not correlate precisely with the antibody titer (Drachman *et al.*, 1982; Drachman, 1994; Lindstrom, 2000).

The picture that emerges is that myasthenia gravis is caused by an autoimmune response primarily to the ACh receptor at the postjunctional endplate. These antibodies reduce the number of recep-

tors detectable either by snake α -neurotoxin-binding assays (Fambrough *et al.*, 1973) or by electrophysiological measurements of ACh sensitivity (Drachman, 1994). The autoimmune reaction enhances receptor degradation (Drachman *et al.*, 1982). Immune complexes along with marked ultrastructural abnormalities appear in the synaptic cleft and enhance receptor degradation. These events appear to be a consequence of complement-mediated lysis of junctional folds in the endplate. A related disease that also compromises neuromuscular transmission is Lambert-Eaton syndrome. Here, antibodies are directed against Ca^{2+} channels that are necessary for presynaptic release of ACh (Lang *et al.*, 1998).

In a subset of approximately 10% of patients presenting with a myasthenic syndrome, muscle weakness has a congenital rather than an autoimmune basis. Characterization of biochemical and genetic bases of the congenital condition has shown mutations to occur in the acetylcholine receptor which affect ligand-binding and channel-opening kinetics (Engel *et al.*, 2003). Other mutations occur as a deficiency in the form of AChE that contains the collagen-like tail unit (Ohno *et al.*, 2000). As expected, following administration of anti-ChE agents (*see below*), subjective improvement is not seen in most congenital myasthenic patients.

Diagnosis. Although the diagnosis of autoimmune myasthenia gravis usually can be made from the history, signs, and symptoms, its differentiation from certain neurasthenic, infectious, endocrine, congenital, neoplastic, and degenerative neuromuscular diseases can be challenging. However, myasthenia gravis is the only condition in which the aforementioned deficiencies can be improved dramatically by anti-ChE medication. The edrophonium test for evaluation of possible myasthenia gravis is performed by rapid intravenous injection of 2 mg of *edrophonium chloride*, followed 45 seconds later by an additional 8 mg if the first dose is without effect; a positive response consists of brief improvement in strength, unaccompanied by lingual fasciculation (which generally occurs in nonmyasthenic patients).

An excessive dose of an anti-ChE drug results in a *cholinergic crisis*. The condition is characterized by weakness resulting from generalized depolarization of the motor endplate; other features result from overstimulation of muscarinic receptors. The weakness resulting from depolarization block may resemble myasthenic weakness, which is manifest when anti-ChE medication is insufficient. The distinction is of obvious practical importance, since the former is treated by withholding, and the latter by administering, the anti-ChE agent. When the edrophonium test is performed cautiously, limiting the dose to 2 mg and with facilities for respiratory resuscitation available, a further decrease in strength indicates cholinergic crisis, while improvement signifies myasthenic weakness. *Atropine sulfate*, 0.4 to 0.6 mg or more intravenously, should be given immediately if a severe muscarinic reaction ensues (for complete details, *see* Osserman *et al.*, 1972; Drachman, 1994). Detection of anti-receptor antibodies in muscle biopsies or plasma is now widely employed to establish the diagnosis.

Treatment. Pyridostigmine, neostigmine, and ambenonium are the standard anti-ChE drugs used in the symptomatic treatment of myasthenia gravis. All can increase the response of myasthenic muscle to repetitive nerve impulses, primarily by the preservation of endogenous ACh. Following AChE inhibition, receptors over a greater cross-sectional area of the endplate presumably are exposed to concentrations of ACh that are sufficient for channel opening and production of a postsynaptic endplate potential.

When the diagnosis of myasthenia gravis has been established, the optimal single oral dose of an anti-ChE agent can be determined

empirically. Baseline recordings are made for grip strength, vital capacity, and a number of signs and symptoms that reflect the strength of various muscle groups. The patient then is given an oral dose of pyridostigmine (30 to 60 mg), neostigmine (7.5 to 15 mg), or ambenonium (2.5 to 5 mg). The improvement in muscle strength and changes in other signs and symptoms are noted at frequent intervals until there is a return to the basal state. After an hour or longer in the basal state, the drug is given again, with the dose increased to one and one-half times the initial amount, and the same observations are repeated. This sequence is continued, with increasing increments of one-half the initial dose, until an optimal response is obtained.

The duration of action of these drugs is such that the interval between oral doses required to maintain a reasonably even level of strength usually is 2 to 4 hours for neostigmine, 3 to 6 hours for pyridostigmine, or 3 to 8 hours for ambenonium. However, the dose required may vary from day to day, and physical or emotional stress, intercurrent infections, and menstruation usually necessitate an increase in the frequency or size of the dose. In addition, unpredictable exacerbations and remissions of the myasthenic state may require adjustment of dosage. Although myasthenia gravis requires physician care at regular intervals, most patients can be taught to modify their dosage regimens according to their changing requirements. Pyridostigmine is available in sustained-release tablets containing a total of 180 mg, of which 60 mg is released immediately and 120 mg over several hours; this preparation is of value in maintaining patients for 6- to 8-hour periods, but should be limited to use at bedtime. Muscarinic cardiovascular and gastrointestinal side effects of anti-ChE agents generally can be controlled by atropine or other anticholinergic drugs (*see* Chapter 7). However, these anticholinergic drugs mask many side effects of an excessive dose of an anti-ChE agent. In most patients, tolerance develops eventually to the muscarinic effects, so that anticholinergic medication is not necessary. A number of drugs, including curariform agents and certain antibiotics and general anesthetics, interfere with neuromuscular transmission (*see* Chapter 9); their administration to patients with myasthenia gravis is hazardous without proper adjustment of anti-ChE dosage and other appropriate precautions.

Other therapeutic measures should be considered as essential elements in the management of this disease. Controlled studies reveal that glucocorticoids promote clinical improvement in a high percentage of patients. However, when treatment with steroids is continued over prolonged periods, a high incidence of side effects may result (*see* Chapter 59). Gradual lowering of maintenance doses and alternate-day regimens of short-acting steroids are used to minimize side effects. Initiation of steroid treatment augments muscle weakness; however, as the patient improves with continued administration of steroids, doses of anti-ChE drugs can be reduced (Drachman, 1994). Other immunosuppressive agents such as *azathioprine* and *cyclosporine* also have been beneficial in more advanced cases (*see* Chapter 52).

Thymectomy should be considered in myasthenia associated with a thymoma or when the disease is not controlled adequately by anti-ChE agents and steroids. The relative risks and benefits of the surgical procedure *versus* anti-ChE and glucocorticoid treatment require careful assessment in each case. Since the thymus contains myoid cells with nicotinic receptors (Schluep *et al.*, 1987), and a predominance of patients have thymic abnormalities, the thymus may be responsible for the initial pathogenesis. It also is the source of autoreactive T-helper cells. However, the thymus is not required for perpetuation of the condition.

In keeping with the presumed autoimmune etiology of myasthenia gravis, plasmapheresis and immune therapy have produced beneficial results in patients who have remained disabled despite thymectomy and treatment with steroids and anti-ChE agents (Drachman, 1994; Drachman, 1996). Improvement in muscle strength correlates with the reduction of the titer of antibody directed against the nicotinic ACh receptor.

Prophylaxis in Cholinesterase Inhibitor Poisoning. Studies in experimental animals have shown that pretreatment with pyridostigmine reduces the incapacitation and mortality associated with nerve agent poisoning, particularly for agents such as soman that show rapid aging. The first large-scale administration of pyridostigmine to humans occurred in 1990 in anticipation of nerve-agent attack in the first Persian Gulf War. At an oral dose of 30 mg every 8 hours, the incidence of side effects was around 1%, but fewer than 0.1% of the subjects had responses sufficient to warrant discontinuing the drug in the setting of military action (Keeler *et al.*, 1991). Long-term follow-up indicates that veterans of the Persian Gulf War who received pyridostigmine showed a low incidence of a neurologic syndrome, now termed the *Persian Gulf War syndrome*. It is characterized by impaired cognition, ataxia, confusion, myoneuropathy, adenopathy, weakness, and incontinence (Haley *et al.*, 1997; Institute of Medicine, 2003). While pyridostigmine has been implicated by some as the causative agent, the absence of similar neuropathies in pyridostigmine-treated myasthenic patients makes it far more likely that a combination of agents, including combusted organophosphates and insect repellents in addition to pyridostigmine, contributed to this persisting syndrome. It also is difficult to distinguish residual chemical toxicity from posttraumatic stress experienced after combat action. Pyridostigmine has recently been approved by the FDA for prophylaxis against soman, an organophosphate that rapidly ages following inhibition of cholinesterases.

Intoxication by Anticholinergic Drugs. In addition to atropine and other muscarinic agents, many other drugs, such as the phenothiazines, antihistamines, and tricyclic antidepressants, have central and peripheral anticholinergic activity. Physostigmine is potentially useful in reversing the central anticholinergic syndrome produced by overdose or an unusual reaction to these drugs (Nilsson, 1982). The effectiveness of physostigmine in reversing the anticholinergic effects of these agents has been clearly documented. However, other toxic effects of the tricyclic antidepressants and phenothiazines (see Chapters 17 and 18), such as intraventricular conduction deficits and ventricular arrhythmias, are not reversed by physostigmine. In addition, physostigmine may precipitate seizures; hence, its usually small potential benefit must be weighed against this risk. The initial intravenous or intramuscular dose of physostigmine is 2 mg, with additional doses given as necessary. Physostigmine, a tertiary amine, crosses the blood-brain barrier, in contrast to the quaternary anti-AChE drugs. The use of anti-ChE agents to reverse the effects of competitive neuromuscular blocking agents is discussed in Chapter 9.

Alzheimer's Disease. A deficiency of intact cholinergic neurons, particularly those extending from subcortical areas such as the nucleus basalis of Meynert, has been observed in patients with progressive dementia of the Alzheimer type (Markesbery, 1998). Using a rationale similar to that in other CNS degenerative diseases (see Chapter 20), therapy for enhancing concentrations of cholinergic

neurotransmitters in the CNS was investigated (Mayeux and Sano, 1999). In 1993, the FDA approved tacrine (tetrahydroaminoacridine) for use in mild to moderate Alzheimer's disease, but a high incidence of hepatotoxicity limits the utility of this drug. About 30% of the patients receiving low doses of tacrine within 3 months have alanine aminotransferase values three times normal; upon discontinuing the drug, liver function values return to normal in 90% of the patients. Other side effects are typical of AChE inhibitors.

More recently, donepezil was approved for clinical use. At 5- and 10-mg daily oral doses, improved cognition and global clinical function were seen in the 21- to 81-week intervals studied (Dooley and Lamb, 2000). In long-term studies, the drug delayed symptomatic progression of the disease for periods up to 55 weeks. Side effects are largely attributable to excessive cholinergic stimulation, with nausea, diarrhea, and vomiting being most frequently reported. The drug is well tolerated in single daily doses. Usually, 5-mg doses are administered at night for 4 to 6 weeks; if this dose is well tolerated, the dose can be increased to 10 mg daily.

Rivastigmine, a long-acting carbamoylating inhibitor, recently has been approved for use in the United States and Europe. Although fewer studies have been conducted, its efficacy, tolerability, and side effects are similar to those of donepezil (Corey-Bloom *et al.*, 1998; Giacobini, 2000). *Eptastigmine*, another carbamoylating inhibitor, was associated with adverse hematologic effects in two studies, resulting in suspension of clinical trials. Galantamine is another AChE inhibitor recently approved by the FDA. It has a side-effect profile similar to those of donepezil and rivastigmine.

Therapeutic strategies with new compounds are directed at maximizing the ratio of central to peripheral ChE inhibition and the use of ChE inhibitors in conjunction with selective cholinergic agonists and antagonists. Combination therapy and other therapeutic strategies are presented in Chapter 20.

AGENTS ACTING AT THE NEUROMUSCULAR JUNCTION AND AUTONOMIC GANGLIA

Palmer Taylor

The nicotinic acetylcholine (ACh) receptor mediates neurotransmission postsynaptically at the neuromuscular junction and peripheral autonomic ganglia; in the CNS, it largely controls release of neurotransmitters from presynaptic sites. The receptor is called *nicotinic acetylcholine receptor* because it is stimulated by both the neurotransmitter ACh and the alkaloid *nicotine*. Distinct subtypes of nicotinic receptors exist at the neuromuscular junction and the ganglia, and several pharmacological agents that act at these receptors discriminate between them. Neuromuscular blocking agents are distinguished by whether they cause depolarization of the motor end plate and thus are classified either as *competitive (stabilizing)* agents, of which *curare* is the classical example, or as *depolarizing* agents, such as *succinylcholine*. The competitive and depolarizing agents are used widely to achieve muscle relaxation during anesthesia. Ganglionic agents act by stimulating or blocking nicotinic receptors on the postganglionic neuron.

THE NICOTINIC ACETYLCHOLINE RECEPTOR

The concept of the nicotinic ACh receptor, with which ACh combines to initiate the end-plate potential (EPP) in muscle or an excitatory postsynaptic potential (EPSP) in peripheral ganglia, was introduced in Chapter 6. Classical studies of the actions of curare and nicotine made this the prototypical pharmacological receptor over a century ago. By taking advantage of specialized structures that have evolved to mediate cholinergic neurotransmission and natural toxins that block motor

activity, peripheral and then central nicotinic receptors were isolated and characterized. These accomplishments represent landmarks in the development of molecular pharmacology.

The electrical organs from the aquatic species of *Electrophorus* and, especially, *Torpedo* provide rich sources of nicotinic receptor. The electrical organ is derived embryologically from myoid tissue; however, in contrast to skeletal muscle, up to 40% of the surface of the membrane is excitable and contains cholinergic receptors. In vertebrate skeletal muscle, motor end plates occupy 0.1% or less of the cell surface. The discovery of seemingly irreversible antagonism of neuromuscular transmission by α toxins from venoms of the krait, *Bungarus multicinctus*, or varieties of the cobra, *Naja naja*, offered suitable markers for identification of the receptor. The α toxins are peptides of about 7000 daltons. Radioisotope-labeled toxins were used by Changeux and colleagues in 1970 to assay the isolated cholinergic receptor *in vitro* (see Changeux and Edelman, 1998). The α toxins have extremely high affinities and slow rates of dissociation from the receptor, yet the interaction is non-covalent. *In situ* and *in vitro*, their behavior resembles that expected for a high-affinity antagonist. Since cholinergic neurotransmission mediates motor activity in marine vertebrates and mammals, a large number of peptide, terpenoid, and alkaloid toxins that block the nicotinic receptors have evolved to enhance predation or protect plant and animal species from predation (Taylor *et al.*, 2000).

Purification of the receptor from *Torpedo* ultimately led to isolation of complementary DNAs (cDNAs) that encode each of the subunits. These cDNAs, in turn, permitted the cloning of genes encoding the multiple receptor subunits from mammalian neurons and muscle (Numa *et al.*, 1983). By simultaneously expressing the genes that encode the individual subunits in cellular systems in various permutations and by measuring binding and the electrophysiological events that result from activation by agonists, researchers have been able to correlate functional properties with details of primary structures of the receptor subtypes (Lindstrom, 2000; Karlin, 2002).

Nicotinic Receptor Structure. The nicotinic receptor of the electrical organ and vertebrate skeletal muscle is a pentamer composed of four distinct subunits (α , β , γ , and δ) in the stoichiometric ratio

of 2:1:1:1, respectively. In mature, innervated muscle end plates, the γ subunit is replaced by ε , a closely related subunit. The individual subunits are about 40% identical in their amino acid sequences, arising from a common primordial gene.

The nicotinic receptor became the prototype for other pentameric ligand-gated ion channels, which include the receptors for the inhibitory amino acids (γ -aminobutyric acid and glycine) and certain serotonin (5-HT₃) receptors. Each of the subunits in the pentameric receptor has a molecular mass of 40,000 to 60,000 daltons. The amino-terminal 210 residues constitute virtually all the extracellular domain. This is followed by four transmembrane-spanning (TM) domains; the region between the third and fourth domains forms most of the cytoplasmic component (Figure 9–1).

Each of the subunits within the nicotinic ACh receptor has an extracellular and an intracellular exposure on the postsynaptic membrane. The five subunits are arranged around a pseudo-axis of symmetry to circumscribe an internally located channel (Changeux and Edelstein, 1998; Karlin, 2000). The receptor is an asymmetrical molecule (14 × 8 nm) of 250,000 daltons, with the bulk of the non-membrane-spanning domain on the extracellular surface. In junctional areas (*i.e.*, the motor end plate in skeletal muscle and the ventral surface of the electrical organ), the receptor is present at high densities (10,000/ μm^2) in a regular packing order. This ordering of the receptors has allowed electron microscopic image reconstruction of its molecular structure (Figure 9–2).

An ACh-binding protein homologous to only the extracellular domain of the nicotinic receptor has been identified in fresh- and saltwater snails and characterized structurally and pharmacologically (Brejc *et al.*, 2001). This protein assembles as a homomeric pentamer and binds nicotinic receptor ligands with the expected selec-

tivity; its crystal structure reveals an atomic organization expected of the nicotinic receptor. Moreover, fusion of the ACh-binding protein and the transmembrane spans of the receptor yields a functional protein that exhibits the channel gating and changes in state expected of the receptor (Bouzat *et al.*, 2004). This binding protein serves as both a structural and functional surrogate of the receptor and has provided a detailed understanding of the determinants governing ligand specificity of the nicotinic receptor.

The agonist-binding sites are found at the subunit interfaces, but in muscle, only two of the five subunit interfaces, $\alpha\gamma$ and $\alpha\delta$, have evolved to bind ligands. The binding of agonists, reversible competitive antagonists, and the elapid α toxin is mutually exclusive and involves overlapping surfaces on the receptor. Both subunits forming the subunit interface contribute to ligand specificity.

Measurements of membrane conductances demonstrate that rates of ion translocation are sufficiently rapid (5×10^7 ions per second) to require ion translocation through an open channel rather than by a rotating carrier of ions. Moreover, agonist-mediated changes in ion permeability (typically an inward movement of primarily Na⁺ and secondarily Ca²⁺) occur through a cation channel intrinsic to the receptor structure. The second transmembrane-spanning region on each of the five subunits forms the internal perimeter of the channel. The agonist-binding site is intimately coupled with an ion channel; in the muscle receptor, simultaneous binding of two agonist molecules results in a rapid conformational change that opens the channel. Both the binding and gating response show positive cooperativity. Details on the kinetics of channel opening have evolved from electrophysiological patch-clamp techniques that distinguish the individual opening and closing events of a single receptor molecule (Sakmann, 1992).

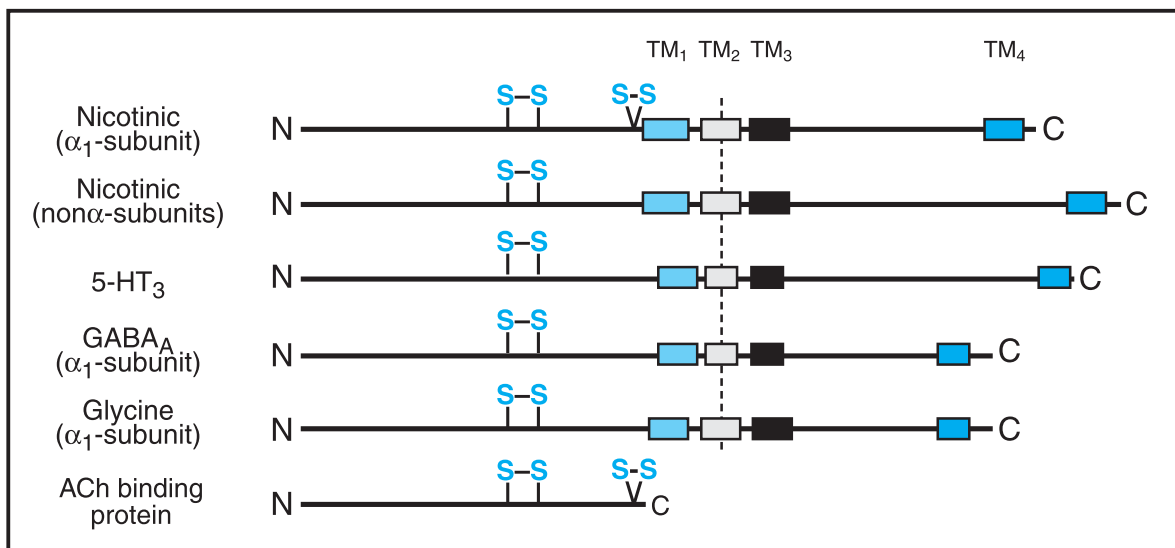

Figure 9–1. Subunit organization of pentameric ligand-gated ion channels and the ACh binding protein. For each receptor, the amino terminal region of about 210 amino acids is found in the extracellular surface. It is then followed by four hydrophobic regions that span the membrane (TM₁–TM₄), leaving the small carboxyl terminus on the extracellular surface. The TM₂ region is α -helical, and TM₂ regions from each subunit of the pentameric receptor line the internal pore of the receptor. Two disulfide loops at positions 128–142 and 192–193 are found in the α -subunit of the nicotinic receptor. The 128–142 motif is conserved in the family of receptors, whereas the vicinal cysteines at 192 and 193 distinguish α -subunits and the acetylcholine binding protein from β , γ , δ , and ε in the nicotinic receptor.

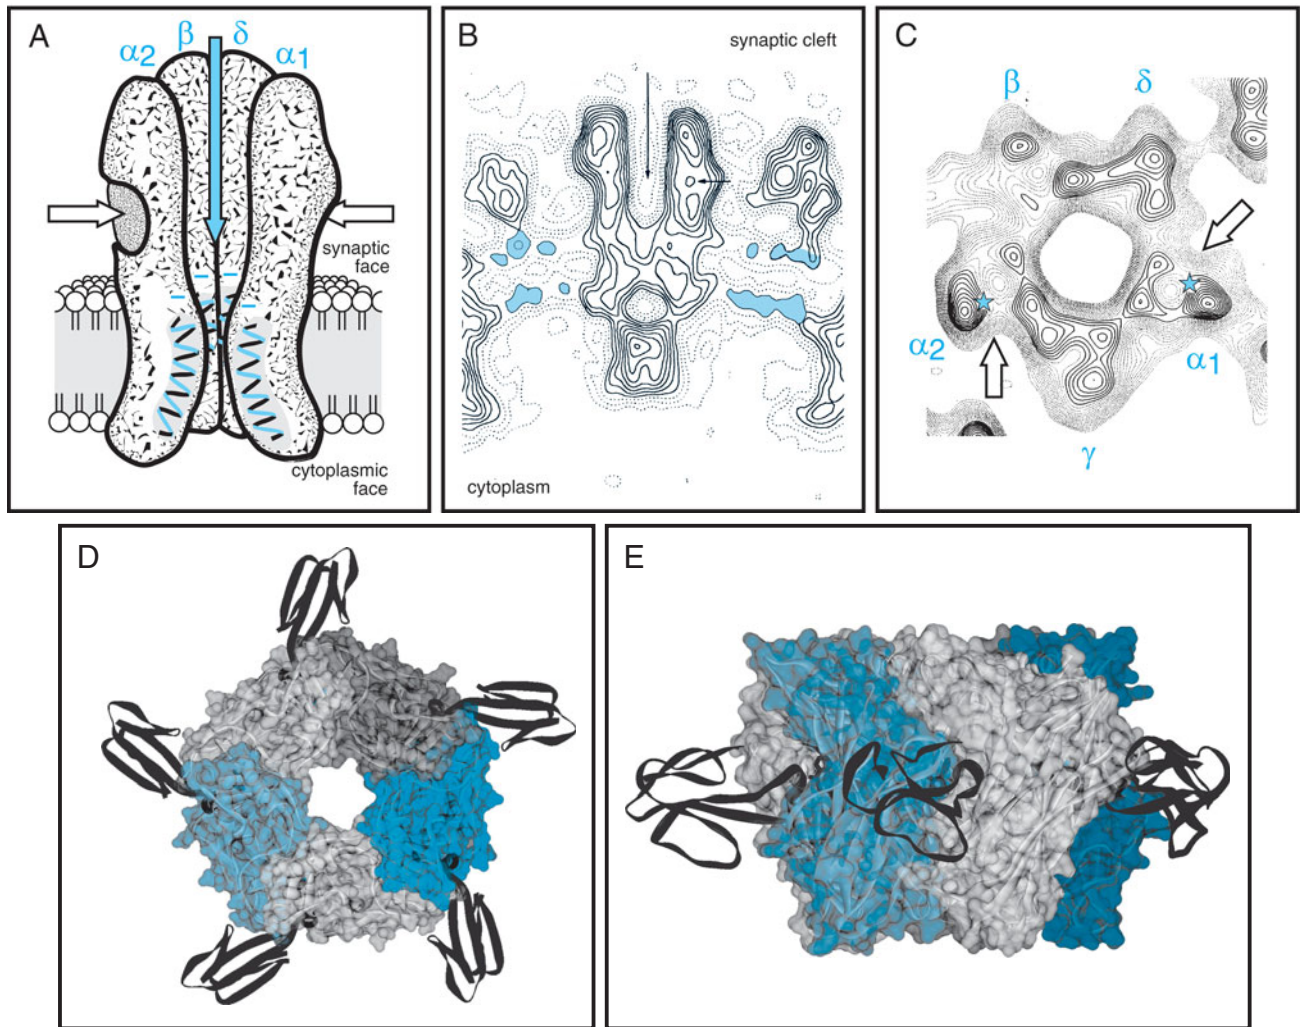

Figure 9–2. Molecular structure of the nicotinic acetylcholine receptor. *A.* Longitudinal view with the γ subunit removed. The remaining subunits, two copies of α , one of β , and one of δ , are shown to surround an internal channel with an outer vestibule and its constriction located deep in the membrane bilayer region. Spans of α -helices with slightly bowed structures form the perimeter of the channel and come from the TM₂ region of the linear sequence (see Figure 9–1). Acetylcholine (ACh)–binding sites, indicated by arrows, are found at the $\alpha\gamma$ and $\alpha\delta$ (not visible) interfaces. Panels *B* and *C* show data on which the structure is based. *B.* Longitudinal view of the electron density of receptor molecules packed in a tubular membrane. Arrows indicate the synaptic surface entry to the pore and agonist site. The additional density in the cytoplasmic region below the receptor arises from an anchoring protein attached to the receptor. *C.* Cross-sectional view of the image-reconstructed electron density taken 30 Å above the plane of the membrane. Pseudofivefold symmetry is evident. The arrows denote the presumed route of entry of the ligand (ACh) to the binding site (shown by the star). α_1 and α_2 in this panel are identical in sequence; the numeric designations show that there are two copies of the α -subunit in the pentamer (see Unwin, 1993 and 2005). The ACh binding protein (panels *D* and *E*) is homologous to the extracellular domain of the nicotinic receptor (see Figure 9–1). The protein is a homopentamer that binds nicotinic receptor ligands with the expected selectivity and, when fused with the TM portions of the receptor, yields a functional ligand-gated channel. The subunit structure of the ACh binding protein is clear from the top view (panel *D*) and side view (panel *E*).

NEURONAL ACETYLCHOLINE RECEPTOR COMPOSITION AND STRUCTURE

Cloning by sequence homology identified the genes encoding the vertebrate nicotinic receptor. Neuronal nicotinic receptors found in ganglia and the CNS also exist as pentamers of one, two, or more subunits. Although only a single subunit of the α -type sequence (denoted as $\alpha 1$) is found in abundance in muscle, along with β , δ , and γ or ϵ , at least eight subtypes of α ($\alpha 2$ through $\alpha 9$) and three of the non- α type (designated as $\beta 2$ through $\beta 4$) are found in neuronal tissues. Although not all permutations of α and β subunits lead to functional receptors, the diversity in subunit composition is large and exceeds the capacity of ligands to distinguish subtypes on the basis of their selectivity. Studies of neuronal receptor subunit abundance and associations in brain and the periphery have enabled investigators to identify subunit combinations that confer function. For example, the $\alpha 3/\beta 4$ and $\alpha 3/\beta 2$ subtypes are prevalent in peripheral ganglia, whereas the $\alpha 4/\beta 2$ subtype is most prevalent in brain. The subtypes $\alpha 2$ through $\alpha 6$ and $\beta 2$ through $\beta 4$ associate as heteromeric pentamers composed of two or three distinct subtypes, whereas $\alpha 7$ through $\alpha 9$ often are seen as homomeric associations. Distinctive selectivities of the receptor subtypes for Na^+ and Ca^{2+} suggest that certain subtypes may possess functions other than rapid trans-synaptic signaling.

NEUROMUSCULAR BLOCKING AGENTS

History, Sources, and Chemistry. *Curare* is a generic term for various South American arrow poisons. The drug has a long and romantic history. It has been used for centuries by the Indians along the Amazon and Orinoco Rivers for immobilizing and paralyzing wild animals used for food; death results from paralysis of skeletal muscles. The preparation of curare was long shrouded in mystery and was entrusted only to tribal witch doctors. Soon after the discovery of the American continent, Sir Walter Raleigh and other early explorers and botanists became interested in curare, and late in the sixteenth century, samples of the native preparations were brought to Europe. Following the pioneering work of the scientist/explorer von Humboldt in 1805, the botanical sources of curare became the object of much field research. The curares from eastern Amazonia come from *Strychnos* species. These and other South American species of *Strychnos* contain chiefly quaternary neuromuscular-blocking alkaloids, whereas the Asiatic, African, and Australian species nearly all contain tertiary strychnine-like alkaloids.

Curare was the important tool that Claude Bernard used to demonstrate a locus of drug action at or near the nerve terminations of muscle. The modern clinical use of curare apparently dates from 1932, when West employed highly purified fractions in patients with tetanus and spastic disorders. Research on curare was acceler-

ated greatly by the work of Gill, who, after prolonged and intimate study of the native methods of preparing curare, brought to the United States a sufficient amount of the authentic drug to permit chemical and pharmacological investigations. Griffith and Johnson reported the first trial of curare for promoting muscular relaxation in general anesthesia in 1942. Details of the fascinating history of curare, its nomenclature, and the chemical identification of the curare alkaloids are presented in previous editions of this book.

King established the essential structure of *tubocurarine* in 1935 (Figure 9-3). A synthetic derivative, *metocurine* (formerly called *dimethyl tubocurarine*), contains three additional methyl groups, one of which quaternizes the second nitrogen; the other two form methyl ethers at the phenolic hydroxyl groups. This compound possesses two to three times the potency of tubocurarine in human beings. The most potent curare alkaloids are the toxiferines, obtained from *Strychnos toxifera*. A semisynthetic derivative, *alcuronium chloride* (*N,N'*-diallylnortoxiferinium dichloride), was widely used clinically in Europe and elsewhere. The seeds of the trees and shrubs of the genus *Erythrina*, widely distributed in tropical and subtropical areas, contain erythroidines that possess curare-like activity.

Gallamine is one of a series of synthetic substitutes for curare described by Bovet and coworkers in 1949. Early structure-activity studies led to the development of the polymethylene bis-trimethylammonium series (referred to as the *methonium compounds*). The most potent agent at the neuromuscular junction was found when the chain contained 10 carbon atoms—*decamethonium* (C10) (Figure 9-3). The member of the series containing 6 carbon atoms in the chain—*hexamethonium* (C6)—was found to be essentially devoid of neuromuscular blocking activity but is particularly effective as a ganglionic blocking agent (see below).

Classification and Chemical Properties of Neuromuscular Blocking Agents

At present, only a single depolarizing agent, succinylcholine, is in general clinical use, whereas multiple competitive or nondepolarizing agents are available (Figure 9-3). Therapeutic selection should be based on achieving a pharmacokinetic profile consistent with the duration of the interventional procedure and minimizing cardiovascular compromise or other side effects (Table 9-1). Two general classifications are useful because they are helpful in distinguishing side effects and pharmacokinetic behavior. The first relates to the duration of drug action, and these agents are categorized as long-, intermediate-, and short-acting. The persistent blockade and difficulty in complete reversal after surgery with D-tubocurarine, metocurine, *pancuronium*, and *doxacurium* led to the development of *vecuronium* and *atracurium*, agents of intermediate duration. This was followed by the development of a short-acting agent, *mivacurium*. Often the long-acting agents are the more potent, requiring the use of low concentrations. The necessity of administering potent agents in low concentrations delays their onset. *Rocuronium* is an agent of intermediate duration but of rapid onset and lower potency. Its rapid onsets allows it

Table 9-1
Classification of Neuromuscular Blocking Agents

AGENT	CHEMICAL CLASS	PHARMACOLOGICAL PROPERTIES	TIME OF ONSET, MIN	CLINICAL DURATION, MIN	MODE OF ELIMINATION
Succinylcholine (ANECTINE, others)	Dicholine ester	Ultrashort duration; depolarizing	1–1.5	5–8	Hydrolysis by plasma cholinesterases
D-Tubocurarine	Natural alkaloid (cyclic benzylisoquinoline)	Long duration; competitive	4–6	80–120	Renal elimination; liver clearance
Atracurium (TRACRIUM)	Benzylisoquinoline	Intermediate duration; competitive	2–4	30–60	Hofmann degradation; hydrolysis by plasma esterases; renal elimination
Doxacurium (NUROMAX)	Benzylisoquinoline	Long duration; competitive	4–6	90–120	Renal elimination
Mivacurium (MIVACRON)	Benzylisoquinoline	Short duration; competitive	2–4	12–18	Hydrolysis by plasma cholinesterases
Pancuronium (PAVULON)	Ammonio steroid	Long duration; competitive	4–6	120–180	Renal elimination
Pipecuronium (ARDUAN)	Ammonio steroid	Long duration; competitive	2–4	80–100	Renal elimination; liver metabolism and clearance
Rocuronium (ZEMURON)	Ammonio steroid	Intermediate duration; competitive	1–2	30–60	Liver metabolism
Vecuronium (NORCURON)	Ammonio steroid	Intermediate duration; competitive	2–4	60–90	Liver metabolism and clearance; renal elimination

to be used as an alternative to succinylcholine in rapid-induction anesthesia and in relaxing the laryngeal and jaw muscles to facilitate tracheal intubation (Bevan, 1994; Savarese *et al.*, 2000).

The second useful classification is derived from the chemical nature of the agents and includes the natural alkaloids or their congeners, the ammonio steroids, and the benzylisoquinolines (Table 9-1). The natural alkaloid D-tubocurarine and the semisynthetic alkaloid alcuronium seldom are used. Apart from a shorter duration of action, the newer agents exhibit greatly diminished frequency of side effects, chief of which are ganglionic blockade, block of vagal responses, and histamine release. The prototype ammonio steroid, pancuronium, induces virtually no histamine release; however, it blocks muscarinic receptors, and this antagonism is manifested primarily in vagal blockade and tachycardia. Tachycardia is eliminated in the newer ammonio steroids, vecuronium and rocuronium.

The benzylisoquinolines appear to be devoid of vagolytic and ganglionic blocking actions but show a slight propensity for histamine release. The unusual metabolism of the prototype compound atracurium and its newer congener mivacurium confers special indications for use of these compounds. For example, atracurium's disappearance from the body depends on hydrolysis of the ester moiety by plasma esterases and by a spontaneous or Hofmann degradation (cleavage of the *N*-alkyl portion in the benzylisoquinoline). Hence two routes for degradation are available, both of which remain functional in renal failure. Mivacurium is extremely sensitive to catalysis by cholinesterase or other plasma hydrolases, therein accounting for its short duration of action.

Structure–Activity Relationships. Several structural features distinguish competitive and depolarizing neuromuscular blocking agents. The competitive agents (*e.g.*, tubocurarine, the benzylisoquinolines, and the ammonio steroids) are relatively bulky, rigid molecules, whereas the depolarizing agents [*e.g.*, *decamethonium* (no longer

marketed in the United States) and succinylcholine] generally have more flexible structures that enable free bond rotations (Figure 9–3). While the distance between quaternary groups in the flexible depolarizing agents can vary up to the limit of the maximal bond distance (1.45 nm for decamethonium), the distance for the rigid competitive blockers is typically 1.0 ± 0.1 nm. L-Tubocurarine is considerably less potent than D-tubocurarine, perhaps because the D-isomer has all the hydrophilic groups localized uniquely to one surface.

Pharmacological Properties

Skeletal Muscle. A localized paralytic action of curare was first described by Claude Bernard in the 1850s. That the site of action of D-tubocurarine and other competitive blocking agents was the motor end plate (a thickened region of postjunctional membrane) subsequently was established by fluorescence and electron microscopy, microiontophoretic application of drugs, patch-clamp analysis of single channels, and intracellular recording. Competitive antagonists combine with the nicotinic ACh receptor at the end plate and thereby competitively block the binding of ACh. When the drug is applied directly to the end plate of a single isolated muscle fiber, the muscle cell becomes insensitive to motor-nerve impulses and to directly applied ACh; however, the end-plate region and the remainder of the muscle fiber membrane retain their normal sensitivity to K^+ depolarization, and the muscle fiber still responds to direct electrical stimulation.

To analyze further the action of antagonists at the neuromuscular junction, consider certain details of receptor activation by ACh. The steps involved in ACh release by the nerve action potential, the development of miniature end-plate potentials (MEPPs), their summation to form a postjunctional end-plate potential (EPP), the triggering of the muscle action potential, and contraction were described in Chapter 6. Biophysical studies with patch electrodes revealed that the fundamental event elicited by ACh or other agonists is an “all or none” opening and closing of the individual receptor channels, which gives rise to a squarewave pulse with an average open-channel conductance of 20 to 30 ps and a duration that is exponentially distributed around a time of about 1 ms. The *duration* of channel opening is far more dependent on the nature of the agonist than is the magnitude of the open-channel conductance (*see* Sakmann, 1992).

Increasing concentrations of the competitive antagonist tubocurarine diminish progressively the amplitude of the excitatory postjunctional EPP. The amplitude of this potential may fall to below 70% of its initial value before it is insufficient to initiate the propagated muscle action potential; this provides a safety factor in neuromuscular transmission. Analysis of the antagonism of tubocurarine on single-channel events shows that, as expected for a competitive antagonist, tubocurarine reduces the frequency of channel-opening events but does not affect the conductance or duration of opening for a single channel (Katz and Miledi, 1978). At higher concentrations, curare and other competitive antagonists block the channel directly in a fashion that is noncompetitive with agonists and dependent on membrane potential (Colquhoun *et al.*, 1979).

The decay time of the MEPP is of the same duration as the average lifetime of channel opening (1 to 2 ms). Since the MEPPs are a consequence of the spontaneous release of one or more quanta of ACh ($\sim 10^5$ molecules), individual molecules of ACh released into the synapse have only a transient opportunity to activate the receptor and do not rebind successively to receptors to activate multiple channels before being hydrolyzed by acetylcholinesterase. The concentration of unbound ACh in the synapse from nerve-released ACh diminishes more rapidly than does the decay of the EPP (or current).

If anticholinesterase (anti-ChE) drugs are present, the EPP is prolonged up to 25 to 30 ms, which is indicative of the rebinding of transmitter to neighboring receptors before diffusion from the synapse. It is therefore not surprising that anti-ChE agents and tubocurarine act in opposing directions, since increasing the duration of ACh retention in the synapse should favor occupation of the receptor by transmitter and displace tubocurarine.

Simultaneous binding by two agonist molecules at the respective $\alpha\gamma$ and $\alpha\delta$ subunit interfaces of the receptor is required for activation. Activation shows positive cooperativity and thus occurs over a narrow range of concentrations (Sine and Claudio, 1991; Changeux and Edelman, 1998). Although two competitive antagonist or snake *a*-toxin molecules can bind to each receptor molecule at the agonist sites, the binding of one molecule of antagonist to each receptor is sufficient to render it nonfunctional (Taylor *et al.*, 1983).

The depolarizing agents, such as succinylcholine, act by a different mechanism. Their initial action is to depolarize the membrane by opening channels in the same manner as ACh. However, they persist for longer durations at the neuromuscular junction primarily because of their resistance to acetylcholinesterase. The depolarization is thus longer-lasting, resulting in a brief period of repetitive excitation that may elicit transient muscle fasciculations. The initial phase is followed by block of neuromuscular transmission and flaccid paralysis. This arises because released ACh binds to receptors on an already depolarized end plate. It is the *change* in EPP elicited by the transient increases in ACh that triggers action potentials. An end plate depolarized from -80 to -55 mV by a depolarizing blocking agent is resistant to further depolarization by ACh. In humans, a sequence of repetitive excitation (fasciculations) followed by block of transmission and neuromuscular paralysis is elicited by depolarizing agents; however, this sequence is influenced by such factors as the anesthetic agent used concurrently, the type of muscle, and the rate of drug administration. The characteristics of depolarization and competitive blockade are contrasted in Table 9–2.

In other animal species and occasionally in humans, decamethonium and succinylcholine produce a blockade that has unique features, some of which combine those of the depolarizing and the competitive agents; thus this type of action is termed a *dual mechanism*. In such cases, the depolarizing agents produce initially the characteristic fasciculations and potentiation of the maximal twitch, followed by the rapid onset of neuromuscular block; this block is potentiated by anti-ChE agents. However, following the onset of blockade, there is a poorly sustained response to tetanic stimulation

Table 9–2
Comparison of Competitive (D-Tubocurarine) and Depolarizing (Decamethonium) Blocking Agents

	D-TUBOCURARINE	DECAMETHONIUM
Effect of D-tubocurarine administered previously	Additive	Antagonistic
Effect of decamethonium administered previously	No effect, or antagonistic	Some tachyphylaxis; but may be additive
Effect of anticholinesterase agents on block	Reversal of block	No reversal
Effect on motor end plate	Elevated threshold to acetylcholine; no depolarization	Partial, persisting depolarization
Initial excitatory effect on striated muscle	None	Transient fasciculations
Character of muscle response to indirect tetanic stimulation during <i>partial</i> block	Poorly sustained contraction	Well-sustained contraction

SOURCE: Based on data in Paton and Zaimis, 1952; Zaimis, 1976.

of the motor nerve, intensification of the block by tubocurarine, and lack of potentiation by anti-ChE agents. The dual action of the depolarizing blocking agents also is seen in intracellular recordings of membrane potential; when agonist is applied continuously, the initial depolarization is followed by a gradual repolarization. The second phase, repolarization, in many respects resembles receptor desensitization.

Under clinical conditions, with increasing concentrations of succinylcholine and over time, the block may convert slowly from a depolarizing to a nondepolarizing type, termed *phase I* and *phase II blocks* (Durant and Katz, 1982). The pattern of neuromuscular blockade produced by depolarizing drugs in anesthetized patients appears to depend, in part, on the anesthetic; fluorinated hydrocarbons may be more apt to predispose the motor end plate to nondepolarization blockade after prolonged use of succinylcholine or decamethonium (see Fogdall and Miller, 1975). The characteristics of phase I and phase II blocks are shown in Table 9–3.

During the initial phase of application, depolarizing agents produce channel opening, which can be measured by the statistical

analysis of fluctuation of muscle EPPs. The probability of channel opening associated with the binding of drug to the receptor is less with decamethonium than with ACh (Katz and Miledi, 1978) and also may result from decamethonium block of the receptor channel (Adams and Sakmann, 1978).

Although the observed fasciculations also may be a consequence of stimulation of the prejunctional nerve terminal by the depolarizing agent, giving rise to stimulation of the motor unit in an antidromic fashion, the primary site of action of both competitive and depolarizing blocking agents is the postjunctional membrane. Presynaptic actions of the competitive agents may become significant on repetitive high-frequency stimulation because prejunctional nicotinic receptors may be involved in the mobilization of ACh for release from the nerve terminal (Bowman *et al.*, 1990; Van der Kloot and Molgo, 1994).

Many drugs and toxins block neuromuscular transmission by other mechanisms, such as interference with the synthesis or release of ACh (Van der Kloot and Molgo, 1994; Ferguson and Blakely, 2004) (see Chapter 6), but most of these agents are not

Table 9–3
Clinical Responses and Monitoring of Phase I and Phase II Neuromuscular Blockade by Succinylcholine Infusion

RESPONSE	PHASE I	PHASE II
End-plate membrane potential	Depolarized to -55mV	Repolarization toward -80mV
Onset	Immediate	Slow transition
Dose-dependence	Lower	Usually higher or follows prolonged infusion
Recovery	Rapid	More prolonged
Train of four and tetanic stimulation	No fade	Fade*
Acetylcholinesterase inhibition	Augments	Reverses or antagonizes
Muscle response	Fasciculations \rightarrow flaccid paralysis	Flaccid paralysis

*Post-tetanic potentiation follows fade.

Figure 9-4. Sites of action of agents at the neuromuscular junction and adjacent structures. The anatomy of the motor end plate, shown at the left, and the sequence of events from liberation of acetylcholine (ACh) by the nerve action potential (AP) to contraction of the muscle fiber, indicated by the middle column, are described in Chapter 6. The modification of these processes by various agents is shown on the right; an arrow marked with an X indicates inhibition or block; an unmarked arrow indicates enhancement or activation. The insets are enlargements of the indicated structures. The highest magnification depicts the receptor in the bilayer of the postsynaptic membrane. A more detailed view of the receptor is shown in Figure 9-2.

employed clinically for this purpose. One exception is *botulinum toxin*, which has been administered locally into muscles of the orbit in the management of ocular blepharospasm and strabismus and has been used to control other muscle spasms and to facilitate facial muscle relaxation (see Chapters 6 and 63). This toxin also has been injected into the lower esophageal sphincter to treat achalasia (see Chapter 38). *Dantrolene* blocks release of Ca²⁺ from the sarcoplasmic reticulum and is used in the treatment of malignant hyperthermia (see below). The sites of action and interrelationship of several agents that serve as pharmacological tools are shown in Figure 9-4.

Sequence and Characteristics of Paralysis. When an appropriate dose of a competitive blocking agent is injected intravenously in human beings, motor weakness progresses to a total flaccid paralysis. Small, rapidly moving muscles

such as those of the eyes, jaw, and larynx relax before those of the limbs and trunk. Ultimately, the intercostal muscles and finally the diaphragm are paralyzed, and respiration then ceases. Recovery of muscles usually occurs in the reverse order to that of their paralysis, and thus the diaphragm ordinarily is the first muscle to regain function (Feldman and Fauvel, 1994; Savarese *et al.*, 2000).

After a single intravenous dose of 10 to 30 mg of a depolarizing agent such as succinylcholine, muscle fasciculations, particularly over the chest and abdomen, occur briefly; then relaxation occurs within 1 minute, becomes maximal within 2 minutes, and disappears as a rule within 5 minutes. Transient apnea usually occurs at the time of maximal effect.

Muscle relaxation of longer duration is achieved by continuous intravenous infusion. After infusion is discontinued, the effects of the drug usually disappear rapidly because of its rapid hydrolysis by plasma and hepatic butyrylcholinesterase. Muscle soreness may follow the administration of succinylcholine. Small prior doses of competitive blocking agents have been employed to minimize fasciculations and muscle pain caused by succinylcholine. However, this procedure is controversial because it increases the requirement for the depolarizing drug.

During prolonged depolarization, muscle cells may lose significant quantities of K^+ and gain Na^+ , Cl^- , and Ca^{2+} . In patients in whom there has been extensive injury to soft tissues, the efflux of K^+ following continued administration of succinylcholine can be life-threatening. The life-threatening complications of succinylcholine-induced hyperkalemia are discussed below, but it is important to stress that there are many conditions for which succinylcholine administration is contraindicated or should be undertaken with great caution. The change in the nature of the blockade produced by succinylcholine (from phase I to phase II) presents an additional complication with long-term infusions.

Central Nervous System. Tubocurarine and other quaternary neuromuscular blocking agents are virtually devoid of central effects following ordinary clinical doses because of their inability to penetrate the blood–brain barrier. The most decisive experiment performed to resolve whether or not curare significantly affects central functions in the dose range used clinically was that of Smith and associates. Smith (an anesthesiologist) permitted himself to receive intravenously two and one-half times the amount of tubocurarine necessary for paralysis of all skeletal muscles. Adequate respiratory exchange was maintained by artificial respiration. At no time was there any evidence of lapse of consciousness, clouding of sensorium, analgesia, or disturbance of special senses. Despite adequate artificially controlled respiration, Smith experienced “shortness of breath” and the sensation of choking due to the accumulation of unswallowed saliva in the pharynx. The experience was decidedly unpleasant. It was concluded that tubocurarine given intravenously even in large doses has no significant central stimulant, depressant, or analgesic effects and that its sole action in anesthesia is the peripheral paralytic effect on skeletal muscle.

Autonomic Ganglia and Muscarinic Sites. Neuromuscular blocking agents show variable potencies in producing ganglionic blockade. Just as at the motor end plate, ganglionic blockade by tubocurarine and other stabilizing drugs is reversed or antagonized by anti-ChE agents.

At the doses of tubocurarine once used clinically, partial blockade probably is produced both at autonomic ganglia and at the adrenal medulla, which results in a fall in blood pressure and tachycardia. Pancuronium shows less ganglionic blockade at common clinical doses. Atracurium, vecuronium, doxacurium, *pipecuronium* (no longer

marketed in the United States), mivacurium, and rocuronium are even more selective (Pollard, 1994; Savarese *et al.*, 2000). The maintenance of cardiovascular reflex responses usually is desired during anesthesia. Pancuronium has a vagolytic action, presumably from blockade of muscarinic receptors, that leads to tachycardia.

Of the depolarizing agents, succinylcholine at doses producing neuromuscular relaxation rarely causes effects attributable to ganglionic blockade. However, cardiovascular effects are sometimes observed, probably owing to the successive stimulation of vagal ganglia (manifested by bradycardia) and sympathetic ganglia (resulting in hypertension and tachycardia).

Histamine Release. Tubocurarine produces typical histamine-like wheals when injected intracutaneously or intra-arterially in humans, and some clinical responses to neuromuscular blocking agents (*e.g.*, bronchospasm, hypotension, excessive bronchial and salivary secretion) appear to be caused by the release of histamine. Succinylcholine, mivacurium, doxacurium, and atracurium also cause histamine release, but to a lesser extent unless administered rapidly. The ammonio steroids, pancuronium, vecuronium, pipecuronium, and rocuronium, have even less tendency to release histamine after intradermal or systemic injection (Basta, 1992; Watkins, 1994). Histamine release typically is a direct action of the muscle relaxant on the mast cell rather than IgE-mediated anaphylaxis (Watkins, 1994).

Actions of Neuromuscular Blocking Agents with Life-Threatening Implications. The depolarizing agents can release K^+ rapidly from intracellular sites; this may be a factor in production of the prolonged apnea in patients who receive these drugs while in electrolyte imbalance. Succinylcholine-induced hyperkalemia is a life-threatening complication of that drug. For example, such alterations in the distribution of K^+ are of particular concern in patients with congestive heart failure who are receiving digoxin or diuretics. For the same reason, caution should be used or depolarizing blocking agents should be avoided in patients with extensive soft tissue trauma or burns. A higher dose of a competitive blocking agent often is indicated in these patients. In addition, succinylcholine administration is contraindicated or should be given with great caution in patients with nontraumatic rhabdomyolysis, ocular lacerations, spinal cord injuries with paraplegia or quadriplegia, or muscular dystrophies. Succinylcholine no longer is indicated for children 8 years of age and younger unless emergency intubation or securing an airway is necessary. Hyperkalemia, rhabdomyolysis, and cardiac arrest have been reported. A subclinical dystrophy frequently is associated

with these adverse responses (Savarese *et al.*, 2000). Neonates also may have an enhanced sensitivity to competitive neuromuscular blocking agents.

Synergisms and Antagonisms. Interactions between competitive and depolarizing neuromuscular blocking agents already have been considered (Table 9–2). From a clinical viewpoint, important pharmacological interactions of these drugs are with certain general anesthetics, certain antibiotics, Ca^{2+} channel blockers, and anti-ChE compounds.

Since the anti-ChE agents *neostigmine*, *pyridostigmine*, and *edrophonium* preserve endogenous ACh and also act directly on the neuromuscular junction, they can be used in the treatment of overdose with competitive blocking agents. Similarly, on completion of the surgical procedure, many anesthesiologists employ neostigmine or edrophonium to reverse and decrease the duration of competitive neuromuscular blockade. Succinylcholine should never be administered after reversal of competitive blockade with neostigmine; in this circumstance, a prolonged and intense blockade often results. A muscarinic antagonist (*atropine* or *glycopyrrolate*) is used concomitantly to prevent stimulation of muscarinic receptors and thereby to avoid slowing of the heart rate. The anti-ChE agents, however, are synergistic with the depolarizing blocking agents, particularly in their initial phase of action. Since they will not reverse depolarizing neuromuscular blockade and, in fact, can enhance it, the distinction in the type of neuromuscular blocking agent must be clear.

Many inhalational anesthetics (*e.g.*, *halothane*, *isoflurane*, and *enflurane*) exert a stabilizing effect on the postjunctional membrane and therefore act synergistically with the competitive blocking agents. Consequently, when such blocking drugs are used for muscle relaxation as adjuncts to these anesthetics, their doses should be reduced (*see* Fogdall and Miller, 1975).

Aminoglycoside antibiotics produce neuromuscular blockade by inhibiting ACh release from the preganglionic terminal (through competition with Ca^{2+}) and to a lesser extent by noncompetitively blocking the receptor. The blockade is antagonized by Ca^{2+} salts but only inconsistently by anti-ChE agents (*see* Chapter 45). The *tetracyclines* also can produce neuromuscular blockade, possibly by chelation of Ca^{2+} . Additional antibiotics that have neuromuscular blocking action, through both presynaptic and postsynaptic actions, include *polymyxin B*, *colistin*, *clindamycin*, and *lincomycin* (*see* Pollard, 1994). *Ca²⁺ channel blockers* enhance neuromuscular blockade produced by both competitive and depolarizing antagonists. It is not clear whether this is a result of a diminution of Ca^{2+} -dependent release of transmitter from the nerve ending or is a postsynaptic action. When neuromuscular blocking agents are administered to patients receiving these agents, dose adjustments should be considered; if recovery of spontaneous respiration is delayed, Ca^{2+} salts may facilitate recovery.

Miscellaneous drugs that may have significant interactions with either competitive or depolarizing neuromuscular blocking agents include *trimethaphan* (no longer marketed in the United States),

opioid analgesics, *procaine*, *lidocaine*, *quinidine*, *phenelzine*, *phenytoin*, *propranolol*, *magnesium salts*, *corticosteroids*, *digitalis glycosides*, *chloroquine*, *catecholamines*, and *diuretics* (*see* Pollard, 1994; Savarese *et al.*, 2000).

Toxicology. The important untoward responses of the neuromuscular blocking agents include prolonged apnea, cardiovascular collapse, those resulting from histamine release, and, rarely, anaphylaxis. Failure of respiration to become adequate in the postoperative period may not always be due directly to excessive muscle paralysis from the drug. An obstruction of the airway, decreased arterial PCO_2 secondary to hyperventilation during the operative procedure, or the neuromuscular depressant effect of excessive amounts of neostigmine used to reverse the action of the competitive blocking drugs also may be implicated. Directly related factors may include alterations in body temperature; electrolyte imbalance, particularly of K^+ (discussed earlier); low plasma butyrylcholinesterase levels, resulting in a reduction in the rate of destruction of succinylcholine; the presence of latent myasthenia gravis or of malignant disease such as small cell carcinoma of the lung (Eaton-Lambert myasthenic syndrome); reduced blood flow to skeletal muscles, causing delayed removal of the blocking drugs; and decreased elimination of the muscle relaxants secondary to reduced renal function. Great care should be taken when administering these agents to dehydrated or severely ill patients.

Malignant Hyperthermia. Malignant hyperthermia is a potentially life-threatening event triggered by the administration of certain anesthetics and neuromuscular blocking agents. The clinical features include contracture, rigidity, and heat production from skeletal muscle resulting in severe hyperthermia, accelerated muscle metabolism, metabolic acidosis, and tachycardia. Uncontrolled release of Ca^{2+} from the sarcoplasmic reticulum of skeletal muscle is the initiating event. Although the halogenated hydrocarbon anesthetics (*e.g.*, *halothane*, *isoflurane*, and *sevoflurane*) and succinylcholine alone have been reported to precipitate the response, most of the incidents arise from the combination of depolarizing blocking agent and anesthetic. Susceptibility to malignant hyperthermia, an autosomal dominant trait, is associated with certain congenital myopathies such as *central core disease*. In the majority of cases, however, no clinical signs are visible in the absence of anesthetic intervention.

Determination of susceptibility is made with an *in vitro* contracture test on a fresh biopsy of skeletal muscle, where contractures in the presence of halothane and caffeine are measured. In over 50% of the families, a linkage is found between the phenotype as measured by the con-

tracture test and a mutation in the gene (*RyR-1*) encoding the skeletal muscle ryanodine receptor (RYR-1). Over 20 mutations in a region of the gene that encodes the cytoplasmic face of the receptor have been described. Other loci have been identified on the L-type Ca^{2+} channel (voltage-gated dihydropyridine receptor) and on other associated proteins or channel subunits. The large size of *RyR-1* and the genetic heterogeneity of the condition have precluded random genotypic determination for malignant hyperthermia (Hopkins, 2000; Jurkat-Rott *et al.*, 2000).

Treatment entails intravenous administration of *dantrolene* (DANTRIUM), which blocks Ca^{2+} release and the metabolic sequelae. Dantrolene inhibits Ca^{2+} release from the sarcoplasmic reticulum of skeletal muscle by limiting the capacity of Ca^{2+} and calmodulin to activate RYR-1 (Fruen *et al.*, 1997). RYR-1 and the L-type Ca^{2+} channel are juxtaposed to associate at a triadic junction formed between the T-tubule and the sarcoplasmic reticulum. The L-type channel with its T-tubular location serves as the voltage sensor receiving the depolarizing activation signal. The intimate coupling of the two proteins at the triad, along with a host of modulatory proteins in the two organelles and the surrounding cytoplasm, regulates the release of and response to Ca^{2+} (Lehmann-Horn and Jurkat-Rott, 1999).

Rapid cooling, inhalation of 100% oxygen, and control of acidosis should be considered adjunct therapy in malignant hyperthermia. Declining fatality rates for malignant hyperthermia relate to anesthesiologists' awareness of the condition and the efficacy of dantrolene.

Patients with central core disease, so named because of the presence of myofibrillar cores seen on biopsy of slow-twitch muscle fibers, show muscle weakness in infancy and delayed motor development. These individuals are highly susceptible to malignant hyperthermia with the combination of an anesthetic and a depolarizing neuromuscular blocker. Central core disease has five allelic variants of *RyR-1* in common with malignant hyperthermia. Patients with other muscle syndromes or dystonias also have an increased frequency of contracture and hyperthermia in the anesthesia setting. Succinylcholine in susceptible individuals also induces *masseter muscle rigidity*, which may complicate endotracheal tube insertion and airway management. This condition has been correlated with a mutation in the gene encoding the α subunit of the voltage-sensitive Na^+ channel (Vita *et al.*, 1995). Masseter muscle rigidity can be an early sign of the onset of malignant hyperthermia if the anesthetic combination is continued (Hopkins, 2000).

Respiratory Paralysis. Treatment of respiratory paralysis arising from an adverse reaction or overdose of a neuromuscular blocking agent should be by positive-pressure

artificial respiration with oxygen and maintenance of a patent airway until recovery of normal respiration is ensured. With the competitive blocking agents, this may be hastened by the administration of neostigmine methylsulfate (0.5 to 2 mg intravenously) or edrophonium (10 mg intravenously, repeated as required) (Watkins, 1994).

Interventional Strategies for Other Toxic Effects.

Neostigmine effectively antagonizes only the skeletal muscular blocking action of the competitive blocking agents and may aggravate such side effects as hypotension or induce bronchospasm. In such circumstances, *sympathomimetic amines* may be given to support the blood pressure. Atropine or glycopyrrolate is administered to counteract muscarinic stimulation. *Antihistamines* are definitely beneficial to counteract the responses that follow the release of histamine, particularly when administered before the neuromuscular blocking agent.

Absorption, Fate, and Excretion.

Quaternary ammonium neuromuscular blocking agents are very poorly and irregularly absorbed from the gastrointestinal tract. This fact was well known to the South American Indians, who ate with impunity the flesh of game killed with curare-poisoned arrows. Absorption is quite adequate from intramuscular sites. Rapid onset is achieved with intravenous administration. The more potent agents, of course, must be given in lower concentrations, and diffusional requirements slow their rate of onset.

When long-acting competitive blocking agents such as D-tubocurarine and pancuronium are administered, blockade may diminish after 30 minutes owing to redistribution of the drug, yet residual blockade and plasma levels of the drug persist. Subsequent doses show diminished redistribution. Long-acting agents may accumulate with multiple doses.

The ammonio steroids contain ester groups that are hydrolyzed in the liver. Typically, the metabolites have about one-half the activity of the parent compound and contribute to the total relaxation profile. Ammonio steroids of intermediate duration of action, such as vecuronium, and rocuronium (Table 9–1), are cleared more rapidly by the liver than is pancuronium. The more rapid decay of neuromuscular blockade with compounds of intermediate duration argues for sequential dosing of these agents rather than administering a single dose of a long-duration neuromuscular blocking agent (Savarese *et al.*, 2000).

Atracurium is converted to less active metabolites by plasma esterases and spontaneous degradation. Because of these alternative routes of metabolism, atracurium does not exhibit an increased half-life in patients with impaired renal function and therefore is the agent of choice in this setting

(Hunter, 1994). Mivacurium shows an even greater susceptibility to butyrylcholinesterase catalysis, and thus has the shortest duration among the nondepolarizing blockers.

The extremely brief duration of action of succinylcholine also is due largely to its rapid hydrolysis by the butyrylcholinesterase of liver and plasma. Among the occasional patients who exhibit prolonged apnea following the administration of succinylcholine or mivacurium, most have an atypical plasma cholinesterase or a deficiency of the enzyme owing to allelic variations (Pantuck, 1993; Primo-Parmo *et al.*, 1996), hepatic or renal disease, or a nutritional disturbance; however, in some, the enzymatic activity in plasma is normal (Whittaker, 1986).

Therapeutic Uses

The main clinical use of the neuromuscular blocking agents is as an adjuvant in surgical anesthesia to obtain relaxation of skeletal muscle, particularly of the abdominal wall, to facilitate operative manipulations. With muscle relaxation no longer dependent on the depth of general anesthesia, a much lighter level of anesthesia suffices. Thus, the risk of respiratory and cardiovascular depression is minimized, and postanesthetic recovery is shortened. These considerations notwithstanding, neuromuscular blocking agents cannot be used to substitute for inadequate depth of anesthesia. Otherwise, a risk of reflex responses to painful stimuli and conscious recall may occur.

Muscle relaxation is also of value in various orthopedic procedures, such as the correction of dislocations and the alignment of fractures. Neuromuscular blocking agents of short duration often are used to facilitate intubation with an endotracheal tube and have been used to facilitate laryngoscopy, bronchoscopy, and esophagoscopy in combination with a general anesthetic agent.

Neuromuscular blocking agents are administered parenterally, nearly always intravenously. As potentially hazardous drugs, they should be administered to patients only by anesthesiologists and other clinicians who have had extensive training in their use and in a setting where facilities for respiratory and cardiovascular resuscitation are immediately at hand. Detailed information on dosage and monitoring the extent of muscle relaxation can be found in anesthesiology textbooks (Pollard, 1994; Savarese *et al.*, 2000).

Measurement of Neuromuscular Blockade in Humans. Assessment of neuromuscular block usually is performed by stimulation of the ulnar nerve. Responses are monitored from compound action potentials or muscle tension developed in the adductor pollicis (thumb) muscle. Responses to repetitive or tetanic stimuli are most useful for evaluation of blockade of transmission because individual measurements of twitch tension must be related to control values obtained prior to the adminis-

tration of drugs. Thus, stimulus schedules such as the “train of four” and the “double burst” or responses to tetanic stimulation are preferred procedures (Waud and Waud, 1972; Drenck *et al.*, 1989). Rates of onset of blockade and recovery are more rapid in the airway musculature (jaw, larynx, and diaphragm) than in the thumb. Hence, tracheal intubation can be performed before onset of complete block at the adductor pollicis, whereas partial recovery of function of this muscle allows sufficient recovery of respiration for extubation (Savarese *et al.*, 2000). Differences in rates of onset of blockade, recovery from blockade, and intrinsic sensitivity between the stimulated muscle and those of the larynx, abdomen, and diaphragm should be considered.

Use to Prevent Trauma during Electroshock Therapy. Electroconvulsive therapy (ECT) of psychiatric disorders occasionally is complicated by trauma to the patient; the seizures induced may cause dislocations or fractures. Inasmuch as the muscular component of the convulsion is not essential for benefit from the procedure, neuromuscular blocking agents and *thiopental* are employed. The combination of the blocking drug, the anesthetic agent, and postictal depression usually results in respiratory depression or temporary apnea. An endotracheal tube and oxygen always should be available. An oropharyngeal airway should be inserted as soon as the jaw muscles relax (after the seizure) and provision made to prevent aspiration of mucus and saliva. Succinylcholine or mivacurium is used most often because of the brevity of relaxation. A cuff may be applied to one extremity to prevent the effects of the drug in that limb; evidence of an effective electroshock is provided by contraction of the group of protected muscles. These agents are also used in capital punishment by electrocution. Although a convulsive response is blocked, ethical concerns have been raised because all motor function is blocked.

Control of Muscle Spasms. Several agents, many of limited efficacy, have been used to treat spasticity involving the α -motor neuron with the objective of increasing functional capacity and relieving discomfort. Agents that act in the CNS at either higher centers or the spinal cord to block spasms are considered in Chapter 20. These include *baclofen*, the *benzodiazepines*, and *tizandine*. Botulinum toxin and dantrolene act peripherally.

The anaerobic bacterium *Clostridium botulinum* produces a family of toxins targeted to presynaptic proteins and that block the release of ACh (*see* Chapter 6). *Botulinum toxin A* (BOTOX), by blocking ACh release, produces flaccid paralysis of skeletal muscle and diminished activity of parasympathetic and sympathetic cholinergic synapses. Inhibition lasts from several weeks to 3 to 4 months, and restoration of function requires nerve sprouting. Immuno-resistance may develop with continued use (Davis and Barnes, 2000). Originally approved for the treatment of the ocular conditions of strabismus and blepharospasm and for hemifacial spasms, botulinum toxin has been used to treat spasms and dystonias such as adductor spasmodic dysphonia, oromandibular dystonia, cervical dystonia and spasms associated with the lower esophageal sphincter and anal fissures. Its dermatological uses include treatment of hyperhidrosis of the palms and axillae that is

Figure 9–5. Autonomic ganglion cells and the excitatory and inhibitory postsynaptic potentials (EPSP and IPSP) recorded from the postganglionic nerve cell body after stimulation of the preganglionic nerve fiber. The initial EPSP, if of sufficient magnitude, triggers an action potential spike, which is followed by a slow IPSP, a slow EPSP, and a late, slow EPSP. The slow IPSP and slow EPSP are not seen in all ganglia. The subsequent electrical events are thought not to trigger spikes directly but rather to increase or decrease the probability of a subsequent EPSP reaching a threshold to trigger a spike. Other interneurons, such as catecholamine-containing, small, intensely fluorescent (SIF) cells, and axon terminals from sensory, afferent neurons also release transmitters and are thought to influence the slow potentials of the postganglionic neuron. A number of cholinergic, peptidergic, adrenergic, and amino acid receptors are found on the dendrites and soma of the postganglionic neuron and the interneurons. The preganglionic terminal releases acetylcholine and peptides; the interneurons store and release catecholamines, amino acids, and peptides; and the sensory afferent nerve terminals release peptides. The initial EPSP is mediated through nicotinic (N) receptors, the slow IPSP and EPSP through M_2 and M_1 muscarinic receptors, and the late, slow EPSP through several types of peptidergic receptors, as detailed in the text (Weight *et al.*, 1979; Jan and Jan, 1983; Elfvin *et al.*, 1993).

resistant to topical and iontophoretic remedies and removal of facial lines associated with excessive nerve stimulation and muscle activity. Treatment involves local intramuscular or intradermal injections (Boni *et al.*, 2000). Botox treatments also have become a popular cosmetic procedure for those seeking a wrinkle-free face. The effect is temporary.

In addition to its use in managing an acute attack of malignant hyperthermia (*see above*), dantrolene also has been explored in the treatment of spasticity and hyperreflexia. With its peripheral action, it causes a generalized weakness. Thus, its use should be reserved to nonambulatory patients with severe spasticity. Hepatotoxicity has been reported with continued use, requiring liver function tests (Kita and Goodkin, 2000).

GANGLIONIC NEUROTRANSMISSION

Neurotransmission in autonomic ganglia has long been recognized to be a far more complex process than that described by a single neurotransmitter–receptor system; intracellular recordings reveal at least four different changes in potential that can be elicited by stimulation of the preganglionic nerve (Weight *et al.*, 1979) (Figure 9–5). The primary event involves a rapid depolarization of postsynaptic sites by ACh. The receptors are nicotinic, and the path-

way is sensitive to classical blocking agents such as *hexamethonium* and trimethaphan. Activation of this primary pathway gives rise to an initial excitatory postsynaptic potential (EPSP). This rapid depolarization is due primarily to an inward Na^+ and perhaps Ca^{2+} current through a neuronal type of nicotinic-receptor channel. Multiple nicotinic-receptor subunits (*e.g.*, $\alpha 3$, $\alpha 5$, $\alpha 7$, $\beta 2$, and $\beta 4$) have been identified in ganglia, with $\alpha 3$ and $\beta 2$ being most abundant.

An action potential is generated in the postganglionic neuron when the initial EPSP attains a critical amplitude. In mammalian sympathetic ganglia *in vivo*, it may be necessary for multiple synapses to be activated before transmission is effective. Discrete end plates with focal localization of receptors do not exist in ganglia; rather, the dendrites and nerve cell bodies contain the receptors.

Iontophoretic application of ACh to the ganglion results in a depolarization with a latency of less than 1 ms; this decays over a period of 10 to 50 ms (Ascher *et al.*, 1979). Measurements of single-channel conductances indicate that the characteristics of nicotinic-receptor channels of the ganglia and the neuromuscular junction are quite similar.

The secondary events that follow the initial depolarization are insensitive to hexamethonium or other nicotinic antagonists. They include the slow EPSP, the late slow EPSP, and an inhibitory postsynaptic potential (IPSP). ACh action on muscarinic receptors generates the slow EPSP, which is blocked by atropine or antagonists that are selective for M_1 muscarinic receptors (*see Chapter 7*). The slow EPSP has a longer latency and a duration of 30 to 60 seconds. In contrast, the late slow EPSP lasts for several minutes and is initiated by the action of

peptides released from presynaptic nerve endings or interneurons in specific ganglia (Dun, 1983). The peptides and ACh may be released from the same nerve ending, but the enhanced stability of the peptide in the ganglion extends its sphere of influence to postsynaptic sites beyond those in immediate proximity to the nerve ending. The slow EPSPs result from decreased K^+ conductance (Weight *et al.*, 1979). The K^+ conductance has been called an *M current*, and it regulates the sensitivity of the cell to repetitive fast-depolarizing events (Adams *et al.*, 1982).

Like the slow EPSP, the IPSP is unaffected by the classical nicotinic-receptor blocking agents. Electrophysiological and neurochemical evidence suggests that catecholamines participate in the generation of the IPSP. *Dopamine* and *norepinephrine* cause hyperpolarization of ganglia, and both the IPSP and catecholamine-induced hyperpolarization are blocked by α adrenergic receptor antagonists. Since the IPSP is sensitive in most systems to blockade by both atropine and α adrenergic receptor antagonists, ACh that is released at the preganglionic terminal may act on catecholamine-containing interneurons to stimulate the release of dopamine or norepinephrine; the catecholamine, in turn, produces hyperpolarization (an IPSP) of ganglion cells. At least in some ganglia, a muscarinic link in the IPSP is mediated through M_2 muscarinic receptors (see Chapter 7). Histochemical studies indicate that dopamine- or norepinephrine-containing small, intensely fluorescent (SIF) cells and adrenergic nerve terminals are present in ganglia. Details of the functional linkage between the SIF cells and the electrogenic mechanism of the IPSP remain to be resolved (Prud'homme *et al.*, 1999; Slavikova *et al.*, 2003).

The relative importance of the secondary pathways and even the nature of the modulating transmitters appear to differ among individual ganglia and between parasympathetic and sympathetic ganglia. A variety of peptides, including gonadotropin-releasing hormone, substance P, angiotensin, calcitonin gene-related peptide, vasoactive intestinal polypeptide, neuropeptide Y, and enkephalins, have been identified in ganglia by immunofluorescence. They appear localized to particular cell bodies, nerve fibers, or SIF cells, are released on nerve stimulation, and are presumed to mediate the late slow EPSP (Elfvin *et al.*, 1993). Other neurotransmitter substances, such as 5-hydroxytryptamine and γ -aminobutyric acid, are known to modify ganglionic transmission. Precise details of their modulatory actions are not understood, but they appear to be most closely associated with the late slow EPSP and inhibition of the M current in various ganglia. It should be emphasized that the secondary synaptic events only modulate the initial EPSP. Conventional ganglionic blocking agents can inhibit ganglionic transmission completely; the same cannot be said for muscarinic antagonists or α adrenergic receptor agonists (Volle, 1980).

Drugs that stimulate cholinergic receptor sites on autonomic ganglia can be grouped into two categories. The first group consists of drugs with nicotinic specificity, including nicotine itself. Their excitatory effects on ganglia are rapid in onset, are blocked by ganglionic nicotinic-receptor antagonists, and mimic the initial EPSP. The second group is composed of agents such as *muscarine*, *McN-A-343*, and *methacholine*. Their excitatory effects on ganglia are delayed in onset, blocked by atropine-like drugs, and mimic the slow EPSP.

Ganglionic blocking agents acting on the nicotinic receptor may be classified into two groups. The first

group includes drugs that initially stimulate the ganglia by an ACh-like action and then block them because of a persistent depolarization (*e.g.*, nicotine); prolonged application of nicotine results in desensitization of the cholinergic receptor site and continued blockade (Volle, 1980). The blockade of autonomic ganglia produced by the second group of blocking drugs, of which hexamethonium and trimethaphan are prototypes, does not involve prior ganglionic stimulation or changes in ganglionic potentials. These agents impair transmission either by competing with ACh for ganglionic nicotinic-receptor sites or by blocking the channel. Trimethaphan acts by competition with ACh, analogous to the mechanism of action of curare at the neuromuscular junction. Hexamethonium appears to block the channel after it opens. This action shortens the duration of current flow because the open channel either becomes occluded or closes (Gurney and Rang, 1984). Regardless of the mechanism, the initial EPSP is blocked, and ganglionic transmission is inhibited.

GANGLIONIC STIMULATING DRUGS

History. Two natural alkaloids, nicotine and *lobeline*, exhibit peripheral actions by stimulating autonomic ganglia. Nicotine (Figure 9–6) was first isolated from leaves of tobacco, *Nicotiana tabacum*, by Posselt and Reiman in 1828, and Orfila initiated the first pharmacological studies of the alkaloid in 1843. Langley and Dickinson painted the superior cervical ganglion of rabbits with nicotine and demonstrated that its site of action was the ganglion rather than the preganglionic or postganglionic nerve fiber. Lobeline, from *Lobelia inflata*, has many of the same actions as nicotine but is less potent.

A number of synthetic compounds also have prominent actions at ganglionic receptor sites. The actions of the “onium” compounds, of which *tetramethylammonium* (TMA) is the simplest prototype, were explored in considerable detail in the last half of the nineteenth century and the early twentieth century.

Nicotine

Nicotine is of considerable medical significance because of its toxicity, presence in tobacco, and propensity for conferring a dependence on its users. The chronic effects of nicotine and the untoward effects of the chronic use of tobacco are considered in Chapter 23.

Nicotine is one of the few natural liquid alkaloids. It is a colorless, volatile base ($pK_a = 8.5$) that turns brown and acquires the odor of tobacco on exposure to air.

Pharmacological Actions. The complex and often unpredictable changes that occur in the body after administration of nicotine are due not only to its actions on a variety of neuroeffector and chemosensitive sites but also to the fact that the alkaloid can stimulate and desensitize receptors. The ultimate response of any one system represents the summation of stimulatory and inhibitory effects of nicotine. For example, the drug can increase heart rate by excitation of sympathetic

Figure 9–6. Ganglionic stimulants.

or paralysis of parasympathetic cardiac ganglia, and it can slow heart rate by paralysis of sympathetic or stimulation of parasympathetic cardiac ganglia. In addition, the effects of the drug on the chemoreceptors of the carotid and aortic bodies and on brain centers influence heart rate, as do also the cardiovascular compensatory reflexes resulting from changes in blood pressure caused by nicotine. Finally, nicotine elicits a discharge of epinephrine from the adrenal medulla, which accelerates heart rate and raises blood pressure.

Peripheral Nervous System. The major action of nicotine consists initially of transient stimulation and subsequently of a more persistent depression of all autonomic ganglia. Small doses of nicotine stimulate the ganglion cells directly and may facilitate impulse transmission. When larger doses of the drug are applied, the initial stimulation is followed very quickly by a blockade of transmission. Whereas stimulation of the ganglion cells coincides with their depolarization, depression of transmission by adequate doses of nicotine occurs both during the depolarization and after it has subsided. Nicotine also possesses a biphasic action on the adrenal medulla; small doses evoke the discharge of catecholamines, and larger doses prevent their release in response to splanchnic nerve stimulation.

The effects of nicotine on the neuromuscular junction are similar to those on ganglia. However, with the exception of avian and denervated mammalian muscle, the stimulant phase is obscured largely by the rapidly developing paralysis. In the latter stage, nicotine also produces neuromuscular blockade by receptor desensitization.

Nicotine, like ACh, is known to stimulate a number of sensory receptors. These include mechanoreceptors that respond to stretch or pressure of the skin, mesentery, tongue, lung, and stomach; chemoreceptors of the carotid body; thermal receptors of the skin and tongue; and pain receptors. Prior administration of hexamethonium prevents stimulation of the sensory receptors by nicotine but has little, if any, effect on the activation of sensory receptors by physiological stimuli.

Central Nervous System. Nicotine markedly stimulates the CNS. Low doses produce weak analgesia; with higher doses, tremors leading to convulsions at toxic doses are evident. The excitation of respiration is a prominent action of nicotine; although large doses act

directly on the medulla oblongata, smaller doses augment respiration reflexly by excitation of the chemoreceptors of the carotid and aortic bodies. Stimulation of the CNS with large doses is followed by depression, and death results from failure of respiration owing to both central paralysis and peripheral blockade of muscles of respiration.

Nicotine induces vomiting by both central and peripheral actions. The central component of the vomiting response is due to stimulation of the emetic chemoreceptor trigger zone in the area postrema of the medulla oblongata. In addition, nicotine activates vagal and spinal afferent nerves that form the sensory input of the reflex pathways involved in the act of vomiting. Studies in isolated higher centers of the brain and spinal cord reveal that the primary sites of action of nicotine in the CNS are prejunctional, causing the release of other transmitters. Accordingly, the stimulatory and pleasure–reward actions of nicotine appear to result from release of excitatory amino acids, dopamine, and other biogenic amines from various CNS centers (MacDermott *et al.*, 1999). Release of excitatory amino acids may account for much of nicotine’s stimulatory action.

Chronic exposure to nicotine in several systems causes a marked increase in the density or number of nicotinic receptors (Di Chiara *et al.*, 2000; Stitzel *et al.*, 2000). While the details of the mechanism are not yet understood, the response may be compensatory to the desensitization of receptor function by nicotine.

Cardiovascular System. When administered intravenously to dogs, nicotine characteristically produces an increase in heart rate and blood pressure. The latter is usually more sustained. In general, the cardiovascular responses to nicotine are due to stimulation of sympathetic ganglia and the adrenal medulla, together with the discharge of catecholamines from sympathetic nerve endings. Also contributing to the sympathomimetic response to nicotine is the activation of chemoreceptors of the aortic and carotid bodies, which reflexly results in vasoconstriction, tachycardia, and elevated blood pressure.

Gastrointestinal Tract. The combined activation of parasympathetic ganglia and cholinergic nerve endings by nicotine results in increased tone and motor activity of the bowel. Nausea, vomiting, and occasional diarrhea are observed following systemic absorption of nicotine in an individual who has not been exposed to nicotine previously.

Exocrine Glands. Nicotine causes an initial stimulation of salivary and bronchial secretions that is followed by inhibition.

Absorption, Fate, and Excretion. Nicotine is readily absorbed from the respiratory tract, buccal membranes, and skin. Severe poisoning has resulted from percutaneous absorption. Being a relatively strong base, its absorption from the stomach is limited. Intestinal absorption is far more efficient. Nicotine in chewing tobacco, because it is absorbed more slowly than inhaled nicotine, has a longer duration of effect. The average cigarette contains 6 to 11 mg nicotine and delivers about 1 to 3 mg nicotine systemically to the smoker; bioavailability can increase as much as threefold with intensity of puffing and technique of the smoker (Henningfield, 1995; Benowitz, 1998). Nicotine is available in several dosage forms to help achieve abstinence from tobacco use. Efficacy results primarily from preventing a withdrawal or abstinence syndrome. Nicotine may be administered orally as a gum (*nicotine polacrilex*, NICORETTE), transdermal patch (NICODERM, HABITROL, others), a nasal spray (NICOTROL NS), and a vapor inhaler (NICOTROL INHALER). The first two are used most widely, and the objective is to obtain a sustained plasma nicotine concentration lower than venous blood concentrations after smoking. Arterial blood concentrations immediately following inhalation can be as much as tenfold higher than venous concentrations. The efficacy of the preceding dosage forms in producing abstinence from smoking is enhanced

when linked to counseling and motivational therapy (Henningfield, 1995; Fant *et al.*, 1999; Benowitz, 1999) (*see* Chapter 23).

Approximately 80% to 90% of nicotine is altered in the body, mainly in the liver but also in the kidney and lung. Cotinine is the major metabolite, with nicotine-1'-N-oxide and 3-hydroxycotinine and conjugated metabolites found in lesser quantities (Benowitz, 1998). The profile of metabolites and the rate of metabolism appear to be similar in smokers and nonsmokers. The half-life of nicotine following inhalation or parenteral administration is about 2 hours. Nicotine and its metabolites are eliminated rapidly by the kidney. The rate of urinary excretion of nicotine diminishes when the urine is alkaline. Nicotine also is excreted in the milk of lactating women who smoke; the milk of heavy smokers may contain 0.5 mg/L.

Acute Nicotine Poisoning. Poisoning from nicotine may occur from accidental ingestion of nicotine-containing insecticide sprays or in children from ingestion of tobacco products. The acutely fatal dose of nicotine for an adult is probably about 60 mg of the base. Smoking tobacco usually contains 1% to 2% nicotine. Apparently, the gastric absorption of nicotine from tobacco taken by mouth is delayed because of slowed gastric emptying, so vomiting caused by the central effect of the initially absorbed fraction may remove much of the tobacco remaining in the GI tract.

The onset of symptoms of acute, severe nicotine poisoning is rapid; they include nausea, salivation, abdominal pain, vomiting, diarrhea, cold sweat, headache, dizziness, disturbed hearing and vision, mental confusion, and marked weakness. Faintness and prostration ensue; the blood pressure falls; breathing is difficult; the pulse is weak, rapid, and irregular; and collapse may be followed by terminal convulsions. Death may result within a few minutes from respiratory failure.

Therapy. Vomiting may be induced, or gastric lavage should be performed. Alkaline solutions should be avoided. A slurry of activated charcoal is then passed through the tube and left in the stomach. Respiratory assistance and treatment of shock may be necessary.

Other Ganglionic Stimulants

Stimulation of ganglia by tetramethylammonium (TMA) or *1,1-dimethyl-4-phenylpiperazine iodide* (DMPP) differs from that produced by nicotine in that the initial stimulation is not followed by a dominant blocking action. DMPP is about three times more potent and slightly more ganglion-selective than nicotine. Although parasympathomimetic drugs stimulate ganglia, their effects usually are obscured by stimulation of other neuroeffector sites. McN-A-343 represents an exception to this; in certain tissues its primary action appears to occur at muscarinic M₁ receptors in ganglia.

GANGLIONIC BLOCKING DRUGS

The chemical diversity of compounds that block autonomic ganglia without causing prior stimulation is shown in Figure 9–7.

History and Structure–Activity Relationship. Although Marshall first described the “nicotine-paralyzing” action of *tetraethylammonium* (TEA) on ganglia in 1913, TEA was largely overlooked until Acheson and Moe published their definitive analyses of the effects of the ion on the cardiovascular system and autonomic ganglia. The *bis*-quaternary ammonium salts were developed and studied independently by Barlow and Ing and Paton and Zaimis. The prototypical ganglionic blocking drug in this series, hexamethonium (C6), has a bridge of six methylene groups between the two quaternary

Figure 9–7. Ganglionic blocking agents.

nitrogen atoms (Figure 9–7). It has minimal neuromuscular and muscarinic blocking activities.

Triethylsulfoniums, like the quaternary and *bis*-quaternary ammonium ions, possess ganglionic blocking actions. This knowledge led to the development of sulfonium ganglionic blocking agents such as trimethaphan (Figure 9–7). *Mecamylamine*, a secondary amine, was introduced into therapy for hypertension in the mid-1950s.

Pharmacological Properties. Nearly all the physiological alterations observed after the administration of ganglionic blocking agents can be anticipated with reasonable accuracy by a careful inspection of Figure 6–1 and by knowing which division of the autonomic nervous system exercises dominant control of various organs (Table 9–4). For example, blockade of sympathetic ganglia interrupts adrenergic control of arterioles and results in vasodilation, improved peripheral blood flow in some vascular beds, and a fall in blood pressure.

Generalized ganglionic blockade also may result in atony of the bladder and gastrointestinal tract, cycloplegia, xerostomia, diminished perspiration, and by abolishing circulatory reflex pathways, postural hypotension. These changes represent the generally undesirable features of ganglionic blockade, which severely limit the therapeutic efficacy of ganglionic blocking agents.

Cardiovascular System. Existing sympathetic tone is critical in determining the degree to which blood pressure is lowered by ganglionic blockade; thus blood pressure may be decreased only minimally in recumbent normotensive subjects but may fall markedly in sitting or standing subjects. Postural hypotension was a major limitation in ambulatory patients receiving ganglionic blocking drugs.

Changes in heart rate following ganglionic blockade depend largely on existing vagal tone. In humans, mild tachycardia usually accompanies the hypotension, a sign that indicates fairly complete ganglionic blockade. However, a decrease may occur if the heart rate is high initially.

Cardiac output often is reduced by ganglionic blocking drugs in patients with normal cardiac function as a consequence of diminished venous return resulting from venous dilation and peripheral

Table 9–4

Usual Predominance of Sympathetic or Parasympathetic Tone at Various Effector Sites, and Consequences of Autonomic Ganglionic Blockade

SITE	PREDOMINANT TONE	EFFECT OF GANGLIONIC BLOCKADE
Arterioles	Sympathetic (adrenergic)	Vasodilation; increased peripheral blood flow; hypotension
Veins	Sympathetic (adrenergic)	Dilation: peripheral pooling of blood; decreased venous return; decreased cardiac output
Heart	Parasympathetic (cholinergic)	Tachycardia
Iris	Parasympathetic (cholinergic)	Mydriasis
Ciliary muscle	Parasympathetic (cholinergic)	Cycloplegia—focus to far vision
Gastrointestinal tract	Parasympathetic (cholinergic)	Reduced tone and motility; constipation; decreased gastric and pancreatic secretions
Urinary bladder	Parasympathetic (cholinergic)	Urinary retention
Salivary glands	Parasympathetic (cholinergic)	Xerostomia
Sweat glands	Sympathetic (cholinergic)	Anhidrosis
Genital tract	Sympathetic and parasympathetic	Decreased stimulation

pooling of blood. In patients with cardiac failure, ganglionic blockade frequently results in increased cardiac output owing to a reduction in peripheral resistance. In hypertensive subjects, cardiac output, stroke volume, and left ventricular work are diminished.

Although total systemic vascular resistance is decreased in patients who receive ganglionic blocking agents, changes in blood flow and vascular resistance of individual vascular beds are variable. Reduction of cerebral blood flow is small unless mean systemic blood pressure falls below 50 to 60 mmHg. Skeletal muscle blood flow is unaltered, but splanchnic and renal blood flow decrease following the administration of a ganglionic blocking agent.

Absorption, Fate, and Excretion. The absorption of quaternary ammonium and sulfonium compounds from the enteric tract is incomplete and unpredictable. This is due both to the limited ability of these ionized substances to penetrate cell membranes and to the depression of propulsive movements of the small intestine and gastric emptying. Although the absorption of mecamylamine is less erratic, a danger exists of reduced bowel activity leading to frank paralytic ileus.

After absorption, the quaternary ammonium- and sulfonium-blocking agents are confined primarily to the extracellular space and are excreted mostly unchanged by the kidney. Mecamylamine concentrates in the liver and kidney and is excreted slowly in an unchanged form.

Untoward Responses and Severe Reactions. Among the milder untoward responses observed are visual disturbances, dry mouth, conjunctival suffusion, urinary hesitancy, decreased potency, subjective chilliness, moderate constipation, occasional diarrhea, abdominal discomfort, anorexia, heartburn, nausea, eructation, and bitter taste and the signs and symptoms of syncope caused by postural hypotension. More severe reactions include marked hypotension, constipation, syncope, paralytic ileus, urinary retention, and cycloplegia.

Therapeutic Uses. Of the ganglionic blocking agents that have appeared on the therapeutic scene, only mecamylamine (INVER-

SINE) is currently available in the United States. Ganglionic blocking agents have been supplanted by superior agents for the treatment of chronic hypertension (*see* Chapter 32). Alternative agents also are available for management of acute hypertensive crises.

The therapeutic use of the ganglionic blocking agents in the production of controlled hypotension [*e.g.*, reduction in blood pressure during surgery to minimize hemorrhage in the operative field, to reduce blood loss in various orthopedic procedures, and to facilitate surgery on blood vessels (Fukusaki *et al.*, 1999)] has been supplanted largely by *nitroprusside* or depressor sedatives.

I. CATECHOLAMINES AND SYMPATHOMIMETIC DRUGS

Most of the actions of catecholamines and sympathomimetic agents can be classified into seven broad types: (1) a peripheral excitatory action on certain types of smooth muscle, such as those in blood vessels supplying skin, kidney, and mucous membranes, and on gland cells, such as those in salivary and sweat glands; (2) a peripheral inhibitory action on certain other types of smooth muscle, such as those in the wall of the gut, in the bronchial tree, and in blood vessels supplying skeletal muscle; (3) a cardiac excitatory action that increases heart rate and force of contraction; (4) metabolic actions, such as an increase in the rate of glycogenolysis in liver and muscle and liberation of free fatty acids from adipose tissue; (5) endocrine actions, such as modulation (increasing or decreasing) of the secretion of insulin, renin, and pituitary hormones; (6) actions in the central nervous system (CNS), such as respiratory stimulation, an increase in wakefulness and psychomotor activity, and a reduction in appetite; and (7) prejunctional actions that either inhibit or facilitate the release of neurotransmitters, the inhibitory action being physiologically more important. Many of these actions and the receptors that mediate them are summarized in Tables 6–1 and 6–8. Not all sympathomimetic drugs show each of the above types of action to the same degree. However, many of the differences in their effects are only quantitative; therefore, the pharmacological properties of these drugs as a class are described in detail for the prototypical agent, *epinephrine*.

Appriation of the pharmacological properties of the drugs described in this chapter depends on an understanding of the classification, distribution, and mechanism of

action of α and β adrenergic receptors (see Figure 10–1 and Chapter 6).

CLASSIFICATION OF SYMPATHOMIMETIC DRUGS

Catecholamines and sympathomimetic drugs are classified as direct acting, indirect acting, or mixed acting sympathomimetics (Figure 10–2). Direct-acting sympathomimetic drugs act directly on one or more of the adrenergic receptors. These agents may exhibit considerable selectivity for a specific receptor subtype (e.g., *phenylephrine* for α_1 , *terbutaline* for β_2) or may have no or minimal selectivity and act on several receptor types (e.g., *epinephrine* for α_1 , α_2 , β_1 , β_2 , β_3 receptors; *norepinephrine* for α_1 , α_2 , β_1 receptors). Indirect-acting drugs increase the availability of norepinephrine or epinephrine to stimulate adrenergic receptors. This can be accomplished in several ways: (1) by releasing or displacing norepinephrine from sympathetic nerve varicosities; (2) by blocking the transport of norepinephrine into sympathetic neurons (e.g., *cocaine*); or (3) by blocking the metabolizing enzymes, monoamine oxidase (MAO) (e.g., *pargyline*) or catechol-*O*-methyltransferase (COMT) (e.g., *entacapone*). Drugs that indirectly release norepinephrine and also directly activate receptors are referred to as mixed-acting sympathomimetic drugs (e.g., *ephedrine*, *dopamine*).

Prototypical drugs for these various mechanisms are listed in Figure 10–2. Although this classification is convenient, there probably is a continuum of activity from predominantly direct-acting to predominantly indirect-acting drugs. Thus, this classification is relative rather than absolute.

Figure 10–1. Subtypes of adrenergic receptors. All of the adrenergic receptors are heptaspanning GPCRs. A representative of each type is shown; each type has three subtypes: α_{1A} , 1B, and 1D; α_{2A} , 2B, and 2C; and $\beta_{1, 2}$, and 3. All β receptor subtypes are coupled to stimulation of adenylyl cyclase activity; similarly, all α_2 adrenergic receptor subtypes affect the same effector systems (*i.e.*, inhibition of adenylyl cyclase, activation of receptor-operated K^+ channels, and inhibition of Ca^{2+} channels). In contrast, there is evidence that different α_1 adrenergic receptor subpopulations couple to different effector systems, the G_q -PLC-IP₃ pathway being a major effector. ψ indicates a site for *N*-glycosylation. $\sim\sim\sim$ indicates a site for thio-acetylation.

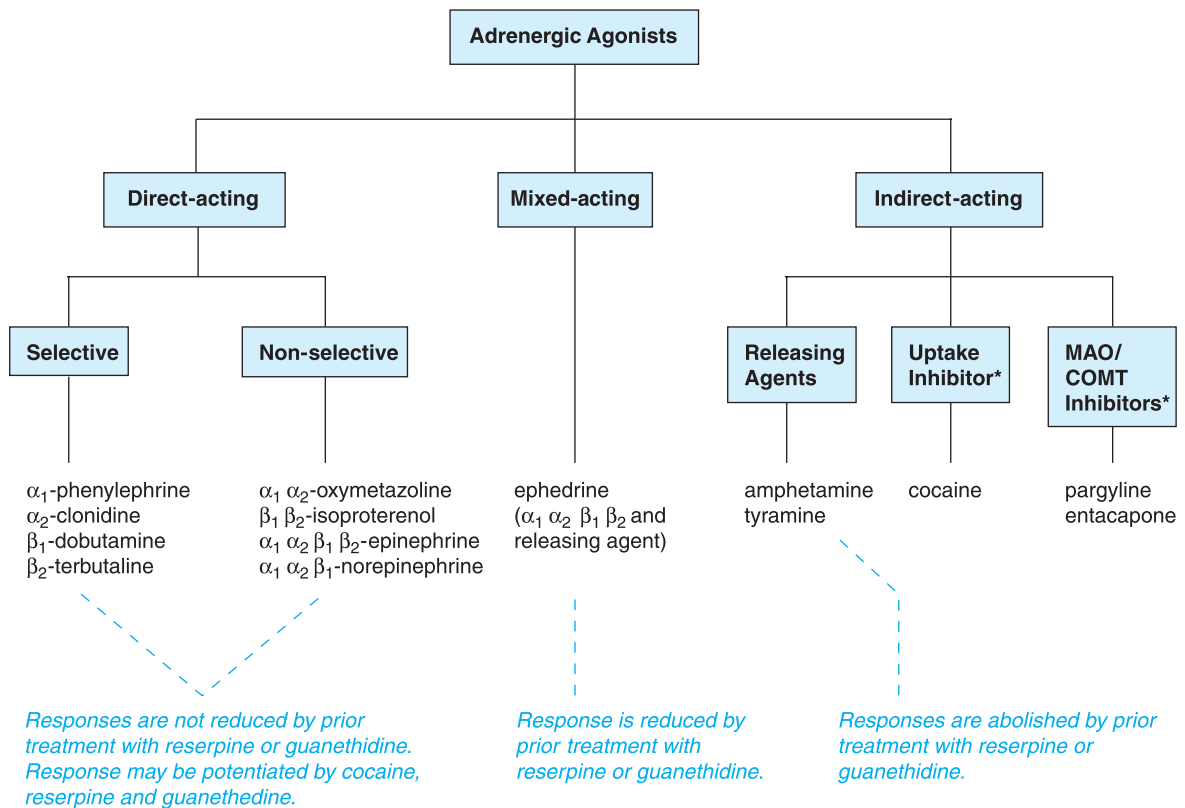

Figure 10–2. Classification of adrenergic receptor agonists (sympathomimetic amines) or drugs that produce sympathomimetic-like effects. For each category, a prototypical drug is shown. *Not actually sympathetic drugs but produce sympathomimetic-like effects.

A feature of direct-acting sympathomimetic drugs is that their responses are not reduced by prior treatment with *reserpine* or *guanethidine*, which deplete norepinephrine from sympathetic neurons. After transmitter depletion, the actions of direct-acting sympathomimetic drugs actually may increase because the loss of the neurotransmitter induces compensatory changes that upregulate receptors or enhance the signaling pathway. In contrast, the responses of indirect-acting sympathomimetic drugs (e.g., *amphetamine*, *tyramine*) are abolished by prior treatment with reserpine or guanethidine. The cardinal feature of mixed-acting sympathomimetic drugs is that their effects are blunted, but not abolished, by prior treatment with reserpine or guanethidine.

Since the actions of norepinephrine are more pronounced on α and β_1 receptors than on β_2 receptors, many noncatecholamines that release norepinephrine have predominantly α receptor-mediated and cardiac effects. However, certain noncatecholamines with both direct and indirect effects on adrenergic receptors show significant β_2 activity and are used clinically for these effects. Thus, ephedrine, although dependent on release of norepinephrine for some of its effects, relieves bronchospasm by its action on β_2 receptors in bronchial smooth muscle, an effect not seen with norepinephrine. Moreover, some noncatecholamines (e.g., phenylephrine) act primarily and directly on target cells. It therefore is impossible to predict precisely the effects of noncatecholamines solely on their ability to provoke norepinephrine release.

Chemistry and Structure–Activity Relationship of Sympathomimetic Amines. *β -Phenylethylamine* (Table 10–1) can be viewed as the parent compound of the sympathomimetic amines, consisting of a benzene ring and an ethylamine side chain. The structure permits substitutions to be made on the aromatic ring, the α - and β -carbon atoms, and the terminal amino group to yield a variety of compounds with sympathomimetic activity. Norepinephrine, epinephrine, dopamine, *isoproterenol*, and a few other agents have hydroxyl groups substituted at positions 3 and 4 of the benzene ring. Since *o*-dihydroxybenzene is also known as *catechol*, sympathomimetic amines with these hydroxyl substitutions in the aromatic ring are termed *catecholamines*.

Many directly acting sympathomimetic drugs influence both α and β receptors, but the ratio of activities varies among drugs in a continuous spectrum from predominantly α activity (phenylephrine) to predominantly β activity (*isoproterenol*). Despite the multiplicity of the sites of action of sympathomimetic amines, several generalizations can be made (Table 10–1).

Separation of Aromatic Ring and Amino Group. By far the greatest sympathomimetic activity occurs when two carbon atoms separate the ring from the amino group. This rule applies with few exceptions to all types of action.

Substitution on the Amino Group. The effects of amino substitution are most readily seen in the actions of catecholamines on α

and β receptors. Increase in the size of the alkyl substituent increases β receptor activity (e.g., *isoproterenol*). Norepinephrine has, in general, rather feeble β_2 activity; this activity is greatly increased in epinephrine by the addition of a methyl group. A notable exception is phenylephrine, which has an *N*-methyl substituent but is an α -selective agonist. β_2 -Selective compounds require a large amino substituent, but depend on other substitutions to define selectivity for β_2 rather than for β_1 adrenergic receptors. In general, the smaller the substitution on the amino group, the greater the selectivity for α activity, although *N*-methylation increases the potency of primary amines. Thus, α activity is maximal in epinephrine, less in norepinephrine, and almost absent in *isoproterenol*.

Substitution on the Aromatic Nucleus. Maximal α and β activity depends on the presence of hydroxyl groups on positions 3 and 4. When one or both of these groups are absent, with no other aromatic substitution, the overall potency is reduced. Phenylephrine is thus less potent than epinephrine at both α and β receptors, with β_2 activity almost completely absent. Studies of the β adrenergic receptor suggest that the hydroxyl groups on serine residues 204 and 207 probably form hydrogen bonds with the catechol hydroxyl groups at positions 3 and 4, respectively (Strader *et al.*, 1989). It also appears that aspartate 113 is a point of electrostatic interaction with the amine group on the ligand. Since the serines are in the fifth membrane-spanning region and the aspartate is in the third (see Chapter 6), it is likely that catecholamines bind parallel to the plane of the membrane, forming a bridge between the two membrane spans. However, models involving dopamine receptors suggest alternative possibilities (Hutchins, 1994).

Hydroxyl groups in positions 3 and 5 confer β_2 receptor selectivity on compounds with large amino substituents. Thus, *meta-proprerenol*, *terbutaline*, and other similar compounds relax the bronchial musculature in patients with asthma, but cause less direct cardiac stimulation than do the nonselective drugs. The response to noncatecholamines is partly determined by their capacity to release norepinephrine from storage sites. These agents thus cause effects that are mostly mediated by α and β_1 receptors, since norepinephrine is a weak β_2 agonist. Phenylethylamines that lack hydroxyl groups on the ring and the β -hydroxyl group on the side chain act almost exclusively by causing the release of norepinephrine from sympathetic nerve terminals.

Since substitution of polar groups on the phenylethylamine structure makes the resultant compounds less lipophilic, unsubstituted or alkyl-substituted compounds cross the blood–brain barrier more readily and have more central activity. Thus, ephedrine, *amphetamine*, and *methamphetamine* exhibit considerable CNS activity. In addition, as noted above, the absence of polar hydroxyl groups results in a loss of direct sympathomimetic activity.

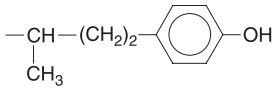

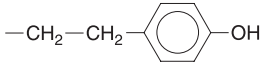

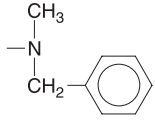

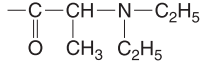

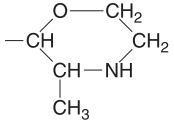

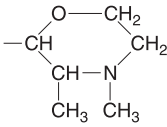

Catecholamines have only a brief duration of action and are ineffective when administered orally, because they are rapidly inactivated in the intestinal mucosa and in the liver before reaching the systemic circulation (see Chapter 6). Compounds without one or both hydroxyl substituents are not acted upon by COMT, and their oral effectiveness and duration of action are enhanced.

Groups other than hydroxyls have been substituted on the aromatic ring. In general, potency at α receptors is reduced and β receptor activity is minimal; the compounds may even block β receptors. For example, *methoxamine*, with methoxy substituents at positions 2 and 5, has highly selective α -stimulating activity,

Table 10-1

Chemical Structures and Main Clinical Uses of Important Sympathomimetic Drugs[†]

					MAIN CLINICAL USES

*Numbers bearing an asterisk refer to the substituents numbered in the bottom rows of the table; substituent 3 replaces the N atom, substituent 5 replaces the phenyl ring, and 6, 7, and 8 are attached directly to the phenyl ring, replacing the ethylamine side chain. †The *α* and *β* in the prototypical formula refer to positions of the C atoms in the ethylamine side chain. ‡Prenalterol has —OCH₂— between the aromatic ring and the carbon atom designated as *β* in the prototypical formula.

and in large doses blocks β receptors. *Albuterol*, a β_2 -selective agonist, has a substituent at position 3 and is an important exception to the general rule of low β receptor activity. The structure of albuterol is:

Substitution on the α -Carbon Atom. This substitution blocks oxidation by MAO, greatly prolonging the duration of action of noncatecholamines because their degradation depends largely on the action of this enzyme. The duration of action of drugs such as ephedrine or amphetamine is thus measured in hours rather than in minutes. Similarly, compounds with an α -methyl substituent persist in the nerve terminals and are more likely to release norepinephrine from storage sites. Agents such as *metaraminol* exhibit a greater degree of indirect sympathomimetic activity.

Substitution on the β -Carbon Atom. Substitution of a hydroxyl group on the β carbon generally decreases actions within the CNS, largely because it lowers lipid solubility. However, such substitution greatly enhances agonist activity at both α and β adrenergic receptors. Although ephedrine is less potent than methamphetamine as a central stimulant, it is more powerful in dilating bronchioles and increasing blood pressure and heart rate.

Optical Isomerism. Substitution on either α - or β -carbon yields optical isomers. Levorotatory substitution on the β -carbon confers the greater peripheral activity, so that the naturally occurring *l*-epinephrine and *l*-norepinephrine are at least 10 times as potent as their unnatural *d*-isomers. Dextrorotatory substitution on the α carbon generally results in a more potent compound. *d*-Amphetamine is more potent than *l*-amphetamine in central but not peripheral activity.

Physiological Basis of Adrenergic Receptor Function.

An important factor in the response of any cell or organ to sympathomimetic amines is the density and proportion of α and β adrenergic receptors. For example, norepinephrine has relatively little capacity to increase bronchial airflow, since the receptors in bronchial smooth muscle are largely of the β_2 subtype. In contrast, isoproterenol and epinephrine are potent bronchodilators. Cutaneous blood vessels physiologically express almost exclusively α receptors; thus, norepinephrine and epinephrine cause constriction of such vessels, whereas isoproterenol has little effect. The smooth muscle of blood vessels that supply skeletal muscles has both β_2 and α receptors; activation of β_2 receptors causes vasodilation, and stimulation of α receptors constricts these vessels. In such vessels, the threshold concentration for activation of β_2 receptors by epinephrine is lower than that for α receptors, but when both types of receptors are activated at high concentrations of epinephrine, the response to α receptors predominates. Physiological concentrations of epinephrine primarily cause vasodilation.

The ultimate response of a target organ to sympathomimetic amines is dictated not only by the direct effects of the agents, but also by the reflex homeostatic adjustments of the organism. One of the most striking effects of many sympathomimetic amines is a rise in arterial blood pressure caused by stimulation of vascular α adrenergic receptors. This stimulation elicits compensatory reflexes that are mediated by the carotid–aortic baroreceptor system. As a result, sympathetic tone is diminished and vagal tone is enhanced; each of these responses leads to slowing of the heart rate. Conversely, when a drug (e.g., a β_2 agonist) lowers mean blood pressure at the mechano-receptors of the carotid sinus and aortic arch, the baroreceptor reflex works to restore pressure by reducing parasympathetic (vagal) outflow from the CNS to the heart, and increasing sympathetic outflow to the heart and vessels. The baroreceptor reflex effect is of special importance for drugs that have little capacity to activate β receptors directly. With diseases such as atherosclerosis, which may impair baroreceptor mechanisms, the effects of sympathomimetic drugs may be magnified (Chapleau *et al.*, 1995).

False-Transmitter Concept. Indirectly acting amines are taken up into sympathetic nerve terminals and storage vesicles, where they replace norepinephrine in the storage complex. Phenylethylamines that lack a β -hydroxyl group are retained there poorly, but β -hydroxylated phenylethylamines and compounds that subsequently become hydroxylated in the synaptic vesicle by dopamine β -hydroxylase are retained in the synaptic vesicle for relatively long periods of time. Such substances can produce a persistent diminution in the content of norepinephrine at functionally critical sites. When the nerve is stimulated, the contents of a relatively constant number of synaptic vesicles are apparently released by exocytosis. If these vesicles contain phenylethylamines that are much less potent than norepinephrine, activation of postsynaptic α and β receptors will be diminished.

This hypothesis, known as the *false-transmitter concept*, is a possible explanation for some of the effects of MAO inhibitors. Phenylethylamines normally are synthesized in the GI tract as a result of the action of bacterial tyrosine decarboxylase. The tyramine formed in this fashion usually is oxidatively deaminated in the GI tract and the liver, and the amine does not reach the systemic circulation in significant concentrations. However, when an MAO inhibitor is administered, tyramine may be absorbed systemically and transported into sympathetic nerve terminals, where its catabolism again is prevented because of the inhibition of MAO at this site; the tyramine then is β -hydroxylated to octopamine and stored in the vesicles in this form. As a consequence, norepinephrine gradually is displaced, and stimulation of the nerve terminal results in the release of a relatively small amount of norepinephrine along with a fraction of octopamine. The latter amine has relatively little ability to activate either α or β receptors. Thus, a functional impairment of sympathetic transmission parallels long-term administration of MAO inhibitors.

Despite such functional impairment, patients who have received MAO inhibitors may experience severe hypertensive cri-

ses if they ingest cheese, beer, or red wine. These and related foods, which are produced by fermentation, contain a large quantity of tyramine, and to a lesser degree, other phenylethylamines. When gastrointestinal and hepatic MAO are inhibited, the large quantity of tyramine that is ingested is absorbed rapidly and reaches the systemic circulation in high concentration. A massive and precipitous release of norepinephrine can result, with consequent hypertension that can be severe enough to cause myocardial infarction or a stroke. The properties of various MAO inhibitors (reversible or irreversible; selective or nonselective at MAO-A and MAO-B) are discussed in Chapter 17.

ENDOGENOUS CATECHOLAMINES

Epinephrine

Epinephrine (adrenaline) is a potent stimulant of both α and β adrenergic receptors, and its effects on target organs are thus complex. Most of the responses listed in Table 6–1 are seen after injection of epinephrine, although the occurrence of sweating, piloerection, and mydriasis depends on the physiological state of the subject. Particularly prominent are the actions on the heart and on vascular and other smooth muscle.

Blood Pressure. Epinephrine is one of the most potent vasopressor drugs known. If a pharmacological dose is given rapidly by an intravenous route, it evokes a characteristic effect on blood pressure, which rises rapidly to a peak that is proportional to the dose. The increase in systolic pressure is greater than the increase in diastolic pres-

sure, so that the pulse pressure increases. As the response wanes, the mean pressure may fall below normal before returning to control levels.

The mechanism of the rise in blood pressure due to epinephrine is threefold: (1) a direct myocardial stimulation that increases the strength of ventricular contraction (positive inotropic action); (2) an increased heart rate (positive chronotropic action); and (3) vasoconstriction in many vascular beds—especially in the precapillary resistance vessels of skin, mucosa, and kidney—along with marked constriction of the veins. The pulse rate, at first accelerated, may be slowed markedly at the height of the rise of blood pressure by compensatory vagal discharge. Small doses of epinephrine ($0.1 \mu\text{g}/\text{kg}$) may cause the blood pressure to fall. The depressor effect of small doses and the biphasic response to larger doses are due to greater sensitivity to epinephrine of vasodilator β_2 receptors than of constrictor α receptors.

The effects are somewhat different when the drug is given by slow intravenous infusion or by subcutaneous injection. Absorption of epinephrine after subcutaneous injection is slow due to local vasoconstrictor action; the effects of doses as large as 0.5 to 1.5 mg can be duplicated by intravenous infusion at a rate of 10 to 30 μg per minute. There is a moderate increase in systolic pressure due to increased cardiac contractile force and a rise in cardiac output (Figure 10–3). Peripheral resistance decreases, owing to a dominant action on β_2 receptors of vessels in skeletal muscle, where blood flow is enhanced; as a consequence, diastolic pressure usually falls. Since the mean blood pressure is not, as a rule, greatly elevat-

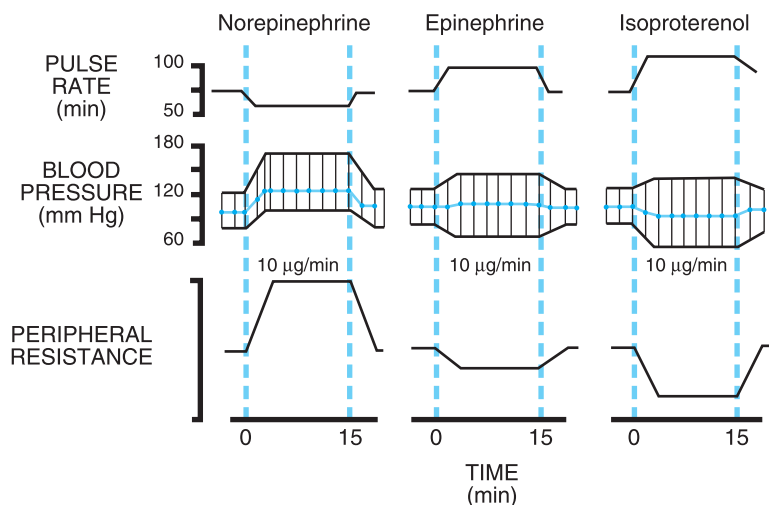

Figure 10–3. Effects of intravenous infusion of norepinephrine, epinephrine, or isoproterenol in humans. (Modified from Allwood *et al.*, 1963, with permission.)

ed, compensatory baroreceptor reflexes do not appreciably antagonize the direct cardiac actions. Heart rate, cardiac output, stroke volume, and left ventricular work per beat are increased as a result of direct cardiac stimulation and increased venous return to the heart, which is reflected by an increase in right atrial pressure. At slightly higher rates of infusion, there may be no change or a slight rise in peripheral resistance and diastolic pressure, depending on the dose and the resultant ratio of α to β responses in the various vascular beds; compensatory reflexes also may come into play. The details of the effects of intravenous infusion of epinephrine, norepinephrine, and isoproterenol in humans are compared in Table 10–2 and Figure 10–3.

Vascular Effects. The chief vascular action of epinephrine is exerted on the smaller arterioles and precapillary sphincters, although veins and large arteries also respond to the drug. Various vascular beds react differently, which results in a substantial redistribution of blood flow.

Injected epinephrine markedly decreases cutaneous blood flow, constricting precapillary vessels and small venules. Cutaneous vasoconstriction accounts for a marked decrease in blood flow in the hands and feet. The “after congestion” of mucosa following the vasoconstriction from locally applied epinephrine probably is due to changes in vascular reactivity as a result of tissue hypoxia rather than to β agonist activity of the drug on mucosal vessels.

Blood flow to skeletal muscles is increased by therapeutic doses in humans. This is due in part to a powerful β_2 -mediated vasodilator action that is only partially counterbalanced by a vasoconstrictor action on the α receptors that also are present in the vascular bed. If an α receptor antagonist is given, the vasodilation in muscle is more pronounced, the total peripheral resistance is decreased, and the mean blood pressure falls (epinephrine reversal). After the administration of a nonselective β receptor antagonist, only vasoconstriction occurs, and the administration of epinephrine is associated with a considerable pressor effect.

The effect of epinephrine on cerebral circulation is related to systemic blood pressure. In usual therapeutic doses, the drug has relatively little constrictor action on cerebral arterioles. It is physiologically advantageous that the cerebral circulation does not constrict in response to activation of the sympathetic nervous system by stressful stimuli. Indeed, autoregulatory mechanisms tend to limit the increase in cerebral blood flow caused by increased blood pressure.

Doses of epinephrine that have little effect on mean arterial pressure consistently increase renal vascular resistance and reduce

renal blood flow by as much as 40%. All segments of the renal vascular bed contribute to the increased resistance. Since the glomerular filtration rate is only slightly and variably altered, the filtration fraction is consistently increased. Excretion of Na^+ , K^+ , and Cl^- is decreased; urine volume may be increased, decreased, or unchanged. Maximal tubular reabsorptive and excretory capacities are unchanged. The secretion of renin is increased as a consequence of a direct action of epinephrine on β_1 receptors in the juxtaglomerular apparatus.

Arterial and venous pulmonary pressures are raised. Although direct pulmonary vasoconstriction occurs, redistribution of blood from the systemic to the pulmonary circulation, due to constriction of the more powerful musculature in the systemic great veins, doubtless plays an important part in the increase in pulmonary pressure. Very high concentrations of epinephrine may cause pulmonary

edema precipitated by elevated pulmonary capillary filtration pressure and possibly by “leaky” capillaries.

Coronary blood flow is enhanced by epinephrine or by cardiac sympathetic stimulation under physiological conditions. The increased flow, which occurs even with doses that do not increase the aortic blood pressure, is the result of two factors. The first is the increased relative duration of diastole at higher heart rates (*see* below); this is partially offset by decreased blood flow during systole because of more forceful contraction of the surrounding myocardium and an increase in mechanical compression of the coronary vessels. The increased flow during diastole is further enhanced if aortic blood pressure is elevated by epinephrine; as a consequence, total coronary flow may be increased. The second factor is a metabolic dilator effect that results from the increased strength of contraction and myocardial oxygen consumption due to the direct effects of epinephrine on cardiac myocytes. This vasodilation is mediated in part by adenosine released from cardiac myocytes, which tends to override a direct vasoconstrictor effect of epinephrine that results from activation of α receptors in coronary vessels.

Cardiac Effects. Epinephrine is a powerful cardiac stimulant. It acts directly on the predominant β_1 receptors of the myocardium and of the cells of the pacemaker and conducting tissues; β_2 , β_3 , and α receptors also are present in the heart, although there are considerable species differences. Considerable recent interest has focused on the role of β_1 and β_2 receptors in the human heart, especially in heart failure. The heart rate increases, and the rhythm often is altered. Cardiac systole is shorter and more powerful, cardiac output is enhanced, and the work of the heart and its oxygen consumption are markedly increased. Cardiac efficiency (work done relative to oxygen consumption) is lessened. Direct responses to epinephrine include increases in contractile force, accelerated rate of rise of isometric tension, enhanced rate of relaxation, decreased time to peak tension, increased excitability, acceleration of the rate of spontaneous beating, and induction of automaticity in specialized regions of the heart.

In accelerating the heart, epinephrine preferentially shortens systole so that the duration of diastole usually is not reduced. Indeed, activation of β receptors increases the rate of relaxation of ventricular muscle. Epinephrine speeds the heart by accelerating the slow depolarization of sinoatrial (SA) nodal cells that takes place during diastole, *i.e.*, during phase 4 of the action potential (*see* Chapter 34). Consequently, the transmembrane potential of the pacemaker cells rises more rapidly to the threshold level of action potential initiation. The amplitude of the action potential and the maximal rate of depolarization (phase 0) also are increased. A shift in the location of the pacemaker within the SA node often occurs, owing to activation of latent pacemaker cells. In Purkinje fibers, epinephrine also accelerates diastolic depolarization and may activate latent pacemaker cells. These changes do not occur in atrial and ventricular muscle fibers, where epinephrine has little effect on the stable, phase 4 membrane potential after repolarization. If large doses of epinephrine

are given, premature ventricular contractions occur and may herald more serious ventricular arrhythmias. This rarely is seen with conventional doses in humans, but ventricular extrasystoles, tachycardia, or even fibrillation may be precipitated by release of endogenous epinephrine when the heart has been sensitized to this action of epinephrine by certain anesthetics or by myocardial ischemia. The mechanism of induction of these cardiac arrhythmias is not clear.

Some effects of epinephrine on cardiac tissues are largely secondary to the increase in heart rate and are small or inconsistent when the heart rate is kept constant. For example, the effect of epinephrine on repolarization of atrial muscle, Purkinje fibers, or ventricular muscle is small if the heart rate is unchanged. When the heart rate is increased, the duration of the action potential is consistently shortened, and the refractory period is correspondingly decreased.

Conduction through the Purkinje system depends on the level of membrane potential at the time of excitation. Excessive reduction of this potential results in conduction disturbances, ranging from slowed conduction to complete block. Epinephrine often increases the membrane potential and improves conduction in Purkinje fibers that have been excessively depolarized.

Epinephrine normally shortens the refractory period of the human atrioventricular (AV) node by direct effects on the heart, although doses of epinephrine that slow the heart through reflex vagal discharge may indirectly tend to prolong it. Epinephrine also decreases the grade of AV block that occurs as a result of disease, drugs, or vagal stimulation. Supraventricular arrhythmias are apt to occur from the combination of epinephrine and cholinergic stimulation. Depression of sinus rate and AV conduction by vagal discharge probably plays a part in epinephrine-induced ventricular arrhythmias, since various drugs that block the vagal effect confer some protection. The actions of epinephrine in enhancing cardiac automaticity and in causing arrhythmias are effectively antagonized by β receptor antagonists such as propranolol. However, α_1 receptors exist in most regions of the heart, and their activation prolongs the refractory period and strengthens myocardial contractions.

Cardiac arrhythmias have been seen in patients after inadvertent intravenous administration of conventional subcutaneous doses of epinephrine. Premature ventricular contractions can appear, which may be followed by multifocal ventricular tachycardia or ventricular fibrillation. Pulmonary edema also may occur.

Epinephrine decreases the amplitude of the T wave of the electrocardiogram (ECG) in normal persons. In animals given relatively larger doses, additional effects are seen on the T wave and the ST segment. After decreasing in amplitude, the T wave may become biphasic, and the ST segment can deviate either above or below the isoelectric line. Such ST-segment changes are similar to those seen in patients with angina pectoris during spontaneous or epinephrine-induced attacks of pain. These electrical changes therefore have been attributed to myocardial ischemia. Also, epinephrine as well as other catecholamines may cause myocardial cell death, particularly after intravenous infusions. Acute toxicity is associated with contraction band necrosis and other pathological changes. Recent interest has focused on the possibility that prolonged sympathetic stimulation of the heart, such as in congestive cardiomyopathy, may promote apoptosis of cardiomyocytes.

Effects on Smooth Muscles. The effects of epinephrine on the smooth muscles of different organs and sys-

tems depend on the type of adrenergic receptor in the muscle (*see* Table 6–1). The effects on vascular smooth muscle are of major physiological importance, whereas those on gastrointestinal smooth muscle are relatively minor. Gastrointestinal smooth muscle is, in general, relaxed by epinephrine. This effect is due to activation of both α and β receptors. Intestinal tone and the frequency and amplitude of spontaneous contractions are reduced. The stomach usually is relaxed and the pyloric and ileocecal sphincters are contracted, but these effects depend on the preexisting tone of the muscle. If tone already is high, epinephrine causes relaxation; if low, contraction.

The responses of uterine muscle to epinephrine vary with species, phase of the sexual cycle, state of gestation, and dose given. Epinephrine contracts strips of pregnant or nonpregnant human uterus *in vitro* by interaction with α receptors. The effects of epinephrine on the human uterus *in situ*, however, differ. During the last month of pregnancy and at parturition, epinephrine inhibits uterine tone and contractions. β_2 -Selective agonists, such as *ritodrine* or *terbutaline*, have been used to delay premature labor, although their efficacy is limited. Effects of these and other drugs on the uterus are discussed below.

Epinephrine relaxes the detrusor muscle of the bladder as a result of activation of β receptors and contracts the trigone and sphincter muscles owing to its α agonist activity. This can result in hesitancy in urination and may contribute to retention of urine in the bladder. Activation of smooth muscle contraction in the prostate promotes urinary retention.

Respiratory Effects. Epinephrine affects respiration primarily by relaxing bronchial muscle. It has a powerful bronchodilator action, most evident when bronchial muscle is contracted because of disease, as in bronchial asthma, or in response to drugs or various autacoids. In such situations, epinephrine has a striking therapeutic effect as a physiological antagonist to substances that cause bronchoconstriction.

The beneficial effects of epinephrine in asthma also may arise from inhibition of antigen-induced release of inflammatory mediators from mast cells, and to a lesser extent from diminution of bronchial secretions and congestion within the mucosa. Inhibition of mast cell secretion is mediated by β_2 receptors, while the effects on the mucosa are mediated by α receptors; however, other drugs, such as glucocorticoids and leukotriene-receptor antagonists, have much more profound antiinflammatory effects in asthma (*see* Chapter 27).

Effects on the Central Nervous System. Because of the inability of this rather polar compound to enter the CNS, epinephrine in conventional therapeutic doses is not a powerful CNS stimulant. While the drug may cause restlessness, apprehension, headache, and tremor in many persons, these effects in part may be secondary to the effects of epinephrine on the cardiovascular system, skeletal muscles, and intermediary metabolism; that is,

they may be the result of somatic manifestations of anxiety. Some other sympathomimetic drugs more readily cross the blood–brain barrier.

Metabolic Effects. Epinephrine has a number of important influences on metabolic processes. It elevates the concentrations of glucose and lactate in blood by mechanisms described in Chapter 6. Insulin secretion is inhibited through an interaction with α_2 receptors and is enhanced by activation of β_2 receptors; the predominant effect seen with epinephrine is inhibition. Glucagon secretion is enhanced by an action on the β receptors of the α cells of pancreatic islets. Epinephrine also decreases the uptake of glucose by peripheral tissues, at least in part because of its effects on the secretion of insulin, but also possibly due to direct effects on skeletal muscle. Glycosuria rarely occurs. The effect of epinephrine to stimulate glycogenolysis in most tissues and in most species involves β receptors (*see* Chapter 6).

Epinephrine raises the concentration of free fatty acids in blood by stimulating β receptors in adipocytes. The result is activation of triglyceride lipase, which accelerates the triglyceride breakdown to free fatty acids and glycerol. The calorogenic action of epinephrine (increase in metabolism) is reflected in humans by an increase of 20% to 30% in oxygen consumption after conventional doses. This effect mainly is due to enhanced breakdown of triglycerides in brown adipose tissue, providing an increase in oxidizable substrate (*see* Chapter 6).

Miscellaneous Effects. Epinephrine reduces circulating plasma volume by loss of protein-free fluid to the extracellular space, thereby increasing hematocrit and plasma protein concentration. However, conventional doses of epinephrine do not significantly alter plasma volume or packed red cell volume under normal conditions, although such doses are reported to have variable effects in the presence of shock, hemorrhage, hypotension, or anesthesia. Epinephrine rapidly increases the number of circulating polymorphonuclear leukocytes, likely due to β receptor-mediated demargination of these cells. Epinephrine accelerates blood coagulation in laboratory animals and humans and promotes fibrinolysis.

The effects of epinephrine on secretory glands are not marked; in most glands secretion usually is inhibited, partly owing to the reduced blood flow caused by vasoconstriction. Epinephrine stimulates lacrimation and a scanty mucus secretion from salivary glands. Sweating and pilomotor activity are minimal after systemic administration of epinephrine, but occur after intradermal injection of very dilute solutions of either epinephrine or norepinephrine. Such effects are inhibited by α receptor antagonists.

Mydriasis is readily seen during physiological sympathetic stimulation but not when epinephrine is instilled into the conjunctival sac of normal eyes. However, epinephrine usually lowers intraocular pressure; the mechanism of this effect is not clear but probably reflects reduced production of aqueous humor due to vasoconstriction and enhanced outflow (*see* Chapter 63).

Although epinephrine does not directly excite skeletal muscle, it facilitates neuromuscular transmission, particularly that following prolonged rapid stimulation of motor nerves. In apparent contrast to the effects of α receptor activation at presynaptic nerve terminals in the autonomic nervous system (α_2 receptors), stimulation of α receptors causes a more rapid increase in transmitter release from the somatic motor neuron, perhaps as a result of enhanced influx of Ca^{2+} . These responses likely are mediated by α_1 receptors. These actions may explain in part the ability of epinephrine (given intra-arterially) to briefly increase strength of the injected limb of patients with myasthenia gravis. Epinephrine also acts directly on white, fast-twitch muscle fibers to prolong the active state, thereby increasing peak tension. Of greater physiological and clinical importance is the capacity of epinephrine and selective β_2 agonists to increase physiological tremor, at least in part due to β receptor-mediated enhancement of discharge of muscle spindles.

Epinephrine promotes a fall in plasma K^+ , largely due to stimulation of K^+ uptake into cells, particularly skeletal muscle, due to activation of β_2 receptors. This is associated with decreased renal K^+ excretion. These receptors have been exploited in the management of hyperkalemic familial periodic paralysis, which is characterized by episodic flaccid paralysis, hyperkalemia, and depolarization of skeletal muscle. The β_2 -selective agonist albuterol apparently is able to ameliorate the impairment in the ability of the muscle to accumulate and retain K^+ .

The administration of large or repeated doses of epinephrine or other sympathomimetic amines to experimental animals damages arterial walls and myocardium, even inducing necrosis in the heart indistinguishable from myocardial infarction. The mechanism of this injury is not yet clear, but α and β receptor antagonists and Ca^{2+} channel blockers may afford substantial protection against the damage. Similar lesions occur in many patients with pheochromocytoma or after prolonged infusions of norepinephrine.

Absorption, Fate, and Excretion. As indicated above, epinephrine is not effective after oral administration because it is rapidly conjugated and oxidized in the GI mucosa and liver. Absorption from subcutaneous tissues occurs relatively slowly because of local vasoconstriction and the rate may be further decreased by systemic hypotension, for example in a patient with shock. Absorption is more rapid after intramuscular injection. In emergencies, it may be necessary to administer epinephrine intravenously. When relatively concentrated solutions (1%) are nebulized and inhaled, the actions of the drug largely are restricted to the respiratory tract; however, systemic reactions such as arrhythmias may occur, particularly if larger amounts are used.

Epinephrine is rapidly inactivated in the body. The liver, which is rich in both of the enzymes responsible for destroying circulating epinephrine (COMT and MAO), is particularly important in this regard (see Figure 6-6 and Table 6-5). Although only small amounts appear in the urine of normal persons, the urine of

patients with pheochromocytoma may contain relatively large amounts of epinephrine, norepinephrine, and their metabolites.

Epinephrine is available in a variety of formulations geared for different clinical indications and routes of administration, such as by injection (usually subcutaneously but sometimes intravenously), by inhalation, or topically. Several practical points are worth noting. First, epinephrine is unstable in alkaline solution; when exposed to air or light, it turns pink from oxidation to adrenochrome and then brown from formation of polymers. Epinephrine injection is available in 1 mg/ml (1:1000), 0.1 mg/ml (1:10,000), and 0.5 mg/ml (1:2,000) solutions. The usual adult dose given subcutaneously ranges from 0.3 to 0.5 mg. The intravenous route is used cautiously if an immediate and reliable effect is mandatory. If the solution is given by vein, it must be adequately diluted and injected very slowly. The dose is seldom as much as 0.25 mg, except for cardiac arrest, when larger doses may be required. Epinephrine suspensions are used to slow subcutaneous absorption and must never be injected intravenously. *Also, a 1% (10 mg/ml; 1:100) formulation is available for administration via inhalation; every precaution must be taken not to confuse this 1:100 solution with the 1:1000 solution designed for parenteral administration, because inadvertent injection of the 1:100 solution can be fatal.*

Toxicity, Adverse Effects, and Contraindications. Epinephrine may cause disturbing reactions, such as restlessness, throbbing headache, tremor, and palpitations. The effects rapidly subside with rest, quiet, recumbency, and reassurance.

More serious reactions include cerebral hemorrhage and cardiac arrhythmias. The use of large doses or the accidental, rapid intravenous injection of epinephrine may result in cerebral hemorrhage from the sharp rise in blood pressure. Ventricular arrhythmias may follow the administration of epinephrine. Angina may be induced by epinephrine in patients with coronary artery disease.

The use of epinephrine generally is contraindicated in patients who are receiving nonselective β receptor blocking drugs, since its unopposed actions on vascular α_1 receptors may lead to severe hypertension and cerebral hemorrhage.

Therapeutic Uses. The clinical uses of epinephrine are based on its actions on blood vessels, heart, and bronchial muscle. In the past, the most common use of epinephrine was to relieve respiratory distress due to bronchospasm; however, β_2 -selective agonists now are preferred. A major use is to provide rapid relief of hypersensitivity reactions, including anaphylaxis, to drugs and other allergens. Epinephrine also is used to prolong the action of local anesthetics, presumably by decreasing local blood flow (see Chapter 14). Its cardiac effects may be of use in restoring cardiac rhythm in patients with cardiac arrest due to various causes. It also is used as a topical hemostatic agent on bleeding surfaces such as in the mouth or in bleeding peptic ulcers during endoscopy of the stomach and duodenum. Systemic absorption of the drug can occur with dental application. In addition, inhalation of epinephrine may be useful in the treatment of postintubation and infectious croup. The therapeutic uses of epinephrine, in relation to other sympathomimetic drugs, are discussed later in this chapter.

Norepinephrine

Norepinephrine (levarterenol, *l*-noradrenaline, *l*- β -[3,4-dihydroxyphenyl]- α -aminoethanol) is a major chemical mediator liberated by mammalian postganglionic sympathetic nerves. It differs from epinephrine only by lacking the methyl substitution in the amino group (Table 10–1). Norepinephrine constitutes 10% to 20% of the catecholamine content of human adrenal medulla and as much as 97% in some pheochromocytomas, which may not express the enzyme phenylethanolamine-*N*-methyltransferase. The history of its discovery and its role as a neurohumoral mediator are discussed in Chapter 6.

Pharmacological Properties. The pharmacological actions of norepinephrine and epinephrine have been extensively compared *in vivo* and *in vitro* (Table 10–2). Both drugs are direct agonists on effector cells, and their actions differ mainly in the ratio of their effectiveness in stimulating α and β_2 receptors. They are approximately equipotent in stimulating β_1 receptors. Norepinephrine is a potent α agonist and has relatively little action on β_2 receptors; however, it is somewhat less potent than epinephrine on the α receptors of most organs.

Cardiovascular Effects. The cardiovascular effects of an intravenous infusion of 10 μ g of norepinephrine per minute in humans are shown in Figure 10–3. Systolic and diastolic pressures, and usually pulse pressure, are increased. Cardiac output is unchanged or decreased, and total peripheral resistance is raised. Compensatory vagal reflex activity slows the heart, overcoming a direct cardioaccelerator action, and stroke volume is increased. The peripheral vascular resistance increases in most vascular beds, and renal blood flow is reduced. Norepinephrine constricts mesenteric vessels and reduces splanchnic and hepatic blood flow. Coronary flow usually is increased, probably owing both to indirectly induced coronary dilation, as with epinephrine, and to elevated blood pressure. Although generally a poor β_2 receptor agonist, norepinephrine may increase coronary blood flow directly by stimulating β_2 receptors on coronary vessels (Sun *et al.*, 2002). The physiological significance of this is not yet established. Patients with Prinzmetal's variant angina may be supersensitive to the α adrenergic vasoconstrictor effects of norepinephrine.

Unlike epinephrine, small doses of norepinephrine do not cause vasodilation or lower blood pressure, since the blood vessels of skeletal muscle constrict rather than dilate; α adrenergic receptor antagonists therefore abolish

the pressor effects but do not cause significant reversal (*i.e.*, hypotension).

Other Effects. Other responses to norepinephrine are not prominent in humans. The drug causes hyperglycemia and other metabolic effects similar to those produced by epinephrine, but these are observed only when large doses are given because norepinephrine is not as effective a "hormone" as epinephrine. Intradermal injection of suitable doses causes sweating that is not blocked by atropine.

Absorption, Fate, and Excretion. Norepinephrine, like epinephrine, is ineffective when given orally and is absorbed poorly from sites of subcutaneous injection. It is rapidly inactivated in the body by the same enzymes that methylate and oxidatively deaminate epinephrine (*see above*). Small amounts normally are found in the urine. The excretion rate may be greatly increased in patients with pheochromocytoma.

Toxicity, Adverse Effects, and Precautions. The untoward effects of norepinephrine are similar to those of epinephrine, although there typically is greater elevation of blood pressure with norepinephrine. Excessive doses can cause severe hypertension, so careful blood pressure monitoring generally is indicated during systemic administration of this agent.

Care must be taken that necrosis and sloughing do not occur at the site of intravenous injection owing to extravasation of the drug. The infusion should be made high in the limb, preferably through a long plastic cannula extending centrally. Impaired circulation at injection sites, with or without extravasation of norepinephrine, may be relieved by infiltrating the area with *phen-tolamine*, an α receptor antagonist. Blood pressure must be determined frequently during the infusion and particularly during adjustment of the rate of the infusion. Reduced blood flow to organs such as kidney and intestines is a constant danger with the use of norepinephrine.

Therapeutic Uses and Status. Norepinephrine (LEVOPHED, others) has only limited therapeutic value. The use of it and other sympathomimetic amines in shock is discussed later in this chapter. In the treatment of low blood pressure, the dose is titrated to the desired pressor response.

Dopamine

Dopamine (3,4-dihydroxyphenylethylamine) (Table 10–1) is the immediate metabolic precursor of norepinephrine and epinephrine; it is a central neurotransmitter particularly important in the regulation of movement (*see* Chapters 12, 18, and 20) and possesses important intrinsic pharmacological properties. In the periphery, it is synthesized in epithelial cells of the proximal tubule and is thought to exert local diuretic and natriuretic effects. Dopamine is a substrate for both MAO and COMT and thus is ineffective when administered orally. Classification of dopamine receptors is described in Chapters 12 and 20.

Pharmacological Properties. Cardiovascular Effects.

The cardiovascular effects of dopamine are mediated by several distinct types of receptors that vary in their affinity for dopamine. At low concentrations, the primary interaction of dopamine is with vascular D_1 receptors, especially in the renal, mesenteric, and coronary beds. By activating adenylyl cyclase and raising intracellular concentrations of cyclic AMP, D_1 receptor stimulation leads to vasodilation (Missale *et al.*, 1998). Infusion of low doses of dopamine causes an increase in glomerular filtration rate, renal blood flow, and Na^+ excretion. Activation of D_1 receptors on renal tubular cells decreases sodium transport by cAMP-dependent and cAMP-independent mechanisms. Increasing cAMP production in the proximal tubular cells and the medullary part of the thick ascending limb of the loop of Henle inhibits the Na^+-H^+ exchanger and the Na^+,K^+ -ATPase pump. The renal tubular actions of dopamine that cause natriuresis may be augmented by the increase in renal blood flow and the small increase in the glomerular filtration rate that follow its administration. The resulting increase in hydrostatic pressure in the peritubular capillaries and reduction in oncotic pressure may contribute to diminished reabsorption of sodium by the proximal tubular cells. As a consequence, dopamine has pharmacologically appropriate effects in the management of states of low cardiac output associated with compromised renal function, such as severe congestive heart failure.

At somewhat higher concentrations, dopamine exerts a positive inotropic effect on the myocardium, acting on β_1 adrenergic receptors. Dopamine also causes the release of norepinephrine from nerve terminals, which contributes to its effects on the heart. Tachycardia is less prominent during infusion of dopamine than of isoproterenol (*see below*). Dopamine usually increases systolic blood pressure and pulse pressure and either has no effect on diastolic blood pressure or increases it slightly. Total peripheral resistance usually is unchanged when low or intermediate doses of dopamine are given, probably because of the ability of dopamine to reduce regional arterial resistance in some vascular beds, such as mesenteric and renal, while causing only minor increases in others. At high concentrations, dopamine activates vascular α_1 receptors, leading to more general vasoconstriction.

Other Effects. Although there are specific dopamine receptors in the CNS, injected dopamine usually has no central effects because it does not readily cross the blood-brain barrier.

Precautions, Adverse Reactions, and Contraindications.

Before dopamine is administered to patients in shock, hypovolemia should be corrected by transfusion of whole blood, plasma, or other appropriate fluid. Untoward effects due to overdosage generally are attributable to excessive sympathomimetic activity (although this also

may be the response to worsening shock). Nausea, vomiting, tachycardia, anginal pain, arrhythmias, headache, hypertension, and peripheral vasoconstriction may be encountered during dopamine infusion. Extravasation of large amounts of dopamine during infusion may cause ischemic necrosis and sloughing. Rarely, gangrene of the fingers or toes has followed prolonged infusion of the drug.

Dopamine should be avoided or used at a much reduced dosage (one-tenth or less) if the patient has received a MAO inhibitor. Careful adjustment of dosage also is necessary in patients who are taking tricyclic antidepressants.

Therapeutic Uses. Dopamine (INTROPIN, others) is used in the treatment of severe congestive failure, particularly in patients with oliguria and low or normal peripheral vascular resistance. The drug also may improve physiological parameters in the treatment of cardiogenic and septic shock. While dopamine may acutely improve cardiac and renal function in severely ill patients with chronic heart disease or renal failure, there is relatively little evidence supporting long-term benefit in clinical outcome (Marik and Iglesias, 1999). The management of shock is discussed below.

Dopamine hydrochloride is used only intravenously. The drug initially is administered at a rate of 2 to 5 $\mu\text{g}/\text{kg}$ per minute; this rate may be increased gradually up to 20 to 50 $\mu\text{g}/\text{kg}$ per minute or more as the clinical situation dictates. During the infusion, patients require clinical assessment of myocardial function, perfusion of vital organs such as the brain, and the production of urine. Most patients should receive intensive care, with monitoring of arterial and venous pressures and the ECG. Reduction in urine flow, tachycardia, or the development of arrhythmias may be indications to slow or terminate the infusion. The duration of action of dopamine is brief, and hence the rate of administration can be used to control the intensity of effect.

Related drugs include *fenoldopam* and *dopexamine*. Fenoldopam (CORLOPAM), a benzazepine derivative, is a rapidly acting vasodilator used for control of severe hypertension (*e.g.*, malignant hypertension with end-organ damage) in hospitalized patients for not more than 48 hours. Fenoldopam is an agonist for D_1 peripheral dopamine receptors and binds with moderate affinity to α_2 adrenergic receptors; it has no significant affinity for D_2 receptors or α_1 or β adrenergic receptors. Fenoldopam is a racemic mixture; the R-isomer is the active component. It dilates a variety of blood vessels, including coronary arteries, afferent and efferent arterioles in the kidney, and mesenteric arteries (Murphy *et al.*, 2001).

Less than 6% of an orally administered dose is absorbed because of extensive first-pass formation of sulfate, methyl, and glucuronide conjugates. The elimination half-life of intravenously infused fenoldopam, estimated from the decline in plasma concentration in hypertensive patients after the cessation of a 2-hour infusion, is 10 minutes. Adverse effects are related to the vasodilation and include headache, flushing, dizziness, and tachycardia or bradycardia.

Dopexamine (DOPACARD) is a synthetic analog related to dopamine with intrinsic activity at dopamine D_1 and D_2 receptors as well as at β_2 receptors; it may have other effects such as inhibition of catecholamine uptake (Fitton and Benfield, 1990). It appears to have favorable hemodynamic actions in patients with severe congestive heart failure, sepsis, and shock. In patients with low cardiac output, dopexamine infusion significantly increases stroke volume with a decrease in systemic vascular resistance. Tachycardia and hypotension can occur, but usually only at high infusion rates. Dopexamine is not currently available in the United States.

β ADRENERGIC RECEPTOR AGONISTS

β Adrenergic receptor agonists have been utilized in many clinical settings but now play a major role only in the treatment of bronchoconstriction in patients with asthma (reversible airway obstruction) or chronic obstructive pulmonary disease (COPD). Minor uses include management of preterm labor, treatment of complete heart block in shock, and short-term treatment of cardiac decompensation after surgery or in patients with congestive heart failure or myocardial infarction.

Epinephrine first was used as a bronchodilator at the beginning of the past century, and ephedrine was introduced into western medicine in 1924, although it had been used in China for thousands of years. The next major advance was the development in the 1940s of isoproterenol, a β receptor-selective agonist; this provided a drug for asthma that lacked α receptor activity. The recent development of β_2 -selective agonists has resulted in drugs with even more valuable characteristics, including adequate oral bioavailability, lack of α adrenergic activity, and diminished likelihood of some adverse cardiovascular effects.

β Receptor agonists may be used to stimulate the rate and force of cardiac contraction. The chronotropic effect is useful in the emergency treatment of arrhythmias such as *torsades de pointes*, bradycardia, or heart block (see Chapter 34), whereas the inotropic effect is useful when it is desirable to augment myocardial contractility. The therapeutic uses of β receptor agonists are discussed later in the chapter.

Isoproterenol

Isoproterenol (isopropylarterenol, isopropyl norepinephrine, isoprenaline, isopropyl noradrenaline, *d,l*- β -[3,4-dihydroxyphenyl]- α -isopropylaminoethanol) (Table 10–1) is a potent, nonselective β receptor agonist with very low affinity for α receptors. Consequently, isoproterenol has powerful effects on all β receptors and almost no action at α receptors.

Pharmacological Actions. The major cardiovascular effects of isoproterenol (compared with epinephrine

and norepinephrine) are illustrated in Figure 10–3. Intravenous infusion of isoproterenol lowers peripheral vascular resistance, primarily in skeletal muscle but also in renal and mesenteric vascular beds. Diastolic pressure falls. Systolic blood pressure may remain unchanged or rise, although mean arterial pressure typically falls. Cardiac output is increased because of the positive inotropic and chronotropic effects of the drug in the face of diminished peripheral vascular resistance. The cardiac effects of isoproterenol may lead to palpitations, sinus tachycardia, and more serious arrhythmias; large doses of isoproterenol may cause myocardial necrosis in animals.

Isoproterenol relaxes almost all varieties of smooth muscle when the tone is high, but this action is most pronounced on bronchial and GI smooth muscle. It prevents or relieves bronchoconstriction. Its effect in asthma may be due in part to an additional action to inhibit antigen-induced release of histamine and other mediators of inflammation; this action is shared by β_2 receptor-selective stimulants.

Absorption, Fate, and Excretion. Isoproterenol is readily absorbed when given parenterally or as an aerosol. It is metabolized primarily in the liver and other tissues by COMT. Isoproterenol is a relatively poor substrate for MAO and is not taken up by sympathetic neurons to the same extent as are epinephrine and norepinephrine. The duration of action of isoproterenol therefore may be longer than that of epinephrine, but it still is brief.

Toxicity and Adverse Effects. Palpitations, tachycardia, headache, and flushing are common. Cardiac ischemia and arrhythmias may occur, particularly in patients with underlying coronary artery disease.

Therapeutic Uses. Isoproterenol (ISUPREL, others) may be used in emergencies to stimulate heart rate in patients with bradycardia or heart block, particularly in anticipation of inserting an artificial cardiac pacemaker or in patients with the ventricular arrhythmia *torsades de pointes*. In disorders such as asthma and shock, isoproterenol largely has been replaced by other sympathomimetic drugs (see below and Chapter 27).

Dobutamine

Dobutamine resembles dopamine structurally but possesses a bulky aromatic substituent on the amino group (Table 10–1). The pharmacological effects of dobutamine are due to direct interactions with α and β receptors; its actions do not appear to result from release of norepinephrine from sympathetic nerve endings, nor are they exerted *via* dopaminergic receptors. Although dobutamine originally was thought to be a relatively selective β_1 receptor agonist, it now is clear that its pharmacological effects are complex. Dobutamine possesses a center of

asymmetry; both enantiomeric forms are present in the racemic mixture used clinically. The (–) isomer of dobutamine is a potent agonist at α_1 receptors and is capable of causing marked pressor responses. In contrast, (+)-dobutamine is a potent α_1 receptor antagonist, which can block the effects of (–)-dobutamine. The effects of these two isomers are mediated *via* β receptors. The (+) isomer is a more potent β receptor agonist than the (–) isomer (approximately tenfold). Both isomers appear to be full agonists.

Cardiovascular Effects. The cardiovascular effects of racemic dobutamine represent a composite of the distinct pharmacological properties of the (–) and (+) stereoisomers. Dobutamine has relatively more prominent inotropic than chronotropic effects on the heart compared to isoproterenol. Although not completely understood, this useful selectivity may arise because peripheral resistance is relatively unchanged. Alternatively, cardiac α_1 receptors may contribute to the inotropic effect. At equivalent inotropic doses, dobutamine enhances automaticity of the sinus node to a lesser extent than does isoproterenol; however, enhancement of atrioventricular and intraventricular conduction is similar for both drugs.

In animals, administration of dobutamine at a rate of 2.5 to 15 $\mu\text{g}/\text{kg}$ per minute increases cardiac contractility and cardiac output. Total peripheral resistance is not greatly affected. The relatively constant peripheral resistance presumably reflects counterbalancing of α_1 receptor–mediated vasoconstriction and β_2 receptor–mediated vasodilation (Ruffolo, 1987). Heart rate increases only modestly when the rate of administration of dobutamine is maintained at less than 20 $\mu\text{g}/\text{kg}$ per minute. After administration of β receptor antagonists, infusion of dobutamine fails to increase cardiac output, but total peripheral resistance increases, confirming that dobutamine has modest direct effects on α adrenergic receptors in the vasculature.

Adverse Effects. In some patients, blood pressure and heart rate increase significantly during dobutamine administration; this may require reduction of the rate of infusion. Patients with a history of hypertension may exhibit such an exaggerated pressor response more frequently. Since dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of marked increases in ventricular response rates; digoxin or other measures may be required to prevent this from occurring. Some patients may develop ventricular ectopic activity. As with any inotropic agent, dobutamine potentially may increase the size of a myocardial infarct by increasing myocardial oxygen demand. This risk must be balanced against the patient's overall clinical status. The efficacy of dobutamine over a period of more than a few days is uncertain; there is evidence for the development of tolerance.

Therapeutic Uses. Dobutamine (DOBUTREX, others) is indicated for the short-term treatment of cardiac decompensation that may occur after cardiac surgery or in patients with congestive heart failure or acute myocardial infarction. Dobutamine increases cardiac output and stroke volume in such patients, usually without a marked increase in heart rate. Alterations in blood pressure or

peripheral resistance usually are minor, although some patients may have marked increases in blood pressure or heart rate. Clinical evidence of longer-term efficacy remains uncertain. An infusion of dobutamine in combination with echocardiography is useful in the noninvasive assessment of patients with coronary artery disease (Madu *et al.*, 1994). Stressing of the heart with dobutamine may reveal cardiac abnormalities in carefully selected patients.

Dobutamine has a half-life of about 2 minutes; the major metabolites are conjugates of dobutamine and 3-*O*-methyldobutamine. The onset of effect is rapid. Consequently, a loading dose is not required, and steady-state concentrations generally are achieved within 10 minutes of initiation of the infusion. The rate of infusion required to increase cardiac output typically is between 2.5 and 10 $\mu\text{g}/\text{kg}$ per minute, although higher infusion rates occasionally are required. The rate and duration of the infusion are determined by the clinical and hemodynamic responses of the patient.

β_2 -Selective Adrenergic Receptor Agonists

Some of the major adverse effects of β receptor agonists in the treatment of asthma are caused by stimulation of β_1 receptors in the heart. Accordingly, drugs with preferential affinity for β_2 receptors compared with β_1 receptors have been developed. However, this selectivity is not absolute and is lost at high concentrations of these drugs.

A second strategy that has increased the usefulness of several β_2 -selective agonists in the treatment of asthma has been structural modification that results in lower rates of metabolism and enhanced oral bioavailability (compared with catecholamines). Modifications have included placing the hydroxyl groups at positions 3 and 5 of the phenyl ring or substituting another moiety for the hydroxyl group at position 3. This has yielded drugs such as metaproterenol, terbutaline, and albuterol, that are not substrates for COMT. Bulky substituents on the amino group of catecholamines contribute to potency at β receptors with decreased activity at α receptors and decreased metabolism by MAO. A final strategy to enhance preferential activation of pulmonary β_2 receptors is the administration by inhalation of small doses of the drug in aerosol form. This approach typically leads to effective activation of β_2 receptors in the bronchi but very low systemic drug concentrations. Consequently, there is less potential to activate cardiac β_1 receptors or to stimulate β_2 receptors in skeletal muscle, which can cause tremor and thereby limit oral therapy.

Administration of β receptor agonists by aerosol (*see* Chapter 27) typically leads to a very rapid therapeutic response, generally within minutes, although some agonists such as *salmeterol* have a delayed onset of action (*see* below). While subcutaneous injec-

tion also causes prompt bronchodilation, the peak effect of a drug given orally may be delayed for several hours. Aerosol therapy depends on the delivery of drug to the distal airways. This, in turn, depends on the size of the particles in the aerosol and respiratory parameters such as inspiratory flow rate, tidal volume, breath-holding time, and airway diameter. Only about 10% of an inhaled dose actually enters the lungs; much of the remainder is swallowed and ultimately may be absorbed. Successful aerosol therapy requires that each patient master the technique of drug administration. Many patients, particularly children and the elderly, do not use optimal techniques, often because of inadequate instructions or incoordination. In these patients, spacer devices may enhance the efficacy of inhalation therapy (see Chapter 27).

In the treatment of asthma, β receptor agonists are used to activate pulmonary receptors that relax bronchial smooth muscle and decrease airway resistance. Although this action appears to be a major therapeutic effect of these drugs in patients with asthma, evidence suggests that β receptor agonists also may suppress the release of leukotrienes and histamine from mast cells in lung tissue, enhance mucociliary function, decrease microvascular permeability, and possibly inhibit phospholipase A_2 (Seale, 1988). The relative importance of these actions in the treatment of human asthma remains to be determined. However, it is becoming increasingly clear that airway inflammation is directly involved in airway hyperresponsiveness; consequently, the use of antiinflammatory drugs such as inhaled steroids may have primary importance (see Chapter 27). The use of β agonists for the treatment of asthma is discussed in Chapter 27.

Metaproterenol. Metaproterenol (called *orciprenaline* in Europe), along with terbutaline and *fenoterol*, belongs to the structural class of resorcinol bronchodilators that have hydroxyl groups at positions 3 and 5 of the phenyl ring (rather than at positions 3 and 4 as in catechols) (Table 10–1). Consequently, metaproterenol is resistant to methylation by COMT, and a substantial fraction (40%) is absorbed in active form after oral administration. It is excreted primarily as glucuronic acid conjugates. Metaproterenol is considered to be β_2 selective, although it probably is less selective than albuterol or terbutaline and hence is more prone to cause cardiac stimulation.

Effects occur within minutes of inhalation and persist for several hours. After oral administration, onset of action is slower, but effects last 3 to 4 hours. Metaproterenol (ALUPENT, others) is used for the long-term treatment of obstructive airway diseases, asthma, and for treatment of acute bronchospasm (see Chapter 27). Side effects are similar to the short- and intermediate-acting sympathomimetic bronchodilators.

Terbutaline. Terbutaline is a β_2 -selective bronchodilator. It contains a resorcinol ring and thus is not a substrate for COMT methylation. It is effective when taken orally, subcutaneously, or by inhalation.

Effects are observed rapidly after inhalation or parenteral administration; after inhalation its action may persist for 3 to 6 hours. With oral administration, the onset of effect may be delayed for 1 to 2 hours. Terbutaline (BRETHINE, others) is used for the long-term treatment of obstructive airway diseases and for treatment of acute bronchospasm, and also is available for parenteral use for the emergency treatment of status asthmaticus (see Chapter 27).

Albuterol. Albuterol (VENTOLIN, PROVENTIL, others) is a selective β_2 receptor agonist with pharmacological properties and therapeutic indications similar to those of terbutaline. It is administered either by inhalation or orally for the symptomatic relief of bronchospasm.

When administered by inhalation, it produces significant bronchodilation within 15 minutes, and effects persist for 3 to 4 hours. The cardiovascular effects of albuterol are considerably weaker than those of isoproterenol when doses that produce comparable bronchodilation are administered by inhalation. Oral albuterol has the potential to delay preterm labor. Although rare, CNS and respiratory side effects are sometimes observed.

Isoetharine. *Isoetharine* was the first β_2 -selective drug widely used for the treatment of airway obstruction. However, its degree of selectivity for β_2 receptors may not approach that of some of the other agents. Although resistant to metabolism by MAO, it is a catecholamine and thus is a good substrate for COMT (Table 10–1). Consequently, it is used only by inhalation for the treatment of acute episodes of bronchoconstriction.

Pirbuterol. *Pirbuterol* is a relatively selective β_2 agonist. Its structure is identical to albuterol except for the substitution of a pyridine ring for the benzene ring. Pirbuterol acetate (MAXAIR) is available for inhalation therapy; dosing is typically every 4 to 6 hours.

Bitolterol. *Bitolterol* (TORNALATE) is a novel β_2 agonist in which the hydroxyl groups in the catechol moiety are protected by esterification with 4-methylbenzoate. Esterases in the lung and other tissues hydrolyze this prodrug to the active form, colterol, or terbutyl-norepinephrine (Table 10–1). Animal studies suggest that these esterases are present in higher concentrations in lung than in tissues such as the heart. The duration of effect of bitolterol after inhalation ranges from 3 to 6 hours.

Fenoterol. Fenoterol (BEROTEC) is a β_2 -selective receptor agonist. After inhalation, it has a prompt onset of action, and its effect typically is sustained for 4 to 6 hours. Fenoterol is under investigation for use in the United States. The possible association of fenoterol use with increased deaths from asthma in New Zealand is controversial (Pearce *et al.*, 1995; Suissa and Ernst, 1997).

Formoterol. *Formoterol* (FORADIL) is a long-acting β_2 -selective receptor agonist. Significant bronchodilation occurs within minutes of inhalation of a therapeutic dose, which may persist for up to 12 hours (Faulds *et al.*, 1991). It is highly lipophilic and has

high affinity for β_2 receptors. Its major advantage over many other β_2 -selective agonists is this prolonged duration of action, which may be particularly advantageous in settings such as nocturnal asthma. Formoterol's sustained action is due to its insertion into the lipid bilayer of the plasma membrane, from which it gradually diffuses to provide prolonged stimulation of β_2 receptors (Nelson, 1995). It is FDA approved for treatment of asthma, bronchospasm, prophylaxis of exercise-induced bronchospasm, and chronic obstructive pulmonary disease (COPD). It can be used concomitantly with short-acting β_2 agonists, glucocorticoids (inhaled or systemic), and theophylline (Goldsmith and Keating, 2004).

Procaterol. *Procaterol* (MASCACIN, others) is a β_2 -selective receptor agonist. After inhalation, it has a prompt onset of action that is sustained for about 5 hours. Procaterol is not available in the United States.

Salmeterol. Salmeterol (SEREVENT) is a selective β_2 receptor agonist with a prolonged duration of action (>12 hours); it has at least fiftyfold greater selectivity for β_2 receptors than albuterol. It provides symptomatic relief and improves lung function and quality of life in patients with COPD; in this setting, it is as effective as the cholinergic antagonist *ipratropium* and more effective than oral *theophylline*. It has additive effects when used in combination with inhaled *ipratropium* or oral *theophylline*. Like formoterol, it is highly lipophilic and has a sustained duration of action; for salmeterol, this long action reflects binding to a specific site within the β_2 receptor that allows for its prolonged activation. It also may have antiinflammatory activity. Salmeterol is metabolized by CYP3A4 to α -hydroxy-salmeterol, which is eliminated primarily in the feces. Since the onset of action of inhaled salmeterol is relatively slow, it is not suitable monotherapy for acute breakthrough attacks of bronchospasm. Salmeterol or formoterol are the agents of choice for nocturnal asthma in patients who remain symptomatic despite antiinflammatory agents and other standard management.

Like formoterol, salmeterol generally is well tolerated but has the potential to increase heart rate and plasma glucose concentration, to produce tremors, and to decrease plasma potassium concentration through effects on extrapulmonary β_2 receptors. Salmeterol should not be used more than twice daily (morning and evening) and should not be used to treat acute asthma symptoms, which should be treated with a short-acting β_2 agonist (*e.g.*, albuterol) when breakthrough symptoms occur despite twice-daily use of salmeterol (Redington, 2001).

Ritodrine. Ritodrine is a selective β_2 receptor agonist that was developed specifically for use as a uterine relaxant. Nevertheless, its pharmacological properties closely resemble those of the other agents in this group.

Ritodrine is rapidly but incompletely (30%) absorbed following oral administration, and 90% of the drug is excreted in the urine as inactive conjugates; about 50% of ritodrine is excreted unchanged after intravenous administration. The pharmacokinetic properties of ritodrine are complex and incompletely defined, especially in pregnant women.

Therapeutic Uses. Ritodrine may be administered intravenously to selected patients to arrest premature labor. Ritodrine and related drugs can prolong pregnancy. However, β_2 -selective agonists may not have clinically significant benefits on perinatal mortality and may actually increase maternal morbidity. Given modern improvements in the care of premature babies, it is possible that existing clinical trials may not have had sufficient statistical power to demonstrate subtle, but potentially important, clinical effects. In a multicenter trial comparing *nifedipine* with ritodrine in managing preterm labor, *nifedipine* was associated with a longer postponement of delivery, fewer maternal side effects, and fewer admissions to the neonatal intensive care unit (Papatonis *et al.*, 1997).

Adverse Effects of β_2 -Selective Agonists. The major adverse effects of β receptor agonists occur as a result of excessive activation of β receptors. Patients with underlying cardiovascular disease are particularly at risk for significant reactions. However, the likelihood of adverse effects can be greatly decreased in patients with lung disease by administering the drug by inhalation rather than orally or parenterally.

Tremor is a relatively common adverse effect of the β_2 -selective receptor agonists. Tolerance generally develops to this effect; it is not clear whether tolerance reflects desensitization of the β_2 receptors of skeletal muscle or adaptation within the CNS. This adverse effect can be minimized by starting oral therapy with a low dose of drug and progressively increasing the dose as tolerance to the tremor develops. Feelings of restlessness, apprehension, and anxiety may limit therapy with these drugs, particularly oral or parenteral administration.

Tachycardia is a common adverse effect of systemically administered β receptor agonists. Stimulation of heart rate occurs primarily *via* β_1 receptors. It is uncertain to what extent the increase in heart rate also is due to activation of cardiac β_2 receptors or to reflex effects that stem from β_2 receptor-mediated peripheral vasodilation. However, during a severe asthma attack, heart rate actually may decrease during therapy with a β agonist, presumably because of improvement in pulmonary function with consequent reduction in endogenous cardiac sympathetic stimulation. In patients without cardiac disease, β agonists rarely cause significant arrhythmias or myocardial ischemia; however, patients with underlying coronary artery disease or preexisting arrhythmias are at greater risk. The risk of adverse cardiovascular effects also is increased in patients who are receiving MAO inhibitors. In general, at least 2 weeks should elapse between the use of MAO inhibitors and administration of β_2 receptor agonists or other sympathomimetics.

Arterial O_2 tension may fall when treatment of patients with acute exacerbations of asthma is begun; this may be due to drug-induced pulmonary vascular dilation, which leads to increased ventilation:perfusion mismatch. This effect usually is small and transient. Supplemental oxygen should be given if necessary. Severe pulmonary edema has been reported in women receiving ritodrine or terbutaline for premature labor.

The results of a number of epidemiologic studies have suggested a possible connection between prolonged use of β receptor agonists and death or near-death from asthma (Suissa *et al.*, 1994). While exact interpretation of these results is difficult, these studies have raised questions about the role of β agonists in the treatment of chronic asthma. Tolerance to effects of β agonists has been studied extensively, both *in vitro* and *in vivo* (see Chapter 6). Their long-term systemic administration leads to downregulation of β receptors in some tissues and decreased pharmacological responses. However, it appears likely that tolerance to the pulmonary effects of these drugs is not a major clinical problem for the majority of asthmatics, who do not exceed recommended dosages of β receptor agonists over prolonged periods.

There is some evidence suggesting that regular use of β_2 -selective agonists may cause increased bronchial hyperreactivity and deterioration in disease control (Hancox *et al.*, 1999). To what extent this potential adverse association may be even more unfavorable for very long-acting β agonists or excess doses of medication is not yet known (Beasley *et al.*, 1999). However, for patients requiring regular use of these drugs over prolonged periods, strong consideration should be given to additional or alternative therapy, such as the use of inhaled glucocorticoids.

Large doses of β receptor agonists cause myocardial necrosis in laboratory animals. When given parenterally, these drugs also may increase the concentrations of glucose, lactate, and free fatty acids in plasma and decrease the concentration of K^+ . The decrease in K^+ concentration may be especially important in patients with cardiac disease, particularly those taking *digoxin* and diuretics. In some diabetic patients, hyperglycemia may be worsened by these drugs, and higher doses of insulin may be required. All these adverse effects are far less likely with inhalation therapy than with parenteral or oral therapy.

α_1 -SELECTIVE ADRENERGIC RECEPTOR AGONISTS

The major clinical effects of a number of sympathomimetic drugs are due to activation of α adrenergic receptors in vascular smooth muscle. As a result, peripheral vascular resistance is increased and blood pressure is maintained or elevated. Although the clinical utility of these drugs is limited, they may be useful in the treatment of some patients with hypotension, including orthostatic hypotension, or shock. Phenylephrine and methoxamine (discontinued in the United States) are direct-acting vasoconstrictors and are selective activators of α_1 receptors. *Mephentermine* and metaraminol act both directly and indirectly. *Midodrine* is a prodrug that is converted, after oral administration, to desglymidodrine, a direct-acting α_1 agonist.

Phenylephrine

Phenylephrine is a selective α_1 receptor agonist; it activates β receptors only at much higher concentrations.

Chemically, phenylephrine differs from epinephrine only in lacking a hydroxyl group at position 4 on the benzene ring (Table 10–1). The pharmacological effects of phenylephrine are similar to those of methoxamine. The drug causes marked arterial vasoconstriction during intravenous infusion. Phenylephrine (NEO-SYNEPHRINE, others) also is used as a nasal decongestant and as a mydriatic in various nasal and ophthalmic formulations (see Chapter 63 for ophthalmic uses).

Mephentermine

Mephentermine (Table 10–1) is a sympathomimetic drug that acts both directly and indirectly; it has many similarities to epinephrine (see below). After an intramuscular injection, the onset of action is prompt (within 5 to 15 minutes), and effects may last for several hours. Since the drug releases norepinephrine, cardiac contraction is enhanced, and cardiac output and systolic and diastolic pressures usually are increased. The change in heart rate is variable, depending on the degree of vagal tone. Adverse effects are related to CNS stimulation, excessive rises in blood pressure, and arrhythmias. Mephentermine (WYAMINE SULFATE) is used to prevent hypotension, which frequently accompanies spinal anesthesia.

Metaraminol

Metaraminol (ARAMINE) (Table 10–1) is a sympathomimetic drug with prominent direct effects on vascular α adrenergic receptors. Metaraminol also is an indirectly acting agent that stimulates the release of norepinephrine. The drug has been used in the treatment of hypotensive states or off-label to relieve attacks of paroxysmal atrial tachycardia, particularly those associated with hypotension (see Chapter 34 for preferable treatments of this arrhythmia).

Midodrine

Midodrine (PROAMATINE) is an orally effective α_1 receptor agonist. It is a prodrug; its activity is due to its conversion to an active metabolite, desglymidodrine, which achieves peak concentrations about 1 hour after a dose of midodrine. The half-life of desglymidodrine is about 3 hours. Consequently, the duration of action is about 4 to 6 hours. Midodrine-induced rises in blood pressure are associated with both arterial and venous smooth muscle contraction. This is advantageous in the treatment of patients with autonomic insufficiency and postural hypotension (McClellan *et al.*, 1998). A frequent complication in these patients is supine hypertension. This can be minimized by avoiding dosing prior to bedtime and elevating the head of the bed. Very cautious use of a short-acting antihypertensive drug at bedtime may be useful in some patients. Typical dosing, achieved by careful titration of blood pressure responses, varies between 2.5 and 10 mg three times daily.

α_2 -SELECTIVE ADRENERGIC RECEPTOR AGONISTS

α_2 -Selective adrenergic agonists are used primarily for the treatment of systemic hypertension. Their efficacy

as antihypertensive agents is somewhat surprising, since many blood vessels contain postsynaptic α_2 adrenergic receptors that promote vasoconstriction (see Chapter 6). Indeed, *clonidine*, the prototypic α_2 agonist, was initially developed as a vasoconstricting nasal decongestant. Its capacity to lower blood pressure results from activation of α_2 receptors in the cardiovascular control centers of the CNS; such activation suppresses the outflow of sympathetic nervous system activity from the brain.

In addition, α_2 agonists reduce intraocular pressure by decreasing the production of aqueous humor. This action first was reported for clonidine and suggested a potential role for α_2 receptor agonists in the management of ocular hypertension and glaucoma. Unfortunately, clonidine lowered systemic blood pressure even if applied topically to the eye (Alward, 1998). Two derivatives of clonidine, *apraclonidine* and *brimonidine*, have been developed that retain the ability to decrease intraocular pressure with little or no effect on systemic blood pressure.

Clonidine

Clonidine, an imidazoline, was synthesized in the early 1960s and found to produce vasoconstriction that was mediated by α receptors. During clinical testing of the drug as a topical nasal decongestant, clonidine was found to cause hypotension, sedation, and bradycardia. The structural formula of clonidine is:

Pharmacological Effects. The major pharmacological effects of clonidine involve changes in blood pressure and heart rate, although the drug has a variety of other important actions. Intravenous infusion of clonidine causes an acute rise in blood pressure, apparently because of activation of postsynaptic α_2 receptors in vascular smooth muscle. The affinity of clonidine for these receptors is high, although the drug is a partial agonist with relatively low efficacy at these sites. The hypertensive response that follows parenteral administration of clonidine generally is not seen when the drug is given orally. However, even after intravenous administration, the transient vasoconstriction is followed by a more prolonged hypotensive response that results from decreased sympathetic outflow from the CNS. The exact mechanism by which clonidine lowers blood pressure is

not completely understood. The effect appears to result, at least in part, from activation of α_2 receptors in the lower brainstem region. This central action has been demonstrated by infusing small amounts of the drug into the vertebral arteries or by injecting it directly into the cisterna magna.

Questions remain about whether the sympatho-inhibitory action of clonidine results solely from its α_2 receptor agonism or whether part or all of its actions are mediated by imidazoline receptors. Imidazoline receptors include three subtypes (I_1 , I_2 , and I_3) and are widely distributed in the body, including the CNS. Clonidine, as an imidazoline, binds to these imidazoline receptors, in addition to its well-described binding to α_2 receptors. Two newer antihypertensive imidazolines, *rilmenidine* and *moxonidine*, have profiles of action similar to clonidine, suggesting a role for I_1 receptors. However, the lack of an antihypertensive effect of clonidine in knockout mice lacking α_{2A} receptors supports a key role for these receptors in blood pressure regulation (MacMillan *et al.*, 1996; Zhu *et al.*, 1999). Others argue that, while the action of clonidine may be mediated by α_2 receptors, the I_1 receptor mediates the effects of moxonidine and rilmenidine. Finally, the α_2 receptor and the imidazoline receptors may cooperatively regulate vasomotor tone and may jointly mediate the hypotensive actions of centrally acting drugs with affinity for both receptor types.

Clonidine decreases discharges in sympathetic preganglionic fibers in the splanchnic nerve and in postganglionic fibers of cardiac nerves. These effects are blocked by α_2 -selective antagonists such as *yohimbine*. Clonidine also stimulates parasympathetic outflow, which may contribute to the slowing of heart rate as a consequence of increased vagal tone and diminished sympathetic drive. In addition, some of the antihypertensive effects of clonidine may be mediated by activation of presynaptic α_2 receptors that suppress the release of norepinephrine, ATP, and NPY from postganglionic sympathetic nerves. Clonidine decreases the plasma concentration of norepinephrine and reduces its excretion in the urine.

Absorption, Fate, and Excretion. Clonidine is well absorbed after oral administration, and its bioavailability is nearly 100%. The peak concentration in plasma and the maximal hypotensive effect are observed 1 to 3 hours after an oral dose. The elimination half-life of the drug ranges from 6 to 24 hours, with a mean of about 12 hours. About half of an administered dose can be recovered unchanged in the urine, and the half-life of the drug may increase with renal failure. There is good correlation between plasma concentrations of clonidine and its pharmacological effects. A transdermal delivery patch permits continuous administration of clonidine as an alternative to oral therapy. The drug is released at an approximately constant rate for a week; 3 or 4 days are required to reach steady-state concentrations in plasma. When the patch is removed, plasma concentrations remain stable for about 8 hours and then decline gradually over a period of several days; this decrease is associated with a rise in blood pressure.

Adverse Effects. The major adverse effects of clonidine are dry mouth and sedation. These responses occur in at least 50% of patients and may require drug discontinuation. However, they may diminish in intensity after several weeks of therapy. Sexual dysfunction also may occur. Marked bradycardia is observed in some

patients. These and some of the other adverse effects of clonidine frequently are related to dose, and their incidence may be lower with transdermal administration of clonidine, since antihypertensive efficacy may be achieved while avoiding the relatively high peak concentrations that occur after oral administration of the drug. About 15% to 20% of patients develop contact dermatitis when using clonidine in the transdermal system. Withdrawal reactions follow abrupt discontinuation of long-term therapy with clonidine in some hypertensive patients.

Therapeutic Uses. The major therapeutic use of clonidine (CATAPRES, others) is in the treatment of hypertension (*see* Chapter 32). Clonidine also has apparent efficacy in the off-label treatment of a range of other disorders. Stimulation of α_2 receptors in the GI tract may increase absorption of sodium chloride and fluid and inhibit secretion of bicarbonate. This may explain why clonidine has been found to be useful in reducing diarrhea in some diabetic patients with autonomic neuropathy. Clonidine also is useful in treating and preparing addicted subjects for withdrawal from narcotics, alcohol, and tobacco (*see* Chapter 23). Clonidine may help ameliorate some of the adverse sympathetic nervous activity associated with withdrawal from these agents, as well as decrease craving for the drug. The long-term benefits of clonidine in these settings and in neuropsychiatric disorders remain to be determined. Clonidine may be useful in selected patients receiving anesthesia because it may decrease the requirement for anesthetic and increase hemodynamic stability (Hayashi and Maze, 1993; *see* Chapter 13). Other potential benefits of clonidine and related drugs such as *dexmedetomidine* (PRECEDEX; a relatively selective α_2 receptor agonist with sedative properties) in anesthesia include preoperative sedation and anxiolysis, drying of secretions, and analgesia. Transdermal administration of clonidine (CATAPRES-TTS) may be useful in reducing the incidence of menopausal hot flashes.

Acute administration of clonidine has been used in the differential diagnosis of patients with hypertension and suspected pheochromocytoma. In patients with primary hypertension, plasma concentrations of norepinephrine are markedly suppressed after a single dose of clonidine; this response is not observed in many patients with pheochromocytoma. The capacity of clonidine to activate postsynaptic α_2 receptors in vascular smooth muscle has been exploited in a limited number of patients whose autonomic failure is so severe that reflex sympathetic responses on standing are absent; postural hypotension is thus marked. Since the central effect of clonidine on blood pressure is unimportant in these patients, the drug can elevate blood pressure and improve the symptoms of postural hypotension. Among the other off-label uses of clonidine are atrial fibrillation, attention-deficit/hyperactivity disorder, constitutional growth delay in children, *cyclosporine*-associated nephrotoxicity, Tourette's syndrome, hyperhidrosis, mania, posthepatic neuralgia, psychosis, restless leg syndrome, ulcerative colitis, and allergy-induced inflammatory reactions in patients with extrinsic asthma.

Apraclonidine

Apraclonidine (IOPIDINE) is a relatively selective α_2 receptor agonist that is used topically to reduce intraocular pressure. It can reduce elevated as well as normal intraocular pressure whether accompanied by glaucoma or not. The reduction in intraocular pressure occurs with minimal or no effects on systemic cardiovascular parameters; thus, apraclonidine

is more useful than clonidine for ophthalmic therapy. Apparently apraclonidine does not cross the blood–brain barrier. The mechanism of action of apraclonidine is related to α_2 receptor–mediated reduction in the formation of aqueous humor.

The clinical utility of apraclonidine is most apparent as short-term adjunctive therapy in glaucoma patients whose intraocular pressure is not well controlled by other pharmacological agents such as β receptor antagonists, parasympathomimetics, or carbonic anhydrase inhibitors. The drug also is used to control or prevent elevations in intraocular pressure that occur in patients after laser trabeculoplasty or iridotomy (*see* Chapter 63).

Brimonidine

Brimonidine (ALPHAGAN), is another clonidine derivative that is administered ocularly to lower intraocular pressure in patients with ocular hypertension or open-angle glaucoma. Brimonidine is a α_2 -selective agonist that reduces intraocular pressure both by decreasing aqueous humor production and by increasing outflow (*see* Chapter 63). The efficacy of brimonidine in reducing intraocular pressure is similar to that of the β receptor antagonist *timolol*. Unlike apraclonidine, brimonidine can cross the blood–brain barrier and can produce hypotension and sedation, although these CNS effects are slight compared to those of clonidine. As with all α_2 receptor agonists, this drug should be used with caution in patients with cardiovascular disease.

Guanfacine

Guanfacine is a phenylacetylguanidine derivative. Its structural formula is:

Guanfacine (TENEX) is an α_2 receptor agonist that is more selective for α_2 receptors than is clonidine. Like clonidine, guanfacine lowers blood pressure by activation of brainstem receptors with resultant suppression of sympathetic activity. The drug is well absorbed after oral administration and has a large volume of distribution (4 to 6 liters/kg). About 50% of guanfacine appears unchanged in the urine; the rest is metabolized. The half-time for elimination ranges from 12 to 24 hours. Guanfacine and clonidine appear to have similar efficacy for the treatment of hypertension. The pattern of adverse effects also is similar for the two drugs, although it has been suggested that some of these effects may be milder and occur less frequently with guanfacine (Sorkin and Heel, 1986). A withdrawal syndrome may occur after the abrupt discontinuation of guanfacine, but it appears to be less frequent and milder than the syndrome that follows clonidine withdrawal. Part of this difference may relate to the longer half-life of guanfacine.

Guanabenz

Guanabenz and guanfacine are closely related chemically and pharmacologically. The structural formula of guanabenz is:

Guanabenz (WYTENSIN, others) is a centrally acting α_2 agonist that decreases blood pressure by a mechanism similar to those of clonidine and guanfacine. Guanabenz has a half-life of 4 to 6 hours and is extensively metabolized by the liver. Dosage adjustment may be necessary in patients with hepatic cirrhosis. The adverse effects caused by guanabenz (*e.g.*, dry mouth and sedation) are similar to those seen with clonidine.

Methyldopa

Methyldopa (α -methyl-3,4-dihydroxyphenylalanine) is a centrally acting antihypertensive agent. It is metabolized to α -methylnorepinephrine in the brain, and this compound is thought to activate central α_2 receptors and lower blood pressure in a manner similar to that of clonidine. Methyldopa is discussed in more detail in Chapter 32.

Tizanidine

Tizanidine (ZANAFLEX, others) is a muscle relaxant used for the treatment of spasticity associated with cerebral and spinal disorders. It also is an α_2 receptor agonist with some properties similar to those of clonidine (Wagstaff and Bryson, 1997).

MISCELLANEOUS SYMPATHOMIMETIC AGONISTS

Amphetamine

Amphetamine, racemic β -phenylisopropylamine (Table 10–1), has powerful CNS stimulant actions in addition to the peripheral α and β actions common to indirect-acting sympathomimetic drugs. Unlike epinephrine, it is effective after oral administration and its effects last for several hours.

Cardiovascular Responses. Amphetamine given orally raises both systolic and diastolic blood pressure. Heart rate often is reflexly slowed; with large doses, cardiac arrhythmias may occur. Cardiac output is not enhanced by therapeutic doses, and cerebral blood flow does not change much. The *l*-isomer is slightly more potent than the *d*-isomer in its cardiovascular actions.

Other Smooth Muscles. In general, smooth muscles respond to amphetamine as they do to other sympathomimetic amines. The contractile effect on the sphincter of the urinary bladder is particularly marked, and for this reason amphetamine has been used in treating enuresis and incontinence. Pain and difficulty in micturition occasionally occur. The gastrointestinal effects of amphetamine are

unpredictable. If enteric activity is pronounced, amphetamine may cause relaxation and delay the movement of intestinal contents; if the gut already is relaxed, the opposite effect may occur. The response of the human uterus varies, but there usually is an increase in tone.

Central Nervous System. Amphetamine is one of the most potent sympathomimetic amines in stimulating the CNS. It stimulates the medullary respiratory center, lessens the degree of central depression caused by various drugs, and produces other signs of CNS stimulation. These effects are thought to be due to cortical stimulation and possibly to stimulation of the reticular activating system. In contrast, the drug can obtund the maximal electroshock seizure discharge and prolong the ensuing period of depression. In elicitation of CNS excitatory effects, the *d*-isomer (*dextroamphetamine*) is three to four times more potent than the *l*-isomer.

The psychic effects depend on the dose and the mental state and personality of the individual. The main results of an oral dose of 10 to 30 mg include wakefulness, alertness, and a decreased sense of fatigue; elevation of mood, with increased initiative, self-confidence, and ability to concentrate; often, elation and euphoria; and increase in motor and speech activities. Performance of simple mental tasks is improved, but, although more work may be accomplished, the number of errors may increase. Physical performance—in athletes, for example—is improved, and the drug often is abused for this purpose. These effects are not invariable and may be reversed by overdose or repeated usage. Prolonged use or large doses are nearly always followed by depression and fatigue. Many individuals given amphetamine experience headache, palpitation, dizziness, vasomotor disturbances, agitation, confusion, dysphoria, apprehension, delirium, or fatigue (*see* Chapter 23).

Fatigue and Sleep. Prevention and reversal of fatigue by amphetamine have been studied extensively in the laboratory, in military field studies, and in athletics. In general, the duration of adequate performance is prolonged before fatigue appears, and the effects of fatigue are at least partly reversed. The most striking improvement appears to occur when performance has been reduced by fatigue and lack of sleep. Such improvement may be partly due to alteration of unfavorable attitudes toward the task. However, amphetamine reduces the frequency of attention lapses that impair performance after prolonged sleep deprivation and thus improves execution of tasks requiring sustained attention. The need for sleep may be postponed, but it cannot be avoided indefinitely. When the drug is discontinued after long use, the pattern of sleep may take as long as 2 months to return to normal.

Analgesia. Amphetamine and some other sympathomimetic amines have a small analgesic effect, but it is not sufficiently pronounced to be therapeutically useful. However, amphetamine can enhance the analgesia produced by opiates.

Respiration. Amphetamine stimulates the respiratory center, increasing the rate and depth of respiration. In normal individuals, usual doses of the drug do not appreciably increase respiratory rate or minute volume. Nevertheless, when respiration is depressed by centrally-acting drugs, amphetamine may stimulate respiration.

Depression of Appetite. Amphetamine and similar drugs have been used for the treatment of obesity, although the wisdom of this

use is at best questionable. Weight loss in obese humans treated with amphetamine is almost entirely due to reduced food intake and only in small measure to increased metabolism. The site of action probably is in the lateral hypothalamic feeding center; injection of amphetamine into this area, but not into the ventromedial region, suppresses food intake. Neurochemical mechanisms of action are unclear but may involve increased release of norepinephrine and/or dopamine (Samanin and Garattini, 1993). In humans, tolerance to the appetite suppression develops rapidly. Hence, continuous weight reduction usually is not observed in obese individuals without dietary restriction (Bray, 1993).

Mechanisms of Action in the CNS. Amphetamine appears to exert most or all of its effects in the CNS by releasing biogenic amines from their storage sites in nerve terminals. The alerting effect of amphetamine, its anorectic effect, and at least a component of its locomotor-stimulating action presumably are mediated by release of norepinephrine from central noradrenergic neurons. These effects can be prevented in experimental animals by treatment with α -methyltyrosine, an inhibitor of tyrosine hydroxylase, and therefore of catecholamine synthesis. Some aspects of locomotor activity and the stereotyped behavior induced by amphetamine probably are a consequence of the release of dopamine from dopaminergic nerve terminals, particularly in the neostriatum. Higher doses are required to produce these behavioral effects, and this correlates with the higher concentrations of amphetamine required to release dopamine from brain slices or synaptosomes *in vitro*. With still higher doses of amphetamine, disturbances of perception and overt psychotic behavior occur. These effects may be due to release of 5-hydroxytryptamine (serotonin, 5-HT) from serotonergic neurons and of dopamine in the mesolimbic system. In addition, amphetamine may exert direct effects on central receptors for 5-HT (see Chapter 11).

Toxicity and Adverse Effects. The acute toxic effects of amphetamine usually are extensions of its therapeutic actions, and as a rule result from overdosage. CNS effects commonly include restlessness, dizziness, tremor, hyperactive reflexes, talkativeness, tenseness, irritability, weakness, insomnia, fever, and sometimes euphoria. Confusion, aggressiveness, changes in libido, anxiety, delirium, paranoid hallucinations, panic states, and suicidal or homicidal tendencies occur, especially in mentally ill patients. However, these psychotic effects can be elicited in any individual if sufficient quantities of amphetamine are ingested for a prolonged period. Fatigue and depression usually follow central stimulation. Cardiovascular effects are common and include headache, chilliness, pallor or flushing, palpitation, cardiac arrhythmias, anginal pain, hypertension or hypotension, and circulatory collapse. Excessive sweating occurs. Gastrointestinal symptoms include dry mouth, metallic taste, anorexia, nausea, vomiting, diarrhea, and abdominal cramps. Fatal poisoning usually terminates in convulsions and coma, and cerebral hemorrhages are the main pathological findings.

The toxic dose of amphetamine varies widely. Toxic manifestations occasionally occur as an idiosyncratic reaction after as little as

2 mg, but are rare with doses of less than 15 mg. Severe reactions have occurred with 30 mg, yet doses of 400 to 500 mg are not uniformly fatal. Larger doses can be tolerated after chronic use of the drug.

Treatment of acute amphetamine intoxication may include acidification of the urine by administration of ammonium chloride; this enhances the rate of elimination. Sedatives may be required for the CNS symptoms. Severe hypertension may require administration of *sodium nitroprusside* or an α adrenergic receptor antagonist.

Chronic intoxication with amphetamine causes symptoms similar to those of acute overdosage, but abnormal mental conditions are more common. Weight loss may be marked. A psychotic reaction with vivid hallucinations and paranoid delusions, often mistaken for schizophrenia, is the most common serious effect. Recovery usually is rapid after withdrawal of the drug, but occasionally the condition becomes chronic. In these persons, amphetamine may act as a precipitating factor hastening the onset of incipient schizophrenia.

The abuse of amphetamine as a means of overcoming sleepiness and of increasing energy and alertness should be discouraged. The drug should be used only under medical supervision. The amphetamines are schedule II drugs under federal regulations. The additional contraindications and precautions for the use of amphetamine generally are similar to those described above for epinephrine. Its use is inadvisable in patients with anorexia, insomnia, asthenia, psychopathic personality, or a history of homicidal or suicidal tendencies.

Dependence and Tolerance. Psychological dependence often occurs when amphetamine or dextroamphetamine is used chronically, as discussed in Chapter 23. Tolerance almost invariably develops to the anorexigenic effect of amphetamines, and often is seen also in the need for increasing doses to maintain improvement of mood in psychiatric patients. Tolerance is striking in individuals who are dependent on the drug, and a daily intake of 1.7 g without apparent ill effects has been reported. Development of tolerance is not invariable, and cases of narcolepsy have been treated for years without requiring an increase in the initially effective dose.

Therapeutic Uses. Amphetamine is used chiefly for its CNS effects. Dextroamphetamine (DEXEDRINE, others), with greater CNS action and less peripheral action, was used off-label for obesity (but no longer is approved for this purpose because of the risk of abuse) and is FDA approved for the treatment of narcolepsy and attention-deficit/hyperactivity disorder. Their uses are discussed below.

Methamphetamine

Methamphetamine (DESOXYN) is closely related chemically to amphetamine and ephedrine (Table 10–1). In the brain, methamphetamine releases dopamine and other biogenic amines, and inhibits neuronal and vesicular monoamine transporters as well as MAO.

Small doses have prominent central stimulant effects without significant peripheral actions; somewhat larger doses produce a sustained rise in systolic and diastolic blood pressures, due mainly

to cardiac stimulation. Cardiac output is increased, although the heart rate may be reflexly slowed. Venous constriction causes peripheral venous pressure to increase. These factors tend to increase the venous return, and thus cardiac output. Pulmonary arterial pressure is raised, probably owing to increased cardiac output. Methamphetamine is a schedule II drug under federal regulations and has high potential for abuse (see Chapter 23). It is widely used as a cheap, accessible recreational drug and methamphetamine abuse is a widespread phenomenon. Its illegal production in clandestine laboratories throughout the United States is common. It is used principally for its central effects, which are more pronounced than those of amphetamine and are accompanied by less prominent peripheral actions. These uses are discussed below.

Methylphenidate

Methylphenidate is a piperidine derivative that is structurally related to amphetamine and has the following formula:

Methylphenidate (RITALIN, others) is a mild CNS stimulant with more prominent effects on mental than on motor activities. However, large doses produce signs of generalized CNS stimulation that may lead to convulsions. Its pharmacological properties are essentially the same as those of the amphetamines. Methylphenidate also shares the abuse potential of the amphetamines and is listed as a schedule II controlled substance in the United States. Methylphenidate is effective in the treatment of narcolepsy and attention-deficit/hyperactivity disorder, as described below.

Methylphenidate is readily absorbed after oral administration and reaches peak concentrations in plasma in about 2 hours. The drug is a racemate; its more potent (+) enantiomer has a half-life of about 6 hours, and the less potent (–) enantiomer has a half-life of about 4 hours. Concentrations in the brain exceed those in plasma. The main urinary metabolite is a deesterified product, ritalinic acid, which accounts for 80% of the dose. The use of methylphenidate is contraindicated in patients with glaucoma.

Dexmethylphenidate

Dexmethylphenidate (FOCALIN) is the *d*-threo enantiomer of racemic methylphenidate. It is FDA approved for the treatment of attention-deficit/hyperactivity disorder and is listed as a schedule II controlled substance in the United States.

Pemoline

Pemoline (CYLERT, others) is structurally dissimilar to methylphenidate but elicits similar changes in CNS function with mini-

mal effects on the cardiovascular system. It is a schedule IV controlled substance in the United States and is employed in treating attention-deficit/hyperactivity disorder. It can be given once daily because of its long half-life. Clinical improvement may require treatment for 3 to 4 weeks. Use of pemoline has been associated with severe hepatic failure.

Ephedrine

Ephedrine is both an α and a β receptor agonist; in addition, it enhances release of norepinephrine from sympathetic neurons and therefore is a mixed-acting sympathomimetic drug. Ephedrine contains two asymmetrical carbon atoms (Table 10–1); only *l*-ephedrine and racemic ephedrine are used clinically.

Pharmacological Actions. Ephedrine does not contain a catechol moiety and is effective after oral administration. The drug stimulates heart rate and cardiac output and variably increases peripheral resistance; as a result, ephedrine usually increases blood pressure. Stimulation of the α receptors of smooth muscle cells in the bladder base may increase the resistance to the outflow of urine. Activation of β receptors in the lungs promotes bronchodilation. Ephedrine is a potent CNS stimulant. After oral administration, effects of the drug may persist for several hours. Ephedrine is eliminated in the urine largely as unchanged drug, with a half-life of about 3 to 6 hours.

Therapeutic Uses and Toxicity. In the past, ephedrine was used to treat Stokes-Adams attacks with complete heart block and as a CNS stimulant in narcolepsy and depressive states. It has been replaced by alternate treatments in each of these disorders. In addition, its use as a bronchodilator in patients with asthma has become much less extensive with the development of β_2 -selective agonists. Ephedrine has been used to promote urinary continence, although its efficacy is not clear. Indeed, the drug may cause urinary retention, particularly in men with benign prostatic hyperplasia. Ephedrine also has been used to treat the hypotension that may occur with spinal anesthesia.

Untoward effects of ephedrine include hypertension, particularly after parenteral administration or with higher-than-recommended oral dosing. Insomnia is a common CNS adverse effect. Tachyphylaxis may occur with repetitive dosing. Concerns have been raised about the safety of ephedrine. Usual or higher-than-recommended doses may cause important adverse effects in susceptible individuals and are especially of concern in patients with underlying cardiovascular disease that might be unrecognized. Of potentially greater cause for concern, large amounts of herbal preparations containing ephedrine (ma huang, *ephedra*) are utilized around the world. There can be considerable variability in the content of ephedrine in these preparations, which may lead to inadvertent consumption of higher-than-usual doses of ephedrine and its isomers. Because of this, the FDA has banned the sale of dietary supplements containing ephedra effective April, 2004.

Other Sympathomimetic Agents

Several sympathomimetic drugs are used primarily as vasoconstrictors for local application to the nasal mucous membrane or the

Figure 10-4. Chemical structures of imidazole derivatives.

eye. The structures of *propylhexedrine* (BENZEDREX, others), *naphazoline* (PRIVINE, NAPHCN, others), *oxymetazoline* (AFRIN, OTCLEAR, others), and *xylometazoline* (OTRIVIN, others) are depicted in Table 10-1 and Figure 10-4. *Ethylnorepinephrine* (BRONKEPHRINE) (Table 10-1) is a β receptor agonist that is used as a bronchodilator. The drug also has α receptor agonist activity; this effect may cause local vasoconstriction and thereby reduce bronchial congestion.

Phenylephrine (*see above*), *pseudoephedrine* (SUDAFED, others) (a stereoisomer of ephedrine), and *phenylpropanolamine* are the sympathomimetic drugs that have been used most commonly in oral preparations for the relief of nasal congestion. Pseudoephedrine is available without a prescription in a variety of solid and liquid dosage forms. Phenylpropanolamine shares the pharmacological properties of ephedrine and is approximately equal in potency except that it causes less CNS stimulation. The drug has been available without prescription in tablets and capsules. In addition, numerous proprietary mixtures marketed for the oral treatment of nasal and sinus congestion contain one of these sympathomimetic amines, usually in combination with an H_1 -histamine receptor antagonist. Also, phenylpropanolamine suppresses appetite by mechanisms possibly different from those of amphetamines. Concern about the possibility that phenylpropanolamine increases the risk of hemorrhagic stroke led the FDA in 2000 to issue a public warning about the risk. In response to this warning, most manufacturers have voluntarily stopped marketing products containing phenylpropanolamine in the United States and the FDA is in the process of withdrawing approval for the drug.

THERAPEUTIC USES OF SYMPATHOMIMETIC DRUGS

The variety of vital functions that are regulated by the sympathetic nervous system and the success that has attended efforts to develop therapeutic agents that can influence adrenergic receptors selectively have resulted in a class of drugs with a large number of important therapeutic uses.

Shock. Shock is a clinical syndrome characterized by inadequate perfusion of tissues; it usually is associated with hypotension and ultimately with the failure of organ systems (Hollenberg *et al.*, 1999). Shock is an immediately life-threatening impairment of delivery of oxygen and nutrients to the organs of the body. Causes of shock include hypovolemia (due to dehydration or blood loss), cardiac failure (extensive myocardial infarction, severe arrhythmia, or cardiac mechanical defects such as ventricular septal defect), obstruction to cardiac output (due to pulmonary embolism, pericardial tamponade, or aortic dissection), and peripheral circulatory dysfunction (sepsis or anaphylaxis). Recent research on shock has focused on the accompanying increased permeability of the GI mucosa to pancreatic proteases, and on the role of these degradative enzymes on microvascular inflammation and multi-organ failure (Schmid-Schonbein and Hugli, 2005). The treatment of shock consists of specific efforts to reverse the underlying pathogenesis as well as nonspecific measures aimed at correcting hemodynamic abnormalities. Regardless of etiology, the accompanying fall in blood pressure generally leads to marked activation of the sympathetic nervous system. This, in turn, causes peripheral vasoconstriction and an increase in the rate and force of cardiac contraction. In the initial stages of shock these mechanisms may maintain blood pressure and cerebral blood flow, although blood flow to the kidneys, skin, and other organs may be decreased, leading to impaired production of urine and metabolic acidosis (Ruffolo, 1992).

The initial therapy of shock involves basic life-support measures. It is essential to maintain blood volume, which often requires monitoring of hemodynamic parameters. Specific therapy (*e.g.*, antibiotics for patients in septic shock) should be initiated immediately. If these measures do not lead to an adequate therapeutic response, it may be necessary to use vasoactive drugs in an effort to improve abnormalities in blood pressure and flow. This therapy generally is empirically based on response to hemodynamic measurements. Many of these pharmacological approaches, while apparently clinically reasonable, are of uncertain efficacy. Adrenergic receptor agonists may be used in an attempt to increase myocardial contractility or to modify peripheral vascular resistance. In general terms, β receptor agonists increase heart rate and force of contraction, α receptor agonists increase peripheral vascular resistance, and dopamine promotes dilation of renal and splanchnic vascular beds, in addition to activating β and α receptors (Breslow and Ligier, 1991).

Cardiogenic shock due to myocardial infarction has a poor prognosis; therapy is aimed at improving peripheral blood flow. Definitive therapy, such as emergency cardiac catheterization followed by surgical revascularization or angioplasty, may be very important. Mechanical left ventricular assist devices also may help to maintain cardiac output and coronary perfusion in critically ill patients. In the setting of severely impaired cardiac output, falling blood pressure leads to intense sympathetic outflow and vasoconstriction. This may further decrease cardiac output as the damaged heart pumps against a higher peripheral resistance. Medical intervention is designed to optimize cardiac filling pressure (preload), myocardial contractility, and peripheral resistance (afterload). Preload may be increased by administration of intravenous fluids or reduced with drugs such as diuretics and nitrates. A number of sympathomimetic amines have been used to increase the force of contraction of the heart. Some of these drugs have disadvantages: isoproterenol is a powerful chronotropic agent and can greatly increase myocardial oxygen demand; norepinephrine intensifies peripheral vasoconstriction; and epinephrine increases heart rate and may predispose the heart to dangerous arrhythmias. Dopamine is an effective inotropic agent that causes less increase in heart rate than does isoproterenol. Dopamine also promotes renal arterial dilation; this may be useful in preserving renal function. When given in high doses (greater than 10 to 20 $\mu\text{g}/\text{kg}$ per minute), dopamine activates α receptors, causing peripheral and renal vasoconstriction. Dobutamine has complex pharmacological actions that are mediated by its stereoisomers; the clinical effects of the drug are to increase myocardial contractility with little increase in heart rate or peripheral resistance.

In some patients in shock, hypotension is so severe that vasoconstricting drugs are required to maintain a blood pressure that is adequate for CNS perfusion (Kulka and Tryba, 1993). Alpha agonists such as norepinephrine, phenylephrine, metaraminol, mephentermine, midodrine, ephedrine, epinephrine, dopamine, and methoxamine all have been used for this purpose. This approach may be advantageous in patients with hypotension due to failure of the sympathetic nervous system (*e.g.*, after spinal anesthesia or injury). However, in patients with other forms of shock, such as cardiogenic shock, reflex vasoconstriction generally is intense, and α receptor agonists may further compromise blood flow to organs such as the kidneys and gut and adversely increase the work of the heart. Indeed, vasodilating drugs such as *nitroprusside* are more likely to improve blood flow and decrease cardiac work in such patients by decreasing afterload if a minimally adequate blood pressure can be maintained.

The hemodynamic abnormalities in septic shock are complex and poorly understood. Most patients with septic shock initially have low or barely normal peripheral vascular resistance, possibly owing to excessive effects of endogenously produced nitric oxide as well as normal or increased cardiac output. If the syndrome progresses, myocardial depression, increased peripheral resistance, and impaired tissue oxygenation occur. The primary treatment of septic shock is antibiotics. Data on the comparative value of various adrenergic agents in the treatment of septic shock are limited. Therapy with drugs such as dopamine or dobutamine is guided by hemodynamic monitoring, with individualization of therapy depending on the patient's overall clinical condition.

Hypotension. Drugs with predominantly α agonist activity can be used to raise blood pressure in patients with decreased peripheral

resistance in conditions such as spinal anesthesia or intoxication with antihypertensive medications. However, hypotension *per se* is not an indication for treatment with these agents unless there is inadequate perfusion of organs such as the brain, heart, or kidneys. Furthermore, adequate replacement of fluid or blood may be more appropriate than drug therapy for many patients with hypotension. In patients with spinal anesthesia that interrupts sympathetic activation of the heart, injections of ephedrine increase heart rate as well as peripheral vascular resistance; tachyphylaxis may occur with repetitive injections, necessitating the use of a directly acting drug.

Patients with orthostatic hypotension (excessive fall in blood pressure with standing) often represent a pharmacological challenge. There are diverse causes for this disorder, including the Shy-Drager syndrome and idiopathic autonomic failure. Therapeutic approaches include physical maneuvers and a variety of drugs (*fludrocortisone*, prostaglandin synthesis inhibitors, somatostatin analogs, *caffeine*, vasopressin analogs, and dopamine antagonists). A number of sympathomimetic drugs also have been used in treating this disorder. The ideal agent would enhance venous constriction prominently and produce relatively little arterial constriction so as to avoid supine hypertension. No such agent currently is available. Drugs used in this disorder to activate α_1 receptors include both direct- and indirect-acting agents. Midodrine shows promise in treating this challenging disorder.

Hypertension. Centrally acting α_2 receptor agonists such as clonidine are useful in the treatment of hypertension. Drug therapy of hypertension is discussed in Chapter 32.

Cardiac Arrhythmias. Cardiopulmonary resuscitation in patients with cardiac arrest due to ventricular fibrillation, electromechanical dissociation, or asystole may be facilitated by drug treatment. Epinephrine is an important therapeutic agent in patients with cardiac arrest; epinephrine and other α agonists increase diastolic pressure and improve coronary blood flow. Alpha agonists also help to preserve cerebral blood flow during resuscitation. Cerebral blood vessels are relatively insensitive to the vasoconstricting effects of catecholamines, and perfusion pressure is increased. Consequently, during external cardiac massage, epinephrine facilitates distribution of the limited cardiac output to the cerebral and coronary circulations. Although it had been thought that the β adrenergic effects of epinephrine on the heart made ventricular fibrillation more susceptible to conversion with electrical countershock, tests in animal models have not confirmed this hypothesis. The optimal dose of epinephrine in patients with cardiac arrest is unclear. Once a cardiac rhythm has been restored, it may be necessary to treat arrhythmias, hypotension, or shock.

In patients with paroxysmal supraventricular tachycardias, particularly those associated with mild hypotension, careful infusion of an α agonist such as phenylephrine or methoxamine to raise blood pressure to about 160 mm Hg may end the arrhythmia by increasing vagal tone. However, this method of treatment has been replaced largely by Ca^{2+} channel blockers with clinically significant effects on the AV node, β receptor antagonists, *adenosine*, and electrical cardioversion (*see* Chapter 34). Beta agonists such as isoproterenol may be used as adjunctive or temporizing therapy with atropine in patients with marked bradycardia who are compromised hemodynamically; if long-term therapy is required, a cardiac pacemaker usually is the treatment of choice.

Congestive Heart Failure. Sympathetic stimulation of β receptors in the heart is an important compensatory mechanism for maintenance of cardiac function in patients with congestive heart failure (Francis and Cohn, 1986). Responses mediated by β receptors are blunted in the failing human heart. While β agonists may increase cardiac output in acute emergency settings such as shock, long-term therapy with β agonists as inotropic agents is not efficacious. Indeed, interest has grown in the use of β receptor antagonists in the treatment of patients with congestive heart failure (see Chapter 33).

Local Vascular Effects of α Adrenergic Receptor Agonists. Epinephrine is used in many surgical procedures in the nose, throat, and larynx to shrink the mucosa and improve visualization by limiting hemorrhage. Simultaneous injection of epinephrine with local anesthetics retards the absorption of the anesthetic and increases the duration of anesthesia (see Chapter 14). Injection of α agonists into the penis may be useful in reversing priapism, a complication of the use of α receptor antagonists or PDE5 inhibitors (e.g., sildenafil) in the treatment of erectile dysfunction. Both phenylephrine and oxymetazoline are efficacious vasoconstrictors when applied locally during sinus surgery.

Nasal Decongestion. α Receptor agonists are used extensively as nasal decongestants in patients with allergic or vasomotor rhinitis and in acute rhinitis in patients with upper respiratory infections. These drugs probably decrease resistance to airflow by decreasing the volume of the nasal mucosa; this may occur by activation of α receptors in venous capacitance vessels in nasal tissues that have erectile characteristics. The receptors that mediate this effect appear to be α_1 receptors. Interestingly, α_2 receptors may mediate contraction of arterioles that supply nutrition to the nasal mucosa. Intense constriction of these vessels may cause structural damage to the mucosa. A major limitation of therapy with nasal decongestants is that loss of efficacy, "rebound" hyperemia, and worsening of symptoms often occur with chronic use or when the drug is stopped. Although mechanisms are uncertain, possibilities include receptor desensitization and damage to the mucosa. Agonists that are selective for α_1 receptors may be less likely to induce mucosal damage (DeBernardis *et al.*, 1987).

For decongestion, α agonists may be administered either orally or topically. Oral ephedrine often causes CNS adverse effects. Pseudoephedrine is a stereoisomer of ephedrine that is less potent than ephedrine in producing tachycardia, increased blood pressure, and CNS stimulation. Sympathomimetic decongestants should be used with great caution in patients with hypertension and in men with prostatic enlargement, and they are contraindicated in patients who are taking MAO inhibitors. A variety of compounds (see above) are available for topical use in patients with rhinitis. Topical decongestants are particularly useful in acute rhinitis because of their more selective site of action, but they are apt to be used excessively by patients, leading to rebound congestion. Oral decongestants are much less likely to cause rebound congestion but carry a greater risk of inducing adverse systemic effects. Indeed, patients with uncontrolled hypertension or ischemic heart disease generally should carefully avoid the oral consumption of over-the-counter products or herbal preparations containing sympathomimetic drugs.

Asthma. Use of β adrenergic agonists in the treatment of asthma is discussed in Chapter 27.

Allergic Reactions. Epinephrine is the drug of choice to reverse the manifestations of serious acute hypersensitivity reactions (e.g., from food, bee sting, or drug allergy). A subcutaneous injection of epinephrine rapidly relieves itching, hives, and swelling of lips, eyelids, and tongue. In some patients, careful intravenous infusion of epinephrine may be required to ensure prompt pharmacological effects. This treatment may be life-saving when edema of the glottis threatens airway patency or when there is hypotension or shock in patients with anaphylaxis. In addition to its cardiovascular effects, epinephrine is thought to activate β receptors that suppress the release from mast cells of mediators such as histamine and leukotrienes. Although glucocorticoids and antihistamines frequently are administered to patients with severe hypersensitivity reactions, epinephrine remains the mainstay.

Ophthalmic Uses. Application of various sympathomimetic amines for diagnostic and therapeutic ophthalmic use is discussed in Chapter 63.

Narcolepsy. Narcolepsy is characterized by hypersomnia, including attacks of sleep that may occur suddenly under conditions that are not normally conducive to sleep. Some patients respond to treatment with tricyclic antidepressants or MAO inhibitors. Alternatively, CNS stimulants such as amphetamine, dextroamphetamine, or methamphetamine may be useful (Mitler *et al.*, 1993). *Modafinil* (PROVIGIL), a CNS stimulant, may have benefit in narcolepsy (Fry, 1998). In the United States, it is a schedule IV controlled substance. Its mechanism of action in narcolepsy is unclear and may not involve adrenergic receptors. Therapy with amphetamines is complicated by the risk of abuse and the likelihood of the development of tolerance. Depression, irritability, and paranoia also may occur. Amphetamines may disturb nocturnal sleep, which increases the difficulty of avoiding daytime attacks of sleep in these patients.

Narcolepsy in rare individuals is caused by mutations in the related orexin neuropeptides (also called hypocretins), which are expressed in the lateral hypothalamus, or in their G protein-coupled receptors (Mignot, 2004). Although such mutations are not present in most subjects with narcolepsy, the levels of orexins in the CSF are markedly diminished, suggesting that deficient orexin signaling may play a pathogenic role. The association of these neuropeptides and their cognate GPCRs with narcolepsy provides an attractive target for the development of novel pharmacotherapies for this disorder.

Weight Reduction. Obesity arises as a consequence of positive caloric balance. Optimally, weight loss is achieved by a gradual increase in energy expenditure from exercise combined with dieting to decrease the caloric intake. However, this obvious approach has a relatively low success rate. Consequently, alternative forms of treatment, including surgery or medications, have been developed in an effort to increase the likelihood of achieving and maintaining weight loss. Amphetamine was found to produce weight loss in early studies of patients with narcolepsy and was subsequently used in the treatment of obesity. The drug promotes weight loss by suppressing appetite rather than by increasing energy expenditure. Other anorexic drugs include methamphetamine, dextroamphetamine, *phentermine*, *benzphetamine*, *phendimetrazine*, *phenmetrazine*, *diethylpropion*, *mazindol*, phenylpropranolamine, and *sibutramine* (a mixed adrenergic/serotonergic drug). In short-term (up to 20 weeks), dou-

ble-blind controlled studies, amphetamine-like drugs have been shown to be more effective than placebo in promoting weight loss; the rate of weight loss typically is increased by about 0.5 pound per week with these drugs. There is little to choose among these drugs in terms of efficacy. However, long-term weight loss has not been demonstrated unless these drugs are taken continuously (Bray, 1993). In addition, other important issues have not yet been resolved, including the selection of patients who might benefit from these drugs, whether the drugs should be administered continuously or intermittently, and the duration of treatment. Adverse effects of treatment include the potential for drug abuse and habituation, serious worsening of hypertension (although in some patients blood pressure actually may fall, presumably as a consequence of weight loss), sleep disturbances, palpitations, and dry mouth. These agents may be effective adjuncts in the treatment of obesity. However, available evidence does not support the isolated use of these drugs in the absence of a more comprehensive program that stresses exercise and modification of diet. β_3 Receptor agonists were found to have remarkable antiobesity and antidiabetic effects in rodents. However, pharmaceutical companies have not yet succeeded in developing β_3 receptor agonists for the treatment of these conditions in humans, perhaps because of important differences in β_3 receptors between humans and rodents. With the cloning of the human β_3 receptor, compounds with favorable metabolic effects have been developed. The use of β_3 agonists in the treatment of obesity remains a possibility for the future (Robidoux *et al.*, 2004; Fernandez-Lopez *et al.*, 2002).

Attention-Deficit/Hyperactivity Disorder (ADHD). This syndrome, usually first evident in childhood, is characterized by excessive motor activity, difficulty in sustaining attention, and impulsiveness. Children with this disorder frequently are troubled by difficulties in school, impaired interpersonal relationships, and excitability. Academic underachievement is an important characteristic. A substantial number of children with this syndrome have characteristics that persist into adulthood, although in modified form. Behavioral therapy may be helpful in some patients. Catecholamines may be involved in the control of attention at the level of the cerebral cortex. A variety of stimulant drugs have been utilized in the treatment of ADHD, and they are particularly indicated in moderate-to-severe cases. Dextroamphetamine has been demonstrated to be more effective than placebo. Methylphenidate is effective in children with ADHD and is the most common intervention (Swanson and Volkow, 2003). Treatment may start with a dose of 5 mg of methylphenidate in the morning and at lunch; the dose is increased gradually over a period of weeks depending on the response as judged by parents, teachers, and the clinician. The total daily dose generally should not exceed 60 mg; because of its short duration of action, most children require two or three doses of methylphenidate each day. The timing of doses is adjusted individually in accordance with rapidity of onset of effect and duration of action. Methylphenidate, dextroamphetamine, and amphetamine probably have similar efficacy in ADHD and are the preferred drugs in this disorder (Elia *et al.*, 1999). Pemo-line appears to be less effective, although like sustained-release preparations of methylphenidate (RITALIN SR, CONCERTA, METADATE) and amphetamine (ADDERAL XR), it may be used once daily in children and adults. Potential adverse effects of these medications include insomnia, abdominal pain, anorexia, and weight loss that may be associated with suppression of growth in children. Minor symptoms may be transient or may respond to adjustment of dosage or administration of the drug with meals. Other drugs that have been

utilized include tricyclic antidepressants, antipsychotic agents, and clonidine (Fox and Rieder, 1993).

II. ADRENERGIC RECEPTOR ANTAGONISTS

Many types of drugs interfere with the function of the sympathetic nervous system and thus have profound effects on the physiology of sympathetically innervated organs. Several of these drugs are important in clinical medicine, particularly for the treatment of cardiovascular diseases. Drugs that decrease the amount of norepinephrine released as a consequence of sympathetic nerve stimulation or that inhibit sympathetic nervous activity by suppressing sympathetic outflow from the brain are discussed in Chapter 32.

The remainder of this chapter focuses on drugs termed adrenergic receptor *antagonists*, which inhibit the interaction of norepinephrine, epinephrine, and other sympathomimetic drugs with α and β receptors (*see* Figure 10–5). Almost all of these agents are competitive antagonists; an important exception is *phenoxybenzamine*, an irreversible antagonist that binds covalently to α receptors. There are important structural differences among the various types of adrenergic receptors (*see* Chapter 6). Since compounds have been developed that have different affinities for the various receptors, it is possible to interfere selectively with responses that result from stimulation of the sympathetic nervous system. For example, selective antagonists of β_1 receptors block most actions of epinephrine and norepinephrine on the heart, while having less effect on β_2 receptors in bronchial smooth muscle and no effect on responses mediated by α_1 or α_2 receptors. Detailed knowledge of the autonomic nervous system and the sites of action of drugs that act on adrenergic receptors is essential for understanding the pharmacological properties and therapeutic uses of this important class of drugs. Additional background material is presented in Chapter 6. Because of their unique antipsychotic activity in the CNS, drugs that block dopamine receptors are considered in Chapter 18.

α ADRENERGIC RECEPTOR ANTAGONISTS

The α adrenergic receptors mediate many of the important actions of endogenous catecholamines. Responses of particular clinical relevance include α_1 receptor–

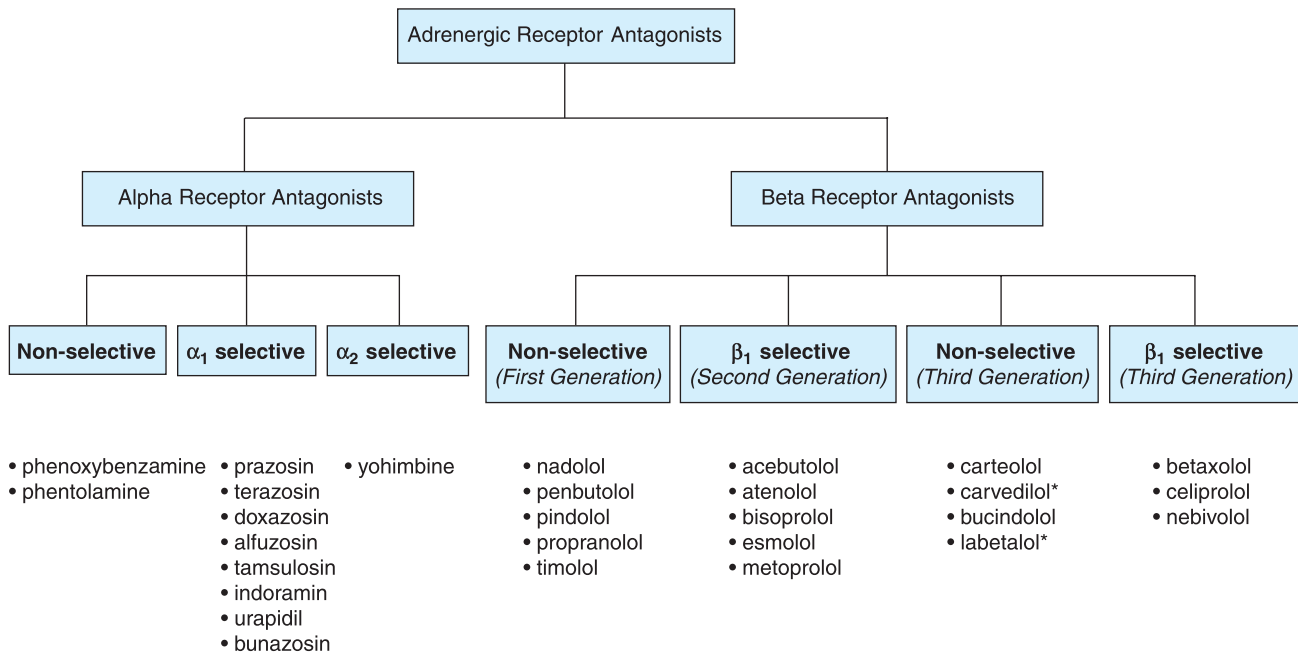

Figure 10–5. Classification of adrenergic receptor antagonists. Drugs marked by an asterisk (*) also block α_1 receptors.

mediated contraction of arterial and venous smooth muscle. The α_2 receptors are involved in suppressing sympathetic output, increasing vagal tone, facilitating platelet aggregation, inhibiting the release of norepinephrine and acetylcholine from nerve endings, and regulating metabolic effects. These effects include suppression of insulin secretion and inhibition of lipolysis. The α_2 receptors also mediate contraction of some arteries and veins.

Alpha receptor antagonists have a wide spectrum of pharmacological specificities (Table 10–3) and are chemically heterogeneous (Figure 10–6). Some of these drugs have markedly different affinities for α_1 and α_2 receptors. For example, *prazosin* is much more potent in blocking α_1 than α_2 receptors (i.e., α_1 selective), whereas *yohimbine* is α_2 selective; *phentolamine* has similar affinities for both of these receptor subtypes. More recently, agents that discriminate among the various subtypes of a particular receptor have become available; for example *tamsulosin* has higher potency at α_{1A} than at α_{1B} receptors.

Chemistry. The structural formulas of a number of α receptor antagonists are shown in Figure 10–6. These structurally diverse drugs can be divided into a number of major groups including β -haloethylamine alkylating agents, imidazoline analogs, piperazinyl quinazolines, and indole derivatives. Table 10–3 summarizes the pharmacological properties of drugs in three of these groups.

Pharmacological Properties

Cardiovascular System. Some of the most important effects of α receptor antagonists observed clinically are on the cardiovascular system. Actions in both the CNS and the periphery are involved; the outcome depends on the cardiovascular status of the patient at the time of drug administration and the relative selectivity of the agent for α_1 and α_2 receptors.

α_1 Receptor Antagonists. Blockade of α_1 adrenergic receptors inhibits vasoconstriction induced by endogenous catecholamines; vasodilation may occur in both arteriolar resistance vessels and veins. The result is a fall in blood pressure due to decreased peripheral resistance. The magnitude of such effects depends on the activity of the sympathetic nervous system at the time the antagonist is administered and thus is less in supine than in upright subjects and is particularly marked if there is hypovolemia. For most α receptor antagonists, the fall in blood pressure is opposed by baroreceptor reflexes that cause increases in heart rate and cardiac output, as well as fluid retention. These reflexes are exaggerated if the antagonist also blocks α_2 receptors on peripheral sympathetic nerve endings, leading to enhanced release of norepinephrine and increased stimulation of postsynaptic β_1 receptors in the heart and on juxtaglomerular cells (Starke *et al.*, 1989) (see Chapter 6). Although stimula-

Table 10–3
Comparative Information About α Adrenergic Receptor Antagonists*

	HALOALKYLAMINES	IMIDAZOLINES	QUINAZOLINES
Prototype	Phenoxybenzamine (DIBENZYLINE) (PBZ)	Phentolamine (REGITINE)	Prazosin (MINIPRESS)
Others		Tolazoline (PRISCOLINE)	Terazosin (HYTRIN) Doxazosin (CARDURA) Trimazosin (CARDOVAR) Alfuzosin (UROXATRAL)
Antagonism	Irreversible	Competitive	Competitive
Selectivity	α_1 with some α_2	Nonselective between α_1 and α_2	Selective for α_1 ; does not distinguish among α_1 subtypes
Hemodynamic effects	Decreased PVR and blood pressure Venodilation is prominent Cardiac stimulation (cardiovascular reflexes and enhanced NE release due to α_2 antagonism)	Similar to PBZ	Decreased PVR and blood pressure Veins less susceptible than arteries; thus, postural hypotension less of a problem Cardiac stimulation is less (NE release is not enhanced due to α_1 selectivity)
Actions other than α blockade	Some antagonism of ACh, 5-HT, and histamine Blockade of neuronal and extraneuronal uptake	Cholinomimetic; adrenomimetic; histamine-like actions Antagonism of 5-HT	At high doses some direct vasodilator action, probably due to PDE inhibition
Routes of administration	Intravenous and oral; oral absorption incomplete and erratic	Similar to PZB	Oral
Adverse reactions	Postural hypotension, tachycardia, miosis, nasal stuffiness, failure of ejaculation	Same as PBZ, plus GI disturbances due to cholinomimetic and histamine-like actions	Some postural hypotension, especially with the first dose; less of a problem overall than with PBZ or phentolamine
Therapeutic uses	Conditions of catecholamine excess (e.g., pheochromocytoma) Peripheral vascular disease	Same as PBZ	Primary hypertension Benign prostatic hypertrophy

*Adapted from Westfall, 2004. *Abbreviations:* ACh, acetylcholine; 5-HT, 5-hydroxytryptamine; PBZ, phenoxybenzamine; NE, norepinephrine; PVR, peripheral vascular resistance.

Figure 10-6. Structural formulas of some α -adrenergic receptor antagonists.

tion of α_1 receptors in the heart may cause an increased force of contraction, the importance of blockade at this site in humans is uncertain.

Blockade of α_1 receptors also inhibits vasoconstriction and the increase in blood pressure produced by the administration of a sympathomimetic amine. The pattern of effects depends on the adrenergic agonist that is administered: pressor responses to phenylephrine can be completely suppressed; those to norepinephrine are only incompletely blocked because of residual stimulation of cardiac β_1 receptors; and pressor responses to epinephrine may be transformed to vasodepressor effects because of residual stimulation of β_2 receptors in the vasculature with resultant vasodilation.

α_2 Adrenergic Receptor Antagonists. The α_2 receptors have an important role in regulation of the activity of the sympathetic nervous system, both peripherally and centrally. As mentioned above, activation of presynaptic α_2 receptors inhibits the release of norepinephrine and other cotransmitters from peripheral sympathetic nerve endings. Activation of α_2 receptors in the pontomedullary region of the CNS inhibits sympathetic nervous system activity and leads to a fall in blood pressure; these receptors are a site of action for drugs such as clonidine. Blockade of α_2 receptors with selective antagonists such as yohimbine thus can increase sympathetic outflow and potentiate the release of norepinephrine from nerve endings, leading to activation of α_1 and β_1 receptors in the heart and peripheral vasculature with a consequent rise in blood pressure. Antagonists that also block α_1 receptors give rise to similar effects on sympathetic outflow and release of norepinephrine, but the net increase in blood pressure is prevented by inhibition of vasoconstriction.

Although certain vascular beds contain α_2 receptors that promote contraction of smooth muscle, it is thought that these receptors are preferentially stimulated by circulating catecholamines, whereas α_1 receptors are activated by norepinephrine released from sympathetic nerve fibers. In other vascular beds, α_2 receptors reportedly promote vasodilation by stimulating the release of NO from endothelial cells. The physiological role of vascular α_2 receptors in the regulation of blood flow within various vascular beds is uncertain. The α_2 receptors contribute to smooth muscle contraction in the human saphenous vein, whereas α_1 receptors are more prominent in dorsal hand veins. The effects of α_2 receptor antagonists on the cardiovascular system are dominated by actions in the CNS and on sympathetic nerve endings.

Other Actions of α Adrenergic Receptor Antagonists. Catecholamines increase the output of glucose from the liver; in humans this effect is mediated predominantly by β receptors, although α receptors may contribute (Rosen *et al.*, 1983). Alpha

receptor antagonists therefore may reduce glucose release. Receptors of the α_{2A} subtype facilitate platelet aggregation; the effect of blockade of platelet α_2 receptors *in vivo* is not clear. Activation of α_2 receptors in the pancreatic islets suppresses insulin secretion; conversely, blockade of pancreatic α_2 receptors may facilitate insulin release (*see* Chapter 60). Alpha receptor antagonists reduce smooth muscle tone in the prostate and neck of the bladder, thereby decreasing resistance to urine outflow in benign prostatic hypertrophy (*see* below).

Phenoxybenzamine and Related Haloalkylamines

Phenoxybenzamine is a haloalkylamine that blocks α_1 and α_2 receptors irreversibly. Although phenoxybenzamine may have slight selectivity for α_1 receptors, it is not clear whether this has any significance in humans.

Chemistry. The haloalkylamine adrenergic blocking drugs are closely related chemically to the nitrogen mustards; as in the latter, the tertiary amine cyclizes with the loss of chlorine to form a reactive ethyleniminium or aziridinium ion (*see* Chapter 51). The molecular configuration directly responsible for blockade probably is a highly reactive carbonium ion formed upon cleavage of the three-membered ring. It is presumed that the arylalkyl amine moiety of the molecule is responsible for the relative specificity of action of these agents, since the reactive intermediate probably reacts with sulfhydryl, amino, and carboxyl groups in many proteins. Because of these chemical reactions, phenoxybenzamine is covalently conjugated with α receptors. Consequently, receptor blockade is irreversible, and restoration of cellular responsiveness to α receptor agonists probably requires the synthesis of new receptors.

Pharmacological Properties. The major effects of phenoxybenzamine result from blockade of α receptors in smooth muscle. Phenoxybenzamine causes a progressive decrease in peripheral resistance and an increase in cardiac output that is due, in part, to reflex sympathetic nerve stimulation. Tachycardia may be accentuated by enhanced release of norepinephrine (because of α_2 blockade) and decreased inactivation of the amine because of inhibition of neuronal and extraneuronal uptake mechanisms (*see* below and Chapter 6). Pressor responses to exogenously administered catecholamines are impaired. Indeed, hypotensive responses to epinephrine occur because of unopposed β receptor-mediated vasodilation. Although phenoxybenzamine has relatively little effect on supine blood pressure in normotensive subjects, there is a marked fall in blood pressure on standing because of antagonism of compensatory vasoconstriction. In addition, the ability to respond to hypovolemia and anesthetic-induced vasodilation is impaired.

Phenoxybenzamine inhibits the uptake of catecholamines into both sympathetic nerve terminals and extraneuronal tissues. In addition to blockade of α receptors, substituted β haloalkylamines irreversibly inhibit responses to 5-HT, histamine, and ACh. However, somewhat higher doses of phenoxybenzamine are required to produce these effects than to produce blockade of α receptors. More detailed discussion can be found in earlier editions of this textbook.

The pharmacokinetic properties of phenoxybenzamine are not well understood. The half-life of phenoxybenzamine probably is less than 24 hours. However, since the drug irreversibly inactivates α receptors, the duration of its effect is dependent not only on the presence of the drug, but also on the rate of synthesis of α receptors. Many days may be required before the number of functional α receptors on the surface of target cells returns to normal. Blunted maximal responses to catecholamines may not be as persistent, since there are "spare" α_1 receptors in vascular smooth muscle.

Therapeutic Uses. A major use of phenoxybenzamine (DIBENZYLIN) is in the treatment of pheochromocytoma. Pheochromocytomas are tumors of the adrenal medulla and sympathetic neurons that secrete enormous quantities of catecholamines into the circulation. The usual result is hypertension, which may be episodic and severe. The vast majority of pheochromocytomas are treated surgically; however, phenoxybenzamine is almost always used to treat the patient in preparation for surgery. The drug controls episodes of severe hypertension and minimizes other adverse effects of catecholamines, such as contraction of plasma volume and injury of the myocardium. A conservative approach is to initiate treatment with phenoxybenzamine (at a dosage of 10 mg twice daily) 1 to 3 weeks before the operation. The dose is increased every other day until the desired effect on blood pressure is achieved. Therapy may be limited by postural hypotension; nasal stuffiness is another frequent adverse effect. The usual daily dose of phenoxybenzamine in patients with pheochromocytoma is 40 to 120 mg given in two or three divided portions. Prolonged treatment with phenoxybenzamine may be necessary in patients with inoperable or malignant pheochromocytoma. In some patients, particularly those with malignant disease, administration of *metyrosine* may be a useful adjuvant (Perry *et al.*, 1990). Metyrosine is a competitive inhibitor of tyrosine hydroxylase, the rate-limiting enzyme in the synthesis of catecholamines (*see* Chapter 6). Beta receptor antagonists also are used to treat pheochromocytoma, but only after the administration of an α receptor antagonist (*see* below).

Albeit off-label, phenoxybenzamine was the first α receptor antagonist used in the medical therapy of benign prostatic hyperplasia (BPH); blockade of α adrenergic receptors in smooth muscle of the prostate and bladder base may decrease both obstructive symptoms and the need to urinate at night. While the results were promising, significant adverse effects occurred and as a result, phenoxybenzamine is not used to treat BPH. Alpha receptor antagonists such as *doxazosin* and *terazosin* are preferred for this disorder (*see* below). Phenoxybenzamine has been used off-label to control the manifestations of autonomic hyperreflexia in patients with spinal cord transection.

Toxicity and Adverse Effects. The major adverse effect of phenoxybenzamine is postural hypotension. This often is accompanied by reflex tachycardia and other arrhythmias. Hypotension can be par-

ticularly severe in hypovolemic patients or under conditions that promote vasodilation (administration of vasodilator drugs, exercise, ingestion of alcohol or large quantities of food). Reversible inhibition of ejaculation may occur because of impaired smooth muscle contraction in the vas deferens and ejaculatory ducts. Phenoxybenzamine is mutagenic in the Ames test, and repeated administration of this drug to experimental animals causes peritoneal sarcomas and lung tumors. The clinical significance of these findings is not known.

Phentolamine and Tolazoline

Phentolamine, an imidazoline, is a competitive α receptor antagonist that has similar affinities for α_1 and α_2 receptors. Its effects on the cardiovascular system are very similar to those of phenoxybenzamine.

Phenoxybenzamine and phentolamine have played an important role in the establishment of the importance of α receptors in cardiovascular regulation. They sometimes are referred to as "classical" α blockers to distinguish them from more recently developed compounds such as prazosin and its derivatives. Phentolamine also can block receptors for 5-HT, and it causes release of histamine from mast cells; phentolamine also blocks K^+ channels (McPherson, 1993). *Tolazoline* is a related but somewhat less potent compound; it is no longer marketed in the United States. Tolazoline and phentolamine stimulate GI smooth muscle, an effect that is antagonized by *atropine*, and they also enhance gastric acid secretion. Tolazoline stimulates secretion by salivary, lacrimal, and sweat glands as well.

The pharmacokinetic properties of phentolamine are not known, although the drug is extensively metabolized.

Therapeutic Uses. Phentolamine (REGITINE) can be used in short-term control of hypertension in patients with pheochromocytoma. Rapid infusions of phentolamine may cause severe hypotension, so the drug should be administered cautiously. Phentolamine also may be useful to relieve pseudo-obstruction of the bowel in patients with pheochromocytoma; this condition may result from the inhibitory effects of catecholamines on intestinal smooth muscle. Phentolamine has been used locally to prevent dermal necrosis after the inadvertent extravasation of an α receptor agonist. The drug also may be useful for the treatment of hypertensive crises that follow the abrupt withdrawal of clonidine or that may result from the ingestion of tyramine-containing foods during the use of nonselective MAO inhibitors. Although excessive activation of α receptors is important in the development of severe hypertension in these settings, there is little information about the safety and efficacy of phentolamine compared with those of other antihypertensive agents in the treatment of such patients. Direct intracavernous injection of phentolamine (in combination with *papaverine*) has been proposed as a treatment for male sexual dysfunction. The long-term efficacy of this treatment is not known. Intracavernous injection of phentolamine may cause orthostatic hypotension and priapism; pharmacological reversal of drug-induced erections can be achieved with an α receptor agonist such as phenylephrine. Repetitive intrapenile injections may cause fibrotic reactions. Buccally or orally administered phentolamine may have efficacy in some men with sexual dysfunction (Becker *et al.*, 1998).

Toxicity and Adverse Effects. Hypotension is the major adverse effect of phentolamine. In addition, reflex cardiac stimulation may cause alarming tachycardia, cardiac arrhythmias, and ischemic cardiac events, including myocardial infarction. GI stimulation may result in abdominal pain, nausea, and exacerbation of peptic ulcer. Phentolamine should be used with particular caution in patients with coronary artery disease or a history of peptic ulcer.

Prazosin and Related Drugs

Prazosin, the prototype of a family of agents that contain a piperazinyl quinazoline nucleus, is a potent and selective α_1 receptor antagonist. Due in part to its greater α_1 receptor selectivity, the quinazoline class of α receptor antagonists exhibits greater clinical utility and has largely replaced the nonselective haloalkylamine (*e.g.*, phenoxybenzamine) and imidazoline (*e.g.*, phentolamine) α receptor antagonists. The affinity of prazosin for α_1 adrenergic receptors is about one thousandfold greater than that for α_2 adrenergic receptors. Prazosin has similar potencies at α_{1A} , α_{1B} , and α_{1D} subtypes. Interestingly, the drug also is a relatively potent inhibitor of cyclic nucleotide phosphodiesterases, and it originally was synthesized for this purpose. The pharmacological properties of prazosin have been characterized extensively, and the drug frequently is used for the treatment of hypertension (*see* Chapter 32).

Pharmacological Properties. Prazosin. The major effects of prazosin result from its blockade of α_1 receptors in arterioles and veins. This leads to a fall in peripheral vascular resistance and in venous return to the heart. Unlike other vasodilating drugs, administration of prazosin usually does not increase heart rate. Since prazosin has little or no α_2 receptor–blocking effect at concentrations achieved clinically, it probably does not promote the release of norepinephrine from sympathetic nerve endings in the heart. In addition, prazosin decreases cardiac preload and thus has little tendency to increase cardiac output and rate, in contrast to vasodilators such as hydralazine that have minimal dilatory effects on veins. Although the combination of reduced preload and selective α_1 receptor blockade might be sufficient to account for the relative absence of reflex tachycardia, prazosin also may act in the CNS to suppress sympathetic outflow. Prazosin appears to depress baroreflex function in hypertensive patients. Prazosin and related drugs in this class tend to have favorable effects on serum lipids in humans, decreasing low-density lipoproteins (LDL) and triglycerides while increasing concentrations of high-density lipoproteins (HDL). Prazosin and related drugs may have effects on cell

growth unrelated to antagonism of α_1 receptors (Yang *et al.*, 1997; Hu *et al.*, 1998).

Prazosin (MINIPRESS, others) is well absorbed after oral administration, and bioavailability is about 50% to 70%. Peak concentrations of prazosin in plasma generally are reached 1 to 3 hours after an oral dose. The drug is tightly bound to plasma proteins (primarily α_1 -acid glycoprotein), and only 5% of the drug is free in the circulation; diseases that modify the concentration of this protein (*e.g.*, inflammatory processes) may change the free fraction. Prazosin is extensively metabolized in the liver, and little unchanged drug is excreted by the kidneys. The plasma half-life is approximately 2 to 3 hours (this may be prolonged to 6 to 8 hours in congestive heart failure). The duration of action of the drug typically is 7 to 10 hours in the treatment of hypertension.

The initial dose should be 1 mg, usually given at bedtime so that the patient will remain recumbent for at least several hours to reduce the risk of syncopal reactions that may follow the first dose of prazosin. Therapy is begun with 1 mg given two or three times daily, and the dose is titrated upward depending on the blood pressure. A maximal effect generally is observed with a total daily dose of 20 mg in patients with hypertension. In the treatment of benign prostatic hyperplasia (BPH), doses from 1 to 5 mg twice daily typically are used. The twice-daily dosing requirement for prazosin is a disadvantage compared with newer α_1 receptor antagonists.

Terazosin. Terazosin (HYTRIN, others) is a close structural analog of prazosin (Kyncl, 1993; Wilde *et al.*, 1993). It is less potent than prazosin but retains high specificity for α_1 receptors; terazosin does not discriminate among α_{1A} , α_{1B} , and α_{1D} receptors. The major distinction between the two drugs is in their pharmacokinetic properties.

Terazosin is more soluble in water than is prazosin, and its bioavailability is high (>90%). The half-time of elimination of terazosin is approximately 12 hours, and its duration of action usually extends beyond 18 hours. Consequently, the drug may be taken once daily to treat hypertension and BPH in most patients. Terazosin has been found more effective than finasteride in treatment of BPH (Lepor *et al.*, 1996). An interesting aspect of the action of terazosin and doxazosin in the treatment of lower urinary tract problems in men with BPH is the induction of apoptosis in prostate smooth muscle cells. This apoptosis may lessen the symptoms associated with chronic BPH by limiting cell proliferation. The apoptotic effect of terazosin and doxazosin appears to be related to the quinazoline moiety rather than α_1 receptor antagonism; tamsulosin, a non-quinazoline α_1 receptor antagonist, does not produce apoptosis (Kyprianou, 2003). Only about 10% of terazosin is excreted unchanged in the urine. An initial first dose of 1 mg is recommended. Doses are titrated upward depending on the therapeutic response. Doses of 10 mg/day may be required for maximal effect in BPH.

Doxazosin. Doxazosin (CARDURA, others) is another structural analog of prazosin. It also is a highly selective antagonist at α_1 receptors, although nonselective among

α_1 receptor subtypes, but it differs in its pharmacokinetic profile (Babamoto and Hirokawa, 1992).

The half-life of doxazosin is approximately 20 hours, and its duration of action may extend to 36 hours. The bioavailability and extent of metabolism of doxazosin and prazosin are similar. Most doxazosin metabolites are eliminated in the feces. The hemodynamic effects of doxazosin appear to be similar to those of prazosin. Doxazosin should be given initially as a 1-mg dose in the treatment of hypertension or BPH. Similarly to terazosin, doxazosin may have beneficial actions in the long-term management of BPH related to apoptosis that are independent of α_1 receptor antagonism.

Alfuzosin. *Alfuzosin* (UROXATRAL) is a quinazoline-based α_1 receptor antagonist with similar affinity at all of the α_1 receptor subtypes (Foglar *et al.*, 1995; Kenny *et al.*, 1996). It has been used extensively in treating BPH. Its bioavailability is about 64%; it has a half-life of 3 to 5 hours. The recommended dosage is one 10-mg extended-release tablet daily to be taken after the same meal each day.

Tamsulosin. *Tamsulosin* (FLOMAX), a benzenesulfonamide, is an α_1 receptor antagonist with some selectivity for α_{1A} (and α_{1D}) subtypes compared to α_{1B} subtype (Kenny *et al.*, 1996). This selectivity may favor blockade of α_{1A} receptors in prostate. Tamsulosin is efficacious in the treatment of BPH with little effect on blood pressure (Wilde and McTavish, 1996; Beduschi *et al.*, 1998). Tamsulosin is well absorbed and has a half-life of 5 to 10 hours. It is extensively metabolized by CYPs. Tamsulosin may be administered at a 0.4-mg starting dose; a dose of 0.8 mg ultimately will be more efficacious in some patients. Abnormal ejaculation is an adverse effect of tamsulosin.

Adverse Effects. A major potential adverse effect of prazosin and its congeners is the first-dose effect; marked postural hypotension and syncope sometimes are seen 30 to 90 minutes after a patient takes an initial dose.

Syncope episodes also have occurred with a rapid increase in dosage or with the addition of a second antihypertensive drug to the regimen of a patient who already is taking a large dose of prazosin. The mechanisms responsible for such exaggerated hypotensive responses or for the development of tolerance to these effects are not clear. An action in the CNS to reduce sympathetic outflow may contribute (*see above*). The risk of the first-dose phenomenon is minimized by limiting the initial dose (*e.g.*, 1 mg at bedtime), by increasing the dosage slowly, and by introducing additional antihypertensive drugs cautiously.

Since orthostatic hypotension may be a problem during long-term treatment with prazosin or its congeners, it is essential to check standing as well as recumbent blood pressure. Nonspecific adverse effects such as headache, dizziness, and asthenia rarely limit treatment with prazosin. The nonspecific complaint of dizziness generally is not due to orthostatic hypotension. Although not extensively documented, the adverse effects of the structural analogs of prazosin appear to be similar to those of the parent compound. For tamsu-

losin, at a dose of 0.4 mg daily, effects on blood pressure are not expected, although impaired ejaculation may occur.

Therapeutic Uses. Prazosin and its congeners have been used successfully in the treatment of essential hypertension (*see Chapter 32*). Considerable interest has focused on the use of α_1 receptor antagonists in the treatment of hypertension, predicted by the tendency of these drugs to improve rather than worsen lipid profiles and glucose-insulin metabolism in patients with hypertension who are at risk for atherosclerotic disease (Grimm, 1991). Also, catecholamines are powerful stimulators of vascular smooth muscle hypertrophy, acting *via* α_1 receptors (Okazaki *et al.*, 1994). To what extent these effects of α_1 antagonists have clinical significance in diminishing the risk of atherosclerosis is not known.

Additional uses for α antagonists, covered below, are in congestive heart failure and in the management of lower urinary tract problems secondary to benign prostatic hypertrophy.

Congestive Heart Failure. Alpha receptor antagonists have been used in the treatment of congestive heart failure, as have other vasodilating drugs. The short-term effects of prazosin in these patients are due to dilation of both arteries and veins, resulting in a reduction of preload and afterload, which increases cardiac output and reduces pulmonary congestion. In contrast to results obtained with inhibitors of angiotensin-converting enzyme or a combination of *hydralazine* and an organic nitrate, prazosin has not been found to prolong life in patients with congestive heart failure (Cohn *et al.*, 1986).

Benign Prostatic Hyperplasia (BPH). BPH produces symptomatic urethral obstruction in a significant percentage of older men that leads to weak stream, urinary frequency, and nocturia. These symptoms are due to a combination of mechanical pressure on the urethra due to the increase in smooth muscle mass and the α_1 receptor-mediated increase in smooth muscle tone in the prostate and neck of the bladder (Kyprianou, 2003). Alpha₁ receptors in the trigone muscle of the bladder and urethra contribute to the resistance to outflow of urine. Prazosin reduces this resistance in some patients with impaired bladder emptying caused by prostatic obstruction or parasympathetic decentralization from spinal injury (Kirby *et al.*, 1987; Andersson, 1988). The efficacy and importance of α receptor antagonists in the medical treatment of benign prostatic hyperplasia have been demonstrated in multiple controlled clinical trials. Transurethral resection of the prostate is the accepted surgical treatment for symptoms of urinary obstruction in men with BPH; however, there are some serious potential complications (*e.g.*, risk of impotence), and improvement may not be permanent. Other, less invasive procedures also are available. Medical therapy has utilized α receptor antagonists for many years. Finasteride, (PROPECIA) and *dutasteride* (AVODART), two drugs that inhibit conversion of testosterone to dihydrotestosterone (*see Chapter 58*), and can reduce prostate volume in some patients, are approved for this indication. However, the overall efficacy appears less than that observed with α_1 receptor antagonists (Lepor *et al.*, 1996). Selective α_1 receptor

antagonists have efficacy in BPH owing to relaxation of smooth muscle in the bladder neck, prostate capsule, and prostatic urethra. These drugs rapidly improve urinary flow, whereas the actions of finasteride are typically delayed for months. Recent studies show that combination therapy with doxazosin and finasteride reduces the risk of overall clinical progression of BPH significantly more than treatment with either drug alone (McConnell *et al.*, 2003). Prazosin, terazosin, doxazosin, tamsulosin, and alfuzosin have been studied extensively and used widely in patients with benign prostatic hyperplasia (Cooper *et al.*, 1999). With the exception of tamsulosin, the comparative efficacies of each of these drugs, especially in comparison with relative adverse effects such as postural hypotension, appear similar, although direct comparisons are limited. Tamsulosin at the recommended dose of 0.4 mg daily is less likely to cause orthostatic hypotension than are the other drugs. There is growing evidence that the predominant α_1 receptor subtype expressed in the human prostate is the α_{1A} receptor (Forray *et al.*, 1994; Ruffulo and Hieble, 1999). Developments in this area will provide the basis for the selection of α receptor antagonists with specificity for the relevant subtype of α_1 receptor. However, the possibility remains that some of the symptoms of BPH are due to α_1 receptors in other sites, such as bladder, spinal cord, or brain.

Other Disorders. Although anecdotal evidence suggested that prazosin might be useful in the treatment of patients with variant angina (Prinzmetal's angina) due to coronary vasospasm, several small controlled trials have failed to demonstrate a clear benefit. Some studies have indicated that prazosin can decrease the incidence of digital vasospasm in patients with Raynaud's disease; however, its relative efficacy as compared with other vasodilators (*e.g.*, Ca^{2+} channel blockers) is not known. Prazosin may have some benefit in patients with other vasospastic disorders (Spittell and Spittell, 1992). Prazosin decreases ventricular arrhythmias induced by coronary artery ligation or reperfusion in laboratory animals; the therapeutic potential for this use in humans is not known. Prazosin also may be useful for the treatment of patients with mitral or aortic valvular insufficiency, presumably because of reduction of afterload.

Additional α Adrenergic Receptor Antagonists

Ergot Alkaloids. The ergot alkaloids were the first adrenergic receptor antagonists to be discovered, and most aspects of their general pharmacology were disclosed in the classic studies of Dale. Ergot alkaloids exhibit a complex variety of pharmacological properties. To varying degrees, these agents act as partial agonists or antagonists at α receptors, dopamine receptors, and serotonin receptors. Additional information about the ergot alkaloids is in Chapter 11 and in previous editions of this book.

Indoramin. *Indoramin* is a selective, competitive α_1 receptor antagonist that has been used for the treatment of hypertension. Competitive antagonism of histamine H_1 and 5-HT receptors also is evident. As an α_1 -selective antagonist, indoramin lowers blood pressure with minimal tachycardia. The drug also decreases the incidence of attacks of Raynaud's phenomenon.

The bioavailability of indoramin generally is less than 30% (with considerable variability), and it undergoes extensive first-pass metabolism. Little unchanged drug is excreted in the urine, and some of the metabolites may be biologically active. The elimination half-life is about 5 hours. Some of the adverse effects of indoramin

include sedation, dry mouth, and failure of ejaculation. Although indoramin is an effective antihypertensive agent, it has complex pharmacokinetics and lacks a well-defined place in current therapy. Indoramin currently is not available in the United States.

Ketanserin. Although developed as a 5-HT-receptor antagonist, *ketanserin* also blocks α_1 receptors. Ketanserin is discussed in Chapter 11.

Urapidil. *Urapidil* is a novel, selective α_1 receptor antagonist that has a chemical structure distinct from those of prazosin and related compounds. Blockade of peripheral α_1 receptors appears to be primarily responsible for the hypotension produced by urapidil, although it has actions in the CNS as well. The drug is extensively metabolized and has a half-life of 3 hours. The role of urapidil in the treatment of hypertension remains to be determined. Urapidil is not currently available for clinical use in the United States.

Bunazosin. *Bunazosin* is an α_1 -selective antagonist of the quinazoline class that has been shown to lower blood pressure in patients with hypertension (Harder and Thurmann, 1994). *Bunazosin* is not currently available in the United States.

Yohimbine. Yohimbine (YOCON) is a competitive antagonist that is selective for α_2 receptors. The compound is an indolealkylamine alkaloid and is found in the bark of the tree *Pausinystalia yohimbe* and in *Rauwolfia* root; its structure resembles that of reserpine. Yohimbine readily enters the CNS, where it acts to increase blood pressure and heart rate; it also enhances motor activity and produces tremors. These actions are opposite to those of clonidine, an α_2 agonist (Grossman *et al.*, 1993). Yohimbine also is an antagonist of 5-HT. In the past, it was used extensively to treat male sexual dysfunction. Although efficacy never was clearly demonstrated, there is renewed interest in the use of yohimbine in the treatment of male sexual dysfunction. The drug enhances sexual activity in male rats and may benefit some patients with psychogenic erectile dysfunction (Reid *et al.*, 1987). However, the efficacies of PDE5 inhibitors (*e.g.*, *sildenafil*, *vardenafil*, and *tadalafil*) and *apomorphine* have been much more conclusively demonstrated in oral treatment of erectile dysfunction. Several small studies suggest that yohimbine also may be useful for diabetic neuropathy and in the treatment of postural hypotension.

Neuroleptic Agents. Natural and synthetic compounds of several other chemical classes developed primarily because they are antagonists of D_2 dopamine receptors also exhibit α receptor blocking activity. *Chlorpromazine*, *haloperidol*, and other neuroleptic drugs of the phenothiazine and butyrophenone types produce significant α receptor blockade in both laboratory animals and humans.

β ADRENERGIC RECEPTOR ANTAGONISTS

Competitive antagonists of β adrenergic receptors, or β blockers, have received enormous clinical attention because

of their efficacy in the treatment of hypertension, ischemic heart disease, congestive heart failure, and certain arrhythmias.

History. Ahlquist's hypothesis that the effects of catecholamines were mediated by activation of distinct α and β receptors provided the initial impetus for the synthesis and pharmacological evaluation of β receptor blocking agents (see Chapter 6). The first such selective agent was *dichloroisoproterenol*. However, this compound is a partial agonist, and this property was thought to preclude its safe clinical use. Sir James Black and his colleagues initiated a program in the late 1950s to develop additional agents of this type. Although the usefulness of their first antagonist, *prone-thalol*, was limited by the production of thymic tumors in mice, *propranolol* soon followed.

Chemistry. The structural formulas of some β receptor antagonists in general use are shown in Figure 10–7. The structural similarities between agonists and antagonists that act on β receptors are closer than those between α receptor agonists and antagonists. Substitution of an isopropyl group or other bulky substituent on the amino nitrogen favors interaction with β receptors. There is a rather wide tolerance for the nature of the aromatic moiety in the nonselective β receptor antagonists; however, the structural tolerance for β_1 -selective antagonists is far more constrained.

Overview. Propranolol is a competitive β receptor antagonist and remains the prototype to which other β antagonists are compared. Additional β antagonists can be distinguished by the following properties: relative affinity for β_1 and β_2 receptors, intrinsic sympathomimetic activity, blockade of α receptors, differences in lipid solubility, capacity to induce vasodilation, and pharmacokinetic properties. Some of these distinguishing characteristics have clinical significance, and they help guide the appropriate choice of a β receptor antagonist for an individual patient.

Propranolol has equal affinity for β_1 and β_2 adrenergic receptors; thus, it is a nonselective β adrenergic receptor antagonist. Agents such as *metoprolol*, *atenolol*, *acebutolol*, *bisoprolol*, and *esmolol* have somewhat greater affinity for β_1 than for β_2 receptors; these are examples of β_1 -selective antagonists, even though the selectivity is not absolute. Propranolol is a pure antagonist, and it has no capacity to activate β receptors. Several β blockers (e.g., *pindolol* and *acebutolol*) activate β receptors partially in the absence of catecholamines; however, the intrinsic activities of these drugs are less than that of a full agonist such as isoproterenol. These partial agonists are said to have intrinsic sympathomimetic activity. Substantial sympathomimetic activity would be counterproductive to the response desired from a β antagonist; however, slight residual activity may, for example, prevent profound bradycardia or neg-

ative inotropy in a resting heart. The potential clinical advantage of this property, however, is unclear and may be disadvantageous in the context of secondary prevention of myocardial infarction (see below). In addition, other β receptor antagonists have been found to have the property of inverse agonism (see Chapter 1). These drugs can decrease basal activity of β receptor signaling by shifting the equilibrium of spontaneously active receptors toward the inactive state (Chidiac *et al.*, 1994). Several β receptor antagonists also have local anesthetic or membrane stabilizing activity, similar to lidocaine, that is independent of β blockade. Such drugs include propranolol, acebutolol, and *carvedilol*. Pindolol, metoprolol, *betaxolol*, and *labetalol* have slight membrane stabilizing effects. Although most β receptor antagonists do not block α adrenergic receptors, *labetalol*, *carvedilol*, and *bucindolol* are examples of agents that block both α_1 and β adrenergic receptors. In addition to *carvedilol*, *labetalol*, and *bucindolol*, many other β receptor antagonists have vasodilating properties due to various mechanisms discussed below. These include *celiprolol*, *nebivolol*, *nipradilol*, *carteolol*, *betaxolol*, *bopindolol*, and *bevantolol* (Toda, 2003).

Pharmacological Properties

As in the case of α receptor blocking agents, the pharmacological properties of β receptor antagonists can be explained largely from knowledge of the responses elicited by the receptors in the various tissues and the activity of the sympathetic nerves that innervate these tissues (see Table 6–1). For example, β receptor blockade has relatively little effect on the normal heart of an individual at rest, but has profound effects when sympathetic control of the heart is dominant, as during exercise or stress.

In this chapter, β -adrenergic receptor antagonists are classified as Non-Subtype Selective β Receptor Antagonists (“First Generation”), β_1 -Selective Receptor Antagonists (“Second Generation”), and Non-Subtype or Subtype Selective β Receptor Antagonists with additional cardiovascular actions (“Third Generation”). These latter drugs have additional cardiovascular properties (especially vasodilation) that seem unrelated to β blockade. Table 10–4 summarizes important pharmacological and pharmacokinetic properties of β receptor antagonists.

Cardiovascular System. The major therapeutic effects of β receptor antagonists are on the cardiovascular system. It is important to distinguish these effects in normal subjects from those in subjects with cardiovascular disease such as hypertension or myocardial ischemia.

Figure 10–7. Structural formulas of some β adrenergic receptor antagonists.

Since catecholamines have positive chronotropic and inotropic actions, β receptor antagonists slow the heart rate and decrease myocardial contractility. When tonic stimulation of β receptors is low, this effect is correspondingly modest. However, when the sympathetic nervous system is activated, as during exercise or stress, β receptor antagonists attenuate the expected rise in heart rate. Short-

term administration of β receptor antagonists such as propranolol decreases cardiac output; peripheral resistance increases in proportion to maintain blood pressure as a result of blockade of vascular β_2 receptors and compensatory reflexes, such as increased sympathetic nervous system activity, leading to activation of vascular α receptors. However, with long-term use of β receptor antagonists,

*Detectable only at doses much greater than required for β blockade.

total peripheral resistance returns to initial values (Mimran and Ducailar, 1988) or decreases in patients with hypertension (Man in't Veld *et al.*, 1988). With β antagonists that also are α_1 receptor antagonists, such as labetalol, carvedilol, and bucindolol, cardiac output is maintained with a greater fall in peripheral resistance. This also is seen with β receptor antagonists that are direct vasodilators.

β Receptor antagonists have significant effects on cardiac rhythm and automaticity. Although it had been thought that these effects were due exclusively to blockade of β_1 receptors, β_2 receptors likely also regulate heart rate in humans (Brodde and Michel, 1999; Altschuld and Billman, 2000). β_3 Receptors also have been identified in normal myocardial tissue in several species, including humans (Moniotte *et al.*, 2001). In con-

trast to β_1 and β_2 receptors, β_3 receptors are linked to G_i and their stimulation inhibits cardiac contraction and relaxation. The physiological role of β_3 receptors in the heart remains to be established (Morimoto *et al.*, 2004). β Receptor antagonists reduce sinus rate, decrease the spontaneous rate of depolarization of ectopic pacemakers, slow conduction in the atria and in the AV node, and increase the functional refractory period of the AV node.

Although high concentrations of many β blockers produce quinidine-like effects (membrane-stabilizing activity), it is doubtful that this is significant at usual doses of these agents. However, this effect may be important when there is overdosage. Interestingly, there is some evidence suggesting that *d*-propranolol may suppress ventricular arrhythmias independently of β receptor blockade (Murray *et al.*, 1990).

The cardiovascular effects of β receptor antagonists are most evident during dynamic exercise. In the presence of β receptor blockade, exercise-induced increases in heart rate and myocardial contractility are attenuated. However, the exercise-induced increase in cardiac output is less affected because of an increase in stroke volume (Shephard, 1982). The effects of β receptor antagonists on exercise are somewhat analogous to the changes that occur with normal aging. In healthy elderly persons, catecholamine-induced increases in heart rate are smaller than in younger individuals; however, the increase in cardiac output in older people may be preserved because of an increase in stroke volume during exercise. β Blockers tend to decrease work capacity, as assessed by their effects on intense short-term or more prolonged steady-state exertion (Kaiser *et al.*, 1986). Exercise performance may be impaired to a lesser extent by β_1 -selective agents than by nonselective antagonists. Blockade of β_2 receptors tends to blunt the increase in blood flow to active skeletal muscle during submaximal exercise (Van Baak, 1988). Blockade of β receptors also may attenuate catecholamine-induced activation of glucose metabolism and lipolysis.

Coronary artery blood flow increases during exercise or stress to meet the metabolic demands of the heart. By increasing heart rate, contractility, and systolic pressure, catecholamines increase myocardial oxygen demand. However, in patients with coronary artery disease, fixed narrowing of these vessels attenuates the expected increase in flow, leading to myocardial ischemia. β Receptor antagonists decrease the effects of catecholamines on the determinants of myocardial oxygen consumption. However, these agents may tend to increase the requirement for oxygen by increasing end-diastolic pressure and systolic ejection period. Usually, the net effect is to improve the relationship between cardiac oxygen supply and demand; exercise tolerance generally is improved in patients with angina, whose capacity to exercise is limited by the development of chest pain (*see* Chapter 31).

Activity as Antihypertensive Agents. β Receptor antagonists generally do not reduce blood pressure in patients with normal blood pressure. However, these drugs lower blood pressure in patients with hypertension. Despite their widespread use, the mechanisms responsible for this important clinical effect are not well understood. The release of renin from the juxtaglomerular apparatus is stimulated by the sympathetic nervous system *via* β_1 receptors, and this effect is blocked by β receptor antagonists (*see* Chapter 30). However, the relationship between this phenomenon and the fall in blood pressure is not clear. Some investigators have found that the antihypertensive effect of propranolol is most marked in patients with elevated concentrations of plasma renin, as compared with patients with low or normal concentrations of renin. However, β receptor antagonists are effective even in patients with low plasma renin, and pindolol is an effective antihypertensive agent that has little or no effect on plasma renin activity.

Presynaptic β receptors enhance the release of norepinephrine from sympathetic neurons, but the importance of

diminished release of norepinephrine to the antihypertensive effects of β antagonists is unclear. Although β blockers would not be expected to decrease the contractility of vascular smooth muscle, long-term administration of these drugs to hypertensive patients ultimately leads to a fall in peripheral vascular resistance (Man in't Veld *et al.*, 1988). The mechanism for this important effect is not known, but this delayed fall in peripheral vascular resistance in the face of a persistent reduction of cardiac output appears to account for much of the antihypertensive effect of these drugs. Although it has been hypothesized that central actions of β blockers also may contribute to their antihypertensive effects, there is relatively little evidence to support this possibility, and drugs that poorly penetrate the blood-brain barrier are effective antihypertensive agents.

As indicated above, some β receptor antagonists have additional effects that may contribute to their capacity to lower blood pressure. These drugs all produce peripheral vasodilation; at least six properties have been proposed to contribute to this effect, including production of nitric oxide, activation of β_2 receptors, blockade of α_1 receptors, blockade of Ca^{2+} entry, opening of K^+ channels, and antioxidant activity. The ability of vasodilating β receptor antagonists to act through one or more of these mechanisms is depicted in Table 10-5 and Figure 10-8. These mechanisms appear to contribute to the antihypertensive effects by enhancing hypotension, increasing peripheral blood flow, and decreasing afterload. Two of these agents (*e.g.*, celiprolol and nebivolol) also have been observed to produce vasodilation and thereby reduce preload.

Although further clinical trials are needed, these agents may be associated with a lower incidence of bronchospasm, impaired lipid metabolism, impotence, reduced regional blood flow, increased vascular resistance, and withdrawal symptoms. A lower incidence of these adverse effects would be particularly beneficial in patients who have insulin resistance and diabetes mellitus in addition to hypertension (Toda, 2003). The clinical significance in humans of some of these relatively subtle differences in pharmacological properties still is unclear. Particular interest has focused on patients with congestive heart failure or peripheral arterial occlusive disease.

Propranolol and other nonselective β receptor antagonists inhibit the vasodilation caused by isoproterenol and augment the pressor response to epinephrine. This is particularly significant in patients with a pheochromocytoma, in whom β receptor antagonists should be used only after adequate α receptor blockade has been established. This

Table 10-5

Third-Generation β Receptor Antagonists with Additional Cardiovascular Actions: Proposed Mechanisms Contributing to Vasodilation

avoids uncompensated α receptor-mediated vasoconstriction caused by epinephrine secreted from the tumor.

Pulmonary System. Nonselective β receptor antagonists such as propranolol block β_2 receptors in bronchial smooth muscle. This usually has little effect on pulmonary function in normal individuals. However, in patients with COPD, such blockade can lead to life-threatening bronchoconstriction. Although β_1 -selective antagonists or antagonists with intrinsic sympathomimetic activity are less likely than propranolol to increase airway resistance in patients with asthma, these drugs should be used only with great caution, if at all, in patients with bronchospastic diseases. Drugs such as celiprolol, with β_1 receptor

selectivity and β_2 receptor partial agonism, are of potential promise, although clinical experience is limited (Pujet *et al.*, 1992).

Metabolic Effects. β Receptor antagonists modify the metabolism of carbohydrates and lipids. Catecholamines promote glycogenolysis and mobilize glucose in response to hypoglycemia. Nonselective β blockers may delay recovery from hypoglycemia in type 1 (insulin-dependent) diabetes mellitus, but infrequently in type 2 diabetes mellitus. In addition to blocking glycogenolysis, β receptor antagonists can interfere with the counterregulatory effects of catecholamines secreted during hypoglycemia by blunting the perception of symptoms such as tremor,

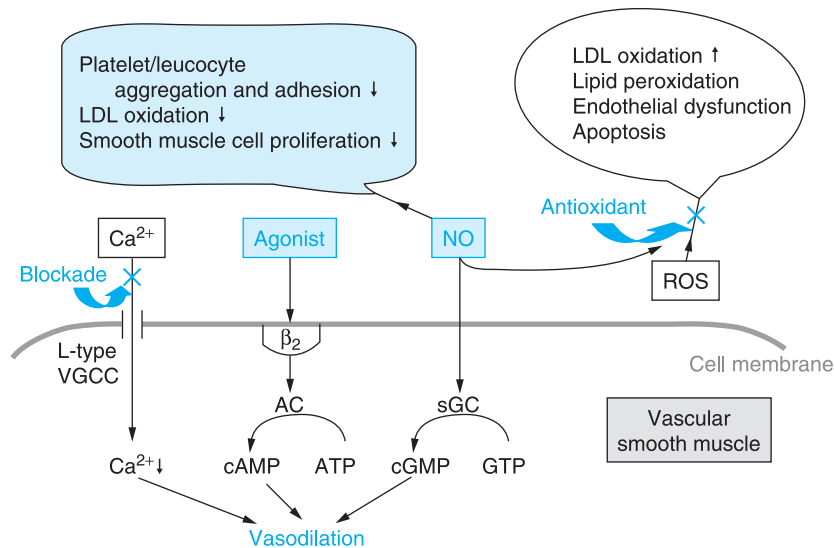

Figure 10-8. Mechanisms underlying actions of vasodilating β blockers in blood vessels. ROS, reactive oxygen species; sGC, soluble guanylyl cyclase; AC, adenylyl cyclase; L-type VGCC, L-type voltage gated Ca^{2+} channel. (Reproduced with permission from Toda, 2003.)

tachycardia, and nervousness. Thus, β adrenergic receptor antagonists should be used with great caution in patients with labile diabetes and frequent hypoglycemic reactions. If such a drug is indicated, a β_1 -selective antagonist is preferred, since these drugs are less likely to delay recovery from hypoglycemia (Dunne *et al.*, 2001; DiBari *et al.*, 2003).

The β receptors mediate activation of hormone-sensitive lipase in fat cells, leading to release of free fatty acids into the circulation (*see* Chapter 6). This increased flux of fatty acids is an important source of energy for exercising muscle. β Receptor antagonists can attenuate the release of free fatty acids from adipose tissue. Nonselective β receptor antagonists consistently reduce HDL cholesterol, increase LDL cholesterol, and increase triglycerides. In contrast, β_1 -selective antagonists, including celiprolol, carteolol, nebivolol, carvedilol, and bevantolol, reportedly improve the serum lipid profile of dyslipidemic patients. While drugs such as propranolol and atenolol increase triglycerides, plasma triglycerides are reduced with chronic celiprolol, carvedilol, and carteolol (Toda, 2003).

In contrast to classical β blockers, which decrease insulin sensitivity, the vasodilating β receptor antagonists (*e.g.*, celiprolol, nipradilol, carteolol, carvedilol, and *dilevalol*) increase insulin sensitivity in patients with insulin resistance. Together with their cardioprotective effects, improvement in insulin sensitivity from vasodilating β receptor antagonists may partially counterbalance the hazard from worsened lipid abnormalities associated with diabetes. If β blockers are to be used, β_1 -selective or vasodilating β receptor antagonists are preferred. In addition, it may be necessary to use β receptor antagonists in conjunction with other drugs, (*e.g.*, HMG-CoA reductase inhibitors) to ameliorate adverse metabolic effects (Dunne *et al.*, 2001).

β Receptor agonists decrease the plasma concentration of K^+ by promoting the uptake of the ion, predominantly into skeletal muscle. At rest, an infusion of epinephrine causes a decrease in the plasma concentration of K^+ . The marked increase in the concentration of epinephrine that occurs with stress (such as myocardial infarction) may cause hypokalemia, which could predispose to cardiac arrhythmias. The hypokalemic effect of epinephrine is blocked by an experimental antagonist, ICI 118551, which has a high affinity for β_2 and β_3 receptors. Exercise causes an increase in the efflux of K^+ from skeletal muscle. Catecholamines tend to buffer the rise in K^+ by increasing its influx into muscle. β blockers negate this buffering effect.

Other Effects. β Receptor antagonists block catecholamine-induced tremor. They also block inhibition of mast-cell degranulation by catecholamines.

NON-SUBTYPE-SELECTIVE β ADRENERGIC RECEPTOR ANTAGONISTS

Propranolol

In view of the extensive experience with propranolol (INDERAL, others), it is a useful prototype (Table 10-4).

Propranolol interacts with β_1 and β_2 receptors with equal affinity, lacks intrinsic sympathomimetic activity, and does not block α receptors.

Absorption, Fate, and Excretion. Propranolol is highly lipophilic and is almost completely absorbed after oral administration. However, much of the drug is metabolized by the liver during its first passage through the portal circulation; on average, only about 25% reaches the systemic circulation. In addition, there is great interindividual variation in the presystemic clearance of propranolol by the liver; this contributes to enormous variability in plasma concentrations (approximately twentyfold) after oral administration of the drug and contributes to the wide range of doses in terms of clinical efficacy. A clinical disadvantage of propranolol is that multiple, increasing steps in drug dose may be required over time. The degree of hepatic extraction of propranolol declines as the dose is increased. The bioavailability of propranolol may be increased by the concomitant ingestion of food and during long-term administration of the drug.

Propranolol has a large volume of distribution (4 liters/kg) and readily enters the CNS. Approximately 90% of the drug in the circulation is bound to plasma proteins. It is extensively metabolized, with most metabolites appearing in the urine. One product of hepatic metabolism is 4-hydroxypropranolol, which has some β adrenergic antagonist activity.

Analysis of the distribution of propranolol, its clearance by the liver, and its activity is complicated by the stereospecificity of these processes (Walle *et al.*, 1988). The (–)-enantiomers of propranolol and other β blockers are the active forms of the drug. The (–)-enantiomer of propranolol appears to be cleared more slowly from the body than is the inactive enantiomer. The clearance of propranolol may vary with hepatic blood flow and liver disease and also may change during the administration of other drugs that affect hepatic metabolism. Monitoring of plasma concentrations of propranolol has found little application, since the clinical endpoints (reduction of blood pressure and heart rate) are readily determined. The relationships between the plasma concentrations of propranolol and its pharmacodynamic effects are complex; for example, despite its short half-life in plasma (about 4 hours), its antihypertensive effect is sufficiently long-lived to permit administration twice daily. Some of the (–)-enantiomer of propranolol and other β blockers is taken up into sympathetic nerve endings and is released upon sympathetic nerve stimulation (Walle *et al.*, 1988).

A sustained-release formulation of propranolol (INDERAL LA) has been developed to maintain therapeutic concentrations of propranolol in plasma throughout a 24-hour period. Suppression of exercise-induced tachycardia is maintained throughout the dosing interval, and patient compliance may be improved.

Therapeutic Uses. For the treatment of hypertension and angina, the initial oral dose of propranolol generally is 40 to 80 mg per day. The

dose may then be titrated upward until the optimal response is obtained. For the treatment of angina, the dose may be increased at intervals of less than 1 week, as indicated clinically. In hypertension, the full blood-pressure response may not develop for several weeks. Typically, doses are less than 320 mg per day. If propranolol is taken twice daily for hypertension, blood pressure should be measured just prior to a dose to ensure that the duration of effect is sufficiently prolonged. Adequacy of β adrenergic blockade can be assessed by measuring suppression of exercise-induced tachycardia. Propranolol also is used to treat supraventricular arrhythmias/tachycardias, ventricular arrhythmias/tachycardias, premature ventricular contractions, digitalis-induced tachyarrhythmias, myocardial infarction, pheochromocytoma, and the prophylaxis of migraine. It also has been used for several off-label indications including parkinsonian tremors (sustained-release only), akathisia induced by antipsychotic drugs, variceal bleeding in portal hypertension, and generalized anxiety disorder (Table 10–6). Propranolol may be administered intravenously for the management of life-threatening arrhythmias or to patients under anesthesia. Under these circumstances, the usual dose is 1 to 3 mg, administered slowly (less than 1 mg per minute) with careful and frequent monitoring of blood pressure, ECG, and cardiac function. If an adequate response is not obtained, a second dose may be given after several minutes. If bradycardia is excessive, atropine should be administered to increase heart rate. Change to oral therapy should be initiated as soon as possible.

Nadolol

Nadolol (CORCARD, others) is a long-acting antagonist with equal affinity for β_1 and β_2 receptors. It is devoid of both membrane-stabilizing and intrinsic sympathomimetic activity. A distinguishing characteristic of nadolol is its relatively long half-life of 12 to 24 hours. It can be used to treat both hypertension and angina pectoris. Unlabeled uses have included migraine prophylaxis, parkinsonian tremors, and variceal bleeding in portal hypertension.

Absorption, Fate, and Excretion. Nadolol is very soluble in water and is incompletely absorbed from the gut; its bioavailability is about 35%. Interindividual variability is less than with propranolol. The low lipid solubility of nadolol may result in lower concentrations of the drug in the brain as compared with more lipid-soluble β receptor antagonists. Although it frequently has been suggested that the incidence of CNS adverse effects is lower with hydrophilic β receptor antagonists, data from controlled trials to support this contention are limited. Nadolol is not extensively metabolized and is largely excreted intact in the urine. The half-life of the drug in plasma is approximately 20 hours; consequently, it generally is administered once daily. Nadolol may accumulate in patients with renal failure, and dosage should be reduced in such individuals.

Timolol

Timolol (BLOCADREN, others) is a potent, non-subtype-selective β receptor antagonist. It has no intrinsic sympathomimetic or membrane-stabilizing activity. It is used

to treat hypertension, congestive heart failure, migraine prophylaxis, and has been widely used in the treatment of open-angle glaucoma and intraocular hypertension.

Absorption, Fate, and Excretion. Timolol is well absorbed from the gastrointestinal tract. It is metabolized extensively by CYP2D6 in the liver and undergoes first-pass metabolism. Only a small amount of unchanged drug appears in the urine. The half-life in plasma is about 4 hours. Interestingly, the ocular formulation of timolol (TIMOPTIC, others), used for the treatment of glaucoma, may be extensively absorbed systemically (see Chapter 63); adverse effects can occur in susceptible patients, such as those with asthma or congestive heart failure. The systemic administration of *cimetidine* with topical ocular timolol increases the degree of β blockade, resulting in a reduction of resting heart rate, intraocular pressure, and exercise tolerance (Ishii *et al.*, 2000).

Pindolol

Pindolol (VISKEN, others) is a non-subtype-selective β receptor antagonist with intrinsic sympathomimetic activity. It has low membrane-stabilizing activity and low lipid solubility.

Although only limited data are available, β blockers with slight partial agonist activity may produce smaller reductions in resting heart rate and blood pressure. Hence, such drugs may be preferred as antihypertensive agents in individuals with diminished cardiac reserve or a propensity for bradycardia. Nonetheless, the clinical significance of partial agonism has not been substantially demonstrated in controlled trials but may be of importance in individual patients (Fitzgerald, 1993). Agents such as pindolol block exercise-induced increases in heart rate and cardiac output.

Absorption, Fate, and Excretion. Pindolol is almost completely absorbed after oral administration and has moderately high bioavailability. These properties tend to minimize interindividual variation in the plasma concentrations of the drug that are achieved after its oral administration. Approximately 50% of pindolol ultimately is metabolized in the liver. The principal metabolites are hydroxylated derivatives that subsequently are conjugated with either glucuronide or sulfate before renal excretion. The remainder of the drug is excreted unchanged in the urine. The plasma half-life of pindolol is about 4 hours; clearance is reduced in patients with renal failure.

β_1 -SELECTIVE ADRENERGIC RECEPTOR ANTAGONISTS

Metoprolol

Metoprolol (LOPRESSOR, others) is a β_1 -selective receptor antagonist that is devoid of intrinsic sympathomimetic activity and membrane-stabilizing activity.

Table 10–6

Summary of Adrenergic Agonists and Antagonists

CLASS	DRUGS	PROMINENT PHARMACOLOGICAL ACTIONS	PRINCIPAL THERAPEUTIC APPLICATIONS	UNTOWARD EFFECTS	COMMENTS
<i>Direct-acting non-selective agonists</i>	Epinephrine ($\alpha_1, \alpha_2, \beta_1, \beta_2, \beta_3$)	Increase in heart rate Increase in blood pressure Increased contractility Slight decrease in PVR Increase in cardiac output Vasoconstriction (viscera) Vasodilation (skeletal muscle) Increase in blood glucose and lactic acid	Open-angle glaucoma With local anesthetics to prolong action Anaphylactic shock Complete heart block or cardiac arrest Bronchodilator in asthma	Palpitation Cardiac arrhythmias Cerebral hemorrhage Headache Tremor Restlessness	Not given orally Life saving in anaphylaxis or cardiac arrest
	Norepinephrine ($\alpha_1, \alpha_2, \beta_1, \gg \beta_2$)	Increase in systolic and diastolic blood pressure Vasoconstriction Increase in PVR Direct increase in heart rate and contraction Reflex decrease in heart rate	Hypotension	Similar to Epi Hypertension	Not absorbed orally
<i>β Receptor Agonists</i> Non-selective ($\beta_1 + \beta_2$)	Isoproterenol	IV administration Decrease in PVR Increase in cardiac output Tachyarrhythmias Bronchodilation	Bronchodilator in asthma Complete heart block or cardiac arrest Shock	Palpitations Tachycardia Headache Flushed skin Cardiac ischemia in patients with CAD	Administered by inhalation in asthma

Table 10–6

Summary of Adrenergic Agonists and Antagonists (Continued)

CLASS	DRUGS	PROMINENT PHARMACOLOGICAL ACTIONS	PRINCIPAL THERAPEUTIC APPLICATIONS	UNTOWARD EFFECTS	COMMENTS
β_1 -selective	Dobutamine	Increase in contractility Some increase in heart rate Increase in AV conduction	Short-term treatment of cardiac decompensation after surgery, or patients with CHF or MI	Increase in blood pressure and heart rate.	Use with caution in patients with hypertension or cardiac arrhythmias Used only IV
β_2 -selective (intermediate acting)	Albuterol	Relaxation of bronchial smooth muscle	Bronchodilators for treatment of asthma and COPD	Skeletal muscle tremor	Use with caution in patients with CV disease (reduced by inhalational administration)
	Bitolterol	Relaxation of uterine smooth muscle	Short/intermediate-acting drugs for acute bronchospasm	Tachycardia and other cardiac effects seen after systemic administration (much less with inhalational use)	
	Fenoterol	Activation of other β_2 receptors after systemic administration			Ritodrine, to stop premature labor
	Isoetharine				
	Metaproterenol				
	Procaterol				
	Terbutaline				
Ritodrine					
(Long acting)	Formoterol Salmeterol		Best choice for prophylaxis due to long action		Long action favored for prophylaxis
α Receptor agonists α_1 -selective	Methoxamine Phenylephrine Mephentermine Metaraminol Midodrine	Vasoconstriction	Nasal congestion (used topically) Postural hypotension	Hypertension Reflex bradycardia Dry mouth, sedation, rebound hypertension upon abrupt withdrawal	Mephentermine and metaraminol also act indirectly to release NE Midodrine is a prodrug converted <i>in vivo</i> to an active compound

α_2 -selective

Clonidine
Apraclonidine
Guanfacine
Guanabenz
Brimonidine
 α -methyl dopa

Decrease sympathetic outflow from brain to periphery resulting in decreased PVR and blood pressure
Decrease nerve-evoked release of sympathetic transmitters
Decrease production of aqueous humor

Adjunctive therapy in shock
Hypertension
To reduce sympathetic response to withdrawal from narcotics, alcohol, and tobacco
Glaucoma

Apraclonidine and brimonidine used topically for glaucoma and ocular hypertension
Methyl dopa is converted in CNS to α -methyl NE, an effective α_2 agonist

Indirect-acting

Amphetamine
Methamphetamine
Methyphenidate
(releases NE peripherally; NE, DA, 5-HT centrally)

CNS stimulation
Increase in blood pressure
Myocardial stimulation

Treatment of ADHD
Narcolepsy
Obesity (rarely)

Restlessness
Tremor
Insomnia
Anxiety
Tachycardia
Hypertension
Cardiac arrhythmias

Schedule II drugs
Marked tolerance occurs
Chronic use leads to dependence
Can result in hemorrhagic stroke in patients with underlying disease
Long-term use can cause paranoid schizophrenia

Mixed-acting

Dopamine (α_1 , α_2 , β_1 , D_1 ; releases NE)

Vasodilation (coronary, renal mesenteric beds)
Increase in glomerular filtration rate and natriuresis
Increase in heart rate and contractility
Increase in systolic blood pressure

Cardiogenic shock
Congestive heart failure
Treatment of acute renal failure

High doses lead to vasoconstriction

Important for its ability to maintain renal blood flow
Administered IV

Ephedrine (α_1 , α_2 , β_1 , β_2 ; releases NE)

Similar to epinephrine but longer lasting
CNS stimulation

Bronchodilator for treatment of asthma
Nasal congestion
Treatment of hypotension and shock

Restlessness
Tremor
Insomnia
Anxiety
Tachycardia
Hypertension

Administered by all routes
Not commonly used

ADHD, attention-deficit/hyperactivity disorder; AV, atrioventricular; BPH, benign prostatic hypertrophy; CAD, coronary artery disease; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CV, cardiovascular; DA, dopamine; D_1 , subtype 1 dopamine receptor; Epi, epinephrine; FFA, free fatty acids; 5-HT, serotonin; ISA, intrinsic sympathomimetic activity; MI, myocardial infarction; NE, norepinephrine; NO, nitric oxide; PVR, peripheral vascular resistance.

Absorption, Fate, and Excretion. Metoprolol is almost completely absorbed after oral administration, but bioavailability is relatively low (about 40%) because of first-pass metabolism. Plasma concentrations of the drug vary widely (up to seventeenfold), perhaps because of genetically determined differences in the rate of metabolism. Metoprolol is extensively metabolized in the liver, with CYP2D6 the major enzyme involved, and only 10% of the administered drug is recovered unchanged in the urine. The half-life of metoprolol is 3 to 4 hours, but can increase to 7 to 8 hours in CYP2D6 poor metabolizers. It recently has been reported that CYP2D6 poor metabolizers have a fivefold higher risk for developing adverse effects during metoprolol treatment than patients who are not poor metabolizers (Wuttke *et al.*, 2002). An extended-release formulation (TOPROL XL) is available for once-daily administration.

Therapeutic Uses. For the treatment of hypertension, the usual initial dose is 100 mg per day. The drug sometimes is effective when given once daily, although it frequently is used in two divided doses. Dosage may be increased at weekly intervals until optimal reduction of blood pressure is achieved. If the drug is taken only once daily, it is important to confirm that blood pressure is controlled for the entire 24-hour period. Metoprolol generally is used in two divided doses for the treatment of stable angina. For the initial treatment of patients with acute myocardial infarction, an intravenous formulation of metoprolol tartrate is available. Oral dosing is initiated as soon as the clinical situation permits. Metoprolol generally is contraindicated for the treatment of acute myocardial infarction in patients with heart rates of less than 45 beats per minute, heart block greater than first-degree (PR interval ≥ 0.24 second), systolic blood pressure <100 mm Hg, or moderate-to-severe heart failure. Metoprolol also has been proven to be effective in chronic heart failure. It has been shown in randomized trials to be associated with a striking reduction in all-cause mortality and hospitalization for worsening heart failure and a modest reduction in all-cause hospitalization (MERIT-HF Study Group, 1999; Prakash and Markham, 2000).

Atenolol

Atenolol (TENORMIN, others) is a β_1 -selective antagonist that is devoid of intrinsic sympathomimetic and membrane stabilizing activity (Wadworth *et al.*, 1991). Atenolol is very hydrophilic and appears to penetrate the CNS only to a limited extent. Its half-life is somewhat longer than that of metoprolol.

Absorption, Fate, and Excretion. Atenolol is incompletely absorbed (about 50%), but most of the absorbed dose reaches the systemic circulation. There is relatively little interindividual variation in the plasma concentrations of atenolol; peak concentrations in different patients vary over only a fourfold range. The drug is excreted largely unchanged in the urine, and the elimination half-life is about 5 to 8 hours. The drug accumulates in patients with renal failure, and dosage should be adjusted for patients whose creatinine clearance is less than 35 ml/minute.

Therapeutic Uses. The initial dose of atenolol for the treatment of hypertension usually is 50 mg per day, given once daily. If an ade-

quate therapeutic response is not evident within several weeks, the daily dose may be increased to 100 mg; higher doses are unlikely to provide any greater antihypertensive effect. Atenolol has been shown to be efficacious, in combination with a diuretic, in elderly patients with isolated systolic hypertension.

Esmolol

Esmolol (BREVIBLOC, others) is a β_1 -selective antagonist with a very short duration of action. It has little if any intrinsic sympathomimetic activity, and it lacks membrane-stabilizing actions. Esmolol is administered intravenously and is used when β blockade of short duration is desired or in critically ill patients in whom adverse effects of bradycardia, heart failure, or hypotension may necessitate rapid withdrawal of the drug.

Absorption, Fate, and Excretion. Esmolol has a half-life of about 8 minutes and an apparent volume of distribution of approximately 2 liters/kg. The drug contains an ester linkage, and it is hydrolyzed rapidly by esterases in erythrocytes. The half-life of the carboxylic acid metabolite of esmolol is far longer (4 hours), and it accumulates during prolonged infusion of esmolol. However, this metabolite has very low potency as a β receptor antagonist (1/500 of the potency of esmolol); it is excreted in the urine.

The onset and cessation of β receptor blockade with esmolol are rapid; peak hemodynamic effects occur within 6 to 10 minutes of administration of a loading dose, and there is substantial attenuation of β blockade within 20 minutes of stopping an infusion. Esmolol may have striking hypotensive effects in normal subjects, although the mechanism of this effect is unclear.

Because esmolol is used in urgent settings where immediate onset of β blockade is warranted, a partial loading dose typically is administered, followed by a continuous infusion of the drug. If an adequate therapeutic effect is not observed within 5 minutes, the same loading dose is repeated, followed by a maintenance infusion at a higher rate. This process, including progressively greater infusion rates, may need to be repeated until the desired endpoint (*e.g.*, lowered heart rate or blood pressure) is approached.

Acebutolol

Acebutolol (SECTRAL, others) is a selective β_1 adrenergic receptor antagonist with some intrinsic sympathomimetic and membrane-stabilizing activity.

Absorption, Fate, and Excretion. Acebutolol is well absorbed, and undergoes significant first-pass metabolism to an active metabolite, diacetolol, which accounts for most of the drug's activity. The elimination half-life of acebutolol typically is about 3 hours, but the half-life of diacetolol is 8 to 12 hours; it is excreted in the urine.

Therapeutic Uses. The initial dose of acebutolol in hypertension usually is 400 mg per day; it may be given as a single dose, but two divided doses may be required for adequate control of blood pressure. Optimal responses usually occur with doses of 400 to 800 mg

per day (range 200 to 1200 mg). For treatment of ventricular arrhythmias, the drug should be given twice daily.

Bisoprolol

Bisoprolol (ZEBETA) is a highly selective β_1 receptor antagonist that does not have intrinsic sympathomimetic or membrane-stabilizing activity (McGavin and Keating, 2002). It is approved for the treatment of hypertension and has been investigated in randomized, double-blind multicenter trials in combination with ACE inhibitors and diuretics in patients with moderate-to-severe chronic heart failure (Simon *et al.*, 2003). All-case mortality was significantly lower with bisoprolol than placebo.

Bisoprolol generally is well tolerated and side effects include dizziness, bradycardia, hypotension, and fatigue. Bisoprolol is well absorbed following oral administration with bioavailability of ~90%. It is eliminated by renal excretion (50%) and liver metabolism to pharmacologically inactive metabolites (50%). Bisoprolol has a plasma half-life of 11 to 17 hours. Bisoprolol can be considered a standard treatment option when selecting a β blocker for use in combination with ACE inhibitors and diuretics in patients with stable, moderate-to-severe chronic heart failure and in treating hypertension (McGavin and Keating, 2002; Owen, 2002; Simon *et al.*, 2003).

β Receptor Antagonists with Additional Cardiovascular Effects ("Third Generation" β Blockers)

In addition to the classical non-subtype selective and β_1 -selective adrenergic receptor antagonists, there also are a series of drugs that possess vasodilatory actions. These effects are produced through a variety of mechanisms including α_1 adrenergic receptor blockade (labetalol, carvedilol, bucindolol, bevantolol, nipradilol), increased production of NO (celiprolol, nebivolol, carteolol, bopindolol, and nipradolol), β_2 -agonist properties (celiprolol, carteolol, and bopindolol), Ca^{2+} entry blockade (carvedilol, betaxolol, and bevantolol), opening of K^+ channels (*tilisolol*), or antioxidant action (carvedilol) (Toda, 2003). These actions are summarized in Table 10–5 and Figure 10–8. Many third generation β receptor antagonists are not yet available in the United States but have undergone clinical trials and are on the market in other countries.

Labetalol

Labetalol (NORMODYNE, TRANDATE, others) is representative of a class of drugs that act as competitive antagonists at both α_1 and β receptors. Labetalol has two optical centers, and the formulation used clinically contains equal

amounts of the four diastereomers. The pharmacological properties of the drug are complex, because each isomer displays different relative activities. The properties of the mixture include selective blockade of α_1 receptors (as compared with the α_2 subtype), blockade of β_1 and β_2 receptors, partial agonist activity at β_2 receptors, and inhibition of neuronal uptake of norepinephrine (cocaine-like effect) (*see* Chapter 6). The potency of the mixture for β receptor blockade is fivefold to tenfold that for α_1 receptor blockade.

The pharmacological effects of labetalol have become clearer since the four isomers were separated and tested individually. The *R,R* isomer is about four times more potent as a β receptor antagonist than is racemic labetalol, and it accounts for much of the β blockade produced by the mixture of isomers, although it no longer is in development as a separate drug (dilevalol). As an α_1 antagonist, this isomer is less than 20% as potent as the racemic mixture. The *R,S* isomer is almost devoid of both α and β blocking effects. The *S,R* isomer has almost no β blocking activity, yet is about five times more potent as an α_1 blocker than is racemic labetalol. The *S,S* isomer is devoid of β blocking activity and has a potency similar to that of racemic labetalol as an α_1 receptor antagonist. The *R,R* isomer has some intrinsic sympathomimetic activity at β_2 adrenergic receptors; this may contribute to vasodilation. Labetalol also may have some direct vasodilating capacity.

The actions of labetalol on both α_1 and β receptors contribute to the fall in blood pressure observed in patients with hypertension. α_1 Receptor blockade leads to relaxation of arterial smooth muscle and vasodilation, particularly in the upright position. The β_1 blockade also contributes to a fall in blood pressure, in part by blocking reflex sympathetic stimulation of the heart. In addition, the intrinsic sympathomimetic activity of labetalol at β_2 receptors may contribute to vasodilation.

Labetalol is available in oral form for therapy of chronic hypertension and as an intravenous formulation for use in hypertensive emergencies. Labetalol has been associated with hepatic injury in a limited number of patients (Clark *et al.*, 1990).

Absorption, Fate, and Excretion. Although labetalol is completely absorbed from the gut, there is extensive first-pass clearance; bioavailability is only about 20% to 40% and is highly variable. Bioavailability may be increased by food intake. The drug is rapidly and extensively metabolized in the liver by oxidative biotransformation and glucuronidation; very little unchanged drug is found in the urine. The rate of metabolism of labetalol is sensitive to changes in hepatic blood flow. The elimination half-life of the drug is about 8 hours. The half-life of the *R,R* isomer of labetalol (dilevalol) is about 15 hours. Labetalol provides an interesting and challenging example of pharmacokinetic-pharmacodynamic modeling applied to a drug that is a racemic mixture of isomers with different kinetics and pharmacological actions (Donnelly and Macphee, 1991).

Carvedilol

Carvedilol (COREG) is a third-generation β receptor antagonist that has a unique pharmacological profile. It blocks

β_1 , β_2 , and α_1 receptors similarly to labetalol, but also has antioxidant and antiproliferative effects. It has membrane-stabilizing activity but it lacks intrinsic sympathomimetic activity. Carvedilol produces vasodilation. It is thought that the additional properties (*e.g.*, antioxidant and antiproliferative effects) contribute to the beneficial effects seen in treating congestive heart failure. Carvedilol does not increase β receptor density and is not associated with high levels of inverse agonist activity (Keating and Jarvis, 2003; Cheng *et al.*, 2001).

Carvedilol has been tested in numerous double-blind, randomized studies including the following: U.S. Carvedilol Heart Failure Trials Program, Carvedilol or Metoprolol European Trial (COMET) (Poole-Wilson *et al.*, 2003), Carvedilol Prospective Randomised Cumulative Survival (COPERNICUS) trial, and the Carvedilol Post Infarct Survival Control in LV Dysfunction (CAPRICORN) trial (Cleland, 2003). These trials showed that carvedilol improves ventricular function and reduces mortality and morbidity in patients with mild-to-severe congestive heart failure. Several experts recommend it as the standard treatment option in this setting. In addition, carvedilol combined with conventional therapy reduces mortality and attenuates myocardial infarction. In patients with chronic heart failure, carvedilol reduces cardiac sympathetic drive, but it is not clear if α_1 receptor-mediated vasodilation is maintained over long periods of time.

Absorption, Fate, Excretion. Carvedilol is rapidly absorbed following oral administration, with peak plasma concentrations occurring in 1 to 2 hours. It is highly lipophilic and thus is extensively distributed into extravascular tissues. It is >95% protein bound and is extensively metabolized in the liver, predominantly by CYP2D6 and CYP2C9. The half life is 7 to 10 hours. Stereoselective first-pass metabolism results in more rapid clearance of S(-)-carvedilol than R(+)-carvedilol. No significant changes in the pharmacokinetics of carvedilol were seen in elderly patients with hypertension, and no change in dosage is needed in patients with moderate-to-severe renal insufficiency (Cleland, 2003; Keating and Jarvis, 2003).

Bucindolol

Bucindolol (SANDONORM) is a third-generation non-selective β receptor antagonist with some α_1 receptor blocking as well as β_2 and β_3 agonistic properties. Although not precisely understood, it appears to be a vasodilator *via* its β_2 agonistic action as well as ancillary mechanisms (Andreka *et al.*, 2002; Maack *et al.*, 2000).

Bucindolol increases left ventricular systolic ejection fraction and decreases peripheral resistance, thereby reducing afterload. It increases plasma HDL cholesterol, but does not affect plasma triglycerides. In contrast to other β receptor antagonists used in large multicenter trials (*e.g.*, carvedilol), bucindolol was not associated with improved survival compared with placebo (The β -

Blocker Evaluation of Survival Trial Investigators, 2001). Although the reasons for a lack of benefit in mortality in the BEST trial are not clear, bucindolol has intrinsic sympathomimetic activity that may be detrimental in the long-term treatment of heart failure (Andreka *et al.*, 2002). Bucindolol is not currently on the U.S. market.

Celiprolol

Celiprolol (SELECTOR) is a third-generation cardioselective, β receptor antagonist. It has low lipid solubility and possesses weak vasodilating and bronchodilating effects attributed to partial selective β_2 agonist activity and possibly papaverine-like relaxant effects on smooth muscle (including bronchial). It also has been reported to have peripheral α_2 -adrenergic receptor inhibitory activity and to promote NO release. There is evidence for intrinsic sympathomimetic activity at the β_2 receptor. Celiprolol is devoid of membrane-stabilizing activity. Weak α_2 antagonistic properties are present, but are not considered clinically significant at therapeutic doses (Toda, 2003).

Celiprolol reduces heart rate and blood pressure and can increase the functional refractory period of the atrioventricular node. Oral bioavailability ranges from 30% to 70%, and peak plasma levels are seen at 2 to 4 hours. It is largely unmetabolized and is excreted unchanged in the urine and feces. Celiprolol does not undergo first-pass metabolism. The predominant mode of excretion is renal. Celiprolol is a safe and effective drug for treatment of hypertension and angina (Witchitz *et al.*, 2000; Felix *et al.*, 2001).

Nebivolol

Nebivolol has a hemodynamic profile different from classic β receptor antagonists such as atenolol, propranolol, and pindolol. It acutely lowers arterial blood pressure without depressing left ventricular function, and reduces systemic vascular resistance. This reduction in systemic vascular resistance is due to a direct vasorelaxant effect that is mediated at least in part by NO (Ignarro *et al.*, 2002). Nebivolol appears to be the most selective β_1 receptor antagonist available clinically and is devoid of intrinsic sympathomimetic activity, inverse agonistic activity, and α_1 receptor blocking properties (de Groot *et al.*, 2004; Brixius *et al.*, 2001). It does not alter exercise capacity in healthy individuals but does inhibit both ADP and collagen-induced platelet aggregation.

Nebivolol is a racemate containing equal amounts of the *d*- and *l*-enantiomers. The *d*-isomer is the active β -blocking component, while the *l*-isomer is responsible for the release of nitric

oxide. Nebivolol was effective in treating hypertension and diastolic heart failure in several well-controlled clinical trials (Czuriga *et al.*, 2003; Rosei *et al.*, 2003; Nodari *et al.*, 2003). Although not yet on the market in the United States, a New Drug Application has been submitted to the FDA for use in the management of hypertension.

Other β Receptor Antagonists

Many other β receptor antagonists have been synthesized and evaluated to varying extents. *Oxprenolol* (no longer marketed in the United States), and *penbutolol* (LEVATOL) are non-subtype-selective β blockers with intrinsic sympathomimetic activity. *Medroxalol* is a nonselective β blocker with α_1 receptor-blocking activity (Rosendorff, 1993). *Levobunolol* (BETAGAN LIQUIFILM, others) is a non-subtype-selective β antagonist used as a topical agent in the treatment of glaucoma (Brooks and Gillies, 1992). *Betaxolol* (BETOPTIC), a β_1 -selective antagonist, is available as an ophthalmic preparation for glaucoma and an oral formulation for systemic hypertension. *Betaxolol* may be less likely to induce bronchospasm than are the ophthalmic preparations of the nonselective β blockers timolol and levobunolol. Similarly, ocular administration of *carteolol* (OCUPRESS) may be less likely than timolol to have systemic effects, possibly because of its intrinsic sympathomimetic activity; cautious monitoring is required nonetheless. *Sotalol* (BETAPACE, BETAPACE AF, others) is a nonselective β antagonist that is devoid of membrane-stabilizing actions. However, it has antiarrhythmic actions independent of its ability to block β adrenergic receptors (Fitton and Sorokin, 1993) (*see* Chapter 34). *Propafenone* (RYTHMOL) is a Na^+ -channel blocking drug that also is a β adrenergic receptor antagonist.

ADVERSE EFFECTS AND PRECAUTIONS

The most common adverse effects of β receptor antagonists arise as pharmacological consequences of blockade of β receptors; serious adverse effects unrelated to β receptor blockade are rare.

Cardiovascular System. Because the sympathetic nervous system provides critical support for cardiac performance in many individuals with impaired myocardial function, β receptor antagonists may induce congestive heart failure in susceptible patients. Thus, β receptor blockade may cause or exacerbate heart failure in patients with compensated heart failure, acute myocardial infarction, or cardiomegaly. It is not known whether β receptor antagonists that possess intrinsic sympathomimetic activity or peripheral vasodilating properties are safer in these settings. Nonetheless, there is convincing evidence that chronic administration of β receptor antagonists is efficacious in prolonging life in the therapy of heart failure in selected patients (*see* below and Chapter 33).

Bradycardia is a normal response to β receptor blockade; however, in patients with partial or complete atrioventricular conduction defects, β antagonists may cause life-threatening bradyarrhythmias. Particular caution is indicated in patients who are taking other drugs, such as *verapamil* or various antiarrhythmic agents, which may impair sinus-node function or AV conduction.

Some patients complain of cold extremities while taking β receptor antagonists. Symptoms of peripheral vascular disease may worsen, although this is uncommon, or Raynaud's phenomenon may develop. The risk of worsening intermittent claudication probably is very small with this class of drugs, and the clinical benefits of β antagonists in patients with peripheral vascular disease and coexisting coronary artery disease may be very important.

Abrupt discontinuation of β receptor antagonists after long-term treatment can exacerbate angina and may increase the risk of sudden death. The underlying mechanism is unclear, but it is well established that there is enhanced sensitivity to β adrenergic receptor agonists in patients who have undergone long-term treatment with certain β receptor antagonists after the blocker is withdrawn abruptly. For example, chronotropic responses to isoproterenol are blunted in patients who are receiving β receptor antagonists; however, abrupt discontinuation of propranolol leads to greater-than-normal sensitivity to isoproterenol. This increased sensitivity is evident several days after stopping propranolol and may persist for at least 1 week. Such enhanced sensitivity can be attenuated by tapering the dose of the β blocker for several weeks before discontinuation. Supersensitivity to isoproterenol also has been observed after abrupt discontinuation of metoprolol, but not of pindolol. This enhanced β responsiveness may result from up-regulation of β receptors. The number of β receptors on circulating lymphocytes is increased in subjects who have received propranolol for long periods; pindolol has the opposite effect. Optimal strategies for discontinuation of β blockers are not known, but it is prudent to decrease the dose gradually and to restrict exercise during this period.

Pulmonary Function. A major adverse effect of β receptor antagonists is caused by blockade of β_2 receptors in bronchial smooth muscle. These receptors are particularly important for promoting bronchodilation in patients with bronchospastic disease, and β blockers may cause a life-threatening increase in airway resistance in such patients. Drugs with selectivity for β_1 adrenergic receptors or those with intrinsic sympathomimetic activity at β_2 adrenergic receptors may be somewhat less

likely to induce bronchospasm. Since the selectivity of current β blockers for β_1 receptors is modest, these drugs should be avoided if at all possible in patients with asthma. However, in some patients with chronic obstructive pulmonary disease, the potential advantage of using β receptor antagonists after myocardial infarction may outweigh the risk of worsening pulmonary function (Gottlieb *et al.*, 1998).

Central Nervous System. The adverse effects of β receptor antagonists that are referable to the CNS may include fatigue, sleep disturbances (including insomnia and nightmares), and depression. The previously ascribed association between these drugs and depression (Thiessen *et al.*, 1990) may not be substantiated by more recent clinical studies (Gerstman *et al.*, 1996; Ried *et al.*, 1998). Interest has focused on the relationship between the incidence of the adverse effects of β receptor antagonists and their lipophilicity; however, no clear correlation has emerged.

Metabolism. As described above, β adrenergic blockade may blunt recognition of hypoglycemia by patients; it also may delay recovery from insulin-induced hypoglycemia. β Receptor antagonists should be used with great caution in patients with diabetes who are prone to hypoglycemic reactions; β_1 -selective agents may be preferable for these patients. The benefits of β receptor antagonists in type 1 diabetes with myocardial infarction may outweigh the risk in selected patients (Gottlieb *et al.*, 1998).

Miscellaneous. The incidence of sexual dysfunction in men with hypertension who are treated with β receptor antagonists is not clearly defined. Although experience with the use of β adrenergic receptor antagonists in pregnancy is increasing, information about the safety of these drugs during pregnancy still is limited.

Overdosage. The manifestations of poisoning with β receptor antagonists depend on the pharmacological properties of the ingested drug, particularly its β_1 selectivity, intrinsic sympathomimetic activity, and membrane-stabilizing properties (Frishman, 1983). Hypotension, bradycardia, prolonged AV conduction times, and widened QRS complexes are common manifestations of overdosage. Seizures and depression may occur. Hypoglycemia is rare, and bronchospasm is uncommon in the absence of pulmonary disease. Significant bradycardia should be treated initially with atropine, but a cardiac pacemaker often is required. Large doses of isoproterenol or an α receptor agonist may be necessary to treat hypotension. Glucagon has positive chronotropic and inotropic effects on the heart that are independent of interactions with β adrenergic receptors, and the drug has been useful in some patients.

Drug Interactions. Both pharmacokinetic and pharmacodynamic interactions have been noted between β receptor antagonists and

other drugs. Aluminum salts, *cholestyramine*, and *colestipol* may decrease the absorption of β blockers. Drugs such as *phenytoin*, *rifampin*, and *phenobarbital*, as well as smoking, induce hepatic biotransformation enzymes and may decrease plasma concentrations of β receptor antagonists that are metabolized extensively (*e.g.*, propranolol). Cimetidine and hydralazine may increase the bioavailability of agents such as propranolol and metoprolol by affecting hepatic blood flow. β Receptor antagonists can impair the clearance of *lidocaine*.

Other drug interactions have pharmacodynamic explanations. For example, β antagonists and Ca^{2+} channel blockers have additive effects on the cardiac conducting system. Additive effects on blood pressure between β blockers and other antihypertensive agents often are employed to clinical advantage. However, the antihypertensive effects of β receptor antagonists can be opposed by *indomethacin* and other nonsteroidal antiinflammatory drugs (*see* Chapter 26).

THERAPEUTIC USES

Cardiovascular Diseases

β Receptor antagonists are used extensively in the treatment of hypertension (*see* Chapter 32), angina and acute coronary syndromes (*see* Chapter 31), and congestive heart failure (*see* Chapter 33). These drugs also are used frequently in the treatment of supraventricular and ventricular arrhythmias (*see* Chapter 34).

Myocardial Infarction. A great deal of interest has focused on the use of β receptor antagonists in the treatment of acute myocardial infarction and in the prevention of recurrences for those who have survived an initial attack. Numerous trials have shown that β receptor antagonists administered during the early phases of acute myocardial infarction and continued long-term may decrease mortality by about 25% (Freemantle *et al.*, 1999). The precise mechanism is not known, but the favorable effects of β receptor antagonists may stem from decreased myocardial oxygen demand, redistribution of myocardial blood flow, and antiarrhythmic actions. There is likely much less benefit if β adrenergic receptor antagonists are administered for only a short time. In studies of secondary prevention, the most extensive, favorable clinical trial data are available for propranolol, metoprolol, and timolol. In spite of these proven benefits, many patients with myocardial infarction do not receive a β adrenergic receptor antagonist.

Congestive Heart Failure. It is a common clinical observation that acute administration of β receptor antagonists can worsen markedly or even precipitate congestive heart failure in compensated patients with multiple forms of heart disease, such as ischemic or congestive cardiomyopathy. Consequently, the hypothesis that β receptor antagonists might be efficacious in the long-term treatment of heart failure originally seemed counterintuitive to many physicians. However,

the reflex sympathetic responses to heart failure may stress the failing heart and exacerbate the progression of the disease, and blocking those responses could be beneficial. A number of well-designed randomized clinical trials involving numerous patients have demonstrated that certain β receptor antagonists are highly effective treatment for patients with all grades of heart failure secondary to left ventricular systolic dysfunction. The drugs have been shown to improve myocardial function, to improve life quality, and to prolong life. From the point of view of the history of therapeutic advances in the treatment of congestive heart failure, it is interesting to note how this drug class has moved from being completely contraindicated to being the standard of care in many settings.

Large trials have been conducted with carvedilol, bisoprolol, metoprolol, *xamoterol*, bucindolol, betaxolol, nebivolol, and *talinolol* (Cleland, 2003). Carvedilol, metoprolol, and bisoprolol all have been shown to reduce the mortality rate in large cohorts of patients with stable chronic heart failure regardless of severity (Bolger and Al-Nasser, 2003; Cleland, 2003). In the initial use of β blockers for treating heart failure, the beginning effects often are neutral or even adverse. Benefits accumulate gradually over a period of weeks to months, although benefits from the third-generation vasodilator β blocker carvedilol may be seen within days in patients with severe heart failure. There also is a reduction in the hospitalization of patients along with a reduction in mortality with fewer sudden deaths and deaths caused by progressive heart failure. These benefits extend to patients with asthma and with diabetes mellitus (Dunne *et al.*, 2001; Self *et al.*, 2003; Cruickshank, 2002; Salpeter, 2003). Patients in atrial fibrillation and heart failure can also benefit from β blockade (Kühlkamp *et al.*, 2002). On the other hand, patients with heart failure and atrial fibrillation are associated with a higher mortality, and the benefit derived from β blockers may not be comparable to those in sinus rhythm (Fung *et al.*, 2003). Long-term β blockade reduces cardiac volume, myocardial hypertrophy, and filling pressure, and increases ejection fraction (*e.g.*, ventricular remodeling). β Receptor antagonists impact mortality even before beneficial effects on ventricular function are observed, possibly due to prevention of arrhythmias or a reduction in acute vascular events.

Some patients are unable to tolerate β blockers. Hopefully, ongoing trials will identify the common characteristics that define this population so that β blockers can be avoided in these patients (Bolger and Al-Nasser, 2003). Because of the real possibility of acutely worsening cardiac function, β receptor antagonists should be initiated only by clinicians experienced in patients with congestive heart failure. As might be anticipated, starting with very low doses of drug and advancing doses slowly over time, depending on each patient's response, are critical for the safe use of these drugs in patients with congestive heart failure.

It is unknown whether it is necessary to block only the β_1 adrenergic receptor or whether nonselective agents would be more desirable in the management of heart failure. Blockade of β_2 adrenergic receptors can enhance peripheral vasoconstriction and bronchoconstriction and therefore have a deleterious effect. On the

other hand, blocking β_2 adrenergic receptors might be advantageous due to more effectively protecting cardiac cells from catecholamine excess and hypokalemia. Some propose that nonselective β antagonists that block both β_1 and β_2 receptors and also have peripheral vasodilatory actions (third-generation β blockers) may offer the best myocardial, metabolic, and hemodynamic benefit (Cleland, 2003) (*see* Chapter 33). Some experts have recommended that β blockers be considered as part of the standard treatment regimen for all patients with mild-to-moderate heart failure (Goldstein, 2002; Maggioni *et al.*, 2003).

β Adrenergic Receptor Signaling in Heart Failure and its Treatment. The underlying cellular or subcellular mechanisms leading to the beneficial effects of β blockers are unclear. Sympathetic nervous system activity is increased in patients with congestive heart failure (Bristow *et al.*, 1985). Infusions of β agonists are toxic to the heart in several animal models. Also, overexpression of β receptors in transgenic mice leads to a dilated cardiomyopathy (Engelhardt *et al.*, 1999). A number of changes in β receptor signaling occur in the myocardium of patients with heart failure and in a variety of animal models (Post *et al.*, 1999). Decreased numbers and functioning of β_1 receptors consistently have been found in heart failure, leading to attenuation of β receptor-mediated stimulation of positive inotropic responses in the failing heart. These changes may be due in part to increased expression of β adrenergic receptor kinase-1 (β ARK-1, GRK2) (Lefkowitz *et al.*, 2000) (*see* Chapter 6).

It is of potential interest that β_2 receptor expression is relatively maintained in these settings of heart failure. While both β_1 and β_2 receptors activate adenylyl cyclase *via* G_s , there is evidence suggesting that β_2 receptors also stimulate G_i , which may attenuate contractile responses and lead to activation of other effector pathways downstream of G_i (Lefkowitz *et al.*, 2000). Overexpression of β_2 adrenergic receptors in mouse heart is associated with increased cardiac force without the development of cardiomyopathy (Liggett *et al.*, 2000). The stimulation of β_3 adrenergic receptors inhibits contraction and relaxation (Gauthier *et al.*, 2000). In contrast to β_1 and β_2 receptors, β_3 receptors are upregulated in heart failure (Moniotte *et al.*, 2001). This has led to the hypothesis that in severe congestive heart failure, as β_1 and β_2 receptor pathways *via* G_s become less responsive, the inhibitory effects of the β_3 receptor pathway may contribute to the detrimental effects of sympathetic stimulation in congestive heart failure (Morimoto *et al.*, 2004). Thus, the blockade of β_3 receptors by β receptor antagonists (*e.g.*, carvedilol) could improve the acute tolerability and benefit of β_1 and β_2 receptor antagonists (Moniotte *et al.*, 2001; Morimoto *et al.*, 2004).

The mechanisms by which β receptor antagonists decrease mortality in patients with congestive heart failure are still unclear. Perhaps this is not surprising, given that the mechanism by which this class of drugs lowers blood pressure in patients with hypertension remains elusive despite years of investigation (*see* Chapter 32). This is much more than an academic undertaking; a deeper understanding of involved pathways could lead to selection of the most appropriate drugs available as well as the development of novel compounds with especially desirable properties. The potential differences among β_1 , β_2 , and β_3 receptor function in heart failure is one example of the complexity of adrenergic pharmacology of this syndrome. Recent research provides evidence for multiple affinity states of the β_1 receptor, for cell-type specific coupling of β receptor subtypes to signalling pathways other than

G_s-adenylyl cyclase–cyclic AMP, and for altered receptor properties when β_2 and β_3 receptors for hetero-oligomers (Rozec *et al.*, 2003; Breit *et al.*, 2004). Such findings suggest opportunities for the development of more focused β antagonist therapy in the future.

A number of mechanisms have been proposed to play a role in the beneficial effects of β receptor antagonists in heart failure. Since excess effects of catecholamines may be toxic to the heart, especially *via* activation of β_1 receptors, inhibition of the pathway may help preserve myocardial function. Also, antagonism of β receptors in the heart may attenuate cardiac remodeling, which ordinarily might have deleterious effects on cardiac function. Interestingly, activation of β receptors may promote myocardial cell death *via* apoptosis (Singh *et al.*, 2000). In addition, properties of certain β receptor antagonists that are due to other, unrelated properties of these drugs may be potentially important. For example, afterload reduction by drugs such as carvedilol may be relevant. The potential importance of the α_1 antagonistic and antioxidant properties of carvedilol in its beneficial effects in patients with heart failure is not clear (Ma *et al.*, 1996).

Use of β Antagonists in Other Cardiovascular Diseases. β Receptor antagonists, particularly propranolol, are used in the treatment of hypertrophic obstructive cardiomyopathy. Propranolol is useful for relieving angina, palpitations, and syncope in patients with this disorder. Efficacy probably is related to partial relief of the pressure gradient along the outflow tract. β Blockers also may attenuate catecholamine-induced cardiomyopathy in pheochromocytoma.

β Blockers are used frequently in the medical management of acute dissecting aortic aneurysm; their usefulness comes from reduction in the force of myocardial contraction and the rate of development of such force. Nitroprusside is an alternative, but when given in the absence of β receptor blockade, it causes an undesirable tachycardia. Patients with Marfan's syndrome may develop progressive dilation of the aorta, which may lead to aortic dissection and regurgitation, a major cause of death in these patients. Chronic treatment with propranolol may be efficacious in slowing the progression of aortic dilation and its complications in patients with Marfan's syndrome (Shores *et al.*, 1994).

Glaucoma

β Receptor antagonists are very useful in the treatment of chronic open-angle glaucoma. Six drugs currently are available: carteolol (OCUPRESS, others), betaxolol (BETAOPTIC, others), levobunolol (BETAGAN, others), *metipranolol* (OPTIPRANOLOL, others), timolol (TIMOPTIC, others), and *levobetaxolol* (BETAXON). Timolol, levobunolol, carteolol, and metipranolol are nonselective, while betaxolol and levobetaxolol are β_1 selective. None of the agents has significant membrane-stabilizing or intrinsic sympathomimetic activities. Topically administered β blockers have little or no effect on pupil size or accommodation and are devoid of blurred vision and night blindness often seen with miotics. These agents decrease the production of aqueous

humor, which appears to be the mechanism for their clinical effectiveness.

The drugs generally are administered as eye drops and have an onset in approximately 30 minutes with a duration of 12 to 24 hours. While topically administered β blockers usually are well tolerated, systemic absorption can lead to adverse cardiovascular and pulmonary effects in susceptible patients. They therefore should be used with great caution in glaucoma patients at risk for adverse systemic effects of β receptor antagonists (*e.g.*, patients with bronchial asthma, severe COPD, or those with bradyarrhythmias). The use of topically administered β blockers for treatment of glaucoma is discussed further in Chapter 63. Recently three β blockers (betaxolol, metipranolol, and timolol) also have been observed to confer protection to retinal neurons, apparently related to their ability to attenuate neuronal Ca²⁺ and Na⁺ influx (Wood *et al.*, 2003). Betaxolol is the most effective antiglaucoma drug at reducing Na⁺/Ca²⁺ influx. It is thought that β blockers may be able to blunt ganglion cell death in glaucoma and that levobetaxolol may be a more important neuroprotectant than timolol because of its greater capacity to block Na⁺ and Ca²⁺ influx (Osborne *et al.*, 2004).

Other Uses

Many of the signs and symptoms of hyperthyroidism are reminiscent of the manifestations of increased sympathetic nervous system activity. Indeed, excess thyroid hormone increases the expression of β receptors in some types of cells. β Receptor antagonists control many of the cardiovascular signs and symptoms of hyperthyroidism and are useful adjuvants to more definitive therapy. In addition, propranolol inhibits the peripheral conversion of thyroxine to triiodothyronine, an effect that may be independent of β receptor blockade. However, caution is advised in treating patients with cardiac enlargement, since the use of β receptor antagonists may precipitate congestive heart failure (*see* Chapter 56 for further discussion of the treatment of hyperthyroidism).

Propranolol, timolol, and metoprolol are effective for the prophylaxis of migraine (Tfelt-Hansen, 1986); the mechanism of this effect is not known, and these drugs are not useful for treatment of acute attacks of migraine.

Propranolol and other β blockers are effective in controlling acute panic symptoms in individuals who are required to perform in public or in other anxiety-provoking situations. Public speakers may be calmed by the prophylactic administration of the drug, and the performance of musicians may be improved. Tachycardia, muscle tremors, and other evidence of increased sympathetic activity are reduced. Propranolol also may be useful in the treatment of essential tremor.

β Blockers may be of some value in the treatment of patients undergoing withdrawal from alcohol or those with akathisia. Propranolol and nadolol are efficacious in the primary prevention of variceal bleeding in patients with portal hypertension caused by cirrhosis of the liver (Villanueva *et al.*, 1996; Bosch, 1998). *Isosorbide mononitrate* may augment the fall in portal pressure seen in some patients treated with β receptor antagonists. These drugs also may be beneficial in reducing the risk of recurrent variceal bleeding.

Selection of a β Receptor Antagonist

The various β receptor antagonists that are used for the treatment of hypertension and angina appear to have similar efficacies. Selection of the most appropriate drug for an individual patient should be based on pharmacokinetic and pharmacodynamic differences among the drugs, cost, and whether there are concurrent medical problems. For some diseases (e.g., myocardial infarction, migraine, cirrhosis with varices, and congestive heart failure), it should not be assumed that all members of this class of drugs are interchangeable; the appropriate drug should be selected from those that have documented efficacy for the disease. β_1 -Selective antagonists are preferable in patients with bronchospasm, diabetes, peripheral vascular disease, or Raynaud's phenomenon. Although no clinical advantage of β receptor antagonists with intrinsic sympathomimetic activity has been clearly established, such drugs may be preferable in patients with bradycardia. In addition, third generation β antagonists that block α_1 receptors, stimulate β_2 receptors, enhance NO production, block Ca^{2+} entry, open K^+ channels, or possess antioxidant properties may offer therapeutic advantages.

5-HYDROXYTRYPTAMINE (SEROTONIN): RECEPTOR AGONISTS AND ANTAGONISTS

Elaine Sanders-Bush and Steven E. Mayer

5-Hydroxytryptamine (5-HT, serotonin) is a regulator of smooth muscle in the cardiovascular system and the gastrointestinal tract, an enhancer of platelet aggregation, and a neurotransmitter in the central nervous system (CNS). 5-HT is found in high concentrations in enterochromaffin cells throughout the gastrointestinal tract, in storage granules in platelets, and broadly throughout the CNS. Although 5-HT is implicated in the regulation of a number of physiological processes and their malfunction, the exact sites and modes of its action are still being defined. Fourteen 5-HT-receptor subtypes have been delineated by pharmacological analyses and cDNA cloning. The availability of cloned receptors has allowed the development of subtype-selective drugs and the elucidation of actions of 5-HT at a molecular level. Increasingly, therapeutic goals are being achieved by drugs that target selectively one or more of the subtypes of 5-HT receptors.

History. In the 1930s, Erspamer began to study the distribution of enterochromaffin cells, which stained with a reagent for indoles. The highest concentrations were found in gastrointestinal mucosa, followed by platelets and the CNS. Page and colleagues were the first to isolate and chemically characterize a vasoconstrictor substance released from platelets in clotting blood. This substance, named *serotonin*, was shown to be identical to the indole isolated by Erspamer. The discovery of biosynthetic and degradative pathways for 5-HT and clinical interest in the pressor effects of 5-HT led to the hypothesis that the symptoms of patients with tumors of intestinal enterochromaffin cells (carcinoid syndrome) result from abnormally high production of 5-HT. Several hundred milligrams of 5-HT and its metabolites may be excreted daily in patients with carcinoid tumors. The gross effects of 5-HT, produced in excess in malignant carcinoid, gave some indication of the physiologic and pharmacologic actions of 5-HT. For example, these patients often display psychotic behaviors similar to those produced by lysergic acid diethylamide (LSD). Several naturally occurring hallucinogenic tryptaminelike substances were identified from animal and plant sources, suggest-

ing that these substances or congeners might be formed *in vivo* and could explain the abnormal behavior of carcinoid patients. In the mid-1950s, 5-HT was proposed as a neurotransmitter in the mammalian CNS. For additional details about the discovery and effects of 5-HT, see Sjoerdsma and Palfreyman, 1990.

Source and Chemistry. 5-HT, 3-(β -aminoethyl)-5-hydroxyindole, is widely distributed in the animal and plant kingdoms (see Figure 11-1 for chemical structures). It occurs in vertebrates; in tunicates, mollusks, arthropods, and coelenterates; and in fruits and nuts. It also is present in venoms, including those of the common stinging nettle and of wasps and scorpions. Numerous synthetic or naturally occurring congeners of 5-HT have pharmacological activity. Many of the *N*- and *O*-methylated indoleamines, such as *N,N*-dimethyltryptamine, are hallucinogens. Because these compounds are behaviorally active and might be synthesized *via* known metabolic pathways, they have long been considered candidates for endogenous psychotomimetic substances, potentially responsible for some psychotic behaviors. Another close relative of 5-HT, *melatonin* (5-methoxy-*N*-acetyltryptamine), is formed by sequential *N*-acetylation and *O*-methylation (Figure 11-2). Melatonin is the principal indoleamine in the pineal gland, where it may be said to constitute a pigment of the imagination. Its synthesis is controlled by external factors including environmental light. Melatonin induces pigment lightening in skin cells and suppresses ovarian functions; it also serves a role in regulating biological rhythms and shows promise in the treatment of jet lag and other sleep disturbances (Cajochen *et al.*, 2003).

Synthesis and Metabolism. 5-HT is synthesized by a two-step pathway from the essential amino acid *tryptophan* (Figure 11-2). Tryptophan is actively transported into the brain by a carrier protein that also transports other large neutral and branched-chain amino acids. The levels of tryptophan in the brain are influenced not only by its plasma concentration, but also by the plasma concentrations of other amino acids that compete for the brain uptake carrier. *Tryptophan hydroxylase*, a mixed-function oxidase that requires molecular oxygen and a reduced pteridine cofactor for activity, is the rate-limiting enzyme in the synthetic pathway. A second, brain-specific isoform of tryptophan hydroxylase has been cloned (Walther *et al.*, 2003); although its distribution differs markedly from that of the classical

Figure 11-1. Structures of representative indolealkylamines.

enzyme, it is not clear whether this translates into differences in function and regulation. Unlike tyrosine hydroxylase, tryptophan hydroxylase is not regulated by end-product inhibition, although regulation by phosphorylation is common to both enzymes. Brain tryptophan hydroxylase is not generally saturated with substrate; consequently the concentration of tryptophan in the brain influences the synthesis of 5-HT.

The enzyme that converts L-5-hydroxytryptophan to 5-HT, aromatic L-amino acid decarboxylase, is widely distributed and has a broad substrate specificity. A long-standing debate about whether L-5-hydroxytryptophan decarboxylase and L-dopa decarboxylase are identical enzymes was clarified when cDNA cloning confirmed that a single gene product decarboxylates both amino acids. 5-Hydroxytryptophan is not detected in the brain because it is rapidly decarboxylated. The synthesized product, 5-HT, is stored in secretory granules by a vesicular transporter; stored 5-HT is released by exocytosis from serotonergic neurons. In the nervous system, the action of released 5-HT is terminated by neuronal uptake mediated by a specific transporter. The 5-HT transporter is localized in the membrane of serotonergic axon terminals (where it terminates the action of 5-HT in the synapse) and in the membrane of platelets (where it takes up 5-HT from the blood). This uptake system is the only way that platelets acquire 5-HT, as they lack the enzymes required to synthesize 5-HT. The 5-HT transporter, as well as other monoamine transporters, has been cloned (*see* Chapters 2 and 12). The deduced amino-acid sequence and predicted membrane topology place the amine transporters in a family clearly distinct from the transport proteins that concentrate amines in intracellular storage vesicles. Furthermore, the vesicular transporter is a nonspecific amine carrier, while the 5-HT transporter and the other amine transporters are highly specific. Neither pharmacological studies nor cDNA cloning has provided evidence to support the existence of multiple 5-HT transporters. Studies have found that the 5-HT transporter is regulated by phosphorylation with subsequent internalization (Ramamoorthy and Blakely, 1999), providing a mechanism for dynamic regulation of serotonergic transmission.

Figure 11-2. Synthesis and inactivation of serotonin. Synthetic enzymes are identified in blue lettering, and cofactors are shown in black lowercase letters.

The principal route of metabolism of 5-HT involves oxidative deamination by monoamine oxidase (MAO), forming an acetaldehyde intermediate; the aldehyde is converted to 5-hydroxyindole acetic acid (5-HIAA) by a ubiquitous enzyme, aldehyde dehydrogenase (Figure 11-2). An alternative route, reduction of the acetal-

dehyde to an alcohol, 5-hydroxytryptophol, is normally insignificant. 5-HIAA is actively transported out of the brain by a process that is sensitive to the nonspecific transport inhibitor probenecid. Since 5-HIAA formation accounts for nearly 100% of the metabolism of 5-HT in brain, the turnover rate of brain 5-HT is estimated by measuring the rate of rise of 5-HIAA after administration of probenecid. 5-HIAA from brain and peripheral sites of 5-HT storage and metabolism is excreted in the urine along with small amounts of 5-hydroxytryptophol sulfate or glucuronide conjugates. The usual range of urinary excretion of 5-HIAA by a normal adult is 2 to 10 mg daily. Larger amounts are excreted by patients with malignant carcinoid, providing a reliable diagnostic test for the disease. Ingestion of ethyl alcohol results in elevated amounts of reduced nicotinamide adenine dinucleotide (NADH), which diverts 5-hydroxyindole acetaldehyde from the oxidative route to the reductive pathway (Figure 11–2), and tends to increase the excretion of 5-hydroxytryptophol and correspondingly reduces the excretion of 5-HIAA.

Two isoforms of monoamine oxidase (MAO-A and -B) were distinguished initially on the basis of substrate and inhibitor specificities. Both isoforms have been cloned, and the properties of the cloned enzymes are consistent with the pharmacological profiles established previously (Shih, 1991; see Chapters 10 and 17). MAO-A preferentially metabolizes 5-HT and norepinephrine; *clorgyline* is a specific inhibitor of this enzyme. MAO-B prefers β -phenylethylamine and benzylamine as substrates; low dose *selegiline* is a relatively selective inhibitor of MAO-B. Dopamine and tryptamine are metabolized equally well by both isoforms. Neurons contain both isoforms of MAO, localized primarily in the outer membrane of mitochondria. MAO-B is the principal isoform in platelets, which contain large amounts of 5-HT.

Other minor pathways of metabolism of 5-HT, such as sulfation and *O*- or *N*-methylation, have been suggested. The latter reaction could lead to formation of an endogenous psychotropic substance, 5-hydroxy-*N,N*-dimethyltryptamine (*bufotenine*; Figure 11–1). However, other methylated indoleamines such as *N,N*-dimethyltryptamine and 5-methoxy-*N,N*-dimethyltryptamine are far more active hallucinogens and are more likely candidates to be endogenous psychotomimetics.

PHYSIOLOGICAL FUNCTIONS OF SEROTONIN

Multiple 5-HT Receptors

Based on data from early studies of 5-HT's actions in peripheral tissues, researchers hypothesized that the multiple actions of 5-HT involved interaction with multiple 5-HT-receptor subtypes. Extensive pharmacological characterization and the cloning of receptor cDNAs have confirmed this hypothesis (for an extensive review see Barnes and Sharp, 1999). The multiple 5-HT-receptor subtypes cloned comprise the largest known neurotransmitter-receptor family. The 5-HT-receptor subtypes are expressed in distinct but often overlapping patterns (Palacios *et al.*, 1990) and are coupled to

different transmembrane-signaling mechanisms (Table 11–1). Four 5-HT-receptor families with defined functions currently are recognized: 5-HT₁ through 5-HT₄. The 5-HT₁, 5-HT₂, and 5-HT₄₋₇ receptor families are members of the superfamily of GPCRs (see Chapter 1). The 5-HT₃ receptor, on the other hand, is a ligand-gated ion channel that gates Na⁺ and K⁺ and has a predicted membrane topology akin to that of the nicotinic cholinergic receptor (see Chapter 9).

History of 5-HT Receptor Subtypes. Gaddum and Picarelli (1957) proposed the existence of two 5-HT-receptor subtypes, which they termed *M* and *D* receptors. *M* receptors were believed to be located on parasympathetic nerve endings, controlling the release of acetylcholine, whereas *D* receptors were thought to be located on smooth muscle. Although subsequent studies in both the periphery and brain were consistent with the notion of multiple subtypes of 5-HT receptor, the radioligand-binding studies of Peroutka and Snyder (1979) provided the first definitive evidence for 2 distinct recognition sites for 5-HT. 5-HT₁ receptors had a high affinity for [³H]5-HT, while 5-HT₂ receptors had a low affinity for [³H]5-HT and a high affinity for [³H]spiperone. Subsequently, high affinity for 5-HT was used as a primary criterion for classifying a receptor subtype as a member of the 5-HT₁ receptor family. This classification strategy proved to be invalid; for example, a receptor expressed in the choroid plexus was named the 5-HT_{1C} receptor because it was the third receptor shown to have a high affinity for 5-HT. However, based on its pharmacological properties, second-messenger function, and deduced amino acid sequence, the 5-HT_{1C} receptor clearly belonged to the 5-HT₂ receptor family and was subsequently renamed the 5-HT_{2C} receptor. The current classification scheme (Hoyer *et al.*, 1994) proposes 7 subfamilies of 5-HT receptors (Table 11–1). It is likely that further modifications of this scheme will be required. Convincing evidence suggests that the 5-HT_{1D β} receptor is the human homolog of the 5-HT_{1B} receptor originally characterized and subsequently cloned from rodent brain. The current designation for species homologs of the same receptor protein is confusing and requires resolution. Although the rat 5-HT_{1B} receptor and the human 5-HT_{1D} receptor show greater than 95% amino-acid sequence homology, they have distinct pharmacological properties. The rat 5-HT_{1B} receptor has an affinity for β adrenergic antagonists, such as pindolol and propranolol, that is 2 to 3 orders of magnitude higher than that of the human 5-HT_{1D} receptor. This difference appears to be due to a single amino acid difference in the seventh transmembrane span (threonine in the human 5-HT_{1D} receptor versus asparagine in the rodent 5-HT_{1B} receptor).

5-HT₁ Receptors. All 5 members of the 5-HT₁-receptor subfamily inhibit adenylyl cyclase. At least one 5-HT₁-receptor subtype, the 5-HT_{1A} receptor, also activates a receptor-operated K⁺ channel and inhibits a voltage-gated Ca²⁺ channel, a common property of receptors coupled to the pertussis toxin-sensitive G_i/G_o family of G proteins. The 5-HT_{1A} receptor is found in the raphe nuclei of the brainstem, where it functions as an inhibitory, somatodendritic autoreceptor on cell bodies of serotonergic neurons

Table 11-1

*Also referred to as 5-HT_{1Dβ}. †Also referred to as 5-HT_{1Eβ}. ABBREVIATIONS: AC, adenylyl cyclase; PLC, phospholipase C; 8-OH-DPAT, 8-hydroxy-(2-*N,N*-dipropylamino)-tetraline; DOI, 1-(2,5-dimethoxy-4-iodophenyl)isopropylamine.

(Figure 11–3). Another subtype, the 5-HT_{1D} receptor, functions as an autoreceptor on axon terminals, inhibiting 5-HT release as does its rat homolog, 5-HT_{1B}. 5-HT_{1D} receptors, abundantly expressed in the substantia nigra and basal ganglia, may regulate the firing rate of dopamine-containing cells and the release of dopamine at axonal terminals.

5-HT₂ Receptors. The 3 subtypes of 5-HT₂ receptors are linked to phospholipase C with the generation of two second messengers, *diacylglycerol* (a cofactor in the activation of protein kinase C) and *inositol trisphosphate* (which mobilizes intracellular stores of Ca²⁺). The 5-HT₂-receptor subtypes couple to pertussis toxin–insensitive G proteins, such as G_q and G₁₁. 5-HT_{2A} receptors are broadly distributed in the CNS, primarily in serotonergic terminal areas. High densities of 5-HT_{2A} receptors are found in prefrontal, parietal, and somatosensory cortex, claustrum, and in platelets. 5-HT_{2A} receptors in the GI tract are thought to correspond to the D subtype of 5-HT receptor originally described by Gaddum and Picarelli. 5-HT_{2B} receptors originally were described in stomach fundus. The expression of 5-HT_{2B} receptor mRNA is highly restricted in the CNS. 5-HT_{2C} receptors have a very high density in the choroid plexus, an epithelial tissue that is the primary site of cerebrospinal fluid production. The 5-HT_{2C} receptor has been implicated in feeding behavior and susceptibility to seizure (Tecott *et al.*, 1995). The 5-HT_{2C} receptor is regulated by RNA editing, a posttrans-

criptional event that alters expression of the genetic code at the level of RNA (Burns *et al.*, 1997). Multiple receptor isoforms with alterations of as many as 3 amino acids within the second intracellular loop are predicted, and these edited isoforms have modified G protein–coupling efficiencies (Sanders-Bush *et al.*, 2003).

5-HT₃ Receptors. The 5-HT₃ receptor is unique, being the only monoamine neurotransmitter receptor that is known to function as a ligand-operated ion channel. The 5-HT₃ receptor corresponds to Gaddum and Picarelli's M receptor. Activation of 5-HT₃ receptors elicits a rapidly desensitizing depolarization, mediated by the gating of cations. These receptors are located on parasympathetic terminals in the GI tract, including vagal and splanchnic afferents. In the CNS, a high density of 5-HT₃ receptors is found in the solitary tract nucleus and in the area postrema. 5-HT₃ receptors in both the gastrointestinal tract and the CNS participate in the emetic response, providing an anatomical basis for the antiemetic property of 5-HT₃-receptor antagonists. Most ligand-operated ion channels are composed of multiple subunits; however, the original, cloned 5-HT₃-receptor subunit forms functional channels that gate cations when expressed in *Xenopus* oocytes or in cultured cells (Maricq *et al.*, 1991). Nevertheless, extensive pharmacological and physiological data obtained in tissues and in intact animals clearly suggest the existence of multiple components of 5-HT₃ receptors. Recently, splice variants of the 5-HT₃ receptor have been identified, perhaps explaining the observed functional diversity.

5-HT₄ Receptors. 5-HT₄ receptors are widely distributed throughout the body. In the CNS, the receptors are found on neurons of the superior and inferior colliculi and in the hippocampus. In the GI tract, 5-HT₄ receptors are located on neurons of the myenteric plexus and on smooth muscle and secretory cells. The 5-HT₄ receptor is thought to evoke secretion in the alimentary tract and to facilitate the peristaltic reflex. 5-HT₄ receptors couple to G_s to activate adenylyl cyclase, leading to a rise in intracellular levels of cyclic AMP (cAMP) (Hegde and Eglen, 1996). The latter effect may explain the utility of prokinetic benzamides in gastrointestinal disorders (*see* Chapter 37).

Additional Cloned 5-HT Receptors. Two other cloned receptors, 5-HT₆ and 5-HT₇, are linked to activation of adenylyl cyclase. Multiple splice variants of the 5-HT₇ receptor have been found, although functional distinctions are not clear. The absence of selective agonists and antagonists has foiled definitive studies of the role of the 5-HT₆ and 5-HT₇ receptors. Circumstantial evidence suggests that 5-HT₇ receptors play a role in smooth-muscle relaxation in the GI

Figure 11–3. Two classes of 5-HT autoreceptors with differential localizations. Somatodendritic 5-HT_{1A} autoreceptors decrease raphe cell firing when activated by 5-HT released from axon collaterals of the same or adjacent neurons. The receptor subtype of the presynaptic autoreceptor on axon terminals in the forebrain has different pharmacological properties and has been classified as 5-HT_{1D} (in human beings) or 5-HT_{1B} (in rodents). This receptor modulates the release of 5-HT. Postsynaptic 5-HT₁ receptors are also indicated.

tract and the vasculature. The atypical antipsychotic drug clozapine has a high affinity for 5-HT₆ and 5-HT₇ receptors; whether this property is related to the broader effectiveness of clozapine compared to conventional antipsychotic drugs is not known. Clozapine appears to be effective in many patients who do not respond to conventional antipsychotic drugs (*see* Chapter 18). Two subtypes of the 5-HT₅ receptor have been cloned; although the 5-HT_{5A} receptor has been shown to inhibit adenylyl cyclase, functional coupling of the cloned 5-HT_{5B} receptor has not yet been described.

Sites of 5-HT Action

Enterochromaffin Cells. Enterochromaffin cells, identified histologically, are located in the GI mucosa, with the highest density found in the duodenum. These cells synthesize 5-HT from tryptophan and store 5-HT and other autacoids, such as the vasodilator peptide substance P and other kinins. Basal release of enteric 5-HT is augmented by mechanical stretching, such as that caused by food or the administration of hypertonic saline, and also by efferent vagal stimulation. 5-HT probably has an additional role in stimulating motility *via* the myenteric network of neurons, located between the layers of smooth muscle (Gershon, 2003; *see also* Chapter 37). The greatly enhanced secretion of 5-HT and other autacoids in malignant carcinoid leads to a multitude of cardiovascular, gastrointestinal, and CNS abnormalities. In addition, the synthesis of large amounts of 5-HT by carcinoid tumors may result in tryptophan and niacin deficiencies (pellagra).

Platelets. Platelets differ from other formed elements of blood in expressing mechanisms for uptake, storage, and endocytotic release of 5-HT. 5-HT is not synthesized in platelets, but is taken up from the circulation and stored in secretory granules by active transport, similar to the uptake and storage of norepinephrine by sympathetic nerve terminals (*see* Chapters 6 and 12). Thus, Na⁺-dependent transport across the surface membrane of platelets is followed by uptake into dense core granules *via* an electrochemical gradient generated by an H⁺-translocating ATPase. A gradient of 5-HT as high as 1000:1 with an internal concentration of 0.6 M in the dense core storage vesicles can be maintained by platelets. Measuring the rate of Na⁺-dependent 5-HT uptake by platelets provides a sensitive assay for 5-HT-uptake inhibitors.

Main functions of platelets include adhesion, aggregation, and thrombus formation to plug holes in the endothelium; conversely, the functional integrity of the endothelium is critical for platelet action. A complex local interplay of multiple factors, including 5-HT, regulates thrombosis and hemostasis (*see* Chapters 25 and 54). When platelets make contact with injured endothelium, they release substances that promote platelet aggregation, and secondarily, they release 5-HT (Figure 11–4). 5-HT binds to platelet 5-HT_{2A} receptors and elicits a weak aggregation response that is markedly augmented by the presence of collagen. If the damaged blood vessel is injured to a depth where vascular smooth muscle is exposed, 5-HT exerts a direct vasoconstrictor effect, thereby contributing to hemostasis, which is enhanced by locally released autacoids (thromboxane A₂, kinins, and vasoactive peptides). Conversely, 5-HT may stimulate production of nitric oxide and antagonize its own vasoconstrictor action, as well as the vasoconstriction produced by other locally released agents.

Cardiovascular System. The classical response of blood vessels to 5-HT is contraction, particularly in the splanchnic, renal, pulmonary, and cerebral vasculatures. This response also occurs in bronchial

smooth muscle. 5-HT also induces a variety of responses by the heart that are the result of activation of multiple 5-HT-receptor subtypes, stimulation or inhibition of autonomic nerve activity, or dominance of reflex responses to 5-HT (Saxena and Villalón, 1990). Thus 5-HT has positive inotropic and chronotropic actions on the heart that may be blunted by simultaneous stimulation of afferent nerves from baroreceptors and chemoreceptors. An effect on vagus nerve endings elicits the Bezold-Jarisch reflex, causing extreme bradycardia and hypotension. The local response of arterial blood vessels to 5-HT also may be inhibitory, the result of stimulated nitric oxide (NO) and prostaglandin synthesis and blockade of norepinephrine release from sympathetic nerves. On the other hand, 5-HT amplifies the local constrictor actions of norepinephrine, angiotensin II, and histamine, which reinforce the hemostatic response to 5-HT.

Gastrointestinal Tract. Enterochromaffin cells in the mucosa appear to be the location of the synthesis and most of the storage of 5-HT in the body and are the source of circulating 5-HT. 5-HT released from these cells enters the portal vein and is subsequently metabolized by MAO-A in the liver. 5-HT that survives hepatic oxidation is rapidly removed by the endothelium of lung capillaries and then inactivated by MAO. 5-HT released by mechanical or vagal stimulation also acts locally to regulate GI function. Motility of gastric and intestinal smooth muscle may be either enhanced or inhibited *via* at least 6 subtypes of 5-HT receptors (Table 11–2). The stimulatory response occurs at nerve endings on longitudinal and circular enteric muscle (5-HT₄), at postsynaptic cells of the enteric ganglia (5-HT₃ and 5-HT_{1P}), and by direct effects of 5-HT on the smooth-muscle cells (5-HT_{2A} in intestine and 5-HT_{2B} in stomach fundus). In esophagus, 5-HT acting at 5-HT₄

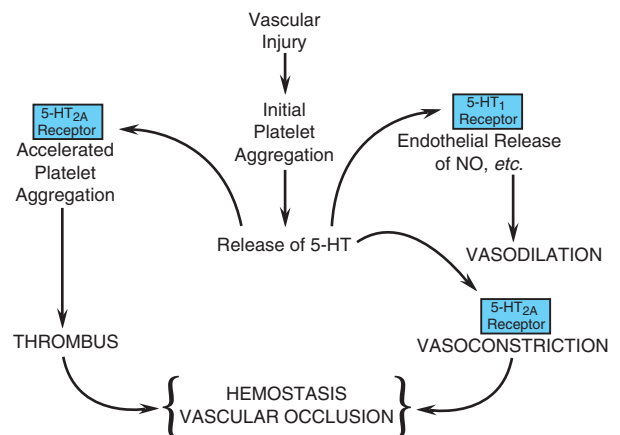

Figure 11–4. Schematic representation of the local influences of platelet 5-HT. The release of 5-HT stored in platelets is triggered by aggregation. The local actions of 5-HT include feedback actions on platelets (shape change and accelerated aggregation) mediated by interaction with platelet 5-HT_{2A} receptors, stimulation of NO production mediated by 5-HT₁-like receptors on vascular endothelium, and contraction of vascular smooth muscle mediated by 5-HT_{2A} receptors. These influences act in concert with many other mediators that are not shown to promote thrombus formation and hemostasis. *See* Chapter 54 for details of adhesion and aggregation of platelets and factors contributing to thrombus formation and blood clotting.

Table 11–2
Some Actions of 5-HT in the Gastrointestinal Tract

SITE	RESPONSE	RECEPTOR
Enterochromaffin cells	Release of 5-HT	5-HT ₃
	Inhibition of 5-HT release	5-HT ₄
Enteric ganglion cells (presynaptic)	Release of ACh	5-HT ₄
	Inhibition of ACh release	5-HT _{1P} , 5-HT _{1A}
Enteric ganglion cells (postsynaptic)	Fast depolarization	5-HT ₃
	Slow depolarization	5-HT _{1P}
Smooth muscle, intestinal	Contraction	5-HT _{2A}
Smooth muscle, stomach fundus	Contraction	5-HT _{2B}
Smooth muscle, esophagus	Contraction	5-HT ₄

ABBREVIATION: ACh, acetylcholine.

receptors causes either relaxation or contraction, depending on the species. Abundant 5-HT₃ receptors on vagal and other afferent neurons and on enterochromaffin cells play a pivotal role in emesis (see Chapter 37). Serotonergic terminals have been described in the myenteric plexus. Enteric 5-HT is released in response to acetylcholine, sympathetic nerve stimulation, increases in intraluminal pressure, and lowered pH (Gershon, 2003), triggering peristaltic contraction.

Central Nervous System. A multitude of brain functions are influenced by 5-HT, including sleep, cognition, sensory perception, motor activity, temperature regulation, nociception, mood, appetite, sexual behavior, and hormone secretion. All of the cloned 5-HT receptors are expressed in the brain, often in overlapping domains. Although patterns of 5-HT receptor expression in individual neurons have not been defined, it is likely that multiple 5-HT receptor subtypes with similar or opposing actions are expressed in individual neurons, leading to a tremendous diversity of actions.

The principal cell bodies of 5-HT neurons are located in raphe nuclei of the brainstem and project throughout the brain and spinal cord (see Chapter 12). In addition to being released at discrete synapses, release of serotonin also seems to occur at sites of axonal swelling, termed *varicosities*, which do not form distinct synaptic contacts (Descarries *et al.*, 1990). 5-HT released at nonsynaptic varicosities is thought to diffuse to outlying targets, rather than acting on discrete synaptic targets. Such nonsynaptic release with an ensuing widespread influence of 5-HT is consistent with the idea that 5-HT acts as a neuromodulator as well as a neurotransmitter (see Chapter 12).

Serotonergic nerve terminals contain all of the proteins needed to synthesize 5-HT from L-tryptophan (Figure 11–2). Newly formed 5-HT is rapidly accumulated in synaptic vesicles, where it is protected from MAO. 5-HT released by nerve-impulse flow is reaccumulated into the pre-synaptic terminal by an Na⁺-dependent carrier, the 5-HT transporter. Pre-synaptic re-uptake is a highly efficient mechanism for terminating the action of 5-HT released by nerve-impulse flow. MAO localized in postsynaptic elements and surrounding cells rapidly inactivates 5-HT that escapes neuronal re-uptake and storage.

Electrophysiology. The physiological consequences of 5-HT release vary with the brain area and the neuronal element involved, as well as with the population of 5-HT receptor subtype(s) expressed

(Aghajanian and Sanders-Bush, 2002). 5-HT has direct excitatory and inhibitory actions (Table 11–3), which may occur in the same preparation, but with distinct temporal patterns. For example, in hippocampal neurons, 5-HT elicits hyperpolarization mediated by 5-HT_{1A} receptors followed by a slow depolarization mediated by 5-HT₄ receptors.

5-HT_{1A} receptor-induced membrane hyperpolarization and reduction in input resistance results from an increase in K⁺ conductance. These ionic effects, which are blocked by pertussis toxin, are independent of cAMP, suggesting that 5-HT_{1A} receptors couple directly, *via* subunits of G_i- or G_o-like G proteins, to receptor-operated K⁺ channels (Andrade *et al.*, 1986). Somatodendritic 5-HT_{1A} receptors on raphe cells also elicit a K⁺-dependent hyperpolarization. The G protein involved is pertussis toxin-sensitive, but the K⁺ current apparently is different from the current elicited at postsynaptic 5-HT_{1A} receptors in the hippocampus. The precise signaling mechanism involved in inhibition of 5-HT release by the 5-HT_{1D} autoreceptor at the synaptic terminal is not known, although inhibition of voltage-gated calcium channels likely contributes.

Slow depolarization induced by 5-HT_{2A}-receptor activation in areas such as the prefrontal cortex, nucleus accumbens, and facial motor nucleus involves a decrease in K⁺ conductance. A second, distinct mechanism involving Ca²⁺-activated membrane currents

Table 11–3
Electrophysiological Effects of 5-HT Receptors

SUBTYPE	RESPONSE
5-HT _{1A,B}	Increase K ⁺ conductance Hyperpolarization
5-HT _{2A}	Decrease K ⁺ conductance Slow depolarization
5-HT ₃	Gating of Na ⁺ , K ⁺ Fast depolarization
5-HT ₄	Decrease K ⁺ conductance Slow depolarization

enhances neuronal excitability and potentiates the response to excitatory signals such as glutamate. The role of the phosphoinositide signaling cascade in these physiological actions of 5-HT_{2A} receptors has not been clearly defined. In areas where 5-HT₁ and 5-HT_{2A} receptors coexist, the effect of 5-HT may reflect a combination of the two opposing responses: a prominent 5-HT₁ receptor-mediated hyperpolarization and an opposing 5-HT_{2A} receptor-mediated depolarization. When 5-HT_{2A} receptors are blocked, hyperpolarization is enhanced. In many cortical areas, 5-HT_{2A} receptors are localized on both GABAergic interneurons and pyramidal cells. Activation of interneurons enhances GABA (γ -aminobutyric acid) release, which secondarily slows the firing rate of pyramidal cells. Thus there is the potential for the 5-HT_{2A} receptor to differentially regulate cortical pyramidal cells, depending on the specific target cells (interneurons *versus* pyramidal cells). 5-HT_{2C} receptors have been shown to depress a K⁺ current in *Xenopus* oocytes expressing the cloned receptor mRNA; a similar action has not been definitively identified in the brain. The 5-HT₄ receptor, which is coupled to activation of adenyl cyclase, also elicits a slow neuronal depolarization mediated by a decrease in K⁺ conductance. It is not clear why two distinct 5-HT receptor families linked to different signaling pathways can elicit a common neurophysiological action. Yet another receptor, the 5-HT_{1P} receptor, elicits a slow depolarization. This receptor, which couples to activation of adenyl cyclase, is restricted to the enteric nervous system and has a unique pharmacological profile (Gershon, 2003).

The fast depolarization elicited by 5-HT₃ receptors reflects direct gating of an ion channel intrinsic to the receptor structure itself. The 5-HT₃ receptor-induced inward current has the characteristics of a cation-selective, ligand-operated channel. Membrane depolarization is mediated by simultaneous increases in Na⁺ and K⁺ conductance. Patch-clamp analyses confirm that the 5-HT₃ receptor functions as a receptor-ion channel complex, comparable to the nicotinic cholinergic receptor. 5-HT₃ receptors have been characterized in the CNS and in sympathetic ganglia, primary afferent parasympathetic and sympathetic nerves, enteric neurons, and neuronally derived clonal cell lines such as NG108-15 cells. The pharmacological properties of 5-HT₃ receptors, which are different from those of other 5-HT receptors, suggest that multiple 5-HT₃ receptor subtypes may exist and may correspond to different combinations of subunits (*see* Chapter 12).

Behavior. The behavioral alterations elicited by drugs that interact with 5-HT receptors are extremely diverse. Many animal behavioral models for initial assessment of agonist and antagonist properties of drugs depend on aberrant motor or reflex responses, such as startle reflexes, hind-limb abduction, head twitches, and other stereotypical behaviors. Operant behavioral paradigms, such as drug discrimination, provide models of specific 5-HT receptor activation and are useful for exploring the action of CNS-active drugs, including agents that interact with 5-HT. For example, investigations of the mechanism of action of hallucinogenic drugs have relied heavily on drug discrimination (as discussed below). The following discussion focuses on animal models that may relate to pathological conditions in human beings and will not attempt to cover the voluminous literature dealing with 5-HT and behavior. *See* Lucki, 1998; Bonasera and Tecott, 2000; and Swerdlow *et al.*, 2000, for excellent reviews on this topic.

Sleep-Wake Cycle. Control of the sleep-wake cycle is one of the first behaviors in which a role for 5-HT was identified. Following pioneering work in cats (for review *see* Jouvet, 1999), many studies showed that depletion of 5-HT with *p*-chlorophenylalanine, a tryptophan

hydroxylase inhibitor, elicited insomnia that was reversed by the 5-HT precursor, 5-hydroxytryptophan. Conversely, treatment with L-tryptophan or with nonselective 5-HT agonists accelerated sleep onset and prolonged total sleep time. 5-HT antagonists reportedly can increase and decrease slow-wave sleep, probably reflecting interacting or opposing roles for subtypes of 5-HT receptors. One relatively consistent finding in humans and in laboratory animals is an increase in slow-wave sleep following administration of a selective 5-HT_{2A/2C}-receptor antagonist such as ritanserin.

Aggression and Impulsivity. Studies in laboratory animals and in human beings suggest that 5-HT serves a critical role in aggression and impulsivity. Many human studies reveal a correlation between low cerebrospinal fluid 5-HIAA and violent impulsivity and aggression. As an example, low 5-HIAA is associated with violent suicidal acts, but not with suicidal ideation *per se*. As with many effects of 5-HT, pharmacological studies of aggressive behavior in laboratory animals are not definitive, but suggest a role for 5-HT. Two genetic studies have reinforced and amplified this notion. The 5-HT_{1B} receptor was the first 5-HT receptor whose function was investigated in knockout mice. Knockout mice lacking this receptor exhibited extreme aggression (Saudou *et al.*, 1994), suggesting either a role for 5-HT_{1B} receptors in the development of neuronal pathways important in aggression or a direct role in the mediation of aggressive behavior. A human genetic study identified a point mutation in the gene encoding MAO-A, which was associated with extreme aggressiveness and mental retardation (Brunner *et al.*, 1993), and this has been confirmed in knockout mice lacking MAO-A (Cases *et al.*, 1995). These genetic studies add credence to the proposition that abnormalities in 5-HT are related to aggressive behaviors.

Anxiety and Depression. The effects of 5-HT-active drugs, like the selective serotonin reuptake inhibitors (SSRIs), in anxiety and depressive disorders strongly suggest an effect of 5-HT in the neurochemical mediation of these disorders. However, 5-HT-related drugs with clinical effects in anxiety and depression have varied effects in classical animal models of these disorders, depending on the experimental paradigm, species, and strain. For example, the effective anxiolytic *bupirone* (BUSPAR, *see* Chapter 17), a 5-HT_{1A}-receptor partial agonist, does not reduce anxiety in classical approach-avoidance paradigms that were instrumental in development of anxiolytic benzodiazepines. However, bupirone and other 5-HT_{1A}-receptor agonists are effective in other animal behavioral tests used to predict anxiolytic effects. Furthermore, studies in 5-HT_{1A}-receptor knockout mice suggest a role for this receptor in anxiety, and possibly depression. Agonists of certain 5-HT receptors, including 5-HT_{2A} and 5-HT_{2C} receptors (*e.g.*, *m*-chlorophenylpiperazine [mCPP]), have been shown to have anxiogenic properties in laboratory animal and human studies. Similarly, these receptors have been implicated in the animal models of depression, such as learned helplessness.

An impressive finding in human beings with depression is the abrupt reversal of the antidepressant effects of drugs such as SSRIs by manipulations that rapidly reduce the amount of 5-HT in the brain. These approaches include administration of *p*-chlorophenylalanine or a tryptophan-free drink containing large quantities of neutral amino acids (Delgado *et al.*, 1990). Curiously, this kind of 5-HT depletion has not been shown to worsen or to induce depression in nondepressed subjects, suggesting that the continued presence of 5-HT is required to maintain the effects of these drugs. This clinical finding adds credence to somewhat less convincing neurochemical findings that suggest a role for 5-HT in the pathogenesis of depression.

Pharmacological Manipulation of the Amount of 5-HT in Tissues

Experimental strategies for evaluating the role of 5-HT depend on techniques that manipulate tissue levels of 5-HT or block 5-HT receptors. Until recently, manipulation of the levels of endogenous 5-HT was the more commonly used strategy, because the actions of 5-HT antagonists were poorly understood.

Tryptophan hydroxylase, the rate-limiting enzyme in 5-HT synthesis, is a vulnerable site. A diet low in tryptophan reduces the concentration of brain 5-HT; conversely, ingestion of a tryptophan load increases levels of 5-HT in the brain. In addition, administration of a tryptophan hydroxylase inhibitor causes a profound depletion of 5-HT. The most widely used selective tryptophan hydroxylase inhibitor is *p*-chlorophenylalanine, which acts irreversibly. *p*-Chlorophenylalanine produces profound, long-lasting depletion of 5-HT levels with no change in levels of catecholamines.

p-Chloroamphetamine and other halogenated amphetamines promote 5-HT release from platelets and neurons. A rapid release of 5-HT is followed by a prolonged and selective depletion of 5-HT in brain. The halogenated amphetamines are valuable experimental tools and two of them, *fenfluramine* and *dexfenfluramine*, were used clinically to reduce appetite; these drugs were withdrawn from the United States market in 1998 after reports of cardiac toxicity associated with their use. The mechanism of action of this class of drugs is controversial. A profound reduction in levels of 5-HT in the brain lasts for weeks and is accompanied by an equivalent loss of proteins selectively localized in 5-HT neurons (5-HT transporter and tryptophan hydroxylase), suggesting that the halogenated amphetamines have a neurotoxic action. Despite these long-lasting biochemical deficits, neuroanatomical signs of neuronal death are not readily apparent. Another class of compounds, ring-substituted tryptamine derivatives such as 5,7-dihydroxytryptamine (see Figure 11–1) leads to unequivocal degeneration of 5-HT neurons. In adult animals, 5,7-dihydroxytryptamine selectively destroys serotonergic axon terminals; the remaining intact cell bodies allow eventual regeneration of axon terminals. In newborn animals, degeneration is permanent because 5,7-dihydroxytryptamine destroys serotonergic cell bodies as well as axon terminals.

Another highly specific mechanism for altering synaptic availability of 5-HT is inhibition of presynaptic reaccumulation of neuronally released 5-HT. SSRIs, such as *fluoxetine* (PROZAC), potentiate and prolong the action of 5-HT released by neuronal activity. When coadministered with L-5-hydroxytryptophan, SSRIs elicit a profound acti-

vation of serotonergic responses. SSRIs are the most widely used treatment for endogenous depression (see Chapter 17). *Sibutramine* (MERIDIA), an inhibitor of the reuptake of 5-HT, norepinephrine, and dopamine, is used as an appetite suppressant in the management of obesity. The drug is converted to two active metabolites that probably account for its therapeutic effects. Whether effects on a single neurotransmitter are primarily responsible for sibutramine's effects in obese patients is unclear.

Nonselective treatments that alter 5-HT levels include MAO inhibitors and reserpine. MAO inhibitors block the principal route of degradation, thereby increasing levels of 5-HT, whereas reserpine releases intraneuronal stores with subsequent depletion of 5-HT. These treatments profoundly alter levels of 5-HT throughout the body. However, because comparable changes occur in the levels of catecholamines, reserpine and MAO inhibitors are of limited utility as research tools. At one time or another, both have been used in the treatment of mental diseases: reserpine as an antipsychotic drug (see Chapter 18) and MAO inhibitors as antidepressants (see Chapter 17).

5-HT-RECEPTOR AGONISTS AND ANTAGONISTS

5-HT-Receptor Agonists

Direct-acting 5-HT-receptor agonists have widely different chemical structures, as well as diverse pharmacological properties (Table 11–4). This diversity is not surprising in light of the number of 5-HT-receptor subtypes. 5-HT_{1A} receptor-selective agonists have helped elucidate the functions of this receptor in the brain and have resulted in a new class of antianxiety drugs including buspirone, *gepirone*, and *ipsapirone* (see Chapter 17). 5-HT_{1D} receptor-selective agonists, such as *sumatriptan*, have unique properties that result in constriction of intracranial blood vessels. Sumatriptan was first in a series of new serotonin-receptor agonists available for treatment of acute migraine attacks (see below). Other such agents now FDA approved in the United States for the acute treatment of migraine include *zolmitriptan* (ZOMIG), *naratriptan* (AMERGE), and *rizatriptan* (MAXALT), all of which are selective for 5-HT_{1D} and 5-HT_{1B} receptors. A number of 5-HT₄ receptor-selective agonists have been developed or are being developed for the treatment of disorders of the GI tract (see Chapter 37). These classes of selective 5-HT-receptor agonists are discussed in more detail in the chapters that deal directly with treatment of the relevant pathological conditions.

Table 11–4*Serotonergic Drugs: Primary Actions and Clinical Uses*

RECEPTOR	ACTION	DRUG EXAMPLES	CLINICAL DISORDER
5-HT _{1A}	Partial agonist	Buspirone, ipsaperone	Anxiety, depression
5-HT _{1D}	Agonist	Sumatriptan	Migraine
5-HT _{2A/2C}	Antagonist	Methysergide, trazodone, risperidone, ketanserin	Migraine, depression, schizophrenia
5-HT ₃	Antagonist	Ondansetron	Chemotherapy-induced emesis
5-HT ₄	Agonist	Cisapride	Gastrointestinal disorders
5-HT transporter	Inhibitor	Fluoxetine, sertraline	Depression, obsessive-compulsive disorder, panic disorder, social phobia, posttraumatic stress disorder

5-HT-Receptor Agonists and Migraine. Migraine headache afflicts 10% to 20% of the population, producing a morbidity estimated at 64 million missed workdays per year in the United States. Although migraine is a specific neurological syndrome, the manifestations vary widely. The principal types are: migraine without aura (common migraine); migraine with aura (classic migraine), which includes subclasses of migraine with typical aura, migraine with prolonged aura, migraine without headache, and migraine with acute-onset aura; and several other rarer types. Auroras also may appear without a subsequent headache. Premonitory aura may begin as long as 24 hours before the onset of pain and often is accompanied by photophobia, hyperacusis, polyuria, and diarrhea, and by disturbances of mood and appetite. A migraine attack may last for hours or days and be followed by prolonged pain-free intervals. The frequency of migraine attacks is extremely variable, but usually ranges from 1 to 2 a year to 1 to 4 per month.

The therapy of migraine headaches is complicated by the variable responses among and within individual patients and by the lack of a firm understanding of the pathophysiology of the syndrome. The efficacy of antimigraine drugs varies with the absence or presence of aura, duration of the headache, its severity and intensity, and as yet undefined environmental and genetic factors (Deleu *et al.*, 1998). A rather vague and inconsistent pathophysiological characteristic of migraine is the spreading depression of neural impulses from a focal point of vasoconstriction followed by vasodilation. However, it is unlikely that vasoconstriction followed by vasodilation (spreading depression) or vasodilation alone accounts for the local edema and focal tenderness often observed in migraine patients.

Consistent with the hypothesis that 5-HT is a key mediator in the pathogenesis of migraine, 5-HT-receptor

agonists have become the mainstay for acute treatment of migraine headaches. This hypothesis is based on evidence obtained in laboratory experiments and on the following evidence obtained in human beings: (1) Plasma and platelet concentrations of 5-HT vary with the different phases of the migraine attack. (2) Urinary concentrations of 5-HT and its metabolites are elevated during most migraine attacks. (3) Migraine may be precipitated by agents such as reserpine and fenfluramine that release biogenic amines, including serotonin, from intracellular storage sites. New treatments for the prevention of migraines, such as botulinum toxin and newer antiepileptic drugs, have unique mechanisms of action, presumably unrelated to 5-HT (Ashkenazi and Silberstein, 2004).

5-HT₁-Receptor Agonists: The Triptans. The introduction of sumatriptan (IMITREX), zolmitriptan (ZOMIG), naratriptan (AMERGE), and rizatriptan (MAXALT and MAXALT-MLT) in the therapy of migraine has led to significant progress in preclinical and clinical research on migraine. The selective pharmacological effects of these agents, dubbed the *triptans*, at 5-HT₁ receptors have led to insights into the pathophysiology of migraine. Clinically, the drugs are effective, acute antimigraine agents. Their ability to decrease, rather than exacerbate, the nausea and vomiting of migraine is an important advance in the treatment of the condition.

History. Sumatriptan emerged from the first experimentally based approach to identify and develop a novel therapy for migraine. In 1972, Humphrey and colleagues initiated a project aimed at identifying novel therapeutic agents in the treatment of migraine (Humphrey *et al.*, 1990). The goal of this project was to develop selective vasoconstrictors of the extracranial circulation based on the theories of the etiology of migraine prevalent in the early 1970s. Humphrey and colleagues focused on the identification of 5-HT receptors in the carotid vasculature based on the evidence that the efficacy of traditional antimigraine drugs such as ergota-

Figure 11-5. Structures of the triptans (selective 5-HT₁-receptor agonists).

mine derived from their capacity to induce vasoconstriction of the carotid arteriovenous anastomoses, presumably *via* their effects on 5-HT receptors. The synthesis of many novel tryptamine analogs was followed by determination of their actions on *in vitro* vascular preparations and in intact animals. Sumatriptan, first synthesized in 1984, potentially contracted the dog isolated saphenous vein, a vessel believed to contain the novel 5-HT receptor located in the carotid circulation. Sumatriptan became available for clinical use in the United States in 1992; since then, several other triptans have been approved for clinical use (Gladstone and Gawel, 2003).

Chemistry. The triptans are indole derivatives, with substituents on the 3 and 5 positions. Their structures are given in Figure 11-5.

Pharmacological Properties. In contrast to ergot alkaloids (*see* below), the pharmacological effects of the triptans appear to be limited to the 5-HT₁ family of receptors, providing evidence that this receptor subclass plays an important role in the acute relief of a migraine attack. The triptans are much more selective agents than are ergot alkaloids in that they interact potently with 5-HT_{1D} and 5-HT_{1B} receptors and have a low or no affinity for other subtypes of 5-HT receptors. The triptans are essentially inactive at α_1 and α_2 adrenergic, β adrenergic, dopaminergic, muscarinic cholinergic, and benzodiazepine receptors. Clinically effective doses of the triptans do not correlate well with their affinity for either 5-HT_{1A} or 5-HT_{1E} receptors, but do correlate well with their affinities for both 5-HT_{1B} and 5-HT_{1D} receptors. Current data are thus consistent with the hypothesis that 5-HT_{1B} and/or 5-HT_{1D} receptors are the most likely receptors involved in the mechanism of action of acute antimigraine drugs.

Mechanism of Action. Two hypotheses have been proposed to explain the efficacy of 5-HT_{1B/1D}-receptor agonists in migraine. One hypothesis implicates the capacity of these receptors to cause constriction of intracranial blood vessels including arteriovenous anastomoses. According to a prominent pathophysiological model of migraine, unknown events lead to the abnormal dilation of carotid arteriovenous anastomoses in the head. As much as 80% of carotid arterial blood flow has been reported to be “shunted” *via* these anastomoses, located

mainly in the cranial skin and ears, diverting blood from the capillary beds and thereby producing cerebral ischemia and hypoxia. Based on this model, an effective antimigraine agent would close the shunts and restore blood flow to the brain. Indeed, ergotamine, dihydroergotamine, and sumatriptan share the capacity to produce this vascular effect with a pharmacological specificity that mirrors the effects of these agents on 5-HT_{1B}- and 5-HT_{1D}-receptor subtypes.

An alternative hypothesis concerning the significance of one or more 5-HT₁ receptors in migraine pathophysiology relates to the observation that both 5-HT_{1B} and 5-HT_{1D} receptors serve as presynaptic autoreceptors, modulating neurotransmitter release from neuronal terminals (Figure 11-3). 5-HT₁ agonists may block the release of proinflammatory neuropeptides at the level of the nerve terminal in the perivascular space. Indeed, ergotamine, dihydroergotamine, and sumatriptan can block the development of neurogenic plasma extravasation in dura mater associated with depolarization of perivascular axons following capsaicin injection or unilateral electrical stimulation of the trigeminal nerve (Moskowitz, 1992). The ability of potent 5-HT₁-receptor agonists to inhibit endogenous neurotransmitter release in the perivascular space could account for their efficacy in the acute treatment of migraine.

Absorption, Fate, and Excretion. When given subcutaneously, sumatriptan reaches its peak plasma concentration in approximately 12 minutes. Following oral administration, peak plasma concentrations occur within 1 to 2 hours. Bioavailability following the subcutaneous route of administration is approximately 97%; after oral administration or nasal spray, bioavailability is only 14% to 17%. The elimination half-life is approximately 1 to 2 hours. Sumatriptan is metabolized predominantly by MAO-A, and its metabolites are excreted in the urine.

Zolmitriptan reaches its peak plasma concentration 1.5 to 2 hours after oral administration. Its bioavailability is about 40% following oral ingestion. Zolmitriptan is converted to an active *N*-desmethyl metabolite, which has severalfold higher affinity for 5-HT_{1B} and 5-HT_{1D} receptors than does the parent drug. Both the metabolite and the parent drug have half-lives of 2 to 3 hours.

Naratriptan, administered orally, reaches its peak plasma concentration in 2 to 3 hours and has an absolute bioavailability of about 70%. It is the longest acting of the triptans, having a half-life of about 6 hours. Fifty percent of an administered dose of naratriptan is excreted unchanged in the urine, and about 30% is excreted as products of oxidation by CYPs.

Rizatriptan has an oral bioavailability of about 45% and reaches peak plasma levels within 1 to 1.5 hours after oral ingestion of tablets of the drug. An orally disintegrating dosage form has a somewhat slower rate of absorption, yielding peak plasma levels of the drug 1.6 to 2.5 hours after administration. The principal route of metabolism of rizatriptan is *via* oxidative deamination by MAO-A.

Plasma protein-binding of the triptans ranges from about 14% (sumatriptan and rizatriptan) to 30% (naratriptan).

Adverse Effects and Contraindications. Rare but serious cardiac events have been associated with the administration of 5-HT₁ agonists, including coronary artery vasospasm, transient myocardial ischemia, atrial and ventricular arrhythmias, and myocardial infarction, predominantly in patients with risk factors for coronary artery disease. In general, however, only minor side effects are seen with the triptans in the acute treatment of migraine. As much as 83% of patients experience at least one side effect after subcutaneous injection of sumatriptan. Most patients report transient mild pain, stinging, or burning sensations at the site of injection. The most common side effect of sumatriptan nasal spray is a bitter taste. Orally administered triptans can cause paresthesias; asthenia and fatigue; flushing; feelings of pressure, tightness, or pain in the chest, neck, and jaw; drowsiness; dizziness; nausea; and sweating.

The triptans are contraindicated in patients who have a history of ischemic or vasospastic coronary artery disease, cerebrovascular or peripheral vascular disease, or other significant cardiovascular diseases. Because triptans may cause an acute, usually small, increase in blood pressure, they also are contraindicated in patients with uncontrolled hypertension. Naratriptan is contraindicated in patients with severe renal or hepatic impairment. Rizatriptan should be used with caution in patients with renal or hepatic disease but is not contraindicated in such patients. Sumatriptan, rizatriptan, and zolmitriptan are contraindicated in patients who are taking monoamine oxidase inhibitors.

Use in Treatment of Migraine. The triptans are effective in the acute treatment of migraine (with or without aura), but are not intended for use in prophylaxis of migraine. Treatment with these agents should begin as soon as possible after onset of a migraine attack. Oral dosage forms of the triptans are the most convenient to use, but they may not be practical in patients experiencing

migraine-associated nausea and vomiting. Approximately 70% of individuals report significant headache relief from a 6-mg subcutaneous dose of sumatriptan. This dose may be repeated once within a 24-hour period if the first dose does not relieve the headache. An oral formulation and a nasal spray of sumatriptan also are available. The onset of action is as early as 15 minutes with the nasal spray. The recommended oral dose of sumatriptan is 25 to 100 mg, which may be repeated after 2 hours up to a total dose of 200 mg over a 24-hour period. When administered by nasal spray, from 5 to 20 mg of sumatriptan is recommended. The dose can be repeated after 2 hours up to a maximum dose of 40 mg over a 24-hour period. Zolmitriptan is given orally in a 1.25- to 2.5-mg dose, which can be repeated after 2 hours, up to a maximum dose of 10 mg over 24 hours, if the migraine attack persists. Naratriptan is given orally in a 1- to 2.5-mg dose, which should not be repeated until 4 hours after the previous dose. The maximum dose over a 24-hour period should not exceed 5 mg. The recommended oral dose of rizatriptan is 5 to 10 mg. The dose can be repeated after 2 hours up to a maximum dose of 30 mg over a 24-hour period. The safety of treating more than 3 or 4 headaches over a 30-day period with triptans has not been established. Triptans should not be used concurrently with (or within 24 hours of) an ergot derivative (*see* below), nor should one triptan be used concurrently or within 24 hours of another.

Ergot and the Ergot Alkaloids. The dramatic abortive effect of ergot ingested during pregnancy has been recognized for more than 2000 years. The active principles of ergot were isolated and chemically identified in the early 20th century. The elucidation of the constituents of ergot and their complex actions was an important chapter in the evolution of modern pharmacology, even though the very complexity of their actions limits their therapeutic uses (Table 11–5). The pharmacological effects of the ergot alkaloids are varied and complex; in general, the effects result from their actions as partial agonists or antagonists at adrenergic, dopaminergic, and serotonergic receptors (*see also* Chapter 10). The spectrum of effects depends on the agent, dosage, species, tissue, physiological and endocrinological state, and experimental conditions.

History. Ergot is the product of a fungus (*Claviceps purpurea*) that grows on rye and other grains. The contamination of an edible grain by a poisonous, parasitic fungus spread death for centuries. As early as 600 B.C., an Assyrian tablet alluded to a “noxious pustule in the ear of grain.” Written descriptions of ergot poisoning first appeared in the Middle Ages. Strange epidemics were described in which the characteristic symptom was gangrene of the feet, legs, hands, and arms. In severe cases, the tissue became dry and black, and mummified limbs separated off without loss of blood. Limbs were said to be consumed by the holy fire, blackened like charcoal with agonizing burning sensa-

Table 11-5
Pharmacological Actions of Selected Ergot Alkaloids

COMPOUND	Pharmacological Actions		
	INTERACTIONS WITH TRYPTAMINERGIC RECEPTORS	INTERACTIONS WITH DOPAMINERGIC RECEPTORS	INTERACTIONS WITH α ADRENERGIC RECEPTORS
Ergotamine	Partial agonist in certain blood vessels; antagonist in various smooth muscles; poor agonist/antagonist in CNS	No notable actions on central or peripheral structures; high emetic potency	Partial agonist and antagonist in blood vessels and various smooth muscles; mainly antagonist in CNS
Dihydroergotamine	Partial agonist and antagonist in a few smooth muscles	Nonselective antagonist in sympathetic ganglia; low emetic potency	Partial agonist; antagonist in blood vessels, various smooth muscles, peripheral nervous system, and CNS
Bromocriptine	Only a few weak antagonistic actions reported	Partial agonist/antagonist in CNS; presumed agonist in inhibiting secretion of prolactin; less emetic potency than ergotamine	No agonistic effects; less potent antagonist than dihydroergotamine
Ergonovine, methyl ergonovine	Partial agonists in human umbilical and placental blood vessels; selective and fairly potent antagonists in various smooth muscles; partial agonists/antagonists in CNS	Weak antagonists in certain blood vessels; partial agonists/antagonists in CNS; less potent than bromocriptine in producing emesis or inhibiting secretion of prolactin	Partial agonists in blood vessels (less than ergotamine); little antagonistic action
Methysergide	Partial agonist in blood vessels and areas of CNS; selective and very potent antagonist in many tissues and areas of CNS	Little evidence for agonistic or antagonistic activity; no emetic activity	Little or no agonistic or antagonistic action

tions. The disease was called holy fire or St. Anthony's fire in honor of the saint at whose shrine relief was said to be obtained. The relief that followed migration to the shrine of St. Anthony was probably real, for the sufferers received a diet free of contaminated grain during their sojourn at the shrine. The symptoms of ergot poisoning were not restricted to limbs. A frequent complication of ergot poisoning was abortion. Indeed, ergot was known as an obstetrical herb before it was identified as the cause of St. Anthony's fire.

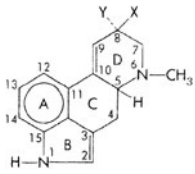

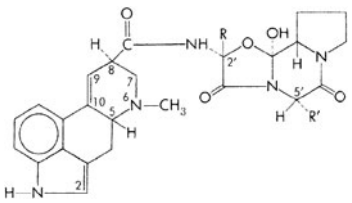

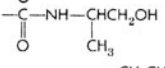

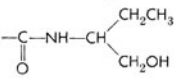

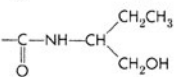

Chemistry. The ergot alkaloids can all be considered to be derivatives of the tetracyclic compound 6-methylergoline (Table 11-6). The naturally occurring alkaloids contain a substituent in the beta configurations at position 8 and a double bond in ring D. The natural alkaloids of therapeutic interest are amide derivatives of *d*-lysergic acid. The first pure ergot alkaloid, ergotamine, was obtained in 1920, followed by the isolation of ergonovine in 1932. Numerous semisynthetic derivatives of the ergot alkaloids have been prepared by catalytic hydrogenation of the natural alkaloids, *e.g.*, dihydroergotamine. Another synthetic derivative, *bromocriptine* (2-bromo- α -ergocryptine), is used to control the secretion of prolactin (*see*

Chapter 55), a property derived from its dopamine agonist effect. Other products of this series include lysergic acid diethylamide (LSD), a potent hallucinogenic drug, and methysergide, a serotonin antagonist. These drugs are discussed later in this chapter.

Absorption, Fate, and Excretion. The oral administration of ergotamine by itself generally results in low or undetectable systemic drug concentrations, because of extensive first-pass metabolism. Bioavailability after sublingual administration probably is less than 1% and is inadequate for therapeutic purposes. The bioavailability after administration of rectal suppositories is greater. Ergotamine is metabolized in the liver by largely undefined pathways, and 90% of the metabolites are excreted in the bile. Only traces of unmetabolized drug are found in urine and feces. Despite a plasma half-life of approximately 2 hours, ergotamine produces vasoconstriction that lasts for 24 hours or longer. Dihydroergotamine is eliminated more rapidly than ergotamine, presumably due to its rapid hepatic clearance.

Ergonovine and methylergonovine are rapidly absorbed after oral administration and reach peak concentrations in plasma within 60 to 90 minutes that are more than tenfold those achieved with an

equivalent dose of ergotamine. An uterotonic effect in postpartum women can be observed within 10 minutes after oral administration of 0.2 mg of ergonovine. Judging from the relative durations of action, ergonovine is metabolized and/or eliminated more rapidly than is ergotamine. The half-life of methylergonovine in plasma ranges between 0.5 and 2 hours.

Use in the Treatment of Migraine. The multiple pharmacological effects of ergot alkaloids have complicated the determination of their precise mechanism of action in the acute treatment of migraine. Based on the mechanism of action of sumatriptan and other 5-HT_{1B/1D}-receptor agonists (discussed above), the actions of ergot alkaloids at 5-HT_{1B/1D} receptors likely mediate their acute antimigraine effects. The ergot derivative methysergide, which acts more commonly as a 5-HT-receptor antagonist, has been used for the prophylactic treatment of migraine headaches and is discussed below, in the section on 5-HT-receptor antagonists.

The use of ergot alkaloids for migraine should be restricted to patients having frequent, moderate migraine or infrequent, severe migraine attacks. As with other medications used to abort an attack, the patient should be advised to take ergot preparations as soon as possible after the onset of a headache. Gastrointestinal absorption of ergot alkaloids is erratic, perhaps contributing to the large variation in

patient response to these drugs. Accordingly, available preparations currently in the United States include sublingual tablets of *ergotamine tartrate* (ERGOMAR) and a nasal spray and solution for injection of *dihydroergotamine mesylate* (MIGRANAL and D.H.E. 45, respectively). The recommended dose for ergotamine tartrate is 2 mg sublingually, which can be repeated at 30-minute intervals if necessary up to a total dose of 6 mg in a 24-hour period or 10 mg a week. Dihydroergotamine mesylate injections can be given intravenously, subcutaneously, or intramuscularly. The recommended dose is 1 mg, which can be repeated after 1 hour if necessary up to a total dose of 2 mg (intravenously) or 3 mg (subcutaneously or intramuscularly) in a 24-hour period or 6 mg in a week. The dose of dihydroergotamine mesylate administered as a nasal spray is 0.5 mg (one spray) in each nostril, repeated after 15 minutes for a total dose of 2 mg (4 sprays). The safety of more than 3 mg over 24 hours or 4 mg over 7 days has not been established.

Adverse Effects and Contraindications. Nausea and vomiting, due to a direct effect on CNS emetic centers, occur in approximately 10% of patients after oral administration of ergotamine, and in about twice that number after parenteral administration. This side effect is problematic, since nausea and sometimes vomiting are part of the symptomatology of a migraine headache. Leg weakness is common, and muscle pains that occasionally are severe may occur in the

extremities. Numbness and tingling of fingers and toes are other reminders of the ergotism that this alkaloid may cause. Precordial distress and pain suggestive of angina pectoris, as well as transient tachycardia or bradycardia, also have been noted, presumably as a result of coronary vasospasm induced by ergotamine. Localized edema and itching may occur in an occasional hypersensitive patient, but usually do not necessitate interruption of ergotamine therapy. In the event of acute or chronic poisoning (ergotism), treatment consists of complete withdrawal of the offending drug and symptomatic measures. The latter include attempts to maintain adequate circulation by agents such as anticoagulants, low-molecular-weight dextran, and potent vasodilator drugs, such as intravenous sodium nitroprusside. Dihydroergotamine has lower potency than does ergotamine as an emetic and as a vasoconstrictor and oxytocic.

Ergot alkaloids are contraindicated in women who are or may become pregnant, because the drugs may cause fetal distress and miscarriage. Ergot alkaloids also are contraindicated in patients with peripheral vascular disease, coronary artery disease, hypertension, impaired hepatic or renal function, and sepsis. Ergot alkaloids should not be taken within 24 hours of the use of the triptans, and should not be used concurrently with other drugs that can cause vasoconstriction.

Use of Ergot Alkaloids in Postpartum Hemorrhage. All of the natural ergot alkaloids markedly increase the motor activity of the uterus. After small doses, contractions are increased in force or frequency, or both, but are followed by a normal degree of relaxation. As the dose is increased, contractions become more forceful and prolonged, resting tone is dramatically increased, and sustained contracture can result. Although this characteristic precludes their use for induction or facilitation of labor, it is quite compatible with their use postpartum or after abortion to control bleeding and maintain uterine contraction. The gravid uterus is very sensitive, and small doses of ergot alkaloids can be given immediately postpartum to obtain a marked uterine response, usually without significant side effects. In current obstetric practice, ergot alkaloids are used primarily to prevent postpartum hemorrhage. Although all natural ergot alkaloids have qualitatively the same effect on the uterus, *ergonovine* is the most active and also is less toxic than ergotamine. For these reasons ergonovine and its semisynthetic derivative *methylergonovine* have replaced other ergot preparations as uterine-stimulating agents in obstetrics.

D-Lysergic Acid Diethylamide (LSD). Of the many drugs that are nonselective 5-HT agonists, LSD is the most remarkable. This ergot derivative profoundly alters human behavior, eliciting perception disturbances such as sensory distortion (especially visual and auditory) and hallucinations at doses as low as 1 $\mu\text{g}/\text{kg}$. The potent, mind-altering effects of LSD explain its abuse by human beings (see Chapter 23), as well as the fascination of scientists with the mechanism of action of LSD. The chemical structure of LSD is shown in Table 11-6.

LSD was synthesized in 1943 by Albert Hoffman, who discovered its unique properties when he accidentally ingested the drug. The chemical precursor, lysergic acid, occurs naturally in a fungus that grows on wheat and rye, but it is devoid of hallucinogenic actions. LSD contains an indolealkylamine moiety embedded within its structure, and early investigators postulated that it would interact with 5-HT receptors. Extensive studies have shown that LSD interacts with brain 5-HT receptors as an agonist/partial agonist. LSD mimics 5-HT at 5-HT_{1A}

autoreceptors on raphe cell bodies, producing a marked slowing of the firing rate of serotonergic neurons. In the raphe, LSD and 5-HT are equi-effective; however, in areas of serotonergic axonal projections (such as visual relay centers), LSD is far less effective than is 5-HT. Current theories focus on the ability of hallucinogens such as LSD to promote glutamate release in thalamocortical terminals, thus causing a dissociation between sensory relay centers and cortical output (Aghajanian and Marek, 1999). In drug discrimination, an animal behavioral model thought to reflect the subjective effects of abused drugs, the discriminative stimulus effects of LSD and other hallucinogenic drugs appear to be mediated by activation of 5-HT_{2A} receptors (Glennon, 1990). Consistent with these behavioral results, analyses of receptor-linked phosphoinositide hydrolysis show that LSD and other hallucinogenic drugs act as partial or full agonists at 5-HT_{2A} and 5-HT_{2C} receptors. An important unanswered question is whether the agonist property of hallucinogenic drugs at 5-HT_{2C} receptors contributes to the behavioral alterations. LSD also interacts potently with many other 5-HT receptors, including cloned receptors whose functions have not yet been determined. On the other hand, the hallucinogenic phenethylamine derivatives such as 1-(4-bromo-2,5-dimethoxyphenyl)-2-aminopropane are selective 5-HT_{2A/2C}-receptor agonists. Promising signs of progress in understanding the actions of hallucinogens are arising from clinical investigations of hallucinogens. It is now possible to test in human beings the hypotheses developed in animal models. For example, positron emission tomography (PET) imaging studies (Vollenweider *et al.*, 1997) revealed that administration of the hallucinogen psilocybin mimics the pattern of brain activation found in schizophrenic patients experiencing hallucinations. Consistent with animal studies, this action of psilocybin is blocked by pretreatment with 5-HT_{2A/2C} antagonists (for a review, see Vollenweider and Geyer, 2001).

8-Hydroxy-(2-N,N-Dipropylamino)-Tetraline (8-OH-DPAT). This prototypic 5-HT_{1A}-selective receptor agonist is a valuable experimental tool. The structure of 8-OH-DPAT is:

8-OH-DPAT does not interact with other members of the 5-HT₁-receptor subfamily or with 5-HT₂, 5-HT₃, or 5-HT₄ receptors. 8-OH-DPAT reduces the firing rate of raphe cells by activating 5-HT_{1A} autoreceptors and inhibits neuronal firing in terminal fields (*e.g.*, hippocampus) by direct interaction with postsynaptic 5-HT_{1A} receptors. A series of long-chain arylpiperazines, such as buspirone, gepirone, and ipsapirone, are selective partial agonists at 5-HT_{1A} receptors. Other closely related arylpiperazines act as 5-HT_{1A}-receptor antagonists. Buspirone, the first clinically available drug in this series, has been effective in the treatment of anxiety (see Chapter 17). The sedative properties of the benzodiazepines, which buspirone does not have, may explain why patients usually prefer the benzodiazepines to relieve anxiety. Other arylpiperazines are being developed for treatment of depression as well as anxiety.

m-Chlorophenylpiperazine (mCPP). The actions of mCPP *in vivo* primarily reflect activation of 5-HT_{1B} and/or 5-HT_{2A/2C} receptors, although this agent is not subtype-

selective in radioligand-binding studies *in vitro*. mCPP (structure below) is an active metabolite of the antidepressant drug *trazodone* (DESYREL).

mCPP has been employed to probe brain 5-HT function in human beings. The drug alters a number of neuroendocrine parameters and elicits profound behavioral effects, with anxiety as a prominent symptom (Murphy, 1990). mCPP elevates cortisol and prolactin secretion, probably *via* a combination of 5-HT₁- and 5-HT_{2A/2C}-receptor activation. It also increases growth hormone secretion, apparently by a 5-HT-independent mechanism. 5-HT_{2A/2C} receptors appear to mediate at least part of the anxiogenic effects of mCPP, as 5-HT_{2A/2C}-receptor antagonists attenuate mCPP-induced anxiety. Animal studies suggest a greater involvement of the 5-HT_{2C} receptor in anxiogenic actions of mCPP.

5-HT-Receptor Antagonists

The properties of 5-HT-receptor antagonists also vary widely. Ergot alkaloids and related compounds tend to be nonspecific 5-HT-receptor antagonists; however, a few ergot derivatives such as *metergoline* bind preferentially to members of the 5-HT₂-receptor family. A number of selective antagonists for 5-HT_{2A/2C} and 5-HT₃ receptors are currently available. Members of these drug classes have widely different chemical structures, with no common structural motif predictably conveying high affinity. Ketanserin is the prototypic 5-HT_{2A}-receptor antagonist (*see below*). A large series of 5-HT₃-receptor antagonists are being explored for treatment of various gastrointestinal disturbances. *Ondansetron* (ZOFTRAN), *dolasetron* (ANZEMET), and *granisetron* (KYTRIL), all 5-HT₃-receptor antagonists, have proven to be highly efficacious in the treatment of chemotherapy-induced nausea (*see Chapter 37*).

Clinical effects of 5-HT-related drugs often exhibit a significant delay in onset. This is particularly the case with drugs used to treat affective disorders such as anxiety and depression (*see Chapter 17*). This delayed onset has generated considerable interest in potential adaptive changes in

5-HT-receptor density and sensitivity after chronic drug treatments. Laboratory studies have documented agonist-promoted receptor subsensitivity and down-regulation of 5-HT-receptor subtypes, a compensatory response common to many neurotransmitter systems. However, an unusual adaptive process, *antagonist-induced down-regulation* of 5-HT_{2C} receptors, takes place in rats and mice after chronic treatment with receptor antagonists (Gray and Roth, 2001). The mechanism of this paradoxical regulation of 5-HT_{2A/2C} receptors has generated considerable interest, since many clinically effective drugs, including clozapine, ketanserin, and amitriptyline, exhibit this unusual property. These drugs, as well as several other 5-HT_{2A/2C}-receptor antagonists, possess negative intrinsic activity, reducing constitutive (spontaneous) receptor activity as well as blocking agonist occupancy (Barker *et al.*, 1994). This property of negative intrinsic activity or inverse agonism is frequently observed when constitutive (agonist-independent) activity can be measured; in the absence of constitutive activity, inverse agonists behave as competitive antagonists (for reviews *see* Milligan, 2003; and Kenakin, 2004). Another group of 5-HT_{2A/2C}-receptor antagonists was found to act in the classical manner, simply blocking receptor occupancy by agonists. Even though there is only scant evidence for constitutive activity *in vivo*, drug development has been further refined by focusing on reduction of preexisting constitutive neuronal activity as opposed to blockade of excess neurotransmitter action.

Ketanserin. *Ketanserin* (SUFREXAL) (structure below) opened a new era in 5-HT-receptor pharmacology. Ketanserin potently blocks 5-HT_{2A} receptors, less potently blocks 5-HT_{2C} receptors, and has no significant effect on 5-HT₃ or 5-HT₄ receptors or any members of the 5-HT₁-receptor family. Notably, ketanserin also has high affinity for α adrenergic receptors and histamine H₁ receptors (Janssen, 1983).

Ketanserin lowers blood pressure in patients with hypertension, causing a reduction comparable to that seen with β adrenergic-receptor antagonists or diuretics. The drug appears to reduce the tone of both capacitance and resistance vessels. This effect likely relates to its blockade of α_1 adrenergic receptors, not its blockade of 5-HT_{2A} receptors. Ketanserin inhibits 5-HT-induced platelet aggregation, but it does not greatly reduce the capacity of other agents to cause aggregation. Ketanserin is not yet marketed in the United States but is available in Europe. Severe side effects after treatment with ketanserin have not been reported. Its oral bioavailability is about 50%, and its plasma half-life is 12 to 25 hours. The primary mechanism of inactivation is hepatic metabolism.

Chemical relatives of ketanserin such as *ritanserin* are more selective 5-HT_{2A}-receptor antagonists with low affinity for α_1 adrenergic receptors. However, ritanserin, as well as most other 5-HT_{2A}-receptor antagonists, also potently antagonize 5-HT_{2C} receptors. The physiological significance of 5-HT_{2C}-receptor blockade is unknown. MDL 100,907 is the prototype of a new series of potent 5-HT_{2A}-receptor antagonists, with high selectivity for 5-HT_{2A} versus 5-HT_{2C} receptors. Clinical trials of MDL 100,907 in the treatment of schizophrenia have been inconclusive.

Atypical Antipsychotic Drugs. *Clozapine* (CLOZARIL), a 5-HT_{2A/2C}-receptor antagonist, represents a class of atypical antipsychotic drugs with reduced incidence of extrapyramidal side effects compared to the classical neuroleptics, and possibly a greater efficacy for reducing negative symptoms of schizophrenia (see Chapter 18). Clozapine also has a high affinity for subtypes of dopamine receptors.

One of the newest strategies for the design of additional atypical antipsychotic drugs is to combine 5-HT_{2A/2C} and dopamine D₂-receptor–blocking actions in the same molecule (Meltzer, 1999). *Risperidone* (RISPERDAL), for example, is a potent 5-HT_{2A}- and D₂-receptor antagonist. Low doses of risperidone have been reported to attenuate negative symptoms of schizophrenia with a low incidence of extrapyramidal side effects. Extrapyramidal effects are commonly seen, however, with doses of risperidone in excess of 6 mg/day. Other atypical antipsychotic agents—*quetiapine* (SEROQUEL) and *olanzapine* (ZYPREXA)—act on multiple receptors, but their antipsychotic properties are thought to be due to antagonism of dopamine and serotonin.

Methysergide. *Methysergide* (SANSERT; 1-methyl-*d*-lysergic acid butanolamide) is a congener of methylergonovine (Table 11–6).

Methysergide blocks 5-HT_{2A} and 5-HT_{2C} receptors, but appears to have partial agonist activity in some preparations. Methysergide inhibits the vasoconstrictor and pressor effects of 5-HT, as well as the actions of 5-HT on various types of extravascular smooth muscle. It has been found to both block and mimic the central effects of 5-HT. Methysergide is not selective: it also interacts with 5-HT₁ receptors, but its therapeutic effects appear primarily to reflect blockade of 5-HT₂ receptors. Although methysergide is an ergot derivative, it has only weak vasoconstrictor and oxytocic activity.

Methysergide has been used for the prophylactic treatment of migraine and other vascular headaches, including Horton's syndrome. It is without benefit when given during an acute migraine attack. The protective effect takes 1 to 2 days to develop and disappears slowly when treatment is terminated. This might be due to the accumulation of an active metabolite of methysergide, methylergometrine, which is more potent than the parent drug. Methysergide

also has been used to combat diarrhea and malabsorption in patients with carcinoid tumors, and may be beneficial in the postgastrectomy dumping syndrome; both of these conditions have a 5-HT–mediated component. However, methysergide is ineffective against other substances (e.g., kinins) that also are released by carcinoid tumors. For this reason, the preferred agent to treat malabsorption in carcinoid patients is a somatostatin analog, *octreotide acetate* (SANDOSTATIN), which inhibits the secretion of all the mediators released by the carcinoid tumors (see Chapter 55).

Side effects of methysergide are usually mild and transient, although drug withdrawal is infrequently required to reverse more severe reactions. Common side effects include gastrointestinal disturbances (heartburn, diarrhea, cramps, nausea, and vomiting), and symptoms related to vasospasm-induced ischemia (numbness and tingling of extremities, pain in the extremities, and low back and abdominal pain). Effects attributable to central actions include unsteadiness, drowsiness, weakness, lightheadedness, nervousness, insomnia, confusion, excitement, hallucinations, and even frank psychotic episodes. Reactions suggestive of vascular insufficiency and exacerbation of angina pectoris have been observed in a few patients. A potentially serious complication of prolonged treatment is inflammatory fibrosis, giving rise to various syndromes that include retroperitoneal fibrosis, pleuropulmonary fibrosis, and coronary and endocardial fibrosis. Usually the fibrosis regresses after drug withdrawal, although persistent cardiac valvular damage has been reported. Because of this danger, other drugs are preferred for the prophylactic treatment of migraine (see earlier discussion of migraine therapy). If methysergide is used chronically, treatment should be interrupted for 3 weeks or more every 6 months.

Cyproheptadine. The structure of *cyproheptadine* (PERIACTIN; see below) resembles that of the phenothiazine histamine H₁-receptor antagonists, and indeed, it is an effective H₁-receptor antagonist. Cyproheptadine also has prominent 5-HT blocking activity on smooth muscle by virtue of its binding to 5-HT_{2A} receptors. In addition, it has weak anticholinergic activity and possesses mild CNS depressant properties.

CYPROHEPTADINE

Cyproheptadine shares the properties and uses of other H_1 -receptor antagonists (see Chapter 24). It is effective in controlling skin allergies, particularly the accompanying pruritus. In allergic conditions, the action of cyproheptadine as a 5-HT-receptor antagonist is irrelevant, since 5-HT_{2A} receptors are not involved in human allergic responses. Some physicians recommend cyproheptadine to counteract the sexual side effects of selective 5-HT-reuptake inhibitors such as fluoxetine and sertraline (see Chapter 17). The 5-HT blocking actions of cyproheptadine explain its value in the postgastrectomy dumping syndrome, intestinal hypermotility of carcinoid, and migraine prophylaxis. Cyproheptadine is not, however, a preferred treatment for these conditions.

Side effects of cyproheptadine include those common to other H_1 -receptor antagonists, such as drowsiness. Weight gain and increased growth in children have been observed and attributed to impaired regulation of growth-hormone secretion.

SECTION III

Drugs Acting on the Central Nervous System

CHAPTER

12

NEUROTRANSMISSION AND THE CENTRAL NERVOUS SYSTEM

Floyd E. Bloom

Drugs that act upon the central nervous system (CNS) influence the daily lives of everyone. These agents are invaluable therapeutically because they can produce specific physiological and psychological effects. Without general anesthetics, modern surgery would be impossible. Drugs that affect the CNS can selectively relieve pain, reduce fever, suppress disordered movement, induce sleep or arousal, reduce appetite, and allay the tendency to vomit. Selectively acting drugs can be used to treat anxiety, depression, mania, or schizophrenia and do so without altering consciousness (*see* Chapters 17 and 18).

The nonmedical self-administration of CNS-active drugs is a widespread practice. Socially acceptable stimulants and antianxiety agents produce stability, relief, and even pleasure. However, the excessive use of such drugs can affect lives adversely when their uncontrolled, compulsive use leads to physical dependence on the drug or to toxic side effects, including lethal overdosage (*see* Chapters 22 and 23).

The quality of drugs that affect the nervous system and behavior presents extraordinary scientific challenge—the attempt to understand the cellular and molecular basis for the enormously complex and varied functions of the human brain. In this effort, pharmacologists have two major goals: to use drugs to elucidate the mechanisms that operate in the normal CNS and to develop appropriate drugs to correct pathophysiological events in the abnormal CNS.

Elucidating the sites and mechanisms of action of CNS drugs demands an understanding of the cellular and molecular biology of the brain. Although knowledge of the anatomy, physiology, and chemistry of the nervous system is far from complete, the acceleration of interdisciplinary research on the CNS has led to remarkable progress. This chapter introduces guidelines and fundamental principles for the comprehensive analysis of drugs that affect the CNS. Specific therapeutic approaches to neurological and psychiatric disorders are discussed in Chapters 13 through 23.

ORGANIZATIONAL PRINCIPLES OF THE BRAIN

The brain is an assembly of interrelated neural systems that regulate their own and each other's activity in a dynamic, complex fashion largely through intercellular chemical neurotransmission (for additional references, *see* Bloom, 1996; Nestler *et al.*, 2001; Cooper *et al.*, 2003).

Macrofunctions of the Brain Regions

The large anatomical divisions provide a superficial classification of the distribution of brain functions.

Cerebral Cortex. The two cerebral hemispheres constitute the largest division of the brain. Regions of the cortex are classified in several ways: (1) by the modality of information processed (*e.g.*, sensory, including somatosensory, visual, auditory, and olfactory, as well as motor and associational); (2) by anatomical position (frontal, temporal, parietal, and occipital); and (3) by the geometric relationship between cell types in the major cortical layers (“cytoarchitectonic” classifications). The specialized functions of a cortical region arise from the interplay between connections from other regions of the cortex (corticocortical systems) and noncortical areas of the brain (subcortical systems) and a basic intracortical processing module of approximately 100 vertically connected cortical columns (Mountcastle, 1997). Varying numbers of adjacent columnar modules may be functionally, but transiently, linked into larger information-processing ensembles. The pathology of Alzheimer’s disease, for example, destroys the integrity of the columnar modules and the corticocortical connections (*see* Chapter 20).

Cortical areas termed association areas process information from primary cortical sensory regions to produce higher cortical functions such as abstract thought, memory, and consciousness. The cerebral cortices also provide supervisory integration of the autonomic nervous system and integrate somatic and vegetative functions, including those of the cardiovascular and gastrointestinal systems.

Limbic System. The “limbic system” is an archaic term for an assembly of brain regions (hippocampal formation, amygdaloid complex, septum, olfactory nuclei, basal ganglia, and selected nuclei of the diencephalon) grouped around the subcortical borders of the underlying brain core to which a variety of complex emotional and motivational functions have been attributed. Modern neuroscience avoids this term because those ill-defined regions of the “limbic system” do not function consistently as a system. Parts of these limbic regions also participate individually in functions that can be more precisely defined. Thus, the basal ganglia or neostriatum (the *caudate nucleus*, *putamen*, *globus pallidus*, and *lentiform nucleus*) form an essential regulatory segment of the *extrapyramidal motor system*. This system complements the function of the pyramidal (or voluntary) motor system. Damage to the extrapyramidal system depresses the ability to initiate voluntary movements and causes disorders characterized by involuntary movements, such as the tremors and rigidity of Parkinson’s disease or the uncontrollable limb movements of Huntington’s chorea (*see* Chapter 20). Similarly, the hippocampus may be crucial to the formation of recent memory, since this function is lost in patients with extensive bilateral damage to the hippocampus. Memory also is disrupted by Alzheimer’s disease, which destroys the intrinsic structure of the hippocampus as well as parts of the frontal cortex.

Diencephalon. The *thalamus* lies in the center of the brain, beneath the cortex and basal ganglia and above the hypothalamus. The neurons of the thalamus are arranged into distinct clusters, or nuclei, which are either paired or midline structures. These nuclei act as relays between the incoming sensory pathways and the cortex, between the discrete regions of the thalamus and the hypothalamus, and between the basal ganglia and the association regions of the cerebral cortex. The thalamic nuclei and the basal ganglia also exert regulatory control over visceral functions; aphagia and adipsia, as well as general sensory neglect, follow damage to the corpus striatum or to selected circuits ending there. The *hypothalamus* is the

principal integrating region for the entire autonomic nervous system and regulates body temperature, water balance, intermediary metabolism, blood pressure, sexual and circadian cycles, secretion of the adenohypophysis, sleep, and emotion. Recent advances in the cytophysiological and chemical dissection of the hypothalamus have clarified the connections and possible functions of individual hypothalamic nuclei.

Midbrain and Brainstem. The *mesencephalon*, *pons*, and *medulla oblongata* connect the cerebral hemispheres and thalamus-hypothalamus to the spinal cord. These “bridge portions” of the CNS contain most of the nuclei of the cranial nerves, as well as the major inflow and outflow tracts from the cortices and spinal cord. These regions contain the *reticular activating system*, an important but incompletely characterized region of gray matter linking peripheral sensory and motor events with higher levels of nervous integration. The major monoamine-containing neurons of the brain (*see* below) are found here. Together, these regions represent the points of central integration for coordination of essential reflexive acts, such as swallowing and vomiting, and those that involve the cardiovascular and respiratory systems; these areas also include the primary receptive regions for most visceral afferent sensory information. The reticular activating system is essential for the regulation of sleep, wakefulness, and level of arousal, as well as for coordination of eye movements. The fiber systems projecting from the reticular formation have been called “nonspecific” because the targets to which they project are relatively more diffuse in distribution than those of many other neurons (*e.g.*, specific thalamocortical projections). However, the chemically homogeneous components of the reticular system innervate targets in a coherent and functional manner despite their broad distribution.

Cerebellum. The cerebellum arises from the posterior pons behind the cerebral hemispheres. It also is highly laminated and redundant in its detailed cytological organization. The lobules and folia of the cerebellum project onto specific deep cerebellar nuclei, which in turn make relatively selective projections to the motor cortex (by way of the thalamus) and to the brainstem nuclei concerned with vestibular (position-stabilization) function. In addition to maintaining the proper tone of antigravity musculature and providing continuous feedback during volitional movements of the trunk and extremities, the cerebellum also may regulate visceral function (*e.g.*, heart rate, so as to maintain blood flow despite changes in posture). In addition, the cerebellum plays a significant role in learning and memory.

Spinal Cord. The spinal cord extends from the caudal end of the medulla oblongata to the lower lumbar vertebrae. Within this mass of nerve cells and tracts, the sensory information from skin, muscles, joints, and viscera is locally coordinated with motoneurons and with primary sensory relay cells that project to and receive signals from higher levels. The spinal cord is divided into anatomical segments (cervical, thoracic, lumbar, and sacral) that correspond to divisions of the peripheral nerves and spinal column (*see* Figure 6–1). Ascending and descending tracts of the spinal cord are located within the white matter at the perimeter of the cord, while intersegmental connections and synaptic contacts are concentrated within the H-shaped internal mass of gray matter. Sensory information flows into the dorsal cord, and motor commands exit *via* the ventral portion. The preganglionic neurons of the autonomic nervous system (*see* Chapter 6) are found in the intermediolateral columns of

the gray matter. Autonomic reflexes (*e.g.*, changes in skin vasculature with alteration of temperature) can be elicited within local segments of the spinal cord, as shown by the maintenance of these reflexes after the cord is severed.

Microanatomy of the Brain

Neurons operate either within layered structures (such as the olfactory bulb, cerebral cortex, hippocampal formation, and cerebellum) or in clustered groupings (the defined collections of central neurons which aggregate into nuclei). The specific connections between neurons within or across the macro-divisions of the brain are essential to the brain's functions. It is through their patterns of neuronal circuitry that individual neurons form functional ensembles to regulate the flow of information within and between the regions of the brain.

Cellular Organization of the Brain. Present understanding of the cellular organization of the CNS can be viewed from the perspective of the size, shape, location, and interconnections between neurons (*see* Cooper *et al.*, 2003; Shepherd, 2003, for additional references).

Cell Biology of Neurons. Neurons are classified according to function (sensory, motor, or interneuron), location, or identity of the transmitter they synthesize and release. Microscopic analysis of a neuron focuses on its general shape, and in particular the complexity of the afferent receptive surfaces on the dendrites and cell body that receive synaptic contacts from other neurons. Neurons exhibit the cytological characteristics of highly active secretory cells with large nuclei: large amounts of smooth and rough endoplasmic reticulum; and frequent clusters of specialized smooth endoplasmic reticulum (Golgi complex), in which secretory products of the cell are packaged into membrane-bound organelles for transport from the cell body proper to the axon or dendrites (Figure 12–1). Neurons and their cellular extensions are rich in microtubules, which support the complex cellular structure and assist in the reciprocal transport of essential macromolecules and organelles between the cell body and the distant axon or dendrites. The sites of interneuronal communication in the CNS are termed *synapses* (*see* below). Although synapses are functionally analogous to “junctions” in the somatic motor and autonomic nervous systems, the central junctions contain an array of specific proteins presumed to be the active zone for transmitter release and response (Husi *et al.*, 2000). Like peripheral “junctions,” central synapses also are denoted by accumulations of tiny (500 to 1500 Å) organelles, termed *synaptic vesicles*. The proteins of these vesicles have been shown to have specific roles in transmitter storage, vesicle docking onto presynaptic membranes, voltage- and Ca²⁺-dependent secretion (*see* Chapter 6), and recycling and restorage of released transmitter (Murthy *et al.*, 2003; Jahn, 2004).

Supportive Cells. Neurons are not the only cells in the CNS. According to most estimates, neurons are outnumbered, perhaps by an order of magnitude, by the various supportive cells: the macroglia, the microglia, the cells of the vascular elements comprising

the intracerebral vasculature as well as the cerebrospinal fluid-forming cells of the choroid plexus found within the intracerebral ventricular system, and the meninges, which cover the surface of the brain and comprise the cerebrospinal fluid-containing envelope. Macroglia are the most abundant supportive cells; some are categorized as *astrocytes* (cells interposed between the vasculature and the neurons, often surrounding individual compartments of synaptic complexes). Astrocytes play a variety of metabolic support roles including furnishing energy intermediates and supplementary removal of extracellular neurotransmitter secretions (Pellerin *et al.*, 2003). The *oligodendroglia*, a second prominent category of macroglia, are the myelin-producing cells. Myelin, made up of multiple layers of their compacted membranes, insulates segments of long axons bioelectrically and accelerates action potential conduction velocity. Microglia are relatively uncharacterized supportive cells believed to be of mesodermal origin and related to the macrophage/monocyte lineage (Carson *et al.*, 1998; Carson, 2002). Some microglia reside within the brain, while additional cells of this class may be recruited to the brain during periods of inflammation following either microbial infection or other brain injury. The response of the brain to inflammation differs strikingly from that of other tissues and presents a therapeutic response that may transcend specific diseases (Ransohoff, 2002; Rosenberg, 2002; Raber *et al.*, 1998).

Blood–Brain Barrier. Apart from the exceptional instances in which drugs are introduced directly into the CNS, the concentration of the agent in the blood after oral or parenteral administration differs substantially from its concentration in the brain. The *blood–brain barrier* (BBB) is an important boundary between the periphery and the CNS that forms a permeability barrier to the passive diffusion of substances from the bloodstream into various regions of the CNS. Evidence of the barrier is provided by the greatly diminished rate of access of chemicals from plasma to the brain (*see* Chapter 1). This barrier is nonexistent in the peripheral nervous system, and is much less prominent in the hypothalamus and in several small, specialized organs (the circumventricular organs) lining the third and fourth ventricles of the brain: the median eminence, area postrema, pineal gland, subfornical organ, and subcommissural organ. While the BBB imposes severe limitations on the diffusion of macromolecules from the bloodstream into the brain, selective barriers to permeation into and out of the brain also exist for small, charged molecules such as neurotransmitters, their precursors and metabolites, and some drugs. These diffusional barriers are viewed as a combination of the partition of solute across the vasculature (which governs passage by definable properties such as molecular weight, charge, and lipophilicity) and the presence or absence of energy-dependent transport systems (*see* Chapter 2). The brain clears metabolites of transmitters into the cerebrospinal fluid by excretion *via* the acid transport system of the choroid plexus. Substances that rarely gain access to the brain from the bloodstream often can reach the brain when injected directly into the cerebrospinal fluid. Under certain conditions, it may be possible to open the BBB, at least transiently, to permit the entry of chemotherapeutic agents. Cerebral ischemia and inflammation also modify the BBB, increasing access to substances that ordinarily would not affect the brain.

Response to Damage: Repair and Plasticity in the CNS

Because the neurons of the CNS are terminally differentiated cells, they do not undergo proliferative responses to damage, although

Figure 12-1. Schematic view of the drug-sensitive sites in prototypical synaptic complexes. In the center, a postsynaptic neuron receives a somatic synapse (shown greatly oversized) from an axonic terminal; an axoaxonic terminal is shown in contact with this presynaptic nerve terminal. Drug-sensitive sites include: (1) microtubules and molecular motors responsible for bidirectional transport of macromolecules between the neuronal cell body and distal processes; (2) electrically conductive membranes; (3) sites for the synthesis and storage of transmitters; (4) sites for the active uptake of transmitters by nerve terminals or glia; (5) sites for the release of transmitter; (6) postsynaptic receptors, cytoplasmic organelles, and postsynaptic proteins for expression of synaptic activity and for long-term mediation of altered physiological states; and (7) presynaptic receptors on adjacent presynaptic processes and (8) on nerve terminals (autoreceptors). Around the central neuron are schematic illustrations of the more common synaptic relationships in the CNS. (Modified from Bodian, 1972, and Cooper *et al.*, 2003.)

recent evidence suggests the possibility of neural stem cell proliferation as a natural means for replacement of neurons in selected areas of the CNS (Gage, 2002); this may provide a future means of repair (Steindler *et al.*, 2002). As a result, neurons have evolved other adaptive mechanisms to maintain function following injury. These adaptive mechanisms endow the brain with considerable capacity for structural and functional modification well into adulthood, including some of the phenomena of memory and learning (Linden, 2003).

INTEGRATIVE CHEMICAL COMMUNICATION IN THE CENTRAL NERVOUS SYSTEM

The cardinal role of the CNS is to integrate information from a variety of external and internal sources, to optimize the needs of the organism within the demands of the

environment. These integrative concepts transcend individual transmitter systems and emphasize the means by which neuronal activity is normally coordinated. Only through a detailed understanding of these integrative functions, and their failure in certain pathophysiological conditions, can effective and specific therapeutic approaches be developed for neurological and psychiatric disorders. The molecular and cellular mechanisms of neural integration are linked to clinical therapeutics because untreatable diseases and unexpected nontherapeutic side effects of drugs often reveal previously unrecognized mechanisms of pathophysiology. The capacity to link molecular processes to normal and pathological behavior provides an exciting aspect of modern neuropharmacological research. A central underlying concept of neuropsychopharmacology is that drugs that influence behavior and improve the functional status of patients with neurological or psychiatric diseases act by enhancing or blunting the effectiveness of specific combinations of synaptic transmitter actions.

Four research strategies provide the neuroscientific substrates of neuropsychological phenomena: molecular (or biochemical), cellular, multicellular (or systems), and behavioral. The intensively exploited molecular and biochemical levels have been the traditional focus for characterizing drugs that alter behavior. Molecular discoveries provide biochemical probes for identifying the appropriate neuronal sites and their mediative mechanisms. Such mechanisms include: (1) ion channels, which provide for changes in excitability induced by neurotransmitters; (2) neurotransmitter receptors; (3) auxiliary intramembranous and cytoplasmic transductive molecules that couple these receptors to intracellular effectors for short-term changes in excitability and for longer-term regulation through alterations in gene expression (Sofroniew *et al.*, 2001); and (4) transporters for the conservation of released transmitter molecules by reaccumulation into nerve terminals, and then into synaptic vesicles (see Chapter 6). Vesicular transporters are distinct from the plasma membrane proteins involved in transmitter uptake into nerve terminals (Figure 12-2) (Nestler *et al.*, 2001; Cooper *et al.*, 2003). Thus, the most basic cellular phenomena of neurons are now understood in terms of such discrete molecular entities. It has long been known that electrical excitability of neurons is achieved through modifications of the ion channels that all neurons express in abundance in their plasma membranes. However, we now understand in considerable detail how the three major cations, Na^+ , K^+ and Ca^{2+} , and the Cl^- anions are regulated in their flow through highly discriminative ion channels (Figures 12-3 and 12-4). In addition to these ion channels, two other families of channels have been recognized: cyclic nucleotide-modulated channels, and transient receptor potential (TRP) channels.

Voltage-dependent ion channels (Figure 12-3) provide for rapid changes in ion permeability along axons and within dendrites and for the excitation-secretion coupling that releases neurotransmitters from presynaptic sites (Catterall and Epstein, 1992; Catterall, 1993). The major cation channels have been defined by functional assessment of recombinant proteins with and without constrained molecular modifications (Figure 12-3A). The intrinsic membrane-embedded domains of the Na^+ and Ca^{2+} channels are

Figure 12-2. Predicted structural motif for neurotransmitter transporters. Transporters for the conservation of released amino acid or amine transmitters all share a 12-transmembrane domain structure, although the exact orientation of the amino terminus is not clear. Transporters for amine transmitters found on synaptic vesicles also share a 12-transmembrane domain structure, but one that is distinct from the transporters of the plasma membrane. See Chapter 2 for structural details of pharmacologically important transport proteins.

envisioned as four tandem repeats of a putative six-transmembrane domain, while the K^+ channel family contains greater molecular diversity. One structural form of voltage-regulated K^+ channels consists of subunits composed of a single putative six-transmembrane domain (Figure 12-3C). The inward rectifier K^+ channel structure, in contrast, retains the general configuration corresponding to transmembrane spans 5 and 6 with the interposed “pore region” that penetrates only the exofacial surface membrane. These two structural categories of K^+ channels can form hetero-oligomers, giving rise to multiple possibilities for regulation by voltage, neurotransmitters, assembly with intracellular auxiliary proteins, or posttranslational modifications. X-ray crystallography confirms these configurations for the K^+ channel (MacKinnon, 2003).

Ligand-gated ion channels, regulated by the binding of neurotransmitters, form a distinct group of ion channels (Figure 12-4). The structurally defined channel molecules now can be examined to determine how drugs, toxins, and imposed voltages alter neuronal excitability (Table 12-1). Within the CNS, variants of the K^+ channels (the delayed rectifier, the Ca^{2+} -activated K^+ channel, and the after-hyperpolarizing K^+ channel) regulated by intracellular second messengers repeatedly have been shown to underlie complex forms of synaptic modulation (Greengard, 2001).

Cyclic nucleotide-modulated channels consist of two groups: the cyclic nucleotide-gated (CNG) channels, which play key roles in sensory transduction for olfactory and photoreceptors, and the hyperpolarization-activated, cyclic nucleotide-gated (HCN) chan-

Figure 12-3. The major molecular motifs of ion channels that establish and regulate neuronal excitability in the central nervous system. **A.** The α subunits of the Ca^{2+} and Na^+ channels share a similar presumptive six-transmembrane structure, repeated four times, in which an intramembranous segment separates transmembrane segments 5 and 6. **B.** The Ca^{2+} channel also requires several auxiliary small proteins (α_2 , β , γ , and δ). The α_2 and δ subunits are linked by a disulfide bond (not shown). Regulatory subunits also exist for Na^+ channels. **C.** Voltage-sensitive K^+ channels (K_v) and the rapidly activating K^+ channel (K_a) share a similar presumptive six-transmembrane domain similar in overall configuration to one repeat unit within the Na^+ and Ca^{2+} channel structure, while the inwardly rectifying K^+ channel protein (K_{ir}) retains the general configuration of just loops 5 and 6. Regulatory β subunits (cytosolic) can alter K_v channel functions. Channels of these two overall motifs can form heteromultimers (Krapivinsky *et al.*, 1995).

nels. The latter channels are unique cation channels that open with hyperpolarization and close with depolarization; upon direct binding of cyclic AMP or cyclic GMP, the activation curves for the channels are shifted to more hyperpolarized potentials. These channels play essential roles in cardiac pacemaker cells and presumably in rhythmically discharging neurons (Hofmann *et al.*, 2004).

Transient receptor potential (TRP) channels, named for their role in *Drosophila* phototransduction, are a family of hexa-spanning receptors with a pore domain between the fifth and sixth transmembrane segments, and a common 25-amino acid TRP “box” C-terminal of the sixth transmembrane domain; these channels are found across the phylogenetic scale from bacteria to mammals. Members of the TRPV subfamily serve as the receptors for endogenous cannabinoids, such as anandamide (see section on diffusible mediators, below) and the hot pepper toxin, capsaicin (Clapham *et al.*, 2004).

Research at the cellular level identifies specific neurons and their most proximate synaptic connections that may mediate a behavior or the behavioral effects of a given drug. For example, research into the basis of emotion exploits both molecular and behavioral leads to the most likely brain sites at which behavioral changes pertinent to emotion can be analyzed. Such research provides clues as to the nature of the interactions in terms of interneuronal communication (*i.e.*, excitation, inhibition, or the more complex forms of synaptic interaction).

An understanding at the systems level is required to assemble the descriptive structural and functional properties of specific central transmitter systems, linking the neurons that make and release a given neurotransmitter to its behavioral effects. While many such transmitter-to-behavior linkages have been postulated, it has proven difficult to validate the essential involvement of specific transmitter-defined neurons in mediating specific mammalian behavior.

Research at the behavioral level often can illuminate the integrative phenomena that link populations of neurons (often through operationally or empirically defined ways) into extended specialized circuits, ensembles, or “systems” that integrate the physiological expression of a learned, reflexive, or spontaneously generated behavioral response. The entire concept of “animal models” of human psychiatric diseases rests on the assumption that scientists can appropriately infer from observations of behavior and physiology (heart rate, respiration, locomotion, etc.) that the states experienced by animals are equivalent to the emotional states experienced by human beings

Figure 12-4. Ionophore receptors for neurotransmitters are composed of subunits with four transmembrane domains and are assembled as tetramers or pentamers (at right). The predicted motif shown likely describes nicotinic cholinergic receptors for ACh, GABA_A receptors for gamma-aminobutyric acid, and receptors for glycine. Ionophore receptors for glutamate, however, probably are not accurately represented by this schematic motif.

*In some instances (e.g., acetylcholine, purines), agents that inhibit metabolism of the transmitter(s) have effects that are analogous to those of inhibitors of transport of other transmitters. Receptor-effector coupling consists of ion channel mechanisms for ionotropic receptors (IR) or coupling to G proteins for GPCRs. All GPCRs modulate neuronal activity by affecting second messenger production, protein phosphorylation, and ion channel function by mechanisms described in Chapter 1. In general, G_s couples to adenylyl cyclase to activate cyclic AMP production, while coupling to G_i inhibits adenylyl cyclase; coupling to G_q activates the PLC-IP₃-Ca²⁺ pathway; βγ subunits of G proteins may modulate ion channels directly. ABBREVIATIONS: 7-OH-DPAT, 7-hydroxy-2 (di-n-propyl-amino) tetralin; 5-HT, 5-hydroxytryptamine (serotonin); L-AP4, L-amino-4-phosphonobutyrate; APDC, 1S, 4R-4-aminopyrrolidine-2,4-dicarboxylate; AVP, arginine vasopressin; CCK, cholecystokinin; CTAP, D-Phe-Cys-Tyr-D-Trp-Arg-Thr-Pen-Thr-NH₂; CTOP, D-Phe-Cys-Tyr-D-Trp-Orn-Thr-Pen-Thr-NH₂; DALCE, [D-Ala², Leu⁵, Cys⁶]enkephalin; DAMGO, [D-Ala², N-Me-Phe⁴, Gly⁵-ol]-enkephalin; DDAVP, 1-desamino-8-D-arginine vasopressin; DHPG, dihydroxyphenylglycine; DPDPE, [d-Pen², d-Pen⁵] enkephalin; DSBULET, Tyr-d-Ser-o-t-butyl-Gly-Phe-Leu-Thr; EPI, epinephrine; NE, norepinephrine; NK, neurokinin; NPY, neuropeptide Y; OT, oxytocin; PCP, phencyclidine; SP, substance P; SRIF, somatotropin release-inhibiting factor; THIP, 4,5,6,7-tetrahydroisoxazolo [5,4-c]-pyridone; VP, vasopressin. All other abbreviations represent experimental drugs coded by their manufacturers.

expressing similar physiological changes (Cowan *et al.*, 2000 and 2002; *see* Chapter 17).

Identification of Central Transmitters

An essential step in understanding the functional properties of neurotransmitters within the context of the circuitry of the brain is to identify which substances are the transmitters for specific interneuronal connections. The criteria for the rigorous identification of central transmitters require the same data used to establish the transmitters of the autonomic nervous system (*see* Chapter 6).

1. *The transmitter must be shown to be present in the presynaptic terminals of the synapse and in the neurons from which those presynaptic terminals arise.* Extensions of this criterion involve the demonstration that the presynaptic neuron synthesizes the transmitter substance, rather than simply storing it after accumulation from a nonneural source. Microscopic cytochemistry with antibodies or *in situ* hybridization, subcellular fractionation, and biochemical analysis of brain tissue are particularly suited to satisfy this criterion. These techniques often are combined in experimental animals with the production of surgical or chemical lesions of presynaptic neurons or their tracts to demonstrate that the lesion eliminates the proposed transmitter from the target region. Detection of the mRNA for specific neurotransmitter receptors within postsynaptic neurons using molecular biological methods can identify candidate postsynaptic cells.
2. *The transmitter must be released from the presynaptic nerve concomitantly with presynaptic nerve activity.* This criterion is best satisfied by electrical stimulation of the nerve pathway *in vivo* and collection of the transmitter in an enriched extracellular fluid within the synaptic target area. Demonstrating release of a transmitter formerly required sampling for prolonged intervals, but modern approaches employ minute microdialysis tubing or microvoltametric electrodes capable of sensitive detection of amine and amino acid transmitters within spatially and temporally meaningful dimensions (Bourne and Nicoll, 1993). Release of transmitter also can be studied *in vitro* by ionic or electrical activation of thin brain slices or subcellular fractions that are enriched in nerve terminals. The release of all transmitter substances so far studied, including presumptive transmitter release from dendrites, is voltage-dependent and requires the influx of Ca^{2+} into the presynaptic terminal. However, transmitter release is relatively insensitive to extracellular Na^+ or to tetrodotoxin, which blocks transmembrane movement of Na^+ .

3. *When applied experimentally to the target cells, the effects of the putative transmitter must be identical to the effects of stimulating the presynaptic pathway.* This criterion can be met loosely by qualitative comparisons (*e.g.*, both the substance and the pathway inhibit or excite the target cell). More convincing is the demonstration that the ionic conductances activated by the pathway are the same as those activated by the candidate transmitter. Alternatively, the criterion can be satisfied less rigorously by demonstration of the pharmacological identity of receptors (order of potency of agonists and antagonists). In general, pharmacological antagonism of the actions of the pathway and those of the candidate transmitter should be achieved by similar concentrations of antagonist. To be convincing, the antagonistic drug should not affect responses of the target neurons to other unrelated pathways or to chemically distinct transmitter candidates. Actions that are qualitatively identical to those that follow stimulation of the pathway also should be observed with synthetic agonists that mimic the actions of the transmitter.

Other studies, especially those implicating peptides as neurotransmitters, suggest that many brain and spinal-cord synapses contain more than one transmitter substance (Hökfelt *et al.*, 2003). Substances that coexist in a given synapse are presumed to be released together, but in a frequency-dependent fashion, with higher-frequency bursts mediating peptide release. Coexisting substances may either act jointly on the postsynaptic membrane, or affect release of transmitter from the presynaptic terminal. Clearly, if more than one substance transmits information, no single agonist or antagonist would faithfully mimic or fully antagonize activation of a given presynaptic element. Costorage and corelease of ATP and norepinephrine are an example (Burnstock, 1995).

CNS Transmitter Discovery Strategies

The earliest transmitters considered for central roles were acetylcholine and norepinephrine, largely because of their established roles in the somatic motor and autonomic nervous systems. In the 1960s, serotonin, epinephrine, and dopamine also were investigated as potential CNS transmitters; although histochemical, biochemical, and pharmacological data yielded results consistent with their roles as neurotransmitters, not all criteria were satisfied. In the early 1970s, the availability of selective and potent antagonists of gamma-aminobutyric acid (GABA), glycine, and glutamate, all known to be enriched in brain, led to their general acceptance as transmitter substances. Also at this time, a search for hypothalamic-hypophyseal factors led to an improvement in the technology to isolate, purify, sequence, and synthetically replicate a growing family of neuropeptides (Hökfelt *et al.*, 2003). This advance, coupled with the widespread application of immunohistochemistry, strongly supported the view that neuropeptides act as transmitters. Adaptation of bioassay technology from studies of pituitary secretions to other effectors (such as smooth-muscle contractility), and later, competitive binding assays with radioactive ligands, gave rise to the discovery of endogenous peptide ligands for drugs acting at opiate receptors (*see* Chapter 21). The search for

endogenous factors whose receptors constituted the drug binding sites later was extended to the benzodiazepine receptors and to a series of endogenous lipid amides as the natural ligands for the cannabinoid receptors, termed the endocannabinoids (Piomelli, 2003).

Assessment of Receptor Properties. Until the 1990s, central synaptic receptors were characterized either by examination of their capacity to bind radiolabeled agonists or antagonists (and on the ability of other unlabeled compounds to compete for such binding sites) or by electrophysiological or biochemical consequences of receptor activation of neurons *in vivo* or *in vitro*. Radioligand-binding assays can quantify binding sites within a region, track their appearance throughout the phylogenetic scale and during brain development, and evaluate how physiologic or pharmacologic manipulation regulates receptor number or affinity (Nestler *et al.*, 2001; Cooper *et al.*, 2003).

The properties of the cellular response to the transmitter can be studied electrophysiologically by the use of microiontophoresis (involving recording from single cells and highly localized drug administration). The patch-clamp technique can be used to study the electrical properties of single ion channels and their regulation by neurotransmitters. These direct electrophysiological tests of neuronal responsiveness can provide qualitative and quantitative information on the receptor-specific effects of a putative transmitter substance (*see* Neubig *et al.*, 2003, for a comprehensive receptor database). Receptor properties also can be studied biochemically when the activated receptor is coupled to an enzymatic reaction, such as the synthesis of a second messenger and its biochemical sequelae.

Molecular biological techniques have led to the identification of mRNAs (or cDNAs) for the receptors for virtually every natural ligand considered as a neurotransmitter. A common practice is to introduce these coding sequences into test cells (frog oocytes or mammalian cells) and to assess the relative effects of ligands on second-messenger production in such cells. Molecular cloning studies have revealed two major motifs (Figures 12–4 and 12–5) and one minor motif of transmitter receptors. Oligomeric ion channel receptors composed of multiple subunits usually have four transmembrane domains (Figure 12–4). The ion channel receptors (ionotropic receptors, or IRs) for neurotransmitters contain sites for reversible phosphorylation by protein kinases and phosphoprotein phosphatases and for voltage-gating. Receptors with this structure include nicotinic cholinergic receptors; the receptors for the amino acids GABA, glycine, glutamate, and aspartate; and the 5-HT₃ receptor.

Figure 12–5. *G protein–coupled receptors are composed of a single subunit, with seven transmembrane domains.* For small neurotransmitters, the binding pocket is buried within the bilayer; sequences in the second cytoplasmic loop and projecting out of the bilayer at the base of transmembrane spans 5 and 6 have been implicated in agonist-facilitated G protein coupling (*see* Chapter 1).

The second major motif comprises the G protein–coupled receptors (GPCRs), a large family of heptahelical receptors with varying cytoplasmic loop lengths connecting the transmembrane domains (Figure 12–5). Multiple mutagenesis strategies have defined how the activated receptors (themselves subject to reversible phosphorylation at one or more functionally distinct sites) can interact with the heterotrimeric GTP-binding protein complex. Such protein–protein interactions can activate, inhibit, or otherwise regulate effector systems such as adenylate cyclase or phospholipase C, and ion channels, such as voltage-gated Ca²⁺ channels or receptor-operated K⁺ channels (*see* Chapter 1). GPCRs are employed by muscarinic cholinergic receptors, one subtype each of GABA and glutamate receptors, and all other aminergic and peptidergic receptors. Transfecting cells lacking GPCRs with mRNAs for GPCRs with no known ligands has led to the identification of novel neuropeptide ligands for these “orphan” receptors (Robas *et al.*, 2003). A third receptor motif is that of a growth factor receptor (GFR), a monospanning membrane protein that has an extracellular binding domain that regulates an intracellular catalytic activity, such as the atrial natriuretic peptide–binding domain that regulates the activity of the membrane-bound guanylyl cyclase (*see* Figure 1–7). Dimerization of GPCRs and GFRs apparently contributes to their activities, as does localization within or outside of caveolae in the membrane (Milligan, 2004) (*see* Chapter 1).

An additional ligand-binding motif expressed within the CNS involves the transporters that conserve transmitters after secretion by an ion-dependent reuptake process (Figure 12–2). These neurotransmitter transporters share a molecular motif with 12 transmembrane domains, similar to glucose transporters and adenylyl cyclase (*see* Chapter 2) (Nestler *et al.*, 2001).

Postsynaptic receptivity of CNS neurons is regulated continuously in terms of the number of receptor sites and the threshold required to generate a response. Receptor number often depends on the concentration of agonist to which the target cell is exposed. Thus, chronic excess of agonist can lead to a reduced number of receptors (desensitization or down-regulation) and consequently to subsensitivity or tolerance to the transmitter. For many GPCRs, short-term down-regulation is achieved by the actions of G protein–linked receptor kinases (GRKs) and internalization of the receptors (*see* Chapter 1). Conversely, deficit of agonist or prolonged pharmacologic blockade of receptors can lead to increased numbers of receptors and supersensitivity of the system. These adaptive processes become especially important when drugs are used to treat chronic illness of the CNS. After prolonged exposure to drug, the actual mechanisms underlying the therapeutic effect may differ strikingly from those that operate when the agent is first introduced. Similar adaptive modifications of neuronal systems also can occur at presynaptic sites, such as those concerned with transmitter synthesis, storage, and release (Murthy and Camilli, 2003).

NEUROTRANSMITTERS, HORMONES, AND MODULATORS: CONTRASTING PRINCIPLES OF NEURONAL REGULATION

Neurotransmitters. Given a definite effect of a neuron on a target cell, a substance found in or secreted by the neuron and producing the effect operationally would be the transmitter from the neuron to the target cell. In some cas-

es, transmitters may produce minimal effects on bioelectric properties, yet activate or inactivate biochemical mechanisms necessary for responses to other circuits. Alternatively, the action of a transmitter may vary with the context of ongoing synaptic events—enhancing excitation or inhibition, rather than operating to impose direct excitation or inhibition (Cooper *et al.*, 2003). Each chemical substance that fits within the broad definition of a transmitter may therefore require operational definition within the spatial and temporal domains in which a specific cell-cell circuit is defined. Those same properties may or may not be generalized to other cells that are contacted by the same presynaptic neurons, with the differences in operation related to differences in postsynaptic receptors and the mechanisms by which the activated receptor produces its effect.

Classically, electrophysiological signs of the action of a *bona fide* transmitter fall into two major categories: (1) *excitation*, in which ion channels are opened to permit net influx of positively charged ions, leading to depolarization with a reduction in the electrical resistance of the membrane; and (2) *inhibition*, in which selective ion movements lead to hyperpolarization, also with decreased membrane resistance. There also may be many “nonclassical” transmitter mechanisms operating in the CNS. In some cases, either depolarization or hyperpolarization is accompanied by a *decreased* ionic conductance (increased membrane resistance) as actions of the transmitter lead to the closure of ion channels (so-called leak channels) that normally are open in some resting neurons (Shepherd, 2003). For transmitters such as monoamines and certain peptides, a “conditional” action may be involved, *i.e.*, a transmitter substance may enhance or suppress the response of the target neuron to classical excitatory or inhibitory transmitters while producing little or no change in membrane potential or ionic conductance when applied alone. Such conditional responses are termed *modulatory*, and specific categories of modulation have been hypothesized (Burnstock, 1995; Aston-Jones *et al.*, 2001). Regardless of the mechanisms that underlie such synaptic operations, their temporal and biophysical characteristics differ substantially from the rapid onset-offset effects previously thought to describe all synaptic events. These differences have thus raised the issue of whether substances that produce slow synaptic effects should be described as neurotransmitters. Some of the alternative terms and the relevant molecules are described below.

Neurohormones. Peptide-secreting cells of the hypothalamohypophysal circuits originally were described as neurosecretory cells, receiving synaptic information from other central neurons, yet secreting transmitters in a hormone-like fashion into the circulation. The transmitter released from such neurons was termed a *neurohormone*, *i.e.*, a substance secreted into the blood by a neuron. This term has lost

much of its original meaning, because these hypothalamic neurons also may form traditional synapses with central neurons. Cytochemical evidence indicates that the same substances that are secreted as hormones from the posterior pituitary (oxytocin, arginine-vasopressin; *see* Chapters 29 and 55), mediate transmission at these sites. Thus the designation *hormone* relates to the site of release at the posterior pituitary and does not necessarily describe all the actions of the peptide.

Neuromodulators. The distinctive feature of a modulator is that it originates from nonsynaptic sites, yet influences the excitability of nerve cells. Florey (1967) specifically designated substances such as CO₂ and ammonia, arising from active neurons or glia, as potential modulators through nonsynaptic actions. Similarly, circulating steroid hormones, steroids produced in the nervous system (*i.e.*, neurosteroids), locally released adenosine, and other purines, eicosanoids, and nitric oxide (NO) are all now regarded as modulators (*see* below).

Neuromediators. Substances that participate in eliciting the postsynaptic response to a transmitter fall under this heading. The clearest examples of such effects are provided by the involvement of cyclic AMP, cyclic GMP, and inositol phosphates as second messengers at specific sites of synaptic transmission (*see* Chapters 1, 6, 7, 10, and 11). However, it is technically difficult to demonstrate in brain that a change in the concentration of cyclic nucleotides occurs prior to the generation of the synaptic potential and that this change in concentration is both necessary and sufficient for its generation. It is possible that changes in the concentration of second messengers can occur and enhance the generation of synaptic potentials. Second messenger-dependent protein phosphorylation can initiate a complex cascade of molecular events that regulate the properties of membrane and cytoplasmic proteins central to neuronal excitability (Greengard, 2001). These possibilities are particularly pertinent to the action of drugs that augment or reduce transmitter effects (*see* below).

Neurotrophic Factors. Neurotrophic factors are substances produced within the CNS by neurons, astrocytes, microglia, or transiently invading peripheral inflammatory or immune cells that assist neurons in their attempts to repair damage. Seven categories of neurotrophic peptides are recognized: (1) the classic neurotrophins (nerve growth factor, brain-derived neurotrophic factor, and the related neurotrophins); (2) the neuropoietic factors, which have effects both in brain and in myeloid cells (*e.g.*, cholinergic differentiation factor [also called leukemia inhibitory factor], ciliary neurotrophic factor, and some interleukins); (3) growth factor peptides, such as epidermal growth factor, transforming growth factors α and β , glial cell-derived neurotrophic factor, and activin A; (4) the fibroblast growth factors; (5) insulin-like growth factors; (6) platelet-derived growth factors; and (7) axon guidance molecules, some of which are also capable of affecting cells of the immune system. Drugs designed to elicit the formation and secretion of these products or to emulate their actions may ultimately provide useful adjuncts to rehabilitative treatments (Huang and Reichardt, 2001).

CENTRAL NEUROTRANSMITTERS

The view that synapses are drug-modifiable control points within neuronal networks requires explicit delineation of the sites at which given neurotransmitters may operate

and the degree of specificity with which such sites may be affected. One principle that underlies the following summaries of individual transmitter substances is the chemical-specificity hypothesis of Dale: A given neuron releases the same transmitter substance at each of its synaptic terminals. Because of the growing indications that some neurons contain more than one transmitter substance (Hökfelt *et al.*, 2000), Dale's hypothesis has been modified to indicate that a given neuron secretes the same set of transmitters from all its terminals. Even this theory may require revision. For example, it is not clear whether a neuron that secretes a given peptide will process the precursor peptide to the same end product at all of its synaptic terminals. Table 12-1 summarizes the pharmacological properties of the transmitters in the CNS that have been studied extensively. Neurotransmitters are discussed below as groups of substances within given chemical categories: amino acids, amines, and neuropeptides. Other substances that may participate in central synaptic transmission include purines (such as adenosine and ATP), nitric oxide (Boehning and Snyder, 2003), and arachidonic acid derivatives (Piomelli, 2003).

Amino Acids. The CNS contains uniquely high concentrations of certain amino acids, notably glutamate and gamma-aminobutyric acid (GABA) (Figure 12-6). Although these amino acids potently alter neuronal discharge, physiologists initially were reluctant to accept them as central neurotransmitters. Their ubiquitous distribution within the brain and the consistent observation that they produced prompt, powerful, and readily reversible but redundant effects on every neuron tested seemed out of keeping with the extreme heterogeneity of distribution and responsiveness seen for other putative transmitters. The dicarboxylic amino acids (*e.g.*, glutamate and aspartate) produced near universal excitation, while the monocarboxylic ω -amino acids (*e.g.*, GABA, glycine, β -alanine, and taurine) produced qualitatively similar, consistent inhibitions. Following the emergence of selective antagonists to the amino acids, identification of selective receptors and receptor subtypes became possible. These data, together with the development of methods for mapping the ligands and their receptors, led to widespread acceptance that the amino acids GABA, glycine, and glutamate are central transmitters. The structures of glycine, glutamate, GABA, and some related compounds are shown in Figure 12-6.

GABA. GABA, the major inhibitory neurotransmitter in the mammalian CNS, was identified as a unique chemical constituent of brain in 1950, but its potency as a CNS depressant was not immediately recognized. GABA initially was identified as the only inhibitory amino acid found exclusively in nerves that inhibit the crustacean

stretch receptor; moreover, the GABA content accounted for the inhibitory potency of extracts from these nerves. Finally, GABA release correlated with the frequency of nerve stimulation and identical increases in muscle Cl^- conductance accompanied GABA application and stimulation of the inhibitory nerve (for further historical references, see the ninth edition of this book).

These same physiological and pharmacological properties helped to establish a role for GABA in the mammalian CNS. Substantial data support the idea that GABA mediates the inhibitory actions of local interneurons in the brain and may also mediate presynaptic inhibition within the spinal cord. Presumptive GABA-containing inhibitory synapses have been demonstrated most clearly between cerebellar Purkinje neurons and their targets in Deiter's nucleus; between small interneurons and the major output cells of the cerebellar cortex, olfactory bulb, cuneate nucleus, hippocampus, and lateral septal nucleus; and between the vestibular nucleus and the trochlear motoneurons. GABA also mediates inhibition within the cerebral cortex and between the caudate nucleus and the substantia nigra. GABA-containing neurons and nerve terminals have been localized with immunocytochemical methods that visualize glutamic acid decarboxylase, the enzyme that catalyzes the synthesis of GABA from glutamic acid, or by *in situ* hybridization of the mRNA for this protein. GABA-containing neurons frequently coexpress one or more neuropeptides (*see* below). The most useful compounds for confirmation of GABA-mediated effects have been bicuculline and picrotoxin (Figure 12-6); however, many convulsants whose actions previously were unexplained (including penicillin and pentylenetetrazol) also may act as relatively selective antagonists of the action of GABA. Useful therapeutic effects have not yet been obtained through the use of agents that mimic GABA (such as muscimol), inhibit its active reuptake (such as 2,4-diaminobutyrate, nipecotic acid, and guvacine), or alter its turnover (such as aminooxyacetic acid).

GABA receptors have been divided into three main types: A, B, and C. The most prominent GABA-receptor subtype, the GABA_A receptor, is a ligand-gated Cl^- ion channel, an "ionotropic receptor" that is opened after release of GABA from presynaptic neurons. The GABA_B receptor is a GPCR. The GABA_C receptor is a transmitter-gated Cl^- channel. The GABA_A receptor subunit proteins have been well characterized due to their abundance. The receptor also has been extensively characterized as the site of action of many neuroactive drugs (*see* Chapters 16 and 22), notably benzodiazepines, barbiturates, ethanol, anesthetic steroids, and volatile anesthetics. Based on sequence homology to the first reported GABA_A subunit cDNAs, more than 15 other subunits have been cloned and appear to be expressed in multiple multimeric, pharmacologically distinctive combinations. In addition to these subunits, which are products of separate genes, splice variants for several subunits have been described. The GABA_A receptor, by analogy with the nicotinic cholinergic receptor, may be either a pentameric or tetrameric protein in which the subunits assemble together around a central ion pore typical for all ionotropic receptors (*see* below). The major form of the GABA_A receptor contains at least three different subunits— α , β , and γ —but their stoichiometry is not known (Whiting, 2003). All three subunits are required to interact with benzodiazepines with the profile expected of the native GABA_A receptor, and inclusion of variant α , β , or γ subunits alters the pharmacological profiles. The GABA_B or metabotropic GABA receptor interacts with G_i to inhibit adenylyl cyclase, activate K^+ channels, and reduce Ca^{2+} conductance. Presynaptic GABA_B receptors function as autoreceptors, inhibiting GABA release, and may play the same role on neurons releasing other transmitters. There are two subtypes of GABA_B receptors, 1a and 1b. The GABA_C recep-

Figure 12-6. Amino acid transmitters and congeners.

tor is less widely distributed than the A and B subtypes and is pharmacologically distinct: GABA is more potent by an order of magnitude at GABA_C than at GABA_A receptors, and a number of GABA_A agonists (*e.g.*, baclofen) and modulators (*e.g.*, benzodiazepines and barbiturates) seem not to interact with GABA_C receptors. GABA_C receptors are found in the retina, spinal cord, superior colliculus, and pituitary (Johnston, 2002; Johnston *et al.*, 2003).

Glycine. Many of the features described for the GABA_A receptor family also apply to the inhibitory glycine receptor that is prominent in the brainstem and spinal cord. Multiple subunits assemble into a variety of glycine receptor subtypes (*see* ninth edition of this volume for earlier references). These pharmacological subtypes are detected in brain tissue with particular neuroanatomical and neurodevelopmental profiles. However, as with the GABA_A receptor, the complete functional significance of the glycine receptor subtypes is not known. There is evidence for clustering of glycine receptors by the anchoring protein gephyrin (Sola *et al.*, 2004).

Glutamate and Aspartate. Glutamate and aspartate are found in very high concentrations in brain, and both amino acids have powerful excitatory effects on neurons in virtually every region of the CNS. Their widespread distribution initially obscured their roles as transmitters, but there now is broad acceptance that glutamate and possibly aspartate are the principal fast (“classical”) excitatory transmitters throughout the CNS (Bleich *et al.*, 2003; Conn, 2003). Over the past decade, multiple subtypes of receptors for excitatory amino acids have been cloned, expressed, and characterized pharmacologically, based on the relative potencies of synthetic agonists and the discovery of potent and selective antagonists (Kotecha and MacDonald, 2003).

Glutamate receptors are classed functionally either as ligand-gated ion channel (“ionotropic”) receptors or as “metabotropic” (G protein-coupled) receptors. Neither the precise number of subunits that assembles to generate a functional glutamate ionotropic receptor ion channel *in vivo* nor the intramembranous topography of each subunit has been established unequivocally. The ligand-gated ion channels are further classified according to the identity of agonists that selectively activate each receptor subtype, and are broadly divided into *N*-methyl-D-aspartate (NMDA) receptors and “non-NMDA” receptors. The non-NMDA receptors include the α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and kainic acid (KA) receptors (Figure 12–6). Selective antagonists for these receptors now are available (Herrling, 1997). In the case of NMDA receptors, agonists include open-channel blockers such as phencyclidine (PCP or “angel dust”), antagonists such as 5,7-dichlorokynurenic acid, which act at an allosteric glycine-binding site, and the novel antagonist ifenprodil, which may act as a closed-channel blocker. In addition, the activity of NMDA receptors is sensitive to pH and also can be modulated by a variety of endogenous modulators including Zn²⁺, some neurosteroids, arachidonic acid, redox reagents, and polyamines such as spermine. Additional diversity of glutamate receptors arises by alternative splicing or by single-base editing of mRNAs encoding the receptors or receptor subunits. Alternative splicing has been described for metabotropic receptors and for subunits of NMDA, AMPA, and kainate receptors. For some subunits of AMPA and kainate receptors, the RNA sequence differs from the genomic sequence in a single codon of the receptor subunit and determines the Ca²⁺ permeability of the receptor channel (Seeburg *et al.*, 2001; Schmauss and Howe, 2002). AMPA and kainate receptors mediate fast depolarization at most glutamatergic synapses in the brain and spinal cord. NMDA receptors also are involved in normal synaptic transmission, but activation of NMDA receptors is associated more closely with the induction of various forms of synaptic plasticity rather than with fast point-to-point signaling in the brain. AMPA or kainate receptors and

NMDA receptors may be co-localized at many glutamatergic synapses. A well-characterized phenomenon involving NMDA receptors is the induction of long-term potentiation (LTP). LTP refers to a prolonged (hours to days) increase in the size of a postsynaptic response to a presynaptic stimulus of given strength. Activation of NMDA receptors is obligatory for the induction of one type of LTP that occurs in the hippocampus. NMDA receptors normally are blocked by Mg²⁺ at resting membrane potentials. Thus, activation of NMDA receptors requires not only binding of synaptically released glutamate, but simultaneous depolarization of the postsynaptic membrane. This is achieved by activation of AMPA/kainate receptors at nearby synapses by inputs from different neurons. AMPA receptors also are dynamically regulated to affect their sensitivity to the synergism with NMDA. Thus, NMDA receptors may function as coincidence detectors, being activated only when there is simultaneous firing of two or more neurons. Interestingly, NMDA receptors also can induce long-term depression (LTD; the converse of LTP) at CNS synapses. Apparently the frequency and pattern of synaptic stimulation dictates whether a synapse undergoes LTP or LTD (Nessler *et al.*, 2001; Cooper *et al.*, 2003).

Glutamate Excitotoxicity. High concentrations of glutamate produce neuronal cell death by mechanisms that have only recently begun to be clarified. Initially, the cascade of events leading to neuronal death was thought to be triggered exclusively by excessive activation of NMDA or AMPA/kainate receptors, allowing significant influx of Ca²⁺ into the neurons. Such glutamate neurotoxicity was thought to underlie the damage that occurs after ischemia or hypoglycemia in the brain, during which a massive release and impaired reuptake of glutamate in the synapse would lead to excess stimulation of glutamate receptors and subsequent cell death. Although NMDA receptor antagonists can attenuate neuronal cell death induced by activation of these receptors (Herrling, 1997), even the most potent antagonists cannot prevent all such damage, causing additional efforts to salvage the therapeutic potential for glutamate antagonists as neuroprotectants. More recent studies (Gillessen *et al.*, 2002; Frandsen and Schousboe, 2003) implicate both local depletion of Na⁺ and K⁺, as well as small but significant elevations of extracellular Zn²⁺ as factors that can activate both necrotic and pro-apoptotic cascades, leading to neuronal death.

Because of the widespread distribution of glutamate receptors in the CNS, they have become targets for diverse therapeutic interventions. For example, a role for disordered glutamatergic transmission in the etiology of chronic neurodegenerative diseases and in schizophrenia has been postulated (*see* Chapters 18 and 20).

Acetylcholine. After acetylcholine (ACh) was identified as the transmitter at neuromuscular and parasympathetic neuroeffector junctions, and at the major synapse of autonomic ganglia (*see* Chapter 6), the amine began to receive considerable attention as a potential central neurotransmitter. Based on its irregular distribution within the CNS and the observation that peripheral cholinergic drugs could produce marked behavioral effects after central administration, many investigators addressed the possibility that ACh also might be a central neurotransmitter. In the late 1950s, Eccles and colleagues satisfied the experimental criteria to identify ACh as a neurotransmitter for the excitation of spinal cord Renshaw interneurons by the recurrent axon collaterals of spinal motoneurons. Subsequently, the capacity of ACh to elicit neuronal

discharge has been replicated on scores of CNS cells (*see* Shepherd, 2003, for more recent references).

In most regions of the CNS, the effects of ACh, assessed either by iontophoresis or by radioligand binding assays, appear to be generated by interaction with a mixture of nicotinic and muscarinic receptors. Several presumptive cholinergic pathways have been proposed in addition to that of the motoneuron-Renshaw cell. By a combination of immunocytochemistry of choline acetyltransferase (ChAT; the enzyme that synthesizes ACh) and ligand binding, or *in situ* hybridization studies for the detection of neurons expressing subunits of nicotinic and muscarinic receptors, eight major clusters of ACh neurons and their pathways have been characterized (Nestler *et al.*, 2001; Cooper *et al.*, 2003; Shepherd, 2003).

Catecholamines. The brain contains separate neuronal systems that utilize three different catecholamines—dopamine, norepinephrine, and epinephrine. Each system is anatomically distinct and serves separate, but similar, functional roles within its field of innervation (*see* Nestler *et al.*, 2001; Cooper *et al.*, 2003; Shepherd, 2003, for additional details).

Dopamine. Although dopamine (DA) originally was regarded only as a precursor of norepinephrine, assays of distinct regions of the CNS revealed that the distributions of dopamine and norepinephrine are markedly different. In fact, more than half the CNS content of catecholamine is dopamine, and extremely large amounts are found in the basal ganglia (especially the caudate nucleus), the nucleus accumbens, the olfactory tubercle, the central nucleus of the amygdala, the median eminence, and restricted fields of the frontal cortex. Of these myriad connections, most attention has been directed to the long projections between the major dopamine-containing nuclei in the substantia nigra and ventral tegmentum and their targets in the striatum, in the limbic zones of the cerebral cortex, and in other major limbic regions (but in general not to the hippocampus). At the cellular level, the actions of dopamine depend on receptor subtype expression and the contingent convergent actions of other transmitters to the same target neurons.

Initial pharmacological studies discriminated between two subtypes of dopamine receptors: D₁ (which couples to G_S and adenylyl cyclase) and D₂ (which couples to G_I to inhibit adenylyl cyclase). Subsequent cloning studies identified three additional genes encoding subtypes of dopamine receptors: one resembling the D₁ receptor, D₃; and two resembling the D₂ receptor, D₃ and D₄, as well as two isoforms of the D₂ receptor that differ in the predicted length of their third intracellular loops, D₂ short (D_{2S}) and D₂ long (D_{2L}) (Nestler *et al.*, 2001; Cooper *et al.*, 2003). The D₁ and D₅ receptors activate adenylyl cyclase. The D₂ receptors couple to multiple effector systems, including the inhibition of adenylyl cyclase activity, suppression of Ca²⁺ currents, and activation of K⁺ currents. The effector systems to which the D₃ and D₄ receptors couple have not been unequivocally defined (Greengard, 2001). Dopamine receptors have been implicated in the pathophysiology of schizophrenia and Parkinson's disease (*see* Chapters 18 and 20).

Norepinephrine. There are relatively large amounts of norepinephrine within the hypothalamus and in certain zones of the limbic system, such as the central nucleus of the amygdala and the dentate gyrus of the hippocampus. However, this catecholamine also is present in significant, although lower, amounts in most brain regions. Detailed mapping studies indicate that noradrenergic neurons of the locus ceruleus innervate specific target cells in a large

number of cortical, subcortical, and spinomedullary fields (Nestler *et al.*, 2001; Cooper *et al.*, 2003). Although norepinephrine has been firmly established as the transmitter at synapses between presumptive noradrenergic pathways and a wide variety of target neurons, a number of features of the mode of action of this biogenic amine have complicated the acquisition of convincing evidence. These problems largely reflect its “nonclassical” electrophysiological synaptic actions, which result in “state-dependent” or “enabling” effects. For example, stimulation of the locus ceruleus depresses the spontaneous activity of target neurons in the cerebellum; this is associated with a slowly developing hyperpolarization and a decrease in membrane conductance. However, activation of the locus ceruleus enhances the higher firing rates produced by stimulation of excitatory inputs to these neurons to a lesser degree, and excitatory postsynaptic potentials are enhanced. All consequences of activation of the locus ceruleus are mimicked by iontophoretic application of norepinephrine and are effectively blocked by α adrenergic antagonists. Although the mechanisms underlying these effects are obscure, there is convincing evidence for intracellular mediation by cyclic AMP (for additional references, *see* Aston-Jones *et al.*, 2001; Nestler *et al.*, 2001; Cooper *et al.*, 2003).

Three types of adrenergic receptors (α_1 , α_2 , and β) and their subtypes have been described in the CNS; all are GPCRs. As in the periphery, these central subtypes can be similarly distinguished in terms of their pharmacological properties and their distribution (*see* Chapter 10 for details). The β adrenergic receptors are coupled to stimulation of adenylyl cyclase activity. The α_1 adrenergic receptors are associated predominantly with neurons, while α_2 adrenergic receptors are more characteristic of glial and vascular elements. The α_1 receptors couple to G_q to stimulate phospholipase C. The α_1 receptors on noradrenergic target neurons of the neocortex and thalamus respond to norepinephrine with prazosin-sensitive, depolarizing responses due to decreases in K⁺ conductances (both voltage-sensitive and voltage-insensitive). However, stimulation of α_1 receptors also can augment cyclic AMP accumulation in neocortical slices in response to vasoactive intestinal polypeptide, possibly an example of G_q-G_S cross-talk involving Ca²⁺/calmodulin and/or PKC (Ostrom *et al.*, 2003). α_2 Adrenergic receptors are prominent on noradrenergic neurons, where they presumably couple to G_i, inhibit adenylyl cyclase, and mediate a hyperpolarizing response due to enhancement of an inwardly rectifying K⁺ channel. In cortical projection fields, α_2 receptors may help restore functional declines of senescence. Until functional roles are better defined among these receptor subtypes, studies of knockout mice lacking these receptors may be revealing (MacMillan *et al.*, 1998).

Epinephrine. Neurons in the CNS that contain epinephrine were recognized only after the development of sensitive enzymatic assays and immunocytochemical staining techniques for phenylethanolamine-N-methyltransferase. Epinephrine-containing neurons are found in the medullary reticular formation and make restricted connections to a few pontine and diencephalic nuclei, eventually coursing as far rostrally as the paraventricular nucleus of the dorsal midline thalamus. Their physiological properties have not been identified.

5-Hydroxytryptamine. Following the chemical determination that a biogenic substance found both in serum (“serotonin”) and in gut (“enteramine”) was 5-hydroxytryptamine (5-HT), assays for this substance revealed its presence in brain (*see* Chapter 11). Subsequent studies of 5-HT have provided pivotal advances in our understand-

ing of the neuropharmacology of the CNS. In mammals, 5-hydroxytryptaminergic neurons are found in nine nuclei lying in or adjacent to the midline (raphe) regions of the pons and upper brainstem.

In the mammalian CNS, cells receiving cytochemically demonstrable 5-HT input, such as the suprachiasmatic nucleus, ventrolateral geniculate body, amygdala, and hippocampus, exhibit a uniform and dense investment of reactive terminals.

Molecular biological approaches have led to identification of 14 distinct mammalian 5-HT receptor subtypes (see Chapter 11 for details). These subtypes exhibit characteristic ligand-binding profiles, couple to different intracellular signaling systems, exhibit subtype-specific distributions within the CNS, and mediate distinct behavioral effects of 5-HT. The 5-HT receptors fall into four broad classes: the 5-HT₁ and 5-HT₂ classes both are GPCRs and include multiple isoforms within each class; the 5-HT₃ receptor is a ligand-gated ion channel with structural similarity to the α subunit of the nicotinic acetylcholine receptor. Similarly to some glutamate receptors, mRNA editing has also been observed for the 5-HT_{2C} subtype (Niswender *et al.*, 2001). Members of the 5-HT₄, 5-HT₅, 5-HT₆, and 5-HT₇ classes all are GPCRs, but have not yet been fully studied electrophysiologically or operationally in the CNS.

The 5-HT₁ receptor subset is composed of at least five receptor subtypes (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F}) that are linked to inhibition of adenylyl cyclase activity or to regulation of K⁺ or Ca²⁺ channels. As an example of the potency and complexity of serotonergic neurotransmission, the 5-HT_{1A} receptors are abundantly expressed on 5-HT neurons of the dorsal raphe nucleus, where they are thought to be involved in temperature regulation. They also are found in regions of the CNS associated with mood and anxiety such as the hippocampus and amygdala. Activation of 5-HT_{1A} receptors opens an inwardly rectifying K⁺ conductance, which leads to hyperpolarization and neuronal inhibition. These receptors can be activated by the drugs buspirone and ipsapirone, which are used to treat anxiety and panic disorders (see Chapter 17). In contrast, 5-HT_{1D} receptors are potently activated by the drug sumatriptan, which is currently prescribed for acute management of migraine headaches (see Chapters 11 and 21).

The 5-HT₂ receptor class has three subtypes: 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C}; these receptors couple to pertussis toxin-insensitive G proteins (*e.g.*, G_q and G₁₁) and link to activation of phospholipase C. Based on ligand binding and mRNA *in situ* hybridization patterns, 5-HT_{2A} receptors are enriched in forebrain regions such as the neocortex and olfactory tubercle, as well as in several nuclei arising from the brainstem. The 5-HT_{2C} receptor, which is very similar in sequence and pharmacology to the 5-HT_{2A} receptor, is expressed abundantly in the choroid plexus, where it may modulate cerebrospinal fluid production (see Chapter 11).

The 5-HT₃ receptors function as ligand-gated ion channels; these receptors were first recognized in the peripheral autonomic nervous system. Within the CNS, they are expressed in the area postrema and solitary tract nucleus, where they couple to potent depolarizing responses that show rapid desensitization to continued 5-HT exposure. Actions of 5-HT at central 5-HT₃ receptors can lead to emesis and antinociceptive actions, and 5-HT₃ antagonists are beneficial in the management of chemotherapy-induced emesis (see Chapter 37).

Within the CNS, 5-HT₄ receptors occur on neurons within the inferior and superior colliculi and in the hippocampus. Activation of 5-HT₄ receptors stimulates the G_s-adenylyl cyclase-cyclic AMP pathway. Other 5-HT receptors are less well studied in the CNS.

The 5-HT₆ and 5-HT₇ receptors also couple to G_s-adenylyl cyclase; their affinity for clozapine may relate to its antipsychotic efficacy (see Chapters 11 and 18). Of the two subtypes of 5-HT₅ receptors, the 5-HT_{5A} receptor seems to inhibit cyclic AMP synthesis, while 5-HT_{5B} receptor-effector coupling has not been described.

The hallucinogen lysergic acid diethylamide (LSD) interacts with 5-HT, primarily through 5-HT₂ receptors. When applied iontophoretically, LSD and 5-HT both potently inhibit the firing of raphe (5-HT) neurons, whereas LSD and other hallucinogens are far more potent excitants on facial motoneurons that receive innervation from the raphe. The inhibitory effect of LSD on raphe neurons offers a plausible explanation for its hallucinogenic effects, namely that these effects result from depression of activity in a system that tonically inhibits visual and other sensory inputs. However, typical LSD-induced behavior is still seen in animals with destroyed raphe nuclei or after blockade of the synthesis of 5-HT by *p*-chlorophenylalanine (Aghajanian and Marek, 1999).

Histamine. For many years, histamine and antihistamines that are active in the periphery have been known to produce significant effects on animal behavior. Recent evidence suggests that histamine also may be a central neurotransmitter. Biochemical detection of histamine synthesis by neurons and direct cytochemical localization of these neurons have defined a histaminergic system in the CNS. Most of these neurons are located in the ventral posterior hypothalamus; they give rise to long ascending and descending tracts to the entire CNS that are typical of the patterns characteristic of other aminergic systems. Based on the presumptive central effects of histamine antagonists, the histaminergic system is thought to regulate arousal, body temperature, and vascular dynamics.

Four subtypes of histamine receptors have been described; all are GPCRs. H₁ receptors, the most prominent, are located on glia and vessels as well as on neurons and act to mobilize Ca²⁺ in receptive cells through the G_q-PLC pathway. H₂ receptors couple *via* G_s to the activation of adenylyl cyclase, perhaps in concert with H₁ receptors in certain circumstances. H₃ receptors, which have the greatest sensitivity to histamine, are localized selectively in basal ganglia and olfactory regions in the rat; consequences of H₃ receptor activation remain unresolved but may include reduced Ca²⁺ influx and feedback inhibition of transmitter synthesis and release (see Chapter 24). The expression of H₄ receptors is confined to cells of hematopoietic origin: eosinophils, T cells, mast cells, basophils, and dendritic cells. H₄ receptors appear to couple to G_{i/o} and G_q, and are postulated to play a role in inflammation and chemotaxis (see Chapter 24 and Thurmond *et al.*, 2004). Unlike the monoamines and amino acid transmitters, there does not appear to be an active process for histamine after its release. In addition, no direct evidence had been obtained for release of histamine from neurons either *in vivo* or *in vitro* (Schwartz *et al.*, 1994) until recently (Yoshitake *et al.*, 2003).

Peptides. The discovery during the 1980s of numerous novel peptides in the CNS, each capable of regulating neural function, produced considerable excitement and an imposing catalog of entities as well as potential medications based

upon their receptors (Darlison and Richter, 1999; Hökfelt *et al.*, 2003). In addition, certain peptides previously thought to be restricted to the gut or to endocrine glands also have been found in the CNS. Relatively detailed neuronal maps are available that show immunoreactivity to peptide-specific antisera. While some CNS peptides may function on their own, most are now thought to act mainly in concert with coexisting transmitters, both amines and amino acids. As noted above, some neurons may contain two or more transmitters, and their release can be independently regulated. Listed below are several approaches that have utility in analyzing the expanding systems of peptidergic neurons.

Organization by Peptide Families. Because of significant homology in amino acid sequences, families of related molecules can be defined as either *ancestral* or *concurrent*. The ancestral relationship is illustrated by peptides such as the tachykinin or the vasotocin (vasopressin/oxytocin) family, in which species' differences can be correlated with modest variations in peptide structure. The concurrent relationship is best exemplified by the endorphins and by the glucagon-secretin family. In the endorphin superfamily, three major systems of endorphin peptides (pro-opiomelanocortin, proenkephalin, and prodynorphin) and at least two populations of minor opioid peptides (the endomorphins and the orphanin/nociceptin peptide) exist in independent neuronal circuits (Cooper *et al.*, 2003, for review). These natural opioid peptides arise from independent but homologous genes. The peptides all share some actions at receptors once classified generally as "opioid," but now are undergoing progressive refinement (*see* Chapter 21). In the glucagon family, multiple and somewhat homologous peptides are found simultaneously in different cells of separate organ systems: glucagon and vasoactive intestinal polypeptide (VIP) in pancreatic islets; secretin in duodenal mucosa; VIP and related peptides in enteric, autonomic, and central neurons (Magistretti *et al.*, 1999); and growth hormone-releasing hormone only in central neurons (Guillemin *et al.*, 1984). The general metabolic effects produced by this family can be viewed as leading to increased blood glucose. To some degree, ancestral and concurrent relationships are not mutually exclusive. For example, multiple members of the tachykinin/substance P family within mammalian brains and intestines may account for the apparent existence of subsets of receptors for these peptides. The mammalian terminus of the vasotocin family also shows two concurrent products, vasopressin and oxytocin, each having evolved to perform separate functions once executed by single vasotocin-related peptides in lower phyla.

Organization by Anatomic Pattern. Some peptide systems follow rather consistent anatomical organizations. Thus, the hypothalamic peptides oxytocin, vasopressin, pro-opiomelanocortin, gonadotropin-releasing hormone, and growth hormone-releasing hormone all tend to be synthesized by single large clusters of neurons that give off multibranched axons to several distant targets. Other peptides, such as somatostatin, cholecystokinin, and enkephalin, can have patterns varying from moderately long hierarchical connections to short-axon, local-circuit neurons that are widely distributed throughout the brain (*see* 10th edition of this volume for earlier references).

Organization by Function. Since almost all peptides were identified initially on the basis of bioassays, their names reflect these biologically assayed functions (*e.g.*, thyrotropin-releasing hormone and vasoactive intestinal polypeptide). These names become trivial if more ubiquitous distributions and additional functions are discovered.

Some general integrative role might be hypothesized for widely separated neurons (and other cells) that make the same peptide. However, a more parsimonious view is that each peptide has unique messenger roles at the cellular level that are used repeatedly in functionally similar pathways within functionally distinct systems. The cloning of the major members of the opioid-peptide receptors revealed unexpected, and as yet unexplained, homology with receptors for somatostatin, angiotensin, and other peptides. For example, open-system methods of peptide-encoding brain mRNAs have yielded unexpected members of the somatostatin and secretin families (Sutcliffe, 2001).

Comparison with Other Transmitters. Peptides differ in several important respects from the monoamine and amino acid transmitters considered earlier. Peptide synthesis is performed in the rough endoplasmic reticulum. The propeptide is cleaved (processed) to the secreted form as secretory vesicles are transported from the perinuclear cytoplasm to the nerve terminals. Furthermore, no active mechanisms for peptides have been described. This increases the dependency of peptidergic nerve terminals on distant sites of synthesis. Perhaps most importantly, linear chains of amino acids can assume many conformations at their receptors, making it difficult to define the sequences and their steric relationships that are critical for activity.

Until recently, it has been difficult to develop nonpeptidic synthetic agonists or antagonists that interact with specific peptide receptors. Such agents now are being developed for many neuropeptides (Hökfelt *et al.*, 2003). Nature also has had limited success in this regard, since only one plant alkaloid, morphine, has been found to act selectively at peptidergic synapses. Fortunately for pharmacologists, morphine was discovered before the endorphins, or rigid molecules capable of acting at peptide receptors might have been deemed impossible to develop.

Other Regulatory Substances. In addition to these major families of neurotransmitters, other endogenous substances also may participate in the regulated flow of signals between neurons, but in sequences of events that differ somewhat from the conventional concepts of neurotransmitter function. These substances have significant potential as regulatory factors and as targets for future drug development.

Purines. Adenosine and uridine di- and triphosphates have roles as extracellular signaling molecules (Edwards and Robertson, 1999; Robertson *et al.*, 2001). ATP is a component of the adrenergic storage vesicle and is released with catecholamines. Intracellular nucleotides may also reach the cell surface by other means (Lazarowski *et al.*, 2003a), and extracellular adenosine can result from cellular release or extracellular production from adenine nucleotides (Jackson and Raghvendra, 2004). These extracellular nucleotides and adenosine act on a family of purinergic receptors that is divided into two classes, P1 and P2. The P1 receptors are GPCRs that interact with adenosine; two of these receptors (A_1 and A_3) couple to G_i and two (A_{2a} and A_{2b}) couple to G_s ; methylxanthines antagonize A_1 and A_3 receptors (*see* Chapter 27). Activation of A_1 receptors is associated with inhibition of adenylyl cyclase, activation of K^+ currents, and in some instances, with activation of PLC; stimulation of A_2 receptors activates adenylyl cyclase. The P2 class consists of a large number of P2X receptors that are ligand-gated ion channels, and of the P2Y receptors, a large subclass of GPCRs that couple to G_q or G_s and their associated effectors. The P2Y₁₄ receptor is expressed in the CNS; it interacts with UDP-glucose and may couple to G_q (Chambers *et al.*, 2000; Lazarowski *et al.*, 2003b). The co-storage of ATP and catecholamines in adrenergic

storage vesicles and their co-release from adrenergic nerves suggests that P2Y receptors in the synaptic region will be stimulated whenever a nerve releases catecholamine. There is *in vitro* evidence for synergistic $G_q \rightarrow G_s$ crosstalk (enhanced β adrenergic response) when β_2 receptors and G_q -linked P2Y receptors are activated simultaneously (Meszaros *et al.*, 2000).

Although many of these receptors can be detected in brain, most of the current interest stems from pharmacological rather than physiological observations. Adenosine can act presynaptically throughout the cortex and hippocampal formation to inhibit the release of amine and amino acid transmitters. ATP-regulated responses have been linked pharmacologically to a variety of supracellular functions, including anxiety, stroke, and epilepsy.

Diffusible Mediators. Certain physiological regulators in systems throughout the body recently have been examined for their roles within the CNS.

Arachidonic acid, normally stored within the cell membrane as a glycerol ester, can be liberated during phospholipid hydrolysis (by pathways involving phospholipases A₂, C, and D). Phospholipases are activated by a variety of receptors (*see* Chapter 1). Arachidonic acid can be converted to highly reactive regulators by three major enzymatic pathways (*see* Chapter 25): cyclooxygenases (leading to *prostaglandins* and *thromboxanes*), lipoxygenases (leading to the *leukotrienes* and other transient catabolites of eicosatetraenoic acid), and CYPs (which are inducible and also expressed at low levels in brain). Arachidonic acid metabolites have been implicated as diffusible modulators in the CNS, particularly for LTP and other forms of plasticity (De Petrocellis *et al.*, 2004).

Nitric oxide (NO) has been recognized as an important regulator of vascular and inflammatory mediation for more than a decade, but came into focus with respect to roles in the CNS after successful efforts to characterize brain nitric oxide synthases (NOS; *see* Boehning and Snyder, 2003). Both constitutive and inducible forms of NOS are expressed in the brain. The availability of potent inhibitors of NOS (such as methyl arginine and nitroarginine) and of NO donors (such as nitroprusside) has led to reports of the presumptive involvement of nitric oxide in a host of CNS phenomena, including LTP, activation of the soluble guanylyl cyclase, neurotransmitter release, and enhancement of glutamate (NMDA)-mediated neurotoxicity. Subsequently, rational analysis based on proposed mechanisms of NO action through binding to the iron in the active site of target enzymes led to the idea that carbon monoxide (CO) may be a second gaseous, labile, diffusible intercellular regulator, at least in the regulation of the soluble guanylyl cyclase in cultured neurons.

Cytokines. The term *cytokines* encompasses a large and diverse family of polypeptide regulators that are produced widely throughout the body by cells of diverse embryological origin. The effects of cytokines are known to be regulated by the conditions imposed by other cytokines, interacting as a network with variable effects leading to synergistic, additive, or opposing actions. Tissue-produced peptidic factors termed *chemokines* serve to attract cells of the immune and inflammatory lines into interstitial spaces. These special cytokines have received much attention as potential regulators in nervous system inflammation (as in early stages of dementia, following infection with human immunodeficiency virus, and during recovery from traumatic injury). The more conventional neuronal and glial-derived growth-enhancing and growth-retardant factors were mentioned above. The fact that neurons and astrocytes may be induced under some pathophysiological conditions to express cytokines or other growth factors further blurs the dividing line between neurons and glia (Wang *et al.*, 2002; Campbell, 2004).

ACTIONS OF DRUGS IN THE CNS

Specificity and Nonspecificity of CNS Drug Actions. The effect of a drug is considered to be specific in the CNS when it affects an identifiable molecular mechanism unique to target cells that bear receptors for that drug. Conversely, a drug is regarded as nonspecific when it produces effects on many different target cells and acts by diverse molecular mechanisms. This distinction often is a property of the dose-response relationship of the drug and the cell or mechanisms under scrutiny (*see* Chapters 1 and 5). Even a drug that is highly specific when tested at a low concentration may exhibit nonspecific actions at higher doses. Conversely, even generally acting drugs may not act equally on all levels of the CNS. For example, sedatives, hypnotics, and general anesthetics would have very limited utility if central neurons that control the respiratory and cardiovascular systems were especially sensitive to their actions. Drugs with specific actions may produce nonspecific effects if the dose and route of administration produce high tissue concentrations.

Drugs whose mechanisms currently appear to be primarily general or nonspecific are classed according to whether they produce behavioral depression or stimulation. Specifically acting CNS drugs can be classed more definitively according to their locus of action or specific therapeutic usefulness. The absence of overt behavioral effects does not rule out the existence of important central actions for a given drug. For example, the impact of muscarinic cholinergic antagonists on the behavior of normal animals may be subtle, but these agents are used extensively in the treatment of movement disorders and motion sickness (*see* Chapter 7).

General (Nonspecific) CNS Depressants. This category includes the anesthetic gases and vapors, the aliphatic alcohols, and some hypnotic-sedative drugs. These agents share the capacity to depress excitable tissue at all levels of the CNS, leading to a decrease in the amount of transmitter released by the nerve impulse, as well as to general depression of postsynaptic responsiveness and ion movement. At subanesthetic concentrations, these agents (*e.g.*, ethanol) can exert relatively specific effects on certain groups of neurons, which may account for differences in their behavioral effects, especially the propensity to produce dependence (*see* Chapters 13, 16, and 22).

General (Nonspecific) CNS Stimulants. The drugs in this category include pentylentetrazol and related agents that are capable of powerful excitation of the CNS, and the methylxanthines, which have a much weaker stimulant action. Stimulation may be accomplished by one of two general mechanisms: (1) by blockade of inhibition or (2) by direct neuronal excitation (which may involve increased transmitter release, more prolonged transmitter action, labilization of the postsynaptic membrane, or decreased synaptic recovery time).

Drugs That Selectively Modify CNS Function. The agents in this group may cause either depression or excitation. In some instances, a drug may produce both effects simultaneously on different sys-

tems. Some agents in this category have little effect on the level of excitability in doses that are used therapeutically. The principal classes of these CNS drugs are: anticonvulsants, drugs used in treating Parkinson's disease, opioid and nonopioid analgesics, appetite suppressants, antiemetics, analgesic-antipyretics, certain stimulants, neuroleptics (antidepressants and antimanic and antipsychotic agents), tranquilizers, sedatives, and hypnotics. Although not yet a broad class, medications employed in the treatment of Alzheimer's disease (cholinesterase inhibitors and antiglutamate neuroprotectants) and compounds promising in the symptomatic treatment of Huntington's disease (tetraabenazine for the depletion of monoamines and reduction in tremor) also may be included.

Although selectivity of action may be remarkable, a drug usually affects several CNS functions to varying degrees. When only one constellation of effects is wanted in a therapeutic situation, the remaining effects of the drug are regarded as limitations in selectivity (*i.e.*, unwanted side effects). The specificity of a drug's action frequently is overestimated. This is partly due to the fact that the drug is identified with the effect that is implied by the class name.

General Characteristics of CNS Drugs. Combinations of centrally acting drugs frequently are administered to therapeutic advantage (*e.g.*, an anticholinergic drug and levodopa for Parkinson's disease). However, other combinations of drugs may be detrimental because of potentially dangerous additive or mutually antagonistic effects.

The effect of a CNS drug is additive with the physiological state and with the effects of other depressant and stimulant drugs. For example, anesthetics are less effective in a hyperexcitable subject than in a normal patient; the converse is true for stimulants. In general, the depressant effects of drugs from all categories are additive (*e.g.*, the fatal combination of barbiturates or benzodiazepines with ethanol), as are the effects of stimulants. Therefore, respiration depressed by morphine is further impaired by depressant drugs, while stimulant drugs can augment the excitatory effects of morphine to produce vomiting and convulsions.

Antagonism between depressants and stimulants is variable. Some instances of true pharmacological antagonism among CNS drugs are known; for example, opioid antagonists are very selective in blocking the effects of opioid analgesics. However, the antagonism exhibited between two CNS drugs is usually physiological in nature. For example, an individual whose CNS is depressed by an opiate cannot be returned entirely to normal by stimulation by caffeine.

The selective effects of drugs on specific neurotransmitter systems may be additive or competitive. This potential for drug interaction must be considered whenever such drugs are administered concurrently. To minimize such interactions, a drug-free period may be required when modifying therapy, and development of desensitized and supersensitive states with prolonged therapy may limit the speed with which one drug may be halted and another started. An excitatory effect is commonly observed with low concentrations of certain

depressant drugs due either to depression of inhibitory systems or to a transient increase in the release of excitatory transmitters. Examples are the stage of excitement during induction of general anesthesia and the stimulant effects of alcohol. The excitatory phase occurs only with low concentrations of the depressant; uniform depression ensues with increasing drug concentration. The excitatory effects can be minimized, when appropriate, by pretreatment with a depressant drug that is devoid of such effects (*e.g.*, benzodiazepines in preanesthetic medication). Acute, excessive stimulation of the cerebrospinal axis normally is followed by depression, which is in part a consequence of neuronal fatigue and exhaustion of stores of transmitters. Postictal depression is additive with the effects of depressant drugs. Acute, drug-induced depression generally is not followed by stimulation. However, chronic drug-induced sedation or depression may be followed by prolonged hyperexcitability upon abrupt withdrawal of the medication (barbiturates or alcohol). This type of hyperexcitability can be controlled effectively by the same or another depressant drug (*see* Chapters 16, 17, and 18).

Organization of CNS–Drug Interactions. The structural and functional properties of neurons provide a means to specify the possible sites at which drugs could interact, specifically or generally, in the CNS (Figure 12–1). In this scheme, drugs that affect neuronal energy metabolism, membrane integrity, or transmembrane ionic equilibria would be generally acting compounds. Similarly general in action would be drugs (*e.g.*, colchicine) that affect the two-way intracellular transport systems. These general effects still can exhibit different dose–response or time–response relationships, based, for example, on such neuronal properties as rate of firing, dependence of discharge on external stimuli or internal pacemakers, resting ionic fluxes, or axon length. In contrast, when drug actions can be related to specific aspects of the metabolism, release, or function of a neurotransmitter, the site, specificity, and mechanism of action of a drug can be defined by systematic studies of dose–response and time–response relationships. From such data, the most sensitive, rapid, or persistent neuronal event can be identified.

Transmitter-dependent actions of drugs can be grouped into presynaptic and postsynaptic categories. The presynaptic category includes all of the events in the perikaryon and nerve terminal that regulate transmitter synthesis (including the acquisition of adequate substrates and cofactors), storage, release, and metabolism. Transmitter concentrations can be lowered by blockade of synthesis, storage, or both. The amount of transmitter released per impulse generally is stable but also can be regulated. The effective concentration of transmitter may be increased by

inhibition of or by blockade of metabolic enzymes. The transmitter that is released at a synapse also can exert actions on the terminal from which it was released by interacting with receptors at these sites (termed *autoreceptors*; see above). Activation of presynaptic autoreceptors can slow the rate of discharge of transmitter and thereby provide a feedback mechanism that controls the concentration of transmitter in the synaptic cleft.

The postsynaptic category includes all the events that follow release of the transmitter in the vicinity of the postsynaptic receptor. Examples include the molecular mechanisms by which receptor occupancy alters the properties of the membrane of the postsynaptic cell (shifts in membrane potential), as well as more enduring biochemical actions (e.g., changes in second messenger concentrations, protein kinase and phosphatase activities, and phosphoprotein formation). Direct postsynaptic effects of drugs generally require relatively high affinity for the receptors or resistance to metabolic degradation. Each of these presynaptic or postsynaptic actions potentially is highly specific and can be envisioned as restricted to a single, chemically defined subset of CNS cells.

Convergence, Synergism, and Antagonism Result from Transmitter Interactions. Although the power of the reductionist approach to clone cDNAs for receptors or receptor subunits and to determine their properties by expression in cells that do not normally express the receptor or subunit cannot be underestimated, *the simplicity of cell culture models of this type may divert attention from the complexity of the intact CNS.* A given neurotransmitter may interact simultaneously with all of the various isoforms of its receptor on neurons that also are under the influence of multiple other afferent pathways and their transmitters. Thus, attempts to predict the behavioral or therapeutic consequences of drugs designed to elicit precise and restricted receptor actions in simple model systems may fail as a consequence of the complexity of the interactions possible, including differences between normal and diseased tissue.

GENERAL ANESTHETICS

Alex S. Evers, C. Michael Crowder, and Jeffrey R. Balsler

General anesthetics depress the central nervous system to a sufficient degree to permit the performance of surgery and other noxious or unpleasant procedures. Not surprisingly, general anesthetics have low therapeutic indices and thus require great care in administration. While all general anesthetics produce a relatively similar anesthetic state, they are quite dissimilar in their secondary actions (side effects) on other organ systems. The selection of specific drugs and routes of administration to produce general anesthesia is based on their pharmacokinetic properties and on the secondary effects of the various drugs, in the context of the proposed diagnostic or surgical procedure and with the consideration of the individual patient's age, associated medical condition, and medication use. Anesthesiologists also employ sedatives (see Chapter 16), neuromuscular blocking agents (see Chapter 9), and local anesthetics (see Chapter 14) as the situation requires.

Before describing the general features of anesthesia, the basic principles that underlie anesthetic actions, and the specific properties of inhalational and intravenous anesthetics and the practical aspects of their use, it is sobering to recall the time, not so very long ago, when surgical anesthesia did not exist, and to be reminded of the development of this field since 1846.

Historical Perspectives. Although Crawford Long, a physician in rural Georgia, first used *ether* anesthesia in 1842, not until the first public demonstration in 1846 by William T.G. Morton, a Boston dentist and medical student, did general anesthesia achieve worldwide discovery, spawning a revolution in medical care. The operating room, now known as “the ether dome” where Gilbert Abbott underwent surgery in an unconscious state at the Massachusetts General Hospital, remains a memorial to this day. Although no longer used in modern practice,

ether was the ideal “first” anesthetic. Chemically, it is readily made in pure form and is relatively nontoxic to vital organs. A liquid at room temperature, it readily vaporizes, and as such is easy to administer. Unlike *nitrous oxide*, ether is potent, so it can produce anesthesia without diluting the oxygen in room air to hypoxic levels. Finally, ether does not greatly compromise respiration or circulation, crucial properties at a time when our understanding of human physiology and technical prowess did not allow for assisted respiration and circulation.

Chloroform was the next anesthetic to receive wide use. Introduced by the Scottish obstetrician James Simpson in 1847, it became quite popular, perhaps because its odor is more pleasant than that of ether. Other than this and its nonflammability, there was little to recommend it; the drug is a hepatotoxin and a severe cardiovascular depressant. Despite the relatively high incidence of intraoperative and postoperative death associated with the use of chloroform, it was championed, especially in Great Britain, for nearly 100 years.

It was at a stage show that Horace Wells, a dentist, noted that while under the influence of nitrous oxide, one of the participants injured himself yet felt no pain. The next day Wells, while breathing nitrous oxide, had one of his own teeth extracted painlessly by a colleague. Shortly thereafter, in 1845, Wells attempted to demonstrate his discovery at the Massachusetts General Hospital in Boston. Unfortunately the patient cried out during the operation, the demonstration was deemed a failure, and nitrous oxide fell into disuse until 1863 when Gardner Q. Colton, a showman, entrepreneur, and partially trained physician reintroduced the drug into American dental and surgical practice. In 1868, the coadministration of nitrous oxide and oxygen was described by Edmond Andrews, a Chicago surgeon, and soon thereafter the two gases became available in steel cylinders, greatly increasing their practical use.

The anesthetic properties of *cyclopropane* were accidentally discovered in 1929 when chemists were analyzing impurities in an isomer, propylene. After extensive clinical trials at the University of Wisconsin, the drug was introduced into practice; cyclopropane was perhaps the most widely used general anesthetic for the next 30 years. However, cyclopropane was flammable, indeed explosive, and with the increasing use of electronic equipment and electrocau-

tery, the need for a safe, nonflammable anesthetic was clear. Efforts by the British Research Council and by chemists at Imperial Chemical Industries were rewarded by the development of *halothane*, a nonflammable anesthetic agent that was introduced into clinical practice in 1956 and quickly became the dominant anesthetic. Most of the newer agents, which are halogenated alkanes and ethers, are modeled after halothane.

Although the desirability of an intravenous anesthetic agent must have been apparent to physicians early in the 20th century, the drugs at hand were few and unsatisfactory. The situation changed dramatically in 1935, when Lundy demonstrated the clinical usefulness of *thiopental*, a rapidly-acting thiobarbiturate. It originally was considered useful as a sole anesthetic agent, but the doses required resulted in serious depression of the circulatory, respiratory, and nervous systems. However, thiopental and other intravenous anesthetics now have become the most common agents for induction of general anesthesia.

GENERAL PRINCIPLES OF SURGICAL ANESTHESIA

Unlike the practice of every other branch of medicine, anesthesia is usually neither therapeutic nor diagnostic. The exceptions to this, such as treatment of status asthmaticus with halothane and intractable angina with epidural local anesthetics, should not obscure this critical point that permeates the training and practice of the specialty. Hence, administration of general anesthesia, as well as the development of new anesthetic agents and physiologic monitoring technology, has been driven by three general objectives:

1. *Minimizing the potentially deleterious direct and indirect effects of anesthetic agents and techniques.*
2. *Sustaining physiologic homeostasis during surgical procedures* that may involve major blood loss, tissue ischemia, reperfusion of ischemic tissue, fluid shifts, exposure to a cold environment, and impaired coagulation.
3. *Improving postoperative outcomes* by choosing techniques that block or treat components of the *surgical stress response*, which may lead to short- or long-term sequelae (Mangano *et al.*, 1996; Balser *et al.*, 1998).

Hemodynamic Effects of General Anesthesia. The most prominent physiological effect of anesthesia induction, associated with the majority of both intravenous and inhalational agents, is a decrease in systemic arterial blood pressure. The causes include direct vasodilation, myocardial depression or both, a blunting of baroreceptor control, and a generalized decrease in central sympathetic tone (Sellgren *et al.*, 1990). Agents vary in the magnitude of their specific effects (*see below*), but in all cases the hypotensive response is enhanced by underlying volume

depletion or preexisting myocardial dysfunction. Even anesthetics that show minimal hypotensive tendencies under normal conditions (*e.g.*, *etomidate* and *ketamine*) must be used with caution in trauma victims, in whom intravascular volume depletion is being compensated by intense sympathetic discharge. Smaller-than-normal anesthetic dosages are employed in patients presumed to be sensitive to hemodynamic effects of anesthetics.

Respiratory Effects of General Anesthesia. Airway maintenance is essential following induction of anesthesia, as nearly all general anesthetics reduce or eliminate both ventilatory drive and the reflexes that maintain airway patency. Therefore, ventilation generally must be assisted or controlled for at least some period during surgery. The gag reflex is lost, and the stimulus to cough is blunted. Lower esophageal sphincter tone also is reduced, so both passive and active regurgitation may occur. Endotracheal intubation was introduced by Kuhn in the early 1900s and has been a major reason for a decline in the number of aspiration deaths during general anesthesia. Muscle relaxation is valuable during the induction of general anesthesia where it facilitates management of the airway, including endotracheal intubation. Neuromuscular blocking agents commonly are used to effect such relaxation (*see Chapter 9*), reducing the risk of coughing or gagging during laryngoscopic-assisted instrumentation of the airway, and thus reducing the risk of aspiration prior to secure placement of an endotracheal tube. Alternatives to an endotracheal tube include a facemask and a laryngeal mask, an inflatable mask placed in the oropharynx forming a seal around the glottis. The choice of airway management is based on the type of procedure and characteristics of the patient.

Hypothermia. Patients commonly develop hypothermia (body temperature $<36^{\circ}\text{C}$) during surgery. The reasons for the hypothermia include low ambient temperature, exposed body cavities, cold intravenous fluids, altered thermoregulatory control, and reduced metabolic rate. General anesthetics lower the core temperature set point at which thermoregulatory vasoconstriction is activated to defend against heat loss. Furthermore, vasodilation produced by both general and regional anesthesia offsets cold-induced peripheral vasoconstriction, thereby redistributing heat from central to peripheral body compartments, leading to a decline in core temperature (Sessler, 2000). Metabolic rate and total body oxygen consumption decrease with general anesthesia by about 30%, reducing heat generation.

Even small drops in body temperatures may lead to an increase in perioperative morbidity, including cardiac complications (Frank *et al.*, 1997), wound infections

(Kurz *et al.*, 1996), and impaired coagulation. Prevention of hypothermia has emerged as a major goal of anesthetic care. Modalities to maintain normothermia include using warm intravenous fluids, heat exchangers in the anesthesia circuit, forced-warm-air covers, and new technology involving water-filled garments with microprocessor feedback control to a core temperature set point.

Nausea and Vomiting. Nausea and vomiting in the postoperative period continue to be significant problems following general anesthesia and are caused by an action of anesthetics on the chemoreceptor trigger zone and the brainstem vomiting center, which are modulated by serotonin (5-HT), histamine, acetylcholine, and dopamine. The 5-HT₃-receptor antagonist *ondansetron* (see Chapter 37) is very effective in suppressing nausea and vomiting. Common treatments also include *droperidol*, *metoclopramide*, *dexamethasone*, and avoidance of N₂O. The use of *propofol* as an induction agent and the nonsteroidal antiinflammatory drug *ketorolac* as a substitute for opioids may decrease the incidence and severity of postoperative nausea and vomiting.

Other Emergence and Postoperative Phenomena. The physiological changes accompanying emergence from general anesthesia can be profound. Hypertension and tachycardia are common as the sympathetic nervous system regains its tone and is enhanced by pain. Myocardial ischemia can appear or markedly worsen during emergence in patients with coronary artery disease. Emergence excitement occurs in 5% to 30% of patients and is characterized by tachycardia, restlessness, crying, moaning and thrashing, and various neurological signs. Postanesthesia shivering occurs frequently because of core hypothermia. A small dose of *meperidine* (12.5 mg) lowers the shivering trigger temperature and effectively stops the activity. The incidence of all of these emergence phenomena is greatly reduced when opioids are employed as part of the intraoperative regimen.

Airway obstruction may occur during the postoperative period because residual anesthetic effects continue to partially obtund consciousness and reflexes (especially in patients who normally snore or who have sleep apnea). Strong inspiratory efforts against a closed glottis can lead to negative-pressure pulmonary edema. Pulmonary function is reduced postoperatively following all types of anesthesia and surgery, and hypoxemia may occur. Hypertension can be prodigious, often requiring aggressive treatment.

Pain control can be complicated in the immediate postoperative period. The respiratory suppression associated with opioids can be problematic among postoperative patients who still have a substantial residual anesthetic

effect. Patients can alternate between screaming in apparent agony and being deeply somnolent with airway obstruction, all in a matter of moments. The nonsteroidal antiinflammatory agent *ketorolac* (30 to 60 mg intravenously) frequently is effective, and the development of injectable cyclooxygenase-2 inhibitors (see Chapter 26) holds promise for analgesia without respiratory depression. In addition, regional anesthetic techniques are an important part of a perioperative multimodal approach that employs local anesthetic wound infiltration; epidural, spinal, and plexus blocks; and nonsteroidal antiinflammatory drugs, opioids, α_2 adrenergic-receptor agonists, and NMDA-receptor antagonists. Patient-controlled administration of intravenous and epidural analgesics makes use of small, computerized pumps activated on demand but programmed with safety limits to prevent overdose. The agents used are opioids (frequently *morphine*) by the intravenous route, and opioid, local anesthetic, or both, by the epidural route. These techniques have revolutionized postoperative pain management, can be continued for hours or days, and promote ambulation and improved bowel function until oral pain medications are initiated.

ACTIONS AND MECHANISMS OF GENERAL ANESTHETICS

The Anesthetic State

General anesthetics are a structurally diverse class of drugs that produce a common end point—a behavioral state referred to as *general anesthesia*. In the broadest sense, general anesthesia can be defined as a global but reversible depression of central nervous system (CNS) function resulting in the loss of response to and perception of all external stimuli. While this definition is appealing in its simplicity, it is not useful for two reasons: First, it is inadequate because anesthesia is not simply a deafferented state; for example, amnesia is an important aspect of the anesthetic state. Second, not all general anesthetics produce identical patterns of deafferentation. Barbiturates, for example, are very effective at producing amnesia and loss of consciousness, but are not effective as analgesics.

An alternative way of defining the anesthetic state is to consider it as a collection of “component” changes in behavior or perception. The components of the anesthetic state include *amnesia*, *immobility* in response to noxious stimulation, *attenuation of autonomic responses* to noxious stimulation, *analgesia*, and *unconsciousness*. It is important to remember that general anesthesia is useful

Table 13–1*Properties of Inhalational Anesthetic Agents*

ANESTHETIC AGENT	MAC* (vol %)	MAC _{AWAKE} [†] (vol %)	EC ₅₀ [‡] FOR SUPPRESSION OF MEMORY (vol %)	VAPOR PRESSURE (mm Hg at 20°C)	PARTITION COEFFICIENT AT 37 °C			RECOVERED AS METABOLITES (%)
					Blood:Gas	Brain:Blood	Fat:Blood	
Halothane	0.75	0.41	—	243	2.3	2.9	51	20
Isoflurane	1.2	0.4	0.24	250	1.4	2.6	45	0.2
Enflurane	1.6	0.4	—	175	1.8	1.4	36	2.4
Sevoflurane	2	0.6	—	160	0.65	1.7	48	3
Desflurane	6	2.4	—	664	0.45	1.3	27	0.02
Nitrous oxide	105	60.0	52.5	Gas	0.47	1.1	2.3	0.004
Xenon	71	32.6	—	Gas	0.12	—	—	0

*MAC (minimum alveolar concentration) values are expressed as vol %, the percentage of the atmosphere that is anesthetic. A value of MAC greater than 100% means that hyperbaric conditions would be required. [†]MAC_{awake} is the concentration at which appropriate responses to commands are lost.

[‡]EC₅₀ is the concentration that produces memory suppression in 50% of patients. —, Not available.

only insofar as it facilitates the performance of surgery or other noxious procedures. The performance of surgery usually requires an immobilized patient who does not have an excessive autonomic response to surgery (blood pressure and heart rate) and who has amnesia for the procedure. Thus, the essential components of the anesthetic state are immobilization, amnesia, and attenuation of autonomic responses to noxious stimulation. Indeed, if an anesthetic produces profound amnesia, it can be difficult in principle to determine if it also produces either analgesia or unconsciousness.

Measurement of Anesthetic Potency

Given the essential requirement that a general anesthetic agent provide an immobilized patient, the potency of general anesthetic agents usually is measured by determining the concentration of general anesthetic that prevents movement in response to surgical stimulation. For inhalational anesthetics, anesthetic potency is measured in MAC units, with 1 MAC defined as the *minimum alveolar concentration* that prevents movement in response to surgical stimulation in 50% of subjects. The strengths of MAC as a measurement are that (1) alveolar concentrations can be monitored continuously by measuring end-tidal anesthetic concentration using infrared spectroscopy or mass spectrometry; (2) it provides a direct correlate of the free concentration of the anesthetic at its site(s) of action in the CNS; (3) it is a simple-to-measure end point that reflects an important clinical goal. End points other than immobilization also can be used to measure anesthetic potency.

For example, the ability to respond to verbal commands (MAC_{awake}) (Stoelting *et al.*, 1970) and the ability to form memories (Dwyer *et al.*, 1992) also have been correlated with alveolar anesthetic concentration. Interestingly, verbal response and memory formation both are suppressed at a fraction of MAC. Furthermore, the ratio of the anesthetic concentrations required to produce amnesia and immobility vary significantly among different inhalational anesthetic agents (nitrous oxide vs. isoflurane) (Table 13–1), suggesting that anesthetic agents may produce these behavioral end points *via* different cellular and molecular mechanisms. The potency of intravenous anesthetic agents is somewhat more difficult to measure because there is not an available method to measure blood or plasma anesthetic concentration continuously, and because the free concentration of the drug at its site of action cannot be determined. Generally, the potency of intravenous agents is defined as the free plasma concentration (at equilibrium) that produces loss of response to surgical incision (or other end points) in 50% of subjects.

Mechanisms of Anesthesia

The molecular and cellular mechanisms by which general anesthetics produce their effects have remained one of the great mysteries of pharmacology. For most of the 20th century, it was theorized that all anesthetics act by a common mechanism (*the unitary theory of anesthesia*). The leading unitary theory was that anesthesia is produced by perturbation of the physical properties of cell membranes. This thinking was based largely on the observation that the

anesthetic potency of a gas correlated with its solubility in olive oil. This correlation, referred to as the *Meyer-Overton rule*, was interpreted as implicating the lipid bilayer as the likely target of anesthetic action. Clear exceptions to the Meyer-Overton rule have now been noted (Koblin *et al.*, 1994). For example, inhalational and intravenous anesthetics can be enantioselective in their action as anesthetics (etomidate, steroids, *isoflurane*) (Tomlin *et al.*, 1998; Lysko *et al.*, 1994; Wittmer *et al.*, 1996). The fact that enantiomers have unique actions but identical physical properties indicates that properties other than bulk solubility are important in determining anesthetic action. This realization has focused thinking on identification of specific protein binding sites for anesthetics.

One impediment to understanding the mechanisms of anesthesia has been the difficulty in precisely defining anesthesia. A substantial body of work indicates that an anesthetic agent produces different components of the anesthetic state *via* actions at different anatomic loci in the nervous system and may produce these component effects *via* different cellular and molecular actions. Moreover, increasing evidence supports the hypothesis that different anesthetic agents produce specific components of anesthesia *via* actions at different molecular targets. Given these insights, the unitary theory of anesthesia has been largely discarded.

Anatomic Sites of Anesthetic Action. In principle, general anesthetics could interrupt nervous system function at myriad levels, including peripheral sensory neurons, the spinal cord, the brainstem, and the cerebral cortex. Delineation of the precise anatomic sites of action is difficult because many anesthetics diffusely inhibit electrical activity in the CNS. For example, *isoflurane* at 2 MAC can cause electrical silence in the brain (Newberg *et al.*, 1983). Despite this, *in vitro* studies have shown that specific cortical pathways exhibit markedly different sensitivities to both inhalational and intravenous anesthetics (MacIver and Roth, 1988; Nicoll, 1972). This suggests that anesthetics may produce specific components of the anesthetic state *via* actions at specific sites in the CNS. Consistent with this possibility, studies show that inhalational anesthetics produce immobilization in response to a surgical incision (the end point used in determining MAC) by action on the spinal cord (Rampil, 1994; Antognini and Schwartz, 1993). Given that amnesia or unconsciousness cannot result from anesthetic actions in the spinal cord, different components of anesthesia are produced at different sites in the CNS. Indeed, recent studies show that the sedative effects of *pentobarbital* and propofol (GABAergic anesthetics) are mediated by GABA_A receptors in the tuberomammillary nucleus (Nelson *et al.*, 2002), and the sedative effects of the intravenous anesthetic *dexmedetomidine* (an α_2 adrenergic-receptor agonist) are produced *via* actions in the locus ceruleus (Mizobe *et al.*, 1996). These findings suggest that the sedative actions of some anesthetics share the neuronal pathways involved in endogenous sleep. While the sites at which other intravenous and inhalational anesthetics produce unconsciousness have not been identified, inhalational anesthetics depress the excitability of thalamic neurons (Ries and Puil,

1999). This suggests the thalamus as a potential locus for the sedative effects of inhalational anesthetics, since blockade of thalamocortical communication would produce unconsciousness. Finally, both intravenous and inhalational anesthetics depress hippocampal neurotransmission (Kendig *et al.*, 1991), a probable locus for their amnestic effects.

Cellular Mechanisms of Anesthesia. General anesthetics produce two important physiologic effects at the cellular level. First, the inhalational anesthetics can hyperpolarize neurons (Nicoll and Madison, 1982). This may be an important effect on neurons serving a pacemaker role and on pattern-generating circuits. It also may be important in synaptic communication, since reduced excitability in a postsynaptic neuron may diminish the likelihood that an action potential will be initiated in response to neurotransmitter release. Second, at anesthetizing concentrations, both inhalational and intravenous anesthetics have substantial effects on synaptic transmission and much smaller effects on action-potential generation or propagation (Larrabee and Posternak, 1952). The inhalational anesthetics inhibit excitatory synapses and enhance inhibitory synapses in various preparations. It seems likely that these effects are produced by both pre- and postsynaptic actions of the inhalational anesthetics. The inhalational anesthetic *isoflurane* clearly can inhibit neurotransmitter release (Perouansky *et al.*, 1995; MacIver *et al.*, 1996), while the small reduction in presynaptic action potential amplitude produced by *isoflurane* (3% reduction at MAC concentration) substantially inhibits neurotransmitter release (Wu *et al.*, 2004b). The latter effect occurs because the reduction in the presynaptic action potential is amplified into a much larger reduction in presynaptic Ca²⁺ influx, which in turn is amplified into an even greater reduction in transmitter release. This effect may account for the majority of the reduction in transmitter release by inhalational anesthetics at some excitatory synapses. Inhalational anesthetics also can act postsynaptically, altering the response to released neurotransmitter. These actions are thought to be due to specific interactions of anesthetic agents with neurotransmitter receptors.

The intravenous anesthetics produce a narrower range of physiological effects. Their predominant actions are at the synapse, where they have profound and relatively specific effects on the postsynaptic response to released neurotransmitter. Most of the intravenous agents act predominantly by enhancing inhibitory neurotransmission, whereas ketamine predominantly inhibits excitatory neurotransmission at glutamatergic synapses.

Molecular Actions of General Anesthetics. The electrophysiological effects of general anesthetics at the cellular level suggest several potential molecular targets for anesthetic action. There is strong evidence that ligand-gated ion channels are important targets for anesthetic action. Chloride channels gated by the inhibitory GABA_A receptors (*see* Chapters 12 and 16) are sensitive to clinical concentrations of a wide variety of anesthetics, including the halogenated inhalational agents and many intravenous agents (propofol, barbiturates, etomidate, and neurosteroids) (Krasowski and Harrison, 1999). At clinical concentrations, general anesthetics increase the sensitivity of the GABA_A receptor to GABA, thus enhancing inhibitory neurotransmission and depressing nervous system activity. The action of anesthetics on the GABA_A receptor probably is mediated by binding of the anesthetics to specific sites on the GABA_A-receptor protein, since point mutations of the receptor can eliminate the effects of the anesthetic on ion channel function (Mihic *et al.*, 1997). There likely are specific binding sites for at least several

classes of anesthetics, as mutations in various regions (and subunits) of the GABA_A receptor selectively affect the actions of various anesthetics (Belelli *et al.*, 1997; Krasowski and Harrison, 1999). Notably, none of the general anesthetics competes with GABA for its binding site on the receptor. The capacity of propofol and etomidate to inhibit the response to noxious stimuli is mediated by a specific site on the β_3 subunit of the GABA_A receptor (Jurd *et al.*, 2003), whereas the sedative effects of these anesthetics are mediated by the same site on the β_2 subunit (Reynolds *et al.*, 2003). These results indicate that two components of anesthesia *can* be mediated by GABA_A receptors; for anesthetics other than propofol and etomidate, which components of anesthesia *are* produced by actions on GABA_A receptors remains a matter of conjecture.

Structurally closely related to the GABA_A receptors are other ligand-gated ion channels including glycine receptors and neuronal nicotinic acetylcholine receptors. Glycine receptors may play a role in mediating inhibition by anesthetics of responses to noxious stimuli. Clinical concentrations of inhalational anesthetics enhance the capacity of glycine to activate glycine-gated chloride channels (glycine receptors), which play an important role in inhibitory neurotransmission in the spinal cord and brainstem. Propofol (Hales and Lambert, 1988), neurosteroids, and barbiturates also potentiate glycine-activated currents, whereas etomidate and ketamine do not (Mascia *et al.*, 1996). Subanesthetic concentrations of the inhalational anesthetics inhibit some classes of neuronal nicotinic acetylcholine receptors (Violet *et al.*, 1997; Flood *et al.*, 1997). However, these actions do not appear to mediate anesthetic immobilization (Eger *et al.*, 2002); rather, neuronal nicotinic receptors could mediate other components of anesthesia such as analgesia or amnesia.

The only general anesthetics that do not have significant effects on GABA_A or glycine receptors are ketamine, nitrous oxide, cyclopropane, and *xenon*. These agents inhibit a different type of ligand-gated ion channel, the *N*-methyl-D-aspartate (NMDA) receptor (see Chapter 12). NMDA receptors are glutamate-gated cation channels that are somewhat selective for calcium and are involved in long-term modulation of synaptic responses (long-term potentiation) and glutamate-mediated neurotoxicity. Ketamine inhibits NMDA receptors by binding to the *phencyclidine* site on the NMDA-receptor protein (Anis *et al.*, 1983), and the NMDA receptor is thought to be the principal molecular target for ketamine's anesthetic actions. Nitrous oxide (Mennerick *et al.*, 1998; Jevtovic-Todorovic *et al.*, 1998), cyclopropane (Raines *et al.*, 2001), and xenon (Franks *et al.*, 1998; de Sousa *et al.*, 2000) are potent and selective inhibitors of NMDA-activated currents, suggesting that these agents also may produce unconsciousness *via* actions on NMDA receptors.

Inhalational anesthetics have two other known molecular targets that may mediate some of their actions. Halogenated inhalational anesthetics activate some members of a class of K⁺ channels known as two-pore domain channels (Gray *et al.*, 1998; Patel *et al.*, 1999); other two-pore domain channel family members are activated by xenon, nitrous oxide, and cyclopropane (Gruss *et al.*, 2004). These channels are important in setting the resting membrane potential of neurons and may be the molecular locus through which these agents hyperpolarize neurons. A second target is the molecular machinery involved in neurotransmitter release. In *Caenorhabditis elegans*, the action of inhalational anesthetics requires a protein complex (syntaxin, SNAP-25, synaptobrevin) involved in synaptic neurotransmitter release (van Swinderen *et al.*, 1999). These molecular interactions may explain in part the capacity of inhalational anesthetics to cause presynaptic inhibition in the hippocampus and could contribute to the amnesic effect of inhalational anesthetics.

Summary. Current evidence supports the view that most intravenous general anesthetics act predominantly through GABA_A receptors and perhaps through some interactions with other ligand-gated ion channels. The halogenated inhalational agents have a variety of molecular targets, consistent with their status as complete (all components) anesthetics. Nitrous oxide, ketamine, and xenon constitute a third category of general anesthetics that are likely to produce unconsciousness *via* inhibition of the NMDA receptor and/or activation of two-pore-domain K⁺ channels. The molecular mechanisms of general anesthetics are reviewed by Rudolph and Antkowiak (2004).

PARENTERAL ANESTHETICS

Pharmacokinetic Principles

Parenteral anesthetics are small, hydrophobic, substituted aromatic or heterocyclic compounds (Figure 13–1). Hydrophobicity is the key factor governing their pharmacokinetics (Shafer and Stanski, 1992). After a single intravenous bolus, these drugs preferentially partition into the highly perfused and lipophilic tissues of the brain and spinal cord where they produce anesthesia within a single circulation time. Subsequently blood levels fall rapidly, resulting in drug redistribution out of the CNS back into the blood. The anesthetic then diffuses into less perfused

Figure 13–1. Structures of parenteral anesthetics.

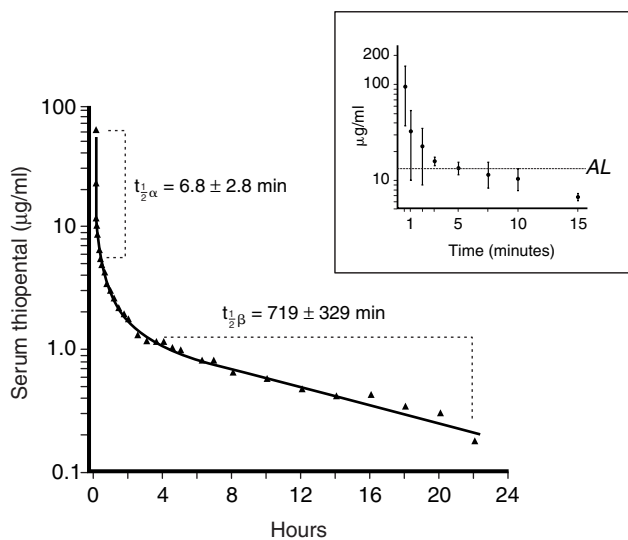

Figure 13–2. Thiopental serum levels after a single intravenous induction dose. Thiopental serum levels after a bolus can be described by two time constants, $t_{1/2\alpha}$ and $t_{1/2\beta}$. The initial fall is rapid ($t_{1/2\alpha} < 10$ min) and is due to redistribution of drug from the plasma and the highly perfused brain and spinal cord into less well-perfused tissues such as muscle and fat. During this redistribution phase, serum thiopental concentration falls to levels at which patients awaken (AL, awakening level; see inset—the average thiopental serum concentration in 12 patients after a 6-mg/kg intravenous bolus of thiopental). Subsequent metabolism and elimination is much slower and is characterized by a half-life ($t_{1/2\beta}$) of more than 10 hours. (Adapted with permission from Burch and Stanski, 1983.)

tissues such as muscle and viscera, and at a slower rate into the poorly perfused but very hydrophobic adipose tissue. Termination of anesthesia after single boluses of parenteral anesthetics primarily reflects redistribution out of the CNS rather than metabolism (Figure 13–2). After redistribution, anesthetic blood levels fall according to a complex interaction between the metabolic rate and the amount and lipophilicity of the drug stored in the peripheral compartments (Hughes *et al.*, 1992; Shafer and Stanski, 1992). Thus, parenteral anesthetic half-lives are “context-sensitive,” and the degree to which a half-life is contextual varies greatly from drug to drug, as might be predicted based on their differing hydrophobicities and metabolic clearances (Table 13–2 and Figure 13–3). For example, after a single bolus of thiopental, patients usually emerge from anesthesia within 10 minutes; however, a patient may require more than a day to awaken from a prolonged thiopental infusion. Most individual variability in sensitivity to parenteral anesthetics can be accounted for by pharmacokinetic factors (Wada *et al.*, 1997). For

Figure 13–3. Context-sensitive half-time of general anesthetics. The duration of action of single intravenous doses of anesthetic/hypnotic drugs is similarly short for all and is determined by redistribution of the drugs away from their active sites (see Figure 13–2). However, after prolonged infusions, drug half-lives and durations of action are dependent on a complex interaction between the rate of redistribution of the drug, the amount of drug accumulated in fat, and the drug’s metabolic rate. This phenomenon has been termed the *context-sensitive half-time*; that is, the half-time of a drug can be estimated only if one knows the context—the total dose and over what time period it has been given. Note that the half-times of some drugs such as etomidate, propofol, and ketamine increase only modestly with prolonged infusions; others (*e.g.*, diazepam and thiopental) increase dramatically. (Reproduced with permission from Reves *et al.*, 1994.)

example, in patients with lower cardiac output, the relative perfusion of and fraction of anesthetic dose delivered to the brain is higher; thus, patients in septic shock or with cardiomyopathy usually require lower doses of anesthetic. The elderly also typically require a smaller anesthetic dose, primarily because of a smaller initial volume of distribution (Homer and Stanski, 1985). As described below, similar principles govern the pharmacokinetics of the hydrophobic inhalational anesthetics, with the added complexity of drug uptake by inhalation.

SPECIFIC PARENTERAL AGENTS

Barbiturates

Chemistry and Formulations. Anesthetic barbiturates are derivatives of barbituric acid (2,4,6-trioxohexahydropyrimidine), with either an oxygen or sulfur at the 2-position (Figure 13–1). The three barbiturates used for clinical anesthesia are *sodium thiopental*, *thia-*

SOURCES: Thiopental: Clarke *et al.*, 1968; Burch and Stanski, 1983; Hudson *et al.*, 1983; Hung *et al.*, 1992; methohexital: Brand *et al.*, 1963; Clarke *et al.*, 1968; Kay and Stephenson, 1981; Hudson *et al.*, 1983; McMurray *et al.*, 1986; propofol: Kirkpatrick *et al.*, 1988; Langley and Heel, 1988; Shafer *et al.*, 1988; etomidate: Doenicke, 1974; Meuldermans and Heykants, 1976; Fragen *et al.*, 1983; Hebron *et al.*, 1983; ketamine: Chang and Glazko, 1974; Clements and Nimmo, 1981; White *et al.*, 1982; Dayton *et al.*, 1983. ABBREVIATIONS: $t_{\frac{1}{2}\beta}$, β phase half-life; CL, clearance; V_{ss} , volume of distribution at steady state; EDTA, ethylenediaminetetraacetic acid; Na-MBS, Na-metabisulfite; PG, propylene glycol; PL, phospholipid.

mylal, and *methohexital*. Sodium thiopental (PENTOTHAL) has been used most frequently for inducing anesthesia. The barbiturate anesthetics are supplied as racemic mixtures despite enantioselectivity in their anesthetic potency (Andrews and Mark, 1982). Barbiturates are formulated as the sodium salts with 6% sodium carbonate and reconstituted in water or isotonic saline to produce 1% (methohexital), 2% (thiamylal), or 2.5% (thiopental) alkaline solutions with pHs of 10 to 11. Once reconstituted, thiobarbiturates are stable in solution for up to 1 week, methohexital for up to 6 weeks if refrigerated. *Mixing with more acidic drugs commonly used during anesthetic induction can result in precipitation of the barbiturate as the free acid; thus, standard practice is to delay the administration of other drugs until the barbiturate has cleared the intravenous tubing.*

Dosages and Clinical Use. Recommended intravenous dosing for parenteral anesthetics in a healthy young adult is given in Table 13–2.

The typical induction dose (3 to 5 mg/kg) of thiopental produces unconsciousness in 10 to 30 seconds with a peak effect in 1 minute and duration of anesthesia of 5 to 8 minutes. Neonates and infants usually require a higher induction dose (5 to 8 mg/kg), whereas elderly and pregnant patients require less (1 to 3 mg/kg) (Homer and Stanski 1985; Jonmarker *et al.*, 1987; Gin *et al.*, 1997). Dosage calculation based on lean body mass reduces individual variation in dosage requirements. Doses can be reduced by 10% to 50% after premedication with benzodiazepines, opiates, or α_2 adrenergic agonists, because of their additive hypnotic effect (Short *et al.*, 1991; Nishina *et al.*, 1994; Wang *et al.*, 1996). Thiamylal is approximately equipotent with and in all aspects similar to thiopental. Methohexital (BREVITAL) is threefold more potent but otherwise similar to thiopental in onset and duration of action. Thiopental and thiamylal produce little to no pain on injection; methohexital elicits mild pain. Veno-irritation can be reduced by injection into larger non-hand veins and by prior intravenous injection of lidocaine (0.5 to 1 mg/kg). Intra-arterial injection of thiobarbiturates can induce a severe inflammatory and potentially necrotic reaction and should be avoided. Thiopental often evokes the taste of garlic just prior to inducing anesthesia. Methohexital and to a lesser degree the other barbiturates can produce excitement phenomena such as muscle tremor, hypertonus, and hiccups. For induction of pediatric patients without IV access, all three drugs can be given per rectum at approximately tenfold the IV dose.

Pharmacokinetics and Metabolism. Pharmacokinetic parameters for parenteral anesthetics are given in Table 13–2. As discussed above, the principal mechanism limiting anesthetic duration after single doses is redistribution of these hydrophobic drugs from the brain to other tissues. However, after multiple doses or infusions, the duration of action of the barbiturates varies considerably depending on their clearances.

Methohexital differs from the other two intravenous barbiturates in its much more rapid clearance; thus, it accumulates less during prolonged infusions (Schwilden and Stoeckel, 1990). Because of their slow elimination and large volumes of distribution, prolonged infusions or very large doses of thiopental and thiamylal can pro-

duce unconsciousness lasting several days. Even single induction doses of thiopental and to a lesser degree methohexital can produce psychomotor impairment lasting up to 8 hours (Korttila *et al.*, 1975; Beskow *et al.*, 1995). Methohexital had been used frequently for outpatient procedures for which rapid return to an alert state is particularly desirable, but for this use it now has been largely replaced by propofol (*see below*). All three barbiturates are primarily eliminated by hepatic metabolism and renal excretion of inactive metabolites; a small fraction of thiopental undergoes desulfuration to the longer-acting hypnotic pentobarbital (Chan *et al.*, 1985). Each drug is highly protein bound (Table 13–2). Hepatic disease or other conditions that reduce serum protein concentration will decrease the volume of distribution and thereby increase the initial free concentration and hypnotic effect of an induction dose.

Side Effects. Nervous System. Besides producing a general anesthesia, barbiturates reduce the cerebral metabolic rate, as measured by cerebral oxygen consumption ($CMRO_2$), in a dose-dependent manner. Induction doses of thiopental reduce $CMRO_2$ by 25% to 30% with a maximal decrease of 55% occurring at two to five times that dose (Stullken *et al.*, 1977). As a consequence of the decrease in $CMRO_2$, cerebral blood flow and intracranial pressure are similarly reduced (Shapiro *et al.*, 1973).

Because it markedly lowers cerebral metabolism, thiopental has been used as a protectant against cerebral ischemia. At least one human study suggests that thiopental may be efficacious in ameliorating ischemic damage in the perioperative setting (Nussmeier *et al.*, 1986). Thiopental also reduces intraocular pressure (Joshi and Bruce, 1975). Presumably in part due to their CNS depressant activity, barbiturates are effective anticonvulsants. Thiopental in particular is a proven medication in the treatment of status epilepticus (Modica *et al.*, 1990).

Cardiovascular. *The anesthetic barbiturates produce dose-dependent decreases in blood pressure.* The effect is due primarily to vasodilation, particularly venodilation, and to a lesser degree to a direct decrease in cardiac contractility. Typically, heart rate increases as a compensatory response to a lower blood pressure, although barbiturates also blunt the baroreceptor reflex.

Hypotension can be severe in patients with an impaired ability to compensate for venodilation such as those with hypovolemia, cardiomyopathy, valvular heart disease, coronary artery disease, cardiac tamponade, or β adrenergic blockade. Thiopental is not contraindicated in patients with coronary artery disease because the ratio of myocardial oxygen supply to demand appears to be adequately maintained within a patient's normal blood pressure range (Reiz *et al.*, 1981). None of the barbiturates has been shown to be arrhythmogenic.

Respiratory. *Barbiturates are respiratory depressants.* Induction doses of thiopental decrease minute ventilation and tidal volume with a smaller and inconsistent decrease in respiratory rate (Grounds *et al.*, 1987); reflex responses

to hypercarbia and hypoxia are diminished by anesthetic barbiturates (Hirshman *et al.*, 1975), and at higher doses or in the presence of other respiratory depressants such as opiates, apnea can result. With the exception of uncommon anaphylactoid reactions, these drugs have little effect on bronchomotor tone and can be used safely in asthmatics (Kingston and Hirshman, 1984).

Other Side Effects. Short-term administration of barbiturates has no clinically significant effect on the hepatic, renal, or endocrine systems. A single induction dose of thiopental does not alter tone of the gravid uterus, but may produce mild transient depression of newborn activity (Kosaka *et al.*, 1969). True allergies to barbiturates are rare (Baldo *et al.*, 1991); however, direct drug-induced histamine release is occasionally seen (Sprung *et al.*, 1997). Barbiturates can induce fatal attacks of porphyria in patients with acute intermittent or variegate porphyria and are contraindicated in such patients. Unlike inhalational anesthetics and succinylcholine, barbiturates and all other parenteral anesthetics apparently do not trigger malignant hyperthermia (Rosenberg *et al.*, 1997).

Propofol

Chemistry and Formulations. Propofol now is the most commonly used parenteral anesthetic in the United States. The active ingredient in propofol, 2,6-diisopropylphenol, is essentially insoluble in aqueous solutions and is formulated only for IV administration as a 1% (10 mg/ml) emulsion in 10% soybean oil, 2.25% glycerol, and 1.2% purified egg phosphatide. In the United States, disodium EDTA (0.05 mg/ml) or sodium metabisulfite (0.25 mg/ml) is added to inhibit bacterial growth. Nevertheless, significant bacterial contamination of open containers has been associated with serious patient infection; propofol should be either administered or discarded shortly after removal from sterile packaging.

Dosage and Clinical Use. The induction dose of propofol (DIPRIVAN) in a healthy adult is 1.5 to 2.5 mg/kg and it has an onset and duration of anesthesia similar to thiopental (Table 13–2). As with barbiturates, dosages should be reduced in the elderly and in the presence of other sedatives and increased in young children. Because of its reasonably short elimination half-life, propofol often is used for maintenance of anesthesia as well as for induction. For short procedures, small boluses (10% to 50% of the induction dose) every 5 minutes or as needed are effective. An infusion of propofol produces a more stable drug level (100 to 300 $\mu\text{g}/\text{kg}$ per minute) and is better suited for longer-term anesthetic maintenance. Infusion rates should be tailored to patient response and the levels of other hypnotics. Sedating doses of propofol are 20% to 50% of those required for general anesthesia. However, even at these lower doses, caregivers should be vigilant and prepared for all of the side effects of propofol discussed below, particularly airway obstruction and apnea. Propofol elicits pain on injection that can be reduced with

lidocaine and the use of larger arm and antecubital veins. Excitatory phenomena during induction with propofol occur at about the same frequency as with thiopental, but much less frequently than with methohexital (Langley and Heel, 1988).

Pharmacokinetics and Metabolism. The pharmacokinetics of propofol are governed by the same principles that apply to barbiturates. Onset and duration of anesthesia after a single bolus are similar to thiopental (Langley and Heel, 1988). Recovery after multiple doses or infusion has been shown to be much faster after propofol than after thiopental or even methohexital (Doze *et al.*, 1986; Langley and Heel, 1988).

Propofol's shorter duration after infusion can be explained by its very high clearance, coupled with the slow diffusion of drug from the peripheral to the central compartment (Figure 13–3). The rapid clearance of propofol explains its less severe hangover compared with barbiturates, and may allow for a more rapid discharge from the recovery room. Propofol is metabolized in the liver to less active metabolites that are renally excreted (Simons *et al.*, 1988); however, its clearance exceeds hepatic blood flow, and anhepatic metabolism has been demonstrated (Veroli *et al.*, 1992). Propofol is highly protein bound, and its pharmacokinetics, like those of the barbiturates, may be affected by conditions that alter serum protein levels (Kirkpatrick *et al.*, 1988).

Side Effects. Nervous System. The CNS effects of propofol are similar to those of barbiturates.

Propofol decreases CMRO_2 , cerebral blood flow, and intracranial and intraocular pressures by about the same amount as thiopental (Langley and Heel, 1988). Like thiopental, propofol has been used in patients at risk for cerebral ischemia (Ravussin and de Tribolet, 1993); however, no human outcome studies have been performed to determine its efficacy as a neuroprotectant. Results from studies on the anticonvulsant effects of propofol have been mixed; some data even suggest it has proconvulsant activity when combined with other drugs (Modica *et al.*, 1990). Thus, unlike thiopental, propofol is not a proven acute intervention for seizures.

Cardiovascular. Propofol produces a dose-dependent decrease in blood pressure that is significantly greater than that produced by thiopental (Grounds *et al.*, 1985; Langley and Heel 1988). The fall in blood pressure can be explained by both vasodilation and mild depression of myocardial contractility (Grounds *et al.*, 1985). Propofol appears to blunt the baroreceptor reflex or is directly vagotonic because smaller increases in heart rate are seen for any given drop in blood pressure after doses of propofol (Langley and Heel, 1988). As with thiopental, propofol should be used with caution in patients at risk for or intolerant of decreases in blood pressure.

Respiratory and Other Side Effects. At equipotent doses, propofol produces a slightly greater degree of respiratory

depression than thiopental (Blouin *et al.*, 1991). Patients given propofol should be monitored to ensure adequate oxygenation and ventilation. Propofol appears to be less likely than barbiturates to provoke bronchospasm (Pizov *et al.*, 1995). It has no clinically significant effects on hepatic, renal, or endocrine organ systems. Unlike thiopental, propofol appears to have significant anti-emetic action and is a good choice for sedation or anesthesia of patients at high risk for nausea and vomiting (McCollum *et al.*, 1988). Propofol provokes anaphylactoid reactions and histamine release at about the same low frequency as thiopental (Laxenaire *et al.*, 1992). Although propofol does cross placental membranes, it is considered safe for use in pregnant women, and like thiopental, only transiently depresses activity in the newborn (Abboud *et al.*, 1995).

Etomidate

Chemistry and Formulation. Etomidate is a substituted imidazole that is supplied as the active D-isomer (Figure 13-1). Etomidate is poorly soluble in water and is formulated as a 2 mg/ml solution in 35% propylene glycol. Unlike thiopental, etomidate does not induce precipitation of neuromuscular blockers or other drugs frequently given during anesthetic induction.

Dosage and Clinical Use. Etomidate (AMIDATE) is primarily used for anesthetic induction of patients at risk for hypotension.

Induction doses of etomidate (0.2 to 0.4 mg/kg) have a rapid onset and short duration of action (Table 13-2) and are accompanied by a high incidence of pain on injection and myoclonic movements. Lidocaine effectively reduces the pain of injection (Galloway *et al.*, 1982), while myoclonic movements can be reduced by premedication with either benzodiazepines or opiates. Etomidate is pharmacokinetically suitable for infusion for anesthetic maintenance (10 μ g/kg per minute) or sedation (5 μ g/kg per minute); however, long-term infusions are not recommended for reasons discussed below. Etomidate also may be given rectally (6.5 mg/kg) with an onset of about 5 minutes.

Pharmacokinetics and Metabolism. An induction dose of etomidate has a rapid onset; redistribution limits the duration of action (Table 13-2). Metabolism occurs in the liver, primarily to inactive compounds (Heykants *et al.*, 1975; Gooding and Corssen, 1976). Elimination is both renal (78%) and biliary (22%). Compared to thiopental, the duration of action of etomidate increases less with repeated doses (Figure 13-3). The plasma protein binding of etomidate is high but less than that of barbiturates and propofol (Table 13-2).

Side Effects. Nervous System. The effects of etomidate on cerebral blood flow, metabolism, and intracranial and intraocular pressures are similar to those of thiopental

(Modica *et al.*, 1992). Etomidate has been used as a protectant against cerebral ischemia; however, animal studies have failed to show a consistent beneficial effect (Drummond *et al.*, 1995), and no controlled human trials have been performed. Etomidate has been shown in some studies to be a proconvulsant and is not a proven treatment for seizures (Modica *et al.*, 1990).

Cardiovascular. Cardiovascular stability after induction is a major advantage of etomidate over either barbiturates or propofol. Induction doses of etomidate typically produce a small increase in heart rate and little or no decrease in blood pressure or cardiac output (Criado *et al.*, 1980). Etomidate has little effect on coronary perfusion pressure while reducing myocardial oxygen consumption (Kettler *et al.*, 1974). Thus, of all induction agents, etomidate is best suited to maintain cardiovascular stability in patients with coronary artery disease, cardiomyopathy, cerebral vascular disease, or hypovolemia.

Respiratory and Other Side Effects. The degree of respiratory depression due to etomidate appears to be less than that due to thiopental (Morgan *et al.*, 1977). Like methohexital, etomidate may induce hiccups but does not significantly stimulate histamine release. Despite minimal cardiac and respiratory effects, etomidate does have two major drawbacks. First, etomidate has been associated with nausea and vomiting (Fragen *et al.*, 1979). Second, etomidate inhibits adrenal biosynthetic enzymes required for the production of cortisol and some other steroids, possibly inhibiting the adrenocortical stress response (Ledingham *et al.*, 1983). Even single induction doses of etomidate may mildly and transiently reduce cortisol levels (Wagner *et al.*, 1984), but no significant differences in outcome after short-term administration have been found, even for variables specifically known to be associated with adrenocortical suppression (Wagner *et al.*, 1984). Thus, while etomidate is not recommended for long-term infusion, it appears safe for anesthetic induction and has some unique advantages in patients prone to hemodynamic instability.

Ketamine

Chemistry and Formulation. Ketamine is an arylcyclohexylamine, a congener of phencyclidine (Figure 13-1). It is supplied as a racemic mixture even though the S-isomer is more potent with fewer side effects (White *et al.*, 1982). Although more lipophilic than thiopental, ketamine is water soluble and available as 10-, 50-, and 100-mg/ml solutions in sodium chloride plus the preservative benzethonium chloride.

Dosage and Clinical Use. Ketamine (KETALAR, others) has unique properties that make it useful for anesthetizing

patients at risk for hypotension and bronchospasm and for certain pediatric procedures. However, significant side effects limit its routine use. Ketamine rapidly produces a hypnotic state quite distinct from that of other anesthetics. Patients have profound analgesia, unresponsiveness to commands, and amnesia, but may have their eyes open, move their limbs involuntarily, and breathe spontaneously. This cataleptic state has been termed *dissociative anesthesia*.

Ketamine typically is administered intravenously but also is effective by intramuscular, oral, and rectal routes. The induction doses are 0.5 to 1.5 mg/kg IV, 4 to 6 mg/kg IM, and 8 to 10 mg/kg PR (White *et al.*, 1982). Onset of action after an intravenous dose is similar to that of the other parenteral anesthetics, but the duration of anesthesia of a single dose is longer (Table 13–2). For anesthetic maintenance, ketamine occasionally is continued as an infusion (25 to 100 µg/kg per minute) (White *et al.*, 1982). Ketamine does not elicit pain on injection or true excitatory behavior as described for methohexital, although involuntary movements produced by ketamine can be mistaken for anesthetic excitement.

Pharmacokinetics and Metabolism. The onset and duration of an induction dose of ketamine are determined by the same distribution/redistribution mechanism operant for all the other parenteral anesthetics.

Ketamine is hepatically metabolized to norketamine, which has reduced CNS activity; norketamine is further metabolized and excreted in urine and bile (Chang *et al.*, 1974). Ketamine has a large volume of distribution and rapid clearance that make it suitable for continuous infusion without the drastic lengthening in duration of action seen with thiopental (Table 13–2 and Figure 13–3). Protein binding is much lower with ketamine than with the other parenteral anesthetics (Table 13–2).

Side Effects. Nervous System. Ketamine has indirect sympathomimetic activity (White *et al.*, 1992). Ketamine's behavioral effects are distinct from those of other anesthetics. The ketamine-induced cataleptic state is accompanied by nystagmus with pupillary dilation, salivation, lacrimation, and spontaneous limb movements with increased overall muscle tone. Although ketamine does not produce the classic anesthetic state, patients are amnesic and unresponsive to painful stimuli. Ketamine produces profound analgesia, a distinct advantage over other parenteral anesthetics (White *et al.*, 1982).

Unlike other parenteral anesthetics, ketamine increases cerebral blood flow and intracranial pressure (ICP) with minimal alteration of cerebral metabolism. These effects can be attenuated by concurrent administration of thiopental and/or benzodiazepines along with hyperventilation (Belopavlovic and Buchthal, 1982; Mayberg *et al.*, 1995). However, given that other anesthetics actually reduce ICP and cerebral metabolism, ketamine is relatively contraindicated for patients with increased intracranial pressure or those at risk for cerebral ischemia. In some

studies, ketamine increased intraocular pressure, and its use for induction of patients with open eye injuries is controversial (Whitacre and Ellis, 1984). The effects of ketamine on seizure activity appear mixed, without either strong pro- or anticonvulsant activity (Modica *et al.*, 1990). Emergence delirium characterized by hallucinations, vivid dreams, and illusions is a frequent complication of ketamine that can result in serious patient dissatisfaction and can complicate postoperative management (White *et al.*, 1982). Delirium symptoms are most frequent in the first hour after emergence and appear to occur less frequently in children (Sussman, 1974). Benzodiazepines reduce the incidence of emergence delirium (Dundee and Lilburn, 1978).

Cardiovascular. Unlike other anesthetics, induction doses of ketamine typically increase blood pressure, heart rate, and cardiac output. The cardiovascular effects are indirect and are most likely mediated by inhibition of both central and peripheral catecholamine reuptake (White *et al.*, 1982). Ketamine has direct negative inotropic and vasodilating activity, but these effects usually are overwhelmed by the indirect sympathomimetic action (Pagel *et al.*, 1992). Thus, ketamine is a useful drug, along with etomidate, for patients at risk for hypotension during anesthesia. While not arrhythmogenic, ketamine increases myocardial oxygen consumption and is not an ideal drug for patients at risk for myocardial ischemia (Reves *et al.*, 1978).

Respiratory. The respiratory effects of ketamine are perhaps the best indication for its use. Induction doses of ketamine produce small and transient decreases in minute ventilation, but respiratory depression is less severe than with other general anesthetics (White *et al.*, 1982). Ketamine is a potent bronchodilator due to its indirect sympathomimetic activity and perhaps some direct bronchodilating activity (Hirshman *et al.*, 1979). Thus, ketamine is particularly well-suited for anesthetizing patients at high risk for bronchospasm.

Summary of Parenteral Anesthetics

Parenteral anesthetics are the most common drugs used for anesthetic induction of adults. Their lipophilicity, coupled with the relatively high perfusion of the brain and spinal cord, results in rapid onset and short duration after a single bolus dose. However, these drugs ultimately accumulate in fatty tissue, prolonging recovery if multiple doses are given, particularly for drugs with lower rates of clearance. Each anesthetic has its own unique set of properties and side effects (summarized in Table 13–3). Thiopental and propofol are the two most commonly used

Table 13–3
Some Pharmacological Effects of Parenteral Anesthetics*

DRUG	CBF	CMRO ₂	ICP	MAP	HR	CO	RR	\dot{V}_E
Thiopental	---	---	---	-	+	-	-	--
Etomidate	---	---	---	0	0	0	-	-
Ketamine	++	0	++	+	++	+	0	0
Propofol	---	---	---	--	+	-	--	---

ABBREVIATIONS: CBF, cerebral blood flow; CMRO₂, cerebral oxygen consumption; ICP, intracranial pressure; MAP, mean arterial pressure; HR, heart rate; CO, cardiac output; RR, respiratory rate; \dot{V}_E , minute ventilation. *Typical effects of a single induction dose in human beings; see text for references. Qualitative scale from --- to +++ = slight, moderate, or large decrease or increase, respectively; 0 indicates no significant change.

parenteral agents. Thiopental has a long-established track record of safety. Propofol is advantageous for procedures where rapid return to a preoperative mental status is desirable. Etomidate usually is reserved for patients at risk for hypotension and/or myocardial ischemia. Ketamine is best suited for patients with asthma or for children undergoing short, painful procedures.

INHALATIONAL ANESTHETICS

Introduction

A wide variety of gases and volatile liquids can produce anesthesia. The structures of the currently used inhalational anesthetics are shown in Figure 13–4. One of the troublesome properties of the inhalational anesthetics is their low safety margin. The inhalational anesthetics have therapeutic indices (LD₅₀/ED₅₀) that range from 2 to 4, making these among the most dangerous drugs in clinical use. The toxicity of these drugs is largely a function of their side effects, and each of the inhalational anesthetics has a unique side-effect profile. Hence, the selection of an inhalational anesthetic often is based on matching a patient's pathophysiology with drug side-effect profiles. The specific adverse effects of each of the inhalational anesthetics are emphasized in the following sections. The inhalational anesthetics also vary widely in their physical properties. Table 13–1 lists the important physical properties of the inhalational agents in clinical use. These properties are important because they govern the pharmacokinetics of the inhalational agents. Ideally, an inhalational agent would produce a rapid induction of anesthesia and a rapid recovery following discontinuation. The pharmacokinetics of the inhalational agents are reviewed in the following section.

Pharmacokinetic Principles

The inhalational agents are some of the very few pharmacological agents administered as gases. The fact that these agents behave as gases rather than as liquids requires that different pharmacokinetic constructs be used in analyzing their uptake and distribution. It is essential to understand that inhalational anesthetics distribute between tissues (or between blood and gas) such that equilibrium is achieved when the partial pressure of anesthetic gas is equal in the two tissues. When a person has breathed an inhalational anesthetic for a sufficiently long time that all tissues are

Figure 13–4. Structures of inhalational general anesthetics. Note that all inhalational general anesthetic agents except nitrous oxide and halothane are ethers and that fluorine progressively replaces other halogens in the development of the halogenated agents. All structural differences are associated with important differences in pharmacological properties.

equilibrated with the anesthetic, the partial pressure of the anesthetic in all tissues will be equal to the partial pressure of the anesthetic in inspired gas. It is important to note that while the partial pressure of the anesthetic may be equal in all tissues, the concentration of anesthetic in each tissue will be different. Indeed, anesthetic partition coefficients are defined as the ratio of anesthetic concentration in two tissues when the partial pressures of anesthetic are equal in the two tissues. Blood:gas, brain:blood, and fat:blood partition coefficients for the various inhalational agents are listed in Table 13–1. These partition coefficients show that inhalational anesthetics are more soluble in some tissues (*e.g.*, fat) than they are in others (*e.g.*, blood), and that there is significant range in the solubility of the various inhalational agents in such tissues.

In clinical practice, one can monitor the equilibration of a patient with anesthetic gas. Equilibrium is achieved when the partial pressure in inspired gas is equal to the partial pressure in end-tidal (alveolar) gas. This defines equilibrium because it is the point at which there is no net uptake of anesthetic from the alveoli into the blood. For inhalational agents that are not very soluble in blood or any other tissue, equilibrium is achieved quickly, as illustrated for nitrous oxide in Figure 13–5. If an agent is more soluble in a tissue such as fat, equilibrium may take many hours to reach. This occurs because fat represents a huge anesthetic reservoir that will be filled slowly because of the modest blood flow to fat. This is illustrated by the slow approach of halothane alveolar partial pressure to inspired partial pressure of halothane in Figure 13–5.

In considering the pharmacokinetics of anesthetics, one important parameter is the speed of anesthetic induction. Anesthesia is produced when anesthetic partial pressure in brain is equal to or greater than MAC. Because the brain is well perfused, anesthetic partial pressure in brain becomes equal to the partial pressure in alveolar gas (and in blood) over the course of several minutes. Therefore, anesthesia is achieved shortly after alveolar partial pressure reaches MAC. While the rate of rise of alveolar partial pressure will be slower for anesthetics that are highly soluble in blood and other tissues, this limitation on speed of induction can be overcome largely by delivering higher inspired partial pressures of the anesthetic.

Elimination of inhalational anesthetics is largely the reverse process of uptake. For agents with low blood and tissue solubility, recovery from anesthesia should mirror anesthetic induction, regardless of the duration of anesthetic administration. For inhalational agents with high blood and tissue solubility, recovery will be a function of the duration of anesthetic administration. This occurs because the accumulated amounts of anesthetic in the fat

Figure 13–5. Uptake of inhalational general anesthetics. The rise in end-tidal alveolar (F_A) anesthetic concentration toward the inspired (F_I) concentration is most rapid with the least soluble anesthetics, nitrous oxide and desflurane, and slowest with the most soluble anesthetic, halothane. All data are from human studies. (Reproduced with permission from Eger, 2000.)

reservoir will prevent blood (and therefore alveolar) partial pressures from falling rapidly. Patients will be arousable when alveolar partial pressure reaches MAC_{awake} , a partial pressure somewhat lower than MAC (Table 13–1).

Halothane

Chemistry and Formulation. Halothane (FLUOTHANE) is 2-bromo-2-chloro-1,1,1-trifluoroethane (Figure 13–4). Halothane is a volatile liquid at room temperature and must be stored in a sealed container. Because halothane is a light-sensitive compound that also is subject to spontaneous breakdown, it is marketed in amber bottles with thymol added as a preservative. Mixtures of halothane with oxygen or air are neither flammable nor explosive.

Pharmacokinetics. Halothane has a relatively high blood:gas partition coefficient and high fat:blood partition coefficient (Table 13–1). Induction with halothane therefore is relatively slow, and the alveolar halothane concentration remains substantially lower than the inspired halothane concentration for many hours of administration. Because halothane is soluble in fat and other body tissues, it will accumulate during prolonged administration. Therefore, the speed of recovery from halothane is lengthened as a function of duration of administration.

Approximately 60% to 80% of halothane taken up by the body is eliminated unchanged *via* the lungs in the first 24 hours after its administration. A substantial amount of the halothane not eliminated in exhaled gas is biotransformed by hepatic CYPs. The major metabolite of halothane is trifluoroacetic acid, which is formed by removal of bromine and chlorine ions (Gruenke *et al.*, 1988). Trifluoroacetic acid, bromine, and chlorine all can be detected in the urine. Trifluoroacetylchloride, an intermediate in oxidative metabo-

lism of halothane, can trifluoroacetylate several proteins in the liver. An immune reaction to these altered proteins may be responsible for the rare cases of fulminant halothane-induced hepatic necrosis (Kenna *et al.*, 1988). A minor reductive pathway accounts for approximately 1% of halothane metabolism that generally is observed only under hypoxic conditions (Van Dyke *et al.*, 1988).

Clinical Use. Halothane, introduced in 1956, was the first of the modern, halogenated inhalational anesthetics used in clinical practice. It is a potent agent that usually is used for maintenance of anesthesia. It is not pungent and is therefore well tolerated for inhalation induction of anesthesia. This is most commonly done in children, in whom preoperative placement of an intravenous catheter can be difficult. Anesthesia is produced by halothane at end-tidal concentrations of 0.7% to 1%. The use of halothane in the United States has diminished substantially in the past decade because of the introduction of newer inhalational agents with better pharmacokinetic and side-effect profiles. Halothane continues to be extensively used in children because it is well tolerated for inhalation induction and because the serious side effects appear to be diminished in children. Halothane has a low cost and therefore still is widely used in developing countries.

Side Effects. Cardiovascular System. The most predictable side effect of halothane is a dose-dependent reduction in arterial blood pressure. Mean arterial pressure typically decreases about 20% to 25% at MAC concentrations of halothane. This reduction in blood pressure primarily is the result of direct myocardial depression leading to reduced cardiac output (Figure 13–6). Myocardial depression is thought to result from attenuation of depolarization-induced intracellular calcium transients (Lynch, 1997). Halothane-induced hypotension usually is accompanied by either bradycardia or a normal heart rate. This absence of a tachycardic (or contractile) response to reduced blood pressure is thought to be due to an inability of the heart to respond to the effector arm of the baroreceptor reflex. Heart rate can be increased during halothane anesthesia by exogenous catecholamine or by sympathoadrenal stimulation. Halothane-induced reductions in blood pressure and heart rate generally disappear after several hours of constant halothane administration, presumably because of progressive sympathetic stimulation.

Halothane does not cause a significant change in systemic vascular resistance. Nonetheless, it does alter the resistance and autoregulation of specific vascular beds, leading to redistribution of blood flow. The vascular beds of the skin and brain are dilated directly by halothane, leading to increased cerebral blood flow and skin perfusion. Conversely, autoregulation of renal, splanchnic, and

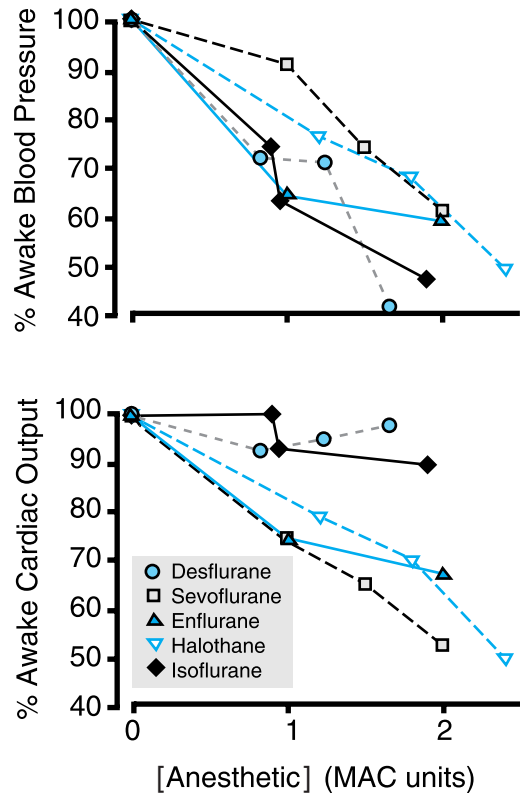

Figure 13–6. Influence of inhalational general anesthetics on the systemic circulation. While all of the inhalational anesthetics reduce systemic blood pressure in a dose-related manner (top), the lower figure shows that cardiac output is well preserved with isoflurane and desflurane, and therefore that the causes of hypotension vary with the agent. (Data are from human studies except for sevoflurane, where data are from swine; Bahlman *et al.*, 1972; Cromwell *et al.*, 1971; Weiskopf *et al.*, 1991; Calverley *et al.*, 1978; Stevens *et al.*, 1971; Eger *et al.*, 1970; Weiskopf *et al.*, 1988.)

cerebral blood flow is inhibited by halothane, leading to reduced perfusion of these organs in the face of reduced blood pressure. Coronary autoregulation is largely preserved during halothane anesthesia. Finally, halothane inhibits hypoxic pulmonary vasoconstriction, leading to increased perfusion to poorly ventilated regions of the lung and an increased alveolar:arterial oxygen gradient.

Halothane also has significant effects on cardiac rhythm. Sinus bradycardia and atrioventricular rhythms occur frequently during halothane anesthesia but usually are benign. These rhythms result mainly from a direct depressive effect of halothane on sinoatrial node discharge. Halothane also can sensitize the myocardium to the arrhythmogenic effects of epinephrine (Sumikawa *et al.*, 1983). Premature ventricular contractions and sustained ventricular tachycardia can

be observed during halothane anesthesia when exogenous administration or endogenous adrenal production elevates plasma epinephrine levels. Epinephrine-induced arrhythmias during halothane anesthesia are thought to be mediated by a synergistic effect on α_1 and β_1 adrenergic receptors (Hayashi *et al.*, 1988).

Respiratory System. Spontaneous respiration is rapid and shallow during halothane anesthesia. The decreased alveolar ventilation results in an elevation in arterial CO₂ tension from 40 mm Hg to >50 mm Hg at 1 MAC (Figure 13–7). The elevated CO₂ does not provoke a compensatory increase in ventilation, because halothane causes a concentration-dependent inhibition of the ventilatory response to CO₂ (Knill and Gelb, 1978). This action of halothane is thought to be mediated by depression of central chemoreceptor mechanisms. Halothane also inhibits peripheral chemoreceptor responses to arterial hypoxemia. Thus, neither hemodynamic (tachycardia and hypertension) nor ventilatory responses to hypoxemia are observed during halothane anesthesia, making it prudent to monitor arterial oxygenation directly. Halothane also is an effective bronchodilator (Yamakage, 1992) and has been effectively used as a treatment of last resort in patients with status asthmaticus (Gold and Helrich, 1970).

Nervous System. Halothane dilates the cerebral vasculature, increasing cerebral blood flow under most conditions. This increase in blood flow can increase intracranial pressure in patients with space-occupying intracranial masses, brain edema, or preexisting intracranial hypertension. For this reason, halothane is relatively contraindicated in patients at risk for elevated intracranial pressure. Halothane also attenuates autoregulation of cerebral blood flow. For this reason, cerebral blood flow can decrease when arterial blood pressure is markedly decreased. Modest decreases in cerebral blood flow generally are well tolerated because halothane also reduces cerebral metabolic consumption of O₂.

Muscle. Halothane causes some relaxation of skeletal muscle *via* its central depressant effects. Halothane also potentiates the actions of nondepolarizing muscle relaxants (curariform drugs; *see* Chapter 9), increasing both their duration of action and the magnitude of their effect. Halothane and the other halogenated inhalational anesthetics can trigger malignant hyperthermia, a syndrome characterized by severe muscle contraction, rapid development of hyperthermia, and a massive increase in metabolic rate in genetically susceptible patients. This syndrome frequently is fatal and is treated by immediate discontinuation of the anesthetic and administration of dantrolene.

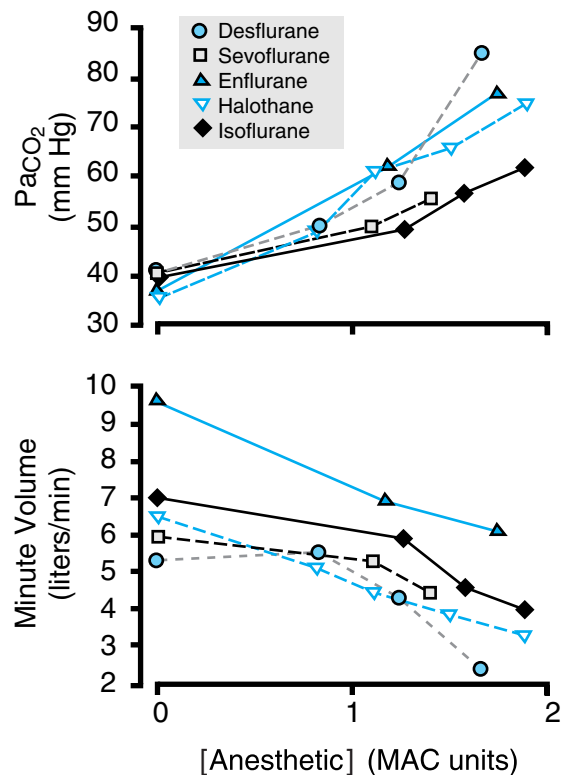

Figure 13–7. Respiratory effects of inhalational anesthetics. Spontaneous ventilation with all of the halogenated inhalational anesthetics reduces minute volume of ventilation in a dose-dependent manner (*lower panel*). This results in an increased arterial carbon dioxide tension (*top panel*). Differences among agents are modest. (Data from Doi and Ikada, 1987; Lockhart *et al.*, 1991; Munson *et al.*, 1966; Calverley *et al.*, 1978; Fourcade *et al.*, 1971.)

Uterine smooth muscle is relaxed by halothane. This is a useful property for manipulation of the fetus (version) in the prenatal period and for delivery of retained placenta postnatally. Halothane, however, inhibits uterine contractions during parturition, prolonging labor and increasing blood loss, and therefore is not used as an analgesic or anesthetic for labor and vaginal delivery.

Kidney. Patients anesthetized with halothane usually produce a small volume of concentrated urine. This is the consequence of halothane-induced reduction of renal blood flow and glomerular filtration rate, which may be reduced by 40% to 50% at 1 MAC. Halothane-induced changes in renal function are fully reversible and are not associated with long-term nephrotoxicity.

Liver and Gastrointestinal Tract. Halothane reduces splanchnic and hepatic blood flow as a consequence of reduced perfusion pressure, as discussed above. This

reduced blood flow has not been shown to produce detrimental effects on hepatic or GI function.

Halothane can produce fulminant hepatic necrosis in a small number of patients. This syndrome generally is characterized by fever, anorexia, nausea, and vomiting, developing several days after anesthesia and can be accompanied by a rash and peripheral eosinophilia. There is a rapid progression to hepatic failure, with a fatality rate of approximately 50%. This syndrome occurs in about 1 in 10,000 patients receiving halothane and is referred to as *halothane hepatitis* (Subcommittee on the National Halothane Study, 1966). Current thinking is that halothane hepatitis is the result of an immune response to hepatic proteins that become trifluoroacetylated as a consequence of halothane metabolism (*see Pharmacokinetics, above*).

Isoflurane

Chemistry and Physical Properties. Isoflurane (FORANE, others) is 1-chloro-2,2,2-trifluoroethyl difluoromethyl ether (Figure 13-4). It is a volatile liquid at room temperature and is neither flammable nor explosive in mixtures of air or oxygen.

Pharmacokinetics. Isoflurane has a blood:gas partition coefficient substantially lower than that of halothane or *enflurane* (Table 13-1). Consequently, induction with isoflurane and recovery from isoflurane are relatively rapid. Changes in anesthetic depth also can be achieved more rapidly with isoflurane than with halothane or *enflurane*. More than 99% of inhaled isoflurane is excreted unchanged *via* the lungs. Approximately 0.2% of absorbed isoflurane is oxidatively metabolized by CYP2E1 (Kharasch and Thummel, 1993). The small amount of isoflurane degradation products produced is insufficient to produce any renal, hepatic, or other organ toxicity. Isoflurane does not appear to be a mutagen, teratogen, or carcinogen (Eger *et al.*, 1978).

Clinical Use. Isoflurane is a commonly used inhalational anesthetic worldwide. It is typically used for maintenance of anesthesia *after induction* with other agents because of its pungent odor, but induction of anesthesia can be achieved in less than 10 minutes with an inhaled concentration of 3% isoflurane in O₂; this concentration is reduced to 1% to 2% for maintenance of anesthesia. The use of other drugs such as opioids or nitrous oxide reduces the concentration of isoflurane required for surgical anesthesia.

Side Effects. Cardiovascular System. Isoflurane produces a concentration-dependent decrease in arterial blood pressure. Unlike halothane, cardiac output is well maintained with isoflurane, and hypotension is the result of decreased systemic vascular resistance (Figure 13-6). Isoflurane produces vasodilation in most vascular beds, with particularly pronounced effects in skin and muscle.

Isoflurane is a potent coronary vasodilator, simultaneously producing increased coronary blood flow and decreased myocardial O₂ consumption. In theory, this makes isoflurane a particularly safe anesthetic to use for patients with ischemic heart disease. However, concern has been raised that isoflurane may produce myocardial ischemia by inducing “coronary steal” (*i.e.*, the diversion of blood flow from poorly perfused to well perfused areas) (Buffington *et al.*, 1988). This concern has not been substantiated in subsequent animal and human studies. Patients anesthetized with isoflurane generally have mildly elevated heart rates as a compensatory response to reduced blood pressure; however, rapid changes in isoflurane concentration can produce both transient tachycardia and hypertension due to isoflurane-induced sympathetic stimulation.

Respiratory System. Isoflurane produces concentration-dependent depression of ventilation. Patients spontaneously breathing isoflurane have a normal respiration rate but a reduced tidal volume, resulting in a marked reduction in alveolar ventilation and an increase in arterial CO₂ tension (Figure 13-7). Isoflurane is particularly effective at depressing the ventilatory response to hypercapnia and hypoxia (Hirshman *et al.*, 1977). While isoflurane is an effective bronchodilator, it also is an airway irritant and can stimulate airway reflexes during induction of anesthesia, producing coughing and laryngospasm.

Nervous System. Isoflurane, like halothane, dilates the cerebral vasculature, producing increased cerebral blood flow and the risk of increased intracranial pressure. Isoflurane also reduces cerebral metabolic O₂ consumption. Isoflurane causes less cerebral vasodilation than do either *enflurane* or halothane, making it a preferred agent for neurosurgical procedures (Drummond *et al.*, 1983). The modest effects of isoflurane on cerebral blood flow can be reversed readily by hyperventilation (McPherson *et al.*, 1989).

Muscle. Isoflurane produces some relaxation of skeletal muscle *via* its central effects. It also enhances the effects of both depolarizing and nondepolarizing muscle relaxants. Isoflurane is more potent than halothane in its potentiation of neuromuscular blocking agents. Like other halogenated inhalational anesthetics, isoflurane relaxes uterine smooth muscle and is not recommended for analgesia or anesthesia for labor and vaginal delivery.

Kidney. Isoflurane reduces renal blood flow and glomerular filtration rate, resulting in a small volume of concentrated urine. Changes in renal function observed during isoflurane anesthesia are rapidly reversed, with no long-term renal sequelae or toxicities.

Liver and Gastrointestinal Tract. Splanchnic and hepatic blood flows are reduced with increasing doses of isoflurane as systemic arterial pressure decreases. Liver function tests are minimally affected by isoflurane, with no reported incidence of hepatic toxicity.

Enflurane

Chemical and Physical Properties. Enflurane (ETHRANE, others) is 2-chloro-1,1,2-trifluoroethyl difluoromethyl ether (Figure 13-4). It is a clear, colorless liquid at room temperature with a mild, sweet odor. Like other inhalational anesthetics, it is volatile and must be stored in a sealed bottle. It is nonflammable and nonexplosive in mixtures of air or oxygen.

Pharmacokinetics. Because of its relatively high blood:gas partition coefficient, induction of anesthesia and recovery from enflurane are relatively slow (Table 13-1). Enflurane is metabolized to a modest extent, with 2% to 8% of absorbed enflurane undergoing oxidative metabolism in the liver by CYP2E1 (Kharasch *et al.*, 1994). Fluoride ions are a by-product of enflurane metabolism, but plasma fluoride levels are low and nontoxic. Patients taking isoniazid exhibit enhanced metabolism of enflurane with significantly elevated serum fluoride concentrations (Mazze *et al.*, 1982).

Clinical Use. As with isoflurane, enflurane is primarily utilized for maintenance rather than induction of anesthesia.

Surgical anesthesia can be induced with enflurane in less than 10 minutes with an inhaled concentration of 4% in oxygen. Anesthesia can be maintained with concentrations from 1.5% to 3%. As with other anesthetics, the enflurane concentrations required to produce anesthesia are reduced when it is coadministered with nitrous oxide or opioids. Use of enflurane has decreased substantially in recent years with the introduction of newer inhalational agents with preferable pharmacokinetic and side-effect profiles.

Side Effects. Cardiovascular System. Enflurane causes a concentration-dependent decrease in arterial blood pressure. Hypotension is due, in part, to depression of myocardial contractility, with some contribution from peripheral vasodilation (Figure 13-6). Enflurane has minimal effects on heart rate and produces neither the bradycardia seen with halothane nor the tachycardia seen with isoflurane.

Respiratory System. The respiratory effects of enflurane are similar to those of halothane. Spontaneous ventilation with enflurane produces a pattern of rapid, shallow breathing. Minute ventilation is markedly decreased, and a P_{aCO_2} of 60 mm Hg can be seen with 1 MAC of enflurane (Figure 13-7). Enflurane produces a greater depression of the ventilatory responses to hypoxia and hypercarbia than do either halothane or isoflurane (Hirshman *et al.*, 1977). Enflurane, like other inhalational anesthetics, is an effective bronchodilator.

Nervous System. Enflurane is a cerebral vasodilator and thus can increase intracranial pressure in some patients. Like other inhalational anesthetics, enflurane reduces cerebral metabolic O_2 consumption. Enflurane has an unusual property of producing electrical seizure activity. High concentrations of enflurane or profound hypocarbia during enflurane anesthesia result in a characteristic high-voltage, high-frequency electroencephalographic (EEG) pattern that progresses to spike-and-dome complexes. The spike-and-dome pattern can be punctuated by frank seizure activity that may or may not be accompanied by peripheral motor manifestations of seizure activity. The seizures are self-limited and are not thought to produce permanent damage. Epileptic patients are not particularly susceptible to enflurane-induced seizures. Nonetheless, enflurane generally is not used in patients with seizure disorders.

Muscle. Enflurane produces significant skeletal muscle relaxation in the absence of muscle relaxants. It also significantly enhances the effects of nondepolarizing muscle relaxants. As with other inhalational agents, enflurane relaxes uterine smooth muscle. It is not widely used for obstetric anesthesia.

Kidney. Like other inhalational anesthetics, enflurane reduces renal blood flow, glomerular filtration rate, and urinary output. These effects are rapidly reversed upon drug discontinuation. Enflurane metabolism produces significant plasma levels of fluoride ions (20 to 40 μ mol) and can produce transient urinary-concentrating defects following prolonged administration (Mazze *et al.*, 1977). There is scant evidence of long-term nephrotoxicity following enflurane use, and it is safe to use in patients with renal impairment, provided that the depth of enflurane anesthesia and the duration of administration are not excessive.

Liver and Gastrointestinal Tract. Enflurane reduces splanchnic and hepatic blood flow in proportion to reduced arterial blood pressure. Enflurane does not appear to alter liver function or to be hepatotoxic.

Desflurane

Chemistry and Physical Properties. *Desflurane* (SUPRANE) is difluoromethyl 1-fluoro-2,2,2-trifluoromethyl ether (Figure 13-4). It is a highly volatile liquid at room temperature (vapor pressure = 681 mm Hg) and thus must be stored in tightly sealed bottles. Delivery of a precise concentration of desflurane requires the use of a specially heated vaporizer that delivers pure vapor that then is diluted appropriately with other gases (O_2 , air, or N_2O). Desflurane is nonflammable and nonexplosive in mixtures of air or oxygen.

Pharmacokinetics. Desflurane has a very low blood:gas partition coefficient (0.42) and also is not very soluble in fat or other peripheral tissues (Table 13-1). For this reason, the alveolar (and blood) concentration rapidly rises to the level of inspired concentration. Indeed, within five minutes of administration, the alveolar concentration reaches 80% of the inspired concentration. This provides for a very rapid induction of anesthesia and for rapid changes in depth

of anesthesia following changes in the inspired concentration. Emergence from anesthesia also is very rapid with desflurane. The time to awakening following desflurane is half as long as with halothane or *sevoflurane* and usually does not exceed 5 to 10 minutes in the absence of other sedative agents (Smiley *et al.*, 1991).

Desflurane is metabolized to a minimal extent, and more than 99% of absorbed desflurane is eliminated unchanged *via* the lungs. A small amount of absorbed desflurane is oxidatively metabolized by hepatic CYPs. Virtually no serum fluoride ions are detectable in serum after desflurane administration, but low concentrations of trifluoroacetic acid are detectable in serum and urine (Koblin *et al.*, 1988).

Clinical Use. Desflurane is a widely used anesthetic for outpatient surgery because of its rapid onset of action and rapid recovery. The drug is irritating to the airway in awake patients and can provoke coughing, salivation, and bronchospasm. Anesthesia therefore usually is induced with an intravenous agent, with desflurane subsequently administered for maintenance of anesthesia. Maintenance of anesthesia usually requires inhaled concentrations of 6% to 8%. Lower concentrations of desflurane are required if it is coadministered with nitrous oxide or opioids.

Side Effects. Cardiovascular System. Desflurane, like all inhalational anesthetics, causes a concentration-dependent decrease in blood pressure. Desflurane has a very modest negative inotropic effect and produces hypotension primarily by decreasing systemic vascular resistance (Eger, 1994) (Figure 13–6). Cardiac output thus is well preserved during desflurane anesthesia, as is blood flow to the major organ beds (splanchnic, renal, cerebral, and coronary). Marked increases in heart rate often are noted during induction of desflurane anesthesia and during abrupt increases in the delivered concentration of desflurane. This transient tachycardia results from desflurane-induced stimulation of the sympathetic nervous system (Ebert and Muzi, 1993). Unlike some inhalational anesthetics, the hypotensive effects of desflurane do not wane with increasing duration of administration.

Respiratory System. Similarly to halothane and enflurane, desflurane causes a concentration-dependent increase in respiratory rate and a decrease in tidal volume. At low concentrations (less than 1 MAC) the net effect is to preserve minute ventilation. At desflurane concentrations greater than 1 MAC, minute ventilation is markedly depressed, resulting in elevated arterial CO₂ tension (Pa_{CO₂}) (Figure 13–7) (Lockhart *et al.*, 1991). Patients spontaneously breathing desflurane at concentrations greater than 1.5 MAC will have extreme elevations of Pa_{CO₂} and may become apneic. Desflurane, like other inhalational agents, is a bronchodilator. However, it also is a strong airway irritant, and can cause coughing, breath-holding,

laryngospasm, and excessive respiratory secretions. Because of its irritant properties, desflurane is not used for induction of anesthesia.

Nervous System. Desflurane decreases cerebral vascular resistance and cerebral metabolic O₂ consumption. Under conditions of normocapnia and normotension, desflurane produces an increase in cerebral blood flow and can increase intracranial pressure in patients with poor intracranial compliance. The vasoconstrictive response to hypocapnia is preserved during desflurane anesthesia, and increases in intracranial pressure thus can be prevented by hyperventilation.

Muscle. Desflurane produces direct skeletal muscle relaxation as well as enhancing the effects of nondepolarizing and depolarizing neuromuscular blocking agents (Caldwell *et al.*, 1991).

Kidney. Desflurane has no reported nephrotoxicity. This is consistent with its minimal metabolic degradation.

Liver and Gastrointestinal Tract. Desflurane is not known to affect liver function tests or to cause hepatotoxicity.

Sevoflurane

Chemistry and Physical Properties. Sevoflurane (ULTANE) is fluoromethyl 2,2,2-trifluoro-1-[trifluoromethyl]ethyl ether (Figure 13–4). It is a clear, colorless, volatile liquid at room temperature and must be stored in a sealed bottle. It is nonflammable and nonexplosive in mixtures of air or oxygen. Sevoflurane can undergo an exothermic reaction with desiccated CO₂ absorbent (BARALYME) to produce airway burns (Fatheree and Leighton, 2004) or spontaneous ignition, explosion and fire (Wu *et al.*, 2004a). *Care must be taken to ensure that sevoflurane is not used with an anesthesia machine in which the CO₂ absorbent has been dried by prolonged gas flow through the absorbent. Sevoflurane reaction with desiccated CO₂ absorbent also can produce CO, which can result in serious patient injury.*

Pharmacokinetics. The low solubility of sevoflurane in blood and other tissues provides for rapid induction of anesthesia, rapid changes in anesthetic depth following changes in delivered concentration, and rapid emergence following discontinuation of administration (Table 13–1).

Approximately 3% of absorbed sevoflurane is biotransformed. Sevoflurane is metabolized in the liver by CYP2E1, with the predominant product being hexafluoroisopropanol (Kharasch *et al.*, 1995). Hepatic metabolism of sevoflurane also produces inorganic fluoride. Serum fluoride concentrations peak shortly after surgery and decline rapidly. Interaction of sevoflurane with soda lime also produces decomposition products. The major product of interest is referred to as compound A and is pentafluoroisopropenyl fluoromethyl ether (*see* Side Effects: Kidney, below) (Hanaki *et al.*, 1987).

Clinical Use. Sevoflurane is widely used, particularly for outpatient anesthesia, because of its rapid recovery profile. It is well-suited for inhalation induction of anesthesia (particularly in children) because it is not irritating to the airway. Induction of anesthesia is rapidly achieved using inhaled concentrations of 2% to 4% sevoflurane.

Side Effects. Cardiovascular System. Sevoflurane, like all other halogenated inhalational anesthetics, produces a concentration-dependent decrease in arterial blood pressure. This hypotensive effect primarily is due to systemic vasodilation, although sevoflurane also produces a concentration-dependent decrease in cardiac output (Figure 13–6). Unlike isoflurane or desflurane, sevoflurane does not produce tachycardia and thus may be a preferable agent in patients prone to myocardial ischemia.

Respiratory System. Sevoflurane produces a concentration-dependent reduction in tidal volume and increase in respiratory rate in spontaneously breathing patients. The increased respiratory frequency does not compensate for reduced tidal volume, with the net effect being a reduction in minute ventilation and an increase in P_{aCO_2} (Doi and Ikeda, 1987) (Figure 13–7). Sevoflurane is not irritating to the airway and is a potent bronchodilator. Because of this combination of properties, sevoflurane is the most effective clinical bronchodilator of the inhalational anesthetics (Rooke *et al.*, 1997).

Nervous System. Sevoflurane produces effects on cerebral vascular resistance, cerebral metabolic O_2 consumption, and cerebral blood flow that are very similar to those produced by isoflurane and desflurane. While sevoflurane can increase intracranial pressure in patients with poor intracranial compliance, the response to hypocapnia is preserved during sevoflurane anesthesia, and increases in intracranial pressure can be prevented by hyperventilation.

Muscle. Sevoflurane produces skeletal muscle relaxation and enhances the effects of nondepolarizing and depolarizing neuromuscular blocking agents. Its effects are similar to those of other halogenated inhalational anesthetics.

Kidney. Controversy has surrounded the potential nephrotoxicity of compound A, the degradation product produced by interaction of sevoflurane with the CO_2 absorbent soda lime. Biochemical evidence of transient renal injury has been reported in human volunteers (Eger *et al.*, 1997). Large clinical studies have shown no evidence of increased serum creatinine, blood urea nitrogen, or any other evidence of renal impairment following sevoflurane administration (Mazze *et al.*, 2000). *The current recommendation of the FDA is that sevoflurane be administered with fresh gas flows of at least 2 L/min to minimize accumulation of compound A.*

Liver and Gastrointestinal Tract. Sevoflurane is not known to cause hepatotoxicity or alterations of hepatic function tests.

Nitrous Oxide

Chemical and Physical Properties. Nitrous oxide (dinitrogen monoxide; N_2O) is a colorless, odorless gas at room temperature (Figure 13–4). It is sold in steel cylinders and must be delivered through calibrated flow meters provided on all anesthesia machines. Nitrous oxide is neither flammable nor explosive, but it does support com-

bustion as actively as oxygen does when it is present in proper concentration with a flammable anesthetic or material.

Pharmacokinetics. Nitrous oxide is very insoluble in blood and other tissues (Table 13–1). This results in rapid equilibration between delivered and alveolar anesthetic concentrations and provides for rapid induction of anesthesia and rapid emergence following discontinuation of administration. The rapid uptake of N_2O from alveolar gas serves to concentrate coadministered halogenated anesthetics; this effect (the “second gas effect”) speeds induction of anesthesia. On discontinuation of N_2O administration, nitrous oxide gas can diffuse from blood to the alveoli, diluting O_2 in the lung. This can produce an effect called *diffusional hypoxia*. *To avoid hypoxia, 100% O_2 rather than air should be administered when N_2O is discontinued.*

Nitrous oxide is almost completely eliminated by the lungs, with some minimal diffusion through the skin. Nitrous oxide is not biotransformed by enzymatic action in human tissue, and 99.9% of absorbed nitrous oxide is eliminated unchanged. Nitrous oxide can be degraded by interaction with vitamin B_{12} in intestinal bacteria. This results in inactivation of methionine synthesis and can produce signs of vitamin B_{12} deficiency (megaloblastic anemia and peripheral neuropathy) following long-term nitrous oxide administration (O’Sullivan *et al.*, 1981). For this reason, N_2O is not used as a chronic analgesic or as a sedative in critical care settings.

Clinical Use. Nitrous oxide is a weak anesthetic agent and produces reliable surgical anesthesia only under hyperbaric conditions. It does produce significant analgesia at concentrations as low as 20% and usually produces sedation in concentrations between 30% and 80%. It frequently is used in concentrations of approximately 50% to provide analgesia and sedation in outpatient dentistry. Nitrous oxide cannot be used at concentrations above 80% because this limits the delivery of an adequate amount of oxygen. Because of this limitation, nitrous oxide is used primarily as an adjunct to other inhalational or intravenous anesthetics. Nitrous oxide substantially reduces the requirement for inhalational anesthetics. For example, at 70% nitrous oxide, the MAC for other inhalational agents is reduced by about 60%, allowing for lower concentrations of halogenated anesthetics and a lesser degree of side effects.

One major problem with N_2O is that it will exchange with N_2 in any air-containing cavity in the body. Moreover, because of their differential blood:gas partition coefficients, nitrous oxide will enter the cavity faster than nitrogen escapes, thereby increasing the volume and/or pressure in this cavity. Examples of air collections that can be expanded by nitrous oxide include a pneumothorax, an obstructed middle ear, an air embolus, an obstructed loop of bowel, an intraocular air bubble, a pulmonary bulla, and intracranial air. Nitrous oxide should be avoided in these clinical settings.

Side Effects. Cardiovascular System. Although N_2O produces a negative inotropic effect on heart muscle *in vitro*, depressant effects on cardiac function generally are not observed in patients because of the stimulatory effects of nitrous oxide on the sympathetic nervous system. The cardiovascular effects of nitrous oxide also are heavily influenced by the concomitant administration of other anesthetic agents. When nitrous oxide is coadministered with halogenated inhalational anesthetics, it generally produces an increase in heart rate, arterial blood pressure, and cardiac output. In contrast, when nitrous oxide is coadministered with an opioid, it generally decreases arterial blood pressure and cardiac output. Nitrous oxide also increases venous tone in both the peripheral and pulmonary vasculature. The effects of N_2O on pulmonary vascular resistance can be exaggerated in patients with pre-existing pulmonary hypertension (Schulte-Sasse *et al.*, 1982) and the drug generally is not used in these patients.

Respiratory System. Nitrous oxide causes modest increases in respiratory rate and decreases in tidal volume in spontaneously breathing patients. The net effect is that minute ventilation is not significantly changed and Pa_{CO_2} remains normal. However, even modest concentrations of nitrous oxide markedly depress the ventilatory response to hypoxia. Thus, it is prudent to monitor arterial O_2 saturation directly in patients receiving or recovering from nitrous oxide.

Nervous System. When administered alone, nitrous oxide can significantly increase cerebral blood flow and intracranial pressure. When nitrous oxide is coadministered with intravenous anesthetic agents, increases in cerebral blood flow are attenuated or abolished. When nitrous oxide is added to a halogenated inhalational anesthetic, its vasodilatory effect on the cerebral vasculature is slightly reduced.

Muscle. Nitrous oxide does not relax skeletal muscle and does not enhance the effects of neuromuscular blocking drugs. Unlike the halogenated anesthetics, nitrous oxide does not trigger malignant hyperthermia.

Kidney, Liver, and Gastrointestinal Tract. Nitrous oxide is not known to produce any changes in renal or hepatic function and is neither nephrotoxic nor hepatotoxic.

Xenon

Xenon is an inert gas that first was identified as an anesthetic agent in 1951. It is not approved for use in the United States and is unlikely to enjoy widespread use because it is a rare gas that cannot be manufactured and must be extracted from air. This limits the quantities of available xenon gas and renders xenon very expensive. Despite these shortcomings, xenon has properties that make it a virtually ideal anesthetic gas that ultimately may be used in critical situations (Lynch *et al.*, 2000).

Xenon is extremely insoluble in blood and other tissues, providing for rapid induction and emergence from anesthesia (Table 13–1). It is sufficiently potent to produce surgical anesthesia when administered with 30% oxygen. Most importantly, xenon has minimal side effects. It has no effects on cardiac output or cardiac rhythm and is not thought to have a significant effect on systemic vascular resistance. It also does not affect pulmonary function and is not known to have any hepatic or renal toxicity. Finally, xenon is not metabolized in the human body. Xenon is an anesthetic that may be available in the future if limitations on its availability and its high cost can be overcome.

ANESTHETIC ADJUNCTS

A general anesthetic is rarely given as the sole agent. Rather, anesthetic adjuncts usually are used to augment specific components of anesthesia, permitting lower doses of general anesthetics with fewer side effects. Because they are such an integral part of general anesthetic drug regimens, their use as anesthetic adjuncts is described briefly here. The detailed pharmacology of each drug is covered in other chapters.

Benzodiazepines

While benzodiazepines (*see* Chapter 16) can produce anesthesia similar to that of barbiturates, they are more commonly used for sedation rather than general anesthesia because prolonged amnesia and sedation may result from anesthetizing doses. As adjuncts, benzodiazepines are used for anxiolysis, amnesia, and sedation prior to induction of anesthesia or for sedation during procedures not requiring general anesthesia. The benzodiazepine most frequently used in the perioperative period is *midazolam* (VERSED) followed distantly by *diazepam* (VALIUM), and *lorazepam* (ATIVAN). Midazolam is water soluble and typically is administered intravenously but also can be given orally, intramuscularly, or rectally; oral midazolam is particularly useful for sedation of young children. Midazolam produces minimal venous irritation as opposed to diazepam and lorazepam, which are formulated in propylene glycol and are painful on injection, sometimes producing thrombophlebitis. Midazolam has the pharmacokinetic advantage, particularly over lorazepam, of being more rapid in onset and shorter in duration of effect. Sedative doses of midazolam (0.01 to 0.07 mg/kg intravenously) reach peak effect in about 2 minutes and provide sedation for about 30 minutes (Reves *et al.*, 1985). Elderly patients tend to be more sensitive to and have a slower recovery from benzodiazepines (Jacobs *et al.*, 1995); thus, titration to the desired effect of smaller doses in this age

group is prudent. Midazolam is hepatically metabolized with a clearance (6 to 11 ml/min per kg), similar to that of methohexital and about 20 and 7 times higher than those of diazepam and lorazepam, respectively (Reves *et al.*, 1985). Either for prolonged sedation or for general anesthetic maintenance, midazolam is more suitable for infusion than are other benzodiazepines, although its duration of action does significantly increase with prolonged infusions (Figure 13–3). Benzodiazepines reduce both cerebral blood flow and metabolism, but at equi-anesthetic doses are less potent in this respect than are barbiturates. They are effective anticonvulsants and sometimes are given to treat status epilepticus (Modica *et al.*, 1990). Benzodiazepines modestly decrease blood pressure and respiratory drive, occasionally resulting in apnea (Reves *et al.*, 1985). Thus, blood pressure and respiratory rate should be monitored in patients sedated with intravenous benzodiazepines.

α_2 Adrenergic Agonists. In 1999 the FDA approved the α_2 adrenergic agonist dexmedetomidine (PRECEDEX) for short-term sedation of critically ill adults. Dexmedetomidine is now widely used in the intensive care unit setting and is beginning to be administered off-label in other clinical scenarios including as an anesthetic adjunct. Dexmedetomidine is an imidazole derivative that is highly selective for the α_2 adrenergic receptor (Kamibayashi *et al.*, 2000). Activation of the α_{2A} adrenergic receptor by dexmedetomidine produces both sedation and analgesia, but does not reliably provide general anesthesia, even at maximal doses (Aho *et al.*, 1992; Lakhani *et al.*, 1997).

The most common side effects of dexmedetomidine include hypotension and bradycardia, both of which are attributed to decreased catecholamine release by activation peripherally and in the CNS of the α_{2A} -receptor (Lakhani *et al.*, 1997). Nausea and dry mouth also are common untoward reactions. At higher drug concentrations, the α_{2B} -subtype is activated, resulting in hypertension and a further decrease in heart rate and cardiac output. Dexmedetomidine has the very useful property of producing sedation and analgesia with minimal respiratory depression (Belleville *et al.*, 1992); thus, it is particularly valuable in sedation of patients who are not endotracheally intubated and mechanically ventilated. The sedation produced by dexmedetomidine has been noted to be more akin to natural sleep, with patients relatively easy to arouse (Hall *et al.*, 2000). However, dexmedetomidine does not appear to provide reliable amnesia and additional agents may need to be employed if lack of recall is desirable (Coursin and Maccioli, 2001).

Dexmedetomidine is supplied as an aqueous solution of the hydrochloride salt and should be diluted in normal saline to a final concentration of 4 $\mu\text{g/ml}$ for intravenous delivery, the only approved route of administration. The recommended loading dose is 1 $\mu\text{g/kg}$ given over 10 minutes, followed by infusion at a rate of 0.2 to 0.7 $\mu\text{g/kg}$ per hour. Infusions for longer than 24 hours are not recommended because of a potential for rebound hypertension. Reduced

doses should be considered in patients with risk factors for severe hypotension. The distribution and terminal half-lives are 6 minutes and 2 hours, respectively (Khan *et al.*, 1999). Dexmedetomidine is highly protein bound and is primarily hepatically metabolized; the glucuronide and methyl conjugates are renally excreted (Bhana *et al.*, 2000).

In summary, dexmedetomidine is a relatively new sedative-hypnotic that provides analgesia with little respiratory depression and in most patients a tolerable decrease in blood pressure and heart rate. Dexmedetomidine is likely to be increasingly used for sedation and as an anesthetic adjunct.

Analgesics

With the exception of ketamine, neither parenteral nor currently available inhalational anesthetics are effective analgesics. Thus, analgesics typically are administered with general anesthetics to reduce anesthetic requirement and minimize hemodynamic changes produced by painful stimuli. Nonsteroidal antiinflammatory drugs, cyclooxygenase-2 inhibitors, or acetaminophen sometimes provide adequate analgesia for minor surgical procedures. However, because of the rapid and profound analgesia produced, opioids are the primary analgesics used during the perioperative period.

Fentanyl (SUBLIMAZE), *sufentanil* (SUFENTA), *alfentanil* (ALFENTA), *remifentanil* (ULTIVA), *meperidine* (DEMEROL), and *morphine* are the major parenteral opioids used in the perioperative period. The primary analgesic activity of each of these drugs is produced by agonist activity at μ -opioid receptors (Pasternak, 1993). Their order of potency (relative to morphine) is: sufentanil (1000x) > remifentanil (300x) > fentanyl (100x) > alfentanil (15x) > morphine (1x) > meperidine (0.1x) (Clotz and Nahata, 1991; Glass *et al.*, 1993; Martin, 1983). Pharmacological properties of these agents are discussed in more detail in Chapter 21.

The choice of a perioperative opioid is based primarily on duration of action, given that at appropriate doses, all produce similar analgesia and side effects. Remifentanil has an ultrashort duration of action (~10 minutes) and accumulates minimally with repeated doses or infusion (Glass *et al.*, 1993); it is particularly well suited for procedures that are briefly painful, but for which little analgesia is required postoperatively. Single doses of fentanyl, alfentanil, and sufentanil all have similar intermediate durations of action (30, 20, and 15 minutes, respectively), but recovery after prolonged administration varies considerably (Shafer *et al.*, 1991). Fentanyl's duration of action lengthens most with infusion, sufentanil's much less so, and alfentanil's the least. Except for remifentanil, all of the above-mentioned opioids are metabolized in the liver followed by renal and biliary excretion of the metabolites (Tegeder *et al.*, 1999). Remifentanil is hydrolyzed by tissue and plasma esterases (Westmoreland *et al.*, 1993). After prolonged administration, morphine metabolites have significant analgesic and hypnotic activity (Christrup, 1997).

During the perioperative period, opioids often are given at induction to preempt responses to predictable painful stimuli (e.g., endotracheal intubation and surgical incision). Subsequent doses either by bolus or infusion are titrated to the surgical stimulus and the patient's hemodynamic response. Marked decreases in respiratory rate and heart rate with much smaller reductions in blood pressure are seen to varying degrees with all opioids (Bowdle, 1998). Muscle rigidity that can impair ventilation sometimes accompanies larger doses of opioids. The incidence of sphincter of Oddi spasm is increased with all opioids, although morphine appears to be more potent in this regard (Hahn *et al.*, 1988). The frequency and severity of nausea, vomiting, and pruritus after emergence from anesthesia are increased by all opioids to about the same degree (Watcha *et al.*, 1992). A useful side effect of meperidine is its capacity to reduce shivering, a common problem during emergence from anesthesia (Pauca *et al.*, 1984); other opioids are not as efficacious against shivering, perhaps due to less κ -receptor agonist activity. Finally, opioids often are administered intrathecally and epidurally for management of acute and chronic pain. Neuraxial opioids with or without local anesthetics can provide profound analgesia for many surgical procedures; however, respiratory depression and pruritus usually limit their use to major operations.

Neuromuscular Blocking Agents

The practical aspects of the use of neuromuscular blockers as anesthetic adjuncts are briefly described here. The detailed pharmacology of this drug class is presented in Chapter 9.

Depolarizing (e.g., *succinylcholine*) and nondepolarizing muscle relaxants (e.g., *pancuronium*) often are administered during the induction of anesthesia to relax muscles of the jaw, neck, and airway and thereby facilitate laryngoscopy and endotracheal intubation. Barbiturates will precipitate when mixed with muscle relaxants and should be allowed to clear from the intravenous line prior to injection of a muscle relaxant. Following induction, continued muscle relaxation is desirable for many procedures to aid surgical exposure and to provide additional insurance of immobility. Of course, muscle relaxants are not by themselves anesthetics and should not be used in lieu of adequate anesthetic depth. The action of nondepolarizing muscle relaxants usually is antagonized, once muscle paralysis is no longer desired, with an acetylcholinesterase inhibitor such as *neostigmine* or *edrophonium* (see Chapter 8) combined with a muscarinic receptor antagonist (e.g., *glycopyrolate* or *atropine*) (see Chapter 7) to offset the muscarinic activation resulting from esterase inhibition. Other than histamine release by some agents, nondepolarizing muscle relaxants used in this manner have few side effects. However, succinylcholine has multiple serious side effects (bradycardia, hyperkalemia, and severe myalgia) including induction of malignant hyperthermia in susceptible individuals.

LOCAL ANESTHETICS

William A. Catterall and Kenneth Mackie

Local anesthetics bind reversibly to a specific receptor site within the pore of the Na⁺ channels in nerves and block ion movement through this pore. When applied locally to nerve tissue in appropriate concentrations, local anesthetics can act on any part of the nervous system and on every type of nerve fiber, reversibly blocking the action potentials responsible for nerve conduction. Thus, a local anesthetic in contact with a nerve trunk can cause both sensory and motor paralysis in the area innervated. These effects of clinically relevant concentrations of local anesthetics are reversible with recovery of nerve function and no evidence of damage to nerve fibers or cells in most clinical applications.

History. The first local anesthetic, *cocaine*, was serendipitously discovered to have anesthetic properties in the late 19th century. Cocaine occurs in abundance in the leaves of the coca shrub (*Erythroxylon coca*). For centuries, Andean natives have chewed an alkali extract of these leaves for its stimulatory and euphoric actions. Cocaine was first isolated in 1860 by Albert Niemann. He, like many chemists of that era, tasted his newly isolated compound and noted that it caused a numbing of the tongue. Sigmund Freud studied cocaine's physiological actions, and Carl Koller introduced cocaine into clinical practice in 1884 as a topical anesthetic for ophthalmological surgery. Shortly thereafter, Halstead popularized its use in infiltration and conduction block anesthesia.

Chemistry and Structure–Activity Relationship. Cocaine is an ester of benzoic acid and the complex alcohol 2-carbomethoxy, 3-hydroxy-tropane (Figure 14–1). Because of its toxicity and addictive properties (*see* Chapter 23), a search for synthetic substitutes for cocaine began in 1892 with the work of Einhorn and colleagues, resulting in the synthesis of *procaine*, which became the prototype for local anesthetics for nearly half a century. The most widely used agents today are procaine, *lidocaine*, *bupivacaine*, and *tetracaine*.

The typical local anesthetics contain hydrophilic and hydrophobic moieties that are separated by an intermediate ester or amide linkage (Figure 14–1). A broad range of compounds containing these minimal structural features can satisfy the requirements for action as local anesthetics. The hydrophilic group usually is a ter-

ry amine but also may be a secondary amine; the hydrophobic moiety must be aromatic. The nature of the linking group determines some of the pharmacological properties of these agents. For example, local anesthetics with an ester link are hydrolyzed readily by plasma esterases.

The structure–activity relationship and the physicochemical properties of local anesthetics have been reviewed by Courtney and Strichartz (1987). Hydrophobicity increases both the potency and the duration of action of the local anesthetics. This arises because association of the drug at hydrophobic sites enhances the partitioning of the drug to its sites of action and decreases the rate of metabolism by plasma esterases and hepatic enzymes. In addition, the receptor site for these drugs on Na⁺ channels is thought to be hydrophobic (*see* below), so that receptor affinity for anesthetic agents is greater for more hydrophobic drugs. Hydrophobicity also increases toxicity, so that the therapeutic index is decreased for more hydrophobic drugs.

Molecular size influences the rate of dissociation of local anesthetics from their receptor sites. Smaller drug molecules can escape from the receptor site more rapidly. This characteristic is important in rapidly firing cells, in which local anesthetics bind during action potentials and dissociate during the period of membrane repolarization. Rapid binding of local anesthetics during action potentials causes the frequency- and voltage-dependence of their action (*see* below).

Mechanism of Action. Local anesthetics act at the cell membrane to prevent the generation and the conduction of nerve impulses. Conduction block can be demonstrated in squid giant axons from which the axoplasm has been removed.

Local anesthetics block conduction by decreasing or preventing the large transient increase in the permeability of excitable membranes to Na⁺ that normally is produced by a slight depolarization of the membrane (*see* Chapter 12) (Strichartz and Ritchie, 1987). This action of local anesthetics is due to their direct interaction with voltage-gated Na⁺ channels. As the anesthetic action progressively develops in a nerve, the threshold for electrical excitability gradually increases, the rate of rise of the action poten-

tial declines, impulse conduction slows, and the safety factor for conduction decreases. These factors decrease the probability of propagation of the action potential, and nerve conduction eventually fails.

Local anesthetics can bind to other membrane proteins (Butterworth and Strichartz, 1990). In particular, they can block K^+ channels (Strichartz and Ritchie, 1987). However, since the interaction of local anesthetics with K^+ channels requires higher concentrations of drug, blockade of conduction is not accompanied by any large or consistent change in resting membrane potential.

Quaternary analogs of local anesthetics block conduction when applied internally to perfused giant axons of squid but are relatively ineffective when applied externally. These observations suggest that the site at which local anesthetics act, at least in their charged form, is accessible only from the inner surface of the membrane (Narahashi and Frazier, 1971; Strichartz and Ritchie, 1987). Therefore, local anesthetics applied externally first must cross the membrane before they can exert a blocking action.

Although a variety of physicochemical models have been proposed to explain how local anesthetics achieve conduction block (Courtney and Strichartz, 1987), it now is generally accepted that the major mechanism of action of these drugs involves their interaction with one or more specific binding sites within the Na^+ channel (Butterworth and Strichartz, 1990). The Na^+ channels of the mammalian brain are complexes of glycosylated proteins with an aggregate molecular size in excess of 300,000 daltons; the individual subunits are designated α (260,000 daltons) and β_1 to β_4 (33,000 to 38,000 daltons). The large α subunit of the Na^+ channel contains four homologous domains (I to IV); each domain is thought to consist of six transmembrane segments in α -helical conformation (S1 to S6; Figure 14–2) and an additional, membrane-reentrant pore (*P*) loop. The Na^+ -selective transmembrane pore of the channel presumably resides in the center of a nearly symmetrical structure formed by the four homologous domains. The voltage dependence of channel opening is hypothesized to reflect conformational changes that result from the movement of “gating charges” (voltage sensors) in response to changes in the transmembrane potential. The gating charges are

located in the S4 transmembrane helix; the S4 helices are both hydrophobic and positively charged, containing lysine or arginine residues at every third position. It is postulated that these residues move perpendicular to the plane of the membrane under the influence of the transmembrane potential, initiating a series of conformational changes in all four domains, which leads to the open state of the channel (Catterall, 2000; Figure 14–2).

The transmembrane pore of the Na^+ channel is thought to be surrounded by the S5 and S6 transmembrane helices and the short membrane-associated segments between them that form the *P* loop. Amino acid residues in these short segments are the most critical determinants of the ion conductance and selectivity of the channel.

After it opens, the Na^+ channel inactivates within a few milliseconds due to closure of an inactivation gate. This functional gate is formed by the short intracellular loop of protein that connects homologous domains III and IV (Figure 14–2). The loop folds over the intracellular mouth of the transmembrane pore during the process of inactivation and also binds to an inactivation gate “receptor” formed by the intracellular mouth of the pore.

Amino acid residues important for local anesthetic binding are found in the S6 segment in domains I, III, and IV (Ragsdale *et al.*, 1994; Yarov-Yarovoy *et al.*, 2002). Hydrophobic amino acid residues near the center and the intracellular end of the S6 segment may interact directly with bound local anesthetics (Figure 14–3). Experimental mutation of a large hydrophobic amino acid residue (isoleucine) to a smaller one (alanine) near the extracellular end of this segment creates a pathway for access of charged local anesthetic drugs from the extracellular solution to the receptor site. These findings place the local anesthetic receptor site within the intracellular half of the transmembrane pore of the Na^+ channel, with part of its structure contributed by amino acids in the S6 segments of domains I, III, and IV.

Frequency- and Voltage-Dependence of Local Anesthetic Action. The degree of block produced by a given concentration of local anesthetic depends on how the nerve has been stimulated and on its resting membrane

← **Figure 14–1. Structural formulas of selected local anesthetics.** Most local anesthetics consist of a hydrophobic (aromatic) moiety (black), a linker region (light blue), and a substituted amine (hydrophilic region, in dark blue). The structures above are grouped by the nature of the linker region. Procaine is a prototypic ester-type local anesthetic; esters generally are well hydrolyzed by plasma esterases, contributing to the relatively short duration of action of drugs in this group. Lidocaine is a prototypic amide-type local anesthetic; these structures generally are more resistant to clearance and have longer durations of action. There are exceptions, including benzocaine (poorly water soluble; used only topically) and the structures with a ketone, an amidine, and an ether linkage. *Chlorprocaine has a chlorine atom on C2 of the aromatic ring of procaine.

Figure 14–2. Structure and function of voltage-gated Na^+ channels. **A.** A two-dimensional representation of the α (center), β_1 (left), and β_2 (right) subunits of the voltage-gated Na^+ channel from mammalian brain. The polypeptide chains are represented by continuous lines with length approximately proportional to the actual length of each segment of the channel protein. Cylinders represent regions of transmembrane α helices. Ψ indicates sites of demonstrated N-linked glycosylation. Note the repeated structure of the four homologous domains (I through IV) of the α subunit. **Voltage Sensing.** The S4 transmembrane segments in each homologous domain of the α subunit serve as voltage sensors. (+) represents the positively charged amino acid residues at every third position within these segments. Electrical field (negative inside) exerts a force on these charged amino acid residues, pulling them toward the intracellular side of the membrane; depolarization allows them to move outward. **Pore.** The S5 and S6 transmembrane segments and the short membrane-associated loop between them (P loop) form the walls of the pore in the center of an approximately symmetrical square array of the four homologous domains (see Panel **B**). The amino acid residues indicated by circles in the P loop are critical for determining the conductance and ion selectivity of the Na^+ channel and its ability to bind the extracellular pore-blocking toxins tetrodotoxin and saxitoxin. **Inactivation.** The short intracellular loop connecting homologous domains III and IV serves as the inactivation gate of the Na^+ channel. It is thought to fold into the intracellular mouth of the pore and occlude it within a few milliseconds after the channel opens. Three hydrophobic residues (isoleucine–phenylalanine–methionine; IFM) at the position marked **h** appear to serve as an inactivation particle, entering the intracellular mouth of the pore and binding therein to an inactivation gate receptor there. **Modulation.** The gating of the Na^+ channel can be modulated by protein phosphorylation. Phosphorylation of the inactivation gate between homologous domains III and IV by protein kinase C slows inactivation. Phosphorylation of sites in the intracellular loop between homologous domains I and II by either protein kinase C (Ⓢ) or cyclic AMP–dependent protein kinase (Ⓟ) reduces Na^+ channel activation. **B.** The four homologous domains of the Na^+ channel α subunit are illustrated as a square array, as viewed looking down on the membrane. The sequence of conformational changes that the Na^+ channel undergoes during activation and inactivation is diagrammed. Upon depolarization, each of the four homologous domains sequentially undergoes a conformational change to an activated state. After all four domains have activated, the Na^+ channel can open. Within a few milliseconds after opening, the inactivation gate between domains III and IV closes over the intracellular mouth of the channel and occludes it, preventing further ion conductance. (Adapted from Catterall, 2000, with permission.)

Figure 14–3. *The local anesthetic receptor site.* **A.** A drawing of the pore structure of a bacterial K^+ channel (KcsA), which is related to the sodium channel. The KcsA channel has two transmembrane segments, analogous to the S5 and S6 segments of sodium channels. The S6-like segment forms the walls of the inner pore while the *P* loop forms the narrow ion selectivity filter at its extracellular (top) end. Four separate KcsA subunits form the pore in their center; only two of the subunits are shown here. **B.** A structural model of the local anesthetic receptor site. The S6 segments from domains I, III, and IV of the sodium channel α subunit are illustrated, based on the structure of the KcsA channel (panel A). The amino acid residues in these three transmembrane segments that contribute to the local anesthetic receptor site are indicated in single letter code and are presented in space-filling representation (light blue). An etidocaine molecule (black) is illustrated bound in the receptor site. Substitutions of the light blue residues with alanine reduce the affinity for local anesthetic block of sodium channels. It therefore is likely that the side chains of these amino acid residues contact bound local anesthetics in their receptor site. I1760 and I409 likely form the outer boundary of the local anesthetic receptor site. Mutations of I1760 allow drug access to the receptor site from the extracellular side (Ragsdale *et al.*, 1994; Yarov-Yarovoy *et al.*, 2002).

potential. Thus, a resting nerve is much less sensitive to a local anesthetic than one that is repetitively stimulated; higher frequency of stimulation and more positive membrane potential cause a greater degree of anesthetic block. These frequency- and voltage-dependent effects of local anesthetics occur because the local anesthetic molecule in its charged form gains access to its binding site within the pore only when the Na^+ channel is in an open state and because the local anesthetic binds more tightly to and stabilizes the inactivated state of the Na^+ channel (Courtney and Strichartz, 1987; Butterworth and Strichartz, 1990). Local anesthetics exhibit these properties to different extents depending on their pK_a , lipid solubility and molecular size. In general, the frequency dependence of local anesthetic action depends critically on the rate of dissociation from the receptor site in the pore of the Na^+ channel. A high frequency of stimulation is required for rapidly dissociating drugs so that drug binding during the action potential exceeds drug dissociation between action potentials. Dissociation of smaller and more hydrophobic drugs is more rapid, so a higher frequency of stimulation is

required to yield frequency-dependent block. Frequency-dependent block of ion channels is most important for the actions of antiarrhythmic drugs (*see* Chapter 34).

Differential Sensitivity of Nerve Fibers to Local Anesthetics. Although there is great individual variation, for most patients treatment with local anesthetics causes the sensation of pain to disappear first, followed by loss of the sensations of temperature, touch, deep pressure, and finally motor function (Table 14–1). Classical experiments with intact nerves showed that the δ wave in the compound action potential, which represents slowly conducting, small-diameter myelinated fibers, was reduced more rapidly and at lower concentrations of cocaine than was the α wave, which represents rapidly conducting, large-diameter fibers (Gasser and Erlanger, 1929). In general, autonomic fibers, small unmyelinated C fibers (mediating pain sensations), and small myelinated $A\delta$ fibers (mediating pain and temperature sensations) are blocked before the larger myelinated $A\gamma$, $A\beta$, and $A\alpha$ fibers (mediating postural, touch, pressure, and motor

Table 14-1

Susceptibility to Block of Types of Nerve Fibers

CONDUCTION BIOPHYSICAL CLASSIFICATION	ANATOMIC LOCATION	MYELIN	DIAMETER, μM	CONDUCTION VELOCITY, M-SEC^{-1}	FUNCTION	CLINICAL SENSITIVITY TO BLOCK
A fibers						
A α	Afferent to and efferent from muscles and joints	Yes	6–22	10–85	Motor and proprioception	+
A β						
A γ	Efferent to muscle spindles	Yes	3–6	15–35	Muscle tone	++
A δ	Sensory roots and afferent peripheral nerves	Yes	1–4	5–25	Pain, temperature, touch	+++
B fibers	Preganglionic sympathetic	Yes	<3	3–15	Vasomotor, visceromotor, sudomotor, pilomotor	++++
C fibers						
Sympathetic	Postganglionic sympathetic	No	0.3–1.3	0.7–1.3	Vasomotor, visceromotor, sudomotor, pilomotor	++++
Dorsal root	Sensory roots and afferent peripheral nerves	No	0.4–1.2	0.1–2	Pain, temperature, touch	++++

information; reviewed in Raymond and Gissen, 1987). The differential rate of block exhibited by fibers mediating different sensations is of considerable practical importance in the use of local anesthetics.

The precise mechanisms responsible for this apparent specificity of local-anesthetic action on pain fibers are not known, but several factors may contribute. The initial hypothesis from the classical work on intact nerves was that sensitivity to local-anesthetic block increases with decreasing fiber size, consistent with high sensitivity for pain sensation mediated by small fibers and low sensitivity for motor function mediated by large fibers (Gasser and Erlanger, 1929). However, when nerve fibers are dissected from nerves to allow direct measurement of action potential generation, no clear correlation of the concentration dependence of local anesthetic block with fiber diameter is observed (Franz and Perry, 1974; Fink and Cairns, 1984; Huang *et al.*, 1997). Therefore, it is unlikely that the fiber size *per se* determines the sensitivity to local anesthetic block under steady-state conditions. However, the spacing of nodes of Ranvier increases with the size of nerve fibers. Because a fixed number of nodes must be blocked to prevent conduction, small fibers with closely

spaced nodes of Ranvier may be blocked more rapidly during treatment of intact nerves, because the local anesthetic reaches a critical length of nerve more rapidly (Franz and Perry, 1974). Differences in tissue barriers and location of smaller C fibers and A δ fibers in nerves also may influence the rate of local anesthetic action.

Effect of pH. Local anesthetics tend to be only slightly soluble as unprotonated amines. Therefore, they generally are marketed as water-soluble salts, usually hydrochlorides. Inasmuch as the local anesthetics are weak bases (typical pK_a values range from 8 to 9), their hydrochloride salts are mildly acidic. This property increases the stability of the local anesthetic esters and catecholamines added as vasoconstrictors. Under usual conditions of administration, the pH of the local anesthetic solution rapidly equilibrates to that of the extracellular fluids.

Although the unprotonated species of the local anesthetic is necessary for diffusion across cellular membranes, it is the cationic species that interacts preferentially with Na^+ channels. The results of experiments on anesthetized mammalian nonmyelinated fibers support this conclusion (Ritchie and Greengard, 1966). In these

experiments, conduction could be blocked or unblocked merely by adjusting the pH of the bathing medium to 7.2 or 9.6, respectively, without altering the amount of anesthetic present. The primary role of the cationic form also was demonstrated by Narahashi and Frazier, who perfused the extracellular and axoplasmic surface of the giant squid axon with tertiary and quaternary amine local anesthetics (Narahashi and Frazier, 1971). However, the unprotonated molecular forms also possess some anesthetic activity (Butterworth and Strichartz, 1990).

Prolongation of Action by Vasoconstrictors. The duration of action of a local anesthetic is proportional to the time of contact with nerve. Consequently, maneuvers that keep the drug at the nerve prolong the period of anesthesia. For instance, cocaine inhibits the neuronal membrane transporters for catecholamines, thereby potentiating the effect of norepinephrine at α adrenergic receptors in the vasculature, resulting in vasoconstriction and reduced cocaine absorption in vascular beds where α adrenergic effects predominate (see Chapters 6 and 10). *Ropivacaine* and *bupivacaine* also cause vasoconstriction. In clinical practice, a vasoconstrictor, usually epinephrine, is often added to local anesthetics. The vasoconstrictor performs a dual service. By decreasing the rate of absorption, it not only localizes the anesthetic at the desired site, but also allows the rate at which it is destroyed in the body to keep pace with the rate at which it is absorbed into the circulation. This reduces its systemic toxicity. It should be noted, however, that epinephrine also dilates skeletal muscle vascular beds through actions at β_2 adrenergic receptors, and therefore has the potential to increase systemic toxicity of anesthetic deposited in muscle tissue.

Some of the vasoconstrictor agent may be absorbed systemically, occasionally to an extent sufficient to cause untoward reactions (see below). There also may be delayed wound healing, tissue edema, or necrosis after local anesthesia. These effects seem to occur partly because sympathomimetic amines increase the oxygen consumption of the tissue; this, together with the vasoconstriction, leads to hypoxia and local tissue damage. The use of vasoconstrictors in local-anesthetic preparations for anatomical regions with limited collateral circulation could produce irreversible hypoxic damage, tissue necrosis, and gangrene, and therefore is contraindicated.

Undesired Effects of Local Anesthetics. In addition to blocking conduction in nerve axons in the peripheral nervous system, local anesthetics interfere with the function of all organs in which conduction or transmission of impulses occurs. Thus, they have important effects on the

central nervous system (CNS), the autonomic ganglia, the neuromuscular junction, and all forms of muscle (for review see Covino, 1987; Garfield and Gugino, 1987; Gintant and Hoffman, 1987). The danger of such adverse reactions is proportional to the concentration of local anesthetic achieved in the circulation. In general, in local anesthetics with chiral centers, the *S*-enantiomer is less toxic than the *R*-enantiomer (McClure, 1996).

Central Nervous System. Following absorption, local anesthetics may cause CNS stimulation, producing restlessness and tremor that may progress to clonic convulsions. In general, the more potent the anesthetic, the more readily convulsions may be produced. Alterations of CNS activity are thus predictable from the local anesthetic agent in question and the blood concentration achieved. Central stimulation is followed by depression; death usually is caused by respiratory failure.

The apparent stimulation and subsequent depression produced by applying local anesthetics to the CNS presumably is due solely to depression of neuronal activity; a selective depression of inhibitory neurons is thought to account for the excitatory phase *in vivo*. Rapid systemic administration of local anesthetics may produce death with no or only transient signs of CNS stimulation. Under these conditions, the concentration of the drug probably rises so rapidly that all neurons are depressed simultaneously. Airway control and ventilatory support are essential features of treatment in the late stage of intoxication. Benzodiazepines or rapidly acting barbiturates administered intravenously are the drugs of choice for both the prevention and arrest of convulsions (see Chapter 16).

Although drowsiness is the most frequent complaint that results from the CNS actions of local anesthetics, lidocaine may produce dysphoria or euphoria and muscle twitching. Moreover, both lidocaine and procaine may produce a loss of consciousness that is preceded only by symptoms of sedation (Covino, 1987). Whereas other local anesthetics also show the effect, cocaine has a particularly prominent effect on mood and behavior. These effects of cocaine and its potential for abuse are discussed in Chapter 23.

Cardiovascular System. Following systemic absorption, local anesthetics act on the cardiovascular system (Covino, 1987). The primary site of action is the myocardium, where decreases in electrical excitability, conduction rate, and force of contraction occur. In addition, most local anesthetics cause arteriolar dilation. Untoward cardiovascular effects usually are seen only after high systemic concentrations are attained and effects on the CNS are produced. However, on rare occasions, lower doses of some local anesthetics will cause cardiovascular collapse and death, probably due to either an action on the pacemaker or the sudden onset of ventricular fibrillation. It should be noted that ventricular tachycardia and fibrillation are relatively uncommon consequences of local anesthetics other than bupivacaine. The effects of local anesthetics such as lido-

caine and *procainamide*, which also are used as antiarrhythmic drugs, are discussed in Chapter 34. Finally, it should be stressed that untoward cardiovascular effects of local anesthetic agents may result from their inadvertent intravascular administration, especially if epinephrine also is present.

Smooth Muscle. Local anesthetics depress contractions in the intact bowel and in strips of isolated intestine (Zipf and Dittmann, 1971). They also relax vascular and bronchial smooth muscle, although low concentrations initially may produce contraction (Covino, 1987). Spinal and epidural anesthesia, as well as instillation of local anesthetics into the peritoneal cavity, cause sympathetic nervous system paralysis, which can result in increased tone of gastrointestinal musculature (*see below*). Local anesthetics may increase the resting tone and decrease the contractions of isolated human uterine muscle; however, uterine contractions seldom are depressed directly during intrapartum regional anesthesia.

Neuromuscular Junction and Ganglionic Synapse. Local anesthetics also affect transmission at the neuromuscular junction. Procaine, for example, can block the response of skeletal muscle to maximal motor-nerve volleys and to acetylcholine at concentrations at which the muscle responds normally to direct electrical stimulation. Similar effects occur at autonomic ganglia. These effects are due to block of the ion channel of the acetylcholine receptor by high concentrations of the local anesthetics (Neher and Steinbach, 1978; Charnet *et al.*, 1990).

Hypersensitivity to Local Anesthetics. Rare individuals are hypersensitive to local anesthetics. The reaction may manifest itself as an allergic dermatitis or a typical asthmatic attack (Covino, 1987). It is important to distinguish allergic reactions from toxic side effects and from the effects of co-administered vasoconstrictors. Hypersensitivity seems to occur more frequently with local anesthetics of the ester type and frequently extends to chemically related compounds. For example, individuals sensitive to procaine also may react to structurally similar compounds (*e.g.*, tetracaine) through reaction to a common metabolite. Although allergic responses to agents of the amide type are uncommon, solutions of such agents may contain preservatives such as methylparaben that may provoke an allergic reaction (Covino, 1987). Local anesthetic preparations containing a vasoconstrictor also may elicit allergic responses due to the sulfite added as an antioxidant for the catecholamine/vasoconstrictor.

Metabolism of Local Anesthetics. The metabolic fate of local anesthetics is of great practical importance, because their toxicity depends largely on the balance between their rates of absorption and elimination. As noted above, the rate of absorption of many anesthetics can be reduced considerably by the incorporation of a

vasoconstrictor agent in the anesthetic solution. However, the rate of degradation of local anesthetics varies greatly, and this is a major factor in determining the safety of a particular agent. Since toxicity is related to the free concentration of drug, binding of the anesthetic to proteins in the serum and to tissues reduces the concentration of free drug in the systemic circulation, and consequently reduces toxicity. For example, in intravenous regional anesthesia of an extremity, about half of the original anesthetic dose still is tissue bound 30 minutes after the restoration of normal blood flow (Arthur, 1987).

Some of the common local anesthetics (*e.g.*, tetracaine) are esters. They are hydrolyzed and inactivated primarily by a plasma esterase, probably plasma cholinesterase. The liver also participates in hydrolysis of local anesthetics. Since spinal fluid contains little or no esterase, anesthesia produced by the intrathecal injection of an anesthetic agent will persist until the local anesthetic agent has been absorbed into the circulation.

The amide-linked local anesthetics are, in general, degraded by the hepatic CYPs (cytochrome P450 enzymes), the initial reactions involving *N*-dealkylation and subsequent hydrolysis (Arthur, 1987). However, with *prilocaine*, the initial step is hydrolytic, forming *o*-toluidine metabolites that can cause methemoglobinemia. The extensive use of amide-linked local anesthetics in patients with severe hepatic disease requires caution. The amide-linked local anesthetics are extensively (55% to 95%) bound to plasma proteins, particularly α_1 -acid glycoprotein. Many factors increase (*e.g.*, cancer, surgery, trauma, myocardial infarction, smoking, and uremia) or decrease (*e.g.*, oral contraceptives) the level of this glycoprotein, thereby changing the amount of anesthetic delivered to the liver for metabolism and thus influencing systemic toxicity. Age-related changes in protein binding of local anesthetics also occur. The neonate is relatively deficient in plasma proteins that bind local anesthetics and thereby is more susceptible to toxicity. Plasma proteins are not the sole determinant of local anesthetic availability. Uptake by the lung also may play an important role in the distribution of amide-linked local anesthetics in the body (Arthur, 1987). Reduced cardiac output slows delivery of the amide compounds to the liver, reducing their metabolism and prolonging their plasma half-lives (*see Chapter 34*).

COCAINE

Chemistry. Cocaine, an ester of benzoic acid and methylecgonine, occurs in abundance in the leaves of the coca shrub. Ecgonine is an amino alcohol base closely related to tropine, the amino alcohol in

atropine. It has the same fundamental structure as the synthetic local anesthetics (Figure 14–1).

Pharmacological Actions and Preparations. The clinically desired actions of cocaine are the blockade of nerve impulses, as a consequence of its local anesthetic properties, and local vasoconstriction, secondary to inhibition of local norepinephrine reuptake. Toxicity and its potential for abuse have steadily decreased the clinical uses of cocaine. Its high toxicity is due to reduced catecholamine uptake in both the central and peripheral nervous systems. Its euphoric properties are due primarily to inhibition of catecholamine uptake, particularly dopamine, in the CNS. Other local anesthetics do not block the uptake of norepinephrine and do not produce the sensitization to catecholamines, vasoconstriction, or mydriasis characteristic of cocaine. Currently, cocaine is used primarily for topical anesthesia of the upper respiratory tract, where its combination of both vasoconstrictor and local anesthetic properties provide anesthesia and shrinking of the mucosa. Cocaine hydrochloride is provided as a 1%, 4%, or 10% solution for topical application. For most applications, the 1% or 4% preparation is preferred to reduce toxicity. Because of its abuse potential, cocaine is listed as a schedule II drug by the U.S. Drug Enforcement Agency.

LIDOCAINE

Lidocaine (XYLOCAINE, others), an aminoethylamide (Figure 14–1), is the prototypical amide local anesthetic.

Pharmacological Actions. Lidocaine produces faster, more intense, longer lasting, and more extensive anesthesia than does an equal concentration of procaine. Lidocaine is an alternative choice for individuals sensitive to ester-type local anesthetics.

Absorption, Fate, and Excretion. Lidocaine is absorbed rapidly after parenteral administration and from the gastrointestinal and respiratory tracts. Although it is effective when used without any vasoconstrictor, epinephrine decreases the rate of absorption, such that the toxicity is decreased and the duration of action usually is prolonged. In addition to preparations for injection, an iontophoretic, needle-free drug-delivery system for a solution of lidocaine and epinephrine (IONTOCAINE) is available. This system generally is used for dermal procedures and provides anesthesia to a depth of up to 10 mm.

A lidocaine transdermal patch (LIDODERM) is used for relief of pain associated with postherpetic neuralgia. The combination of lidocaine (2.59%) and prilocaine (2.5%) in an occlusive dressing (EMLA ANESTHETIC DISC) is used as an anesthetic prior to venipuncture, skin graft harvesting, and infiltration of anesthetics into genitalia.

Lidocaine is dealkylated in the liver by CYPs to monoethylglycine xylidide and glycine xylidide, which can be metabolized further to monoethylglycine and xylidide. Both monoethylglycine xylidide and glycine xylidide retain local anesthetic activity. In humans, about 75% of the xylidide is excreted in the urine as the further metabolite 4-hydroxy-2, 6-dimethylaniline (Arthur, 1987).

Toxicity. The side effects of lidocaine seen with increasing dose include drowsiness, tinnitus, dysgeusia, dizziness, and twitching. As the dose increases, seizures, coma, and respiratory depression and arrest will occur. Clinically significant cardiovascular depression

usually occurs at serum lidocaine levels that produce marked CNS effects. The metabolites monoethylglycine xylidide and glycine xylidide may contribute to some of these side effects.

Clinical Uses. Lidocaine has a wide range of clinical uses as a local anesthetic; it has utility in almost any application where a local anesthetic of intermediate duration is needed. Lidocaine also is used as an antiarrhythmic agent (*see* Chapter 34).

BUPIVACAINE

Pharmacological Actions. Bupivacaine (MARCAINE, SENSORCAINE), is a widely used amide local anesthetic; its structure is similar to that of lidocaine except that the amine-containing group is a butyl piperidine (Figure 14–1). *Levobupivacaine* (CHIROCAINE), the *S*-enantiomer of bupivacaine, also is available. Bupivacaine is a potent agent capable of producing prolonged anesthesia. Its long duration of action plus its tendency to provide more sensory than motor block has made it a popular drug for providing prolonged analgesia during labor or the postoperative period. By taking advantage of indwelling catheters and continuous infusions, bupivacaine can be used to provide several days of effective analgesia.

Toxicity. Bupivacaine and *etidocaine*, below, are more cardiotoxic than equi-effective doses of lidocaine. Clinically, this is manifested by severe ventricular arrhythmias and myocardial depression after inadvertent intravascular administration of large doses of bupivacaine. Although lidocaine and bupivacaine both rapidly block cardiac Na⁺ channels during systole, bupivacaine dissociates much more slowly than does lidocaine during diastole, so a significant fraction of Na⁺ channels at physiological heart rates remains blocked with bupivacaine at the end of diastole (Clarkson and Hondeghem, 1985). Thus, the block by bupivacaine is cumulative and substantially more than would be predicted by its local anesthetic potency. At least a portion of the cardiac toxicity of bupivacaine may be mediated centrally, as direct injection of small quantities of bupivacaine into the medulla can produce malignant ventricular arrhythmias (Thomas *et al.*, 1986). Bupivacaine-induced cardiac toxicity can be very difficult to treat, and its severity is enhanced by coexisting acidosis, hypercarbia, and hypoxemia. The *S*-enantiomer and the racemate are equally efficacious and potent; however, both animal studies (Groban *et al.*, 2001) and experience in humans (Foster and Markham, 2000) suggest that levobupivacaine is less cardiotoxic.

OTHER SYNTHETIC LOCAL ANESTHETICS

The number of synthetic local anesthetics is so large that it is impractical to consider them all here. Some local anesthetic agents are too toxic to be given by injection. Their use is restricted to topical application to the eye (*see* Chapter 63), the mucous membranes, or the skin (*see* Chapter 62). Many local anesthetics are suitable, however, for infiltration or injection to produce nerve block; some of them also are useful for topical application. The main categories of local anesthetics are given below; agents are listed alphabetically. (*See* Figure 14–1 for structures.)

Local Anesthetics Suitable for Injection

Articaine. *Articaine* (SEPTOCAINE) is a recently introduced amino amide, approved in the United States for dental and periodontal procedures. It exhibits a rapid onset (1 to 6 minutes) and duration of action of approximately 1 hour.

Chloroprocaine. *Chloroprocaine* (NESACAINE), an ester local anesthetic introduced in 1952, is a chlorinated derivative of procaine. Its major assets are its rapid onset and short duration of action and its reduced acute toxicity due to its rapid metabolism (plasma half-life approximately 25 seconds). Enthusiasm for its use has been tempered by reports of prolonged sensory and motor block after epidural or subarachnoid administration of large doses. This toxicity appears to have been a consequence of low pH and the use of sodium metabisulfite as a preservative in earlier formulations. There are no reports of neurotoxicity with newer preparations of chloroprocaine, which contain calcium EDTA as the preservative, although these preparations also are not recommended for intrathecal administration. A higher-than-expected incidence of muscular back pain following epidural anesthesia with 2-chloroprocaine also has been reported (Stevens *et al.*, 1993). This back pain is thought to be due to tetany in the paraspinus muscles, which may be a consequence of Ca^{2+} binding by the EDTA included as a preservative; the incidence of back pain appears to be related to the volume of drug injected and its use for skin infiltration.

Etidocaine. *Etidocaine* (DURANEST), is a long-acting amino amide with an onset of action faster than that of bupivacaine and comparable to that of lidocaine, and a duration of action similar to that of bupivacaine. Compared to bupivacaine, etidocaine produces preferential motor blockade. Thus, while it is useful for surgery requiring intense skeletal muscle relaxation, its utility in labor or postoperative analgesia is limited. Its cardiac toxicity is similar to that of bupivacaine. Etidocaine no longer is marketed in the United States.

Mepivacaine. *Mepivacaine* (CARBOCAINE, POLOCAINE) is an intermediate-acting amino amide. Its pharmacological properties are similar to those of lidocaine. Mepivacaine, however, is more toxic to the neonate and thus is not used in obstetrical anesthesia. The increased toxicity of mepivacaine in the neonate is related to ion trapping of this agent because of the lower pH of neonatal blood and the pK_a of mepivacaine rather than to its slower metabolism in the neonate. It appears to have a slightly higher therapeutic index in adults than does lidocaine. Its onset of action is similar to that of lidocaine and its duration slightly longer (about 20%) than that of lidocaine in the absence of a coadministered vasoconstrictor. Mepivacaine is not effective as a topical anesthetic.

Prilocaine. *Prilocaine* (CITANEST) is an intermediate-acting amino amide. It has a pharmacological profile similar to that of lidocaine. The primary differences are that it causes little vasodilation and thus can be used without a vasoconstrictor if desired, and its increased volume of distribution reduces its CNS toxicity, making it suitable for intravenous regional blocks (*see below*). It is unique among the local anesthetics in its propensity to cause methemoglobinemia. This effect is a consequence of the metabolism of the aromatic ring to *o*-toluidine. Development of methemoglobinemia is dependent on the total dose administered, usually appearing after a dose of 8 mg/kg. In healthy persons, methemoglobinemia usually is not a problem. If necessary, it can be treated by the

intravenous administration of methylene blue (1 to 2 mg/kg). Methemoglobinemia following prilocaine has limited its use in obstetrical anesthesia, because it complicates evaluation of the newborn. Also, methemoglobinemia is more common in neonates due to decreased resistance of fetal hemoglobin to oxidant stresses and the immaturity of enzymes in the neonate that convert methemoglobin back to the ferrous state.

Ropivacaine. The cardiac toxicity of bupivacaine stimulated interest in developing a less toxic, long-lasting local anesthetic. One result of that search was the development of the amino ethylamide ropivacaine (NAROPIN), the *S*-enantiomer of 1-propyl-2',6'-pipecoloxylidide. The *S*-enantiomer was chosen because it has a lower toxicity than the *R*-isomer (McClure, 1996). Ropivacaine is slightly less potent than bupivacaine in producing anesthesia. In several animal models, it appears to be less cardiotoxic than equi-effective doses of bupivacaine. In clinical studies, ropivacaine appears to be suitable for both epidural and regional anesthesia, with a duration of action similar to that of bupivacaine. Interestingly, it seems to be even more motor-sparing than bupivacaine.

Procaine. Procaine (NOVOCAIN), introduced in 1905, was the first synthetic local anesthetic and is an amino ester. It has been supplanted by newer agents, and its use now is confined to infiltration anesthesia and occasionally for diagnostic nerve blocks. This is because of its low potency, slow onset, and short duration of action. While its toxicity is fairly low, it is hydrolyzed *in vivo* to produce para-aminobenzoic acid, which inhibits the action of sulfonamides. Thus, large doses should not be administered to patients taking sulfonamide drugs.

Tetracaine. Tetracaine (PONTOCAINE), is a long-acting amino ester. It is significantly more potent and has a longer duration of action than procaine. Tetracaine may exhibit increased systemic toxicity because it is more slowly metabolized than the other commonly used ester local anesthetics. Currently, it is widely used in spinal anesthesia when a drug of long duration is needed. Tetracaine also is incorporated into several topical anesthetic preparations. With the introduction of bupivacaine, tetracaine is rarely used in peripheral nerve blocks because of the large doses often necessary, its slow onset, and its potential for toxicity.

Local Anesthetics Used Primarily to Anesthetize Mucous Membranes and Skin

Some anesthetics are either too irritating or too ineffective to be applied to the eye. However, they are useful as topical anesthetic agents on the skin and/or mucous membranes. These preparations are effective in the symptomatic relief of anal and genital pruritus, poison ivy rashes, and numerous other acute and chronic dermatoses. They sometimes are combined with a glucocorticoid or antihistamine and are available in a number of proprietary formulations (*see* Figure 14-1 for structures).

Dibucaine (NUPERCAINAL) is a quinoline derivative. Its toxicity resulted in its removal from the United States market as an injectable preparation; however, it retains wide popularity outside the United States as a spinal anesthetic. It currently is available as a cream and an ointment for use on the skin.

Dyclonine hydrochloride (DYCLONE) has a rapid onset of action and duration of effect comparable to that of procaine. It is absorbed through the skin and mucous membranes. The compound has been

used as 0.5% or 1% solution for topical anesthesia during endoscopy, for oral mucositis pain following radiation or chemotherapy, and for anogenital procedures; however, marketing of these solutions has been discontinued in the United States. Dyclonine is an active ingredient in a number of over-the-counter medications including sore throat lozenges (SUCRETS, others), a gel for cold sores (TANAC), and a 0.75% solution (SKIN SHIELD) to protect against contact dermatitis.

Pramoxine hydrochloride (ANUSOL, TRONOTHANE, others) is a surface anesthetic agent that is not a benzoate ester. Its distinct chemical structure may help minimize the danger of cross-sensitivity reactions in patients allergic to other local anesthetics. Pramoxine produces satisfactory surface anesthesia and is reasonably well tolerated on the skin and mucous membranes. It is too irritating to be used on the eye or in the nose. Various preparations, usually containing 1% pramoxine, are available for topical application.

Anesthetics of Low Solubility

Some local anesthetics are poorly soluble in water, and consequently are too slowly absorbed to be toxic. They can be applied directly to wounds and ulcerated surfaces, where they remain localized for long periods of time, producing a sustained anesthetic action. Chemically, they are esters of para-aminobenzoic acid lacking the terminal amino group possessed by the previously described local anesthetics. The most important member of the series is benzocaine (ethyl aminobenzoate; AMERICAINE ANESTHETIC, others). Benzocaine is structurally similar to procaine, but lacks the terminal diethylamino group (Figure 14–1). It is incorporated into a large number of topical preparations. Benzocaine can cause methemoglobinemia (*see* text concerning methemoglobinemia caused by prilocaine, above); consequently, dosing recommendations must be followed carefully.

Local Anesthetics Largely Restricted to Ophthalmological Use

Anesthesia of the cornea and conjunctiva can be obtained readily by topical application of local anesthetics. However, most of the local anesthetics described above are too irritating for ophthalmological use. The first local anesthetic used in ophthalmology, cocaine, has the severe disadvantages of producing mydriasis and corneal sloughing and has fallen out of favor. The two compounds used most frequently today are *proparacaine* (ALCAINE, OPHTHAINE, others) and tetracaine (Figure 14–1). In addition to being less irritating during administration, proparacaine has the added advantage of bearing little antigenic similarity to the other benzoate local anesthetics. Thus, it sometimes can be used in individuals sensitive to the amino ester local anesthetics.

For use in ophthalmology, these local anesthetics are instilled a single drop at a time. If anesthesia is incomplete, successive drops are applied until satisfactory conditions are obtained. The duration of anesthesia is determined chiefly by the vascularity of the tissue; thus it is longest in normal cornea and shortest in inflamed conjunctiva. In the latter case repeated instillations may be necessary to maintain adequate anesthesia for the duration of the procedure. Long-term administration of topical anesthesia to the eye has been associated with retarded healing, pitting and sloughing of the corneal epithelium, and predisposition of the eye to inadvertent injury. Thus, these drugs should not be prescribed for self-administration. For drug delivery, pharmacokinetic, and toxicity issues unique to drugs for ophthalmic use, *see* Chapter 63.

Tetrodotoxin and Saxitoxin

These two biological toxins also block the pore of the Na⁺ channel. *Tetrodotoxin* is found in the gonads and other visceral tissues of some fish of the order Tetraodontiformes (to which the Japanese *fugu*, or puffer fish, belongs); it also occurs in the skin of some newts of the family Salamandridae and of the Costa Rican frog *Atelopus*. *Saxitoxin*, and possibly some related toxins, are elaborated by the dinoflagellates *Gonyaulax catenella* and *Gonyaulax tamarensis* and are retained in the tissues of clams and other shellfish that eat these organisms. Given the right conditions of temperature and light, the *Gonyaulax* may multiply so rapidly as to discolor the ocean, causing the condition known as *red tide*. Shellfish feeding on *Gonyaulax* at this time become extremely toxic to human beings and are responsible for periodic outbreaks of paralytic shellfish poisoning (Stommel and Watters, 2004). Although the toxins are chemically different from each other, their mechanisms of action are similar (Ritchie, 1980). Both toxins, in nanomolar concentrations, specifically block the outer mouth of the pore of Na⁺ channels in the membranes of excitable cells. As a result, the action potential is blocked. The receptor site for these toxins is formed by amino acid residues in the P loop of the Na⁺ channel α subunit (Figure 14–2) in all four domains (Terlau *et al.*, 1991; Catterall, 2000). Not all Na⁺ channels are equally sensitive to tetrodotoxin; some Na⁺ channels in cardiac myocytes and dorsal root ganglion neurons are resistant, and a tetrodotoxin-resistant Na⁺ channel is expressed when skeletal muscle is denervated. Tetrodotoxin and saxitoxin are two of the most potent poisons known; the minimal lethal dose of each in the mouse is about 8 $\mu\text{g}/\text{kg}$. Both toxins have caused fatal poisoning in humans due to paralysis of the respiratory muscles. Therefore the treatment of severe cases of poisoning requires support of respiration. Blockade of vasomotor nerves, together with a relaxation of vascular smooth muscle, seems to be responsible for the hypotension that is characteristic of tetrodotoxin poisoning. Early gastric lavage and pressor support also are indicated. If the patient survives paralytic shellfish poisoning for 24 hours, the prognosis is good.

CLINICAL USES OF LOCAL ANESTHETICS

Local anesthesia is the loss of sensation in a body part without the loss of consciousness or the impairment of central control of vital functions. It offers two major advantages. First, physiological perturbations associated with general anesthesia are avoided; second, neurophysiological responses to pain and stress can be modified beneficially. As discussed above, local anesthetics potentially can produce deleterious side effects. Proper choice of a local anesthetic and care in its use are the primary determinants in avoiding toxicity. There is a poor relationship between the amount of local anesthetic injected and peak plasma levels in adults. Furthermore, peak plasma levels vary widely depending on the area of injection. They are highest with interpleural or intercostal blocks and lowest with subcutaneous infiltration. Thus, recommended maximum doses serve only as general guidelines.

The following discussion summarizes the pharmacological and physiological consequences of the use of local anesthetics categorized by method of administration. A

more comprehensive discussion of their use and administration is presented in textbooks on regional anesthesia (e.g., Cousins and Bridenbaugh, 1998).

Topical Anesthesia

Anesthesia of mucous membranes of the nose, mouth, throat, tracheobronchial tree, esophagus, and genitourinary tract can be produced by direct application of aqueous solutions of salts of many local anesthetics or by suspension of the poorly soluble local anesthetics. Tetracaine (2%), lidocaine (2% to 10%), and cocaine (1% to 4%) typically are used. Cocaine is used only in the nose, nasopharynx, mouth, throat, and ear, where it uniquely produces vasoconstriction as well as anesthesia. The shrinking of mucous membranes decreases operative bleeding while improving surgical visualization. Comparable vasoconstriction can be achieved with other local anesthetics by the addition of a low concentration of a vasoconstrictor such as phenylephrine (0.005%). Epinephrine, topically applied, has no significant local effect and does not prolong the duration of action of local anesthetics applied to mucous membranes because of poor penetration. *Maximal* safe total dosages for topical anesthesia in a healthy 70-kg adult are 300 mg for lidocaine, 150 mg for cocaine, and 50 mg for tetracaine.

Peak anesthetic effect following topical application of cocaine or lidocaine occurs within 2 to 5 minutes (3 to 8 minutes with tetracaine), and anesthesia lasts for 30 to 45 minutes (30 to 60 minutes with tetracaine). Anesthesia is entirely superficial; it does not extend to submucosal structures. This technique does not alleviate joint pain or discomfort from subdermal inflammation or injury.

Local anesthetics are absorbed rapidly into the circulation following topical application to mucous membranes or denuded skin. Thus, topical anesthesia always carries the risk of systemic toxic reactions. Systemic toxicity has occurred even following the use of local anesthetics to control discomfort associated with severe diaper rash in infants. Absorption is particularly rapid when local anesthetics are applied to the tracheobronchial tree. Concentrations in blood after instillation of local anesthetics into the airway are nearly the same as those following intravenous injection. Surface anesthetics for the skin and cornea have been described above.

The introduction of an eutectic mixture of lidocaine (2.5%) and prilocaine (2.5%) (EMLA) bridges the gap between topical and infiltration anesthesia. The efficacy of this combination lies in the fact that the mixture of prilocaine and lidocaine has a melting point less than that of either compound alone, existing at room temperature as an oil that can penetrate intact skin. EMLA cream produces anesthesia to a maximum depth of 5 mm and is applied as a cream on intact skin under an occlusive dressing, which must be left in place for at least 1 hour. It is effective for procedures involving skin and superficial subcutaneous structures (e.g., venipuncture and skin graft harvesting). The component local anesthetics will be absorbed into the systemic circulation, potentially producing toxic effects (*see* above). Guidelines are available to calculate the maximum amount of cream that can be applied and area of skin covered. It must not be used on mucous membranes or abraded skin, as rapid absorption across these surfaces may result in systemic toxicity.

Infiltration Anesthesia

Infiltration anesthesia is the injection of local anesthetic directly into tissue without taking into consideration the course of cutaneous nerves. Infiltration anesthesia can be so superficial as to include

only the skin. It also can include deeper structures, including intra-abdominal organs, when these too are infiltrated.

The duration of infiltration anesthesia can be approximately doubled by the addition of epinephrine (5 µg/ml) to the injection solution; epinephrine also decreases peak concentrations of local anesthetics in blood. *Epinephrine-containing solutions should not, however, be injected into tissues supplied by end arteries—for example, fingers and toes, ears, the nose, and the penis. The resulting vasoconstriction may cause gangrene.* For the same reason, epinephrine should be avoided in solutions injected intracutaneously. Since epinephrine also is absorbed into the circulation, its use should be avoided in those for whom adrenergic stimulation is undesirable.

The local anesthetics used most frequently for infiltration anesthesia are lidocaine (0.5% to 1%), procaine (0.5% to 1%), and bupivacaine (0.125% to 0.25%). When used without epinephrine, up to 4.5 mg/kg of lidocaine, 7 mg/kg of procaine, or 2 mg/kg of bupivacaine can be employed in adults. When epinephrine is added, these amounts can be increased by one-third.

The advantage of infiltration anesthesia and other regional anesthetic techniques is that it can provide satisfactory anesthesia without disrupting normal bodily functions. The chief disadvantage of infiltration anesthesia is that relatively large amounts of drug must be used to anesthetize relatively small areas. This is no problem with minor surgery. When major surgery is performed, however, the amount of local anesthetic that is required makes systemic toxic reactions likely. The amount of anesthetic required to anesthetize an area can be reduced significantly and the duration of anesthesia increased markedly by specifically blocking the nerves that innervate the area of interest. This can be done at one of several levels: subcutaneously, at major nerves, or at the level of the spinal roots.

Field Block Anesthesia

Field block anesthesia is produced by subcutaneous injection of a solution of local anesthetic in order to anesthetize the region distal to the injection. For example, subcutaneous infiltration of the proximal portion of the volar surface of the forearm results in an extensive area of cutaneous anesthesia that starts 2 to 3 cm distal to the site of injection. The same principle can be applied with particular benefit to the scalp, the anterior abdominal wall, and the lower extremity.

The drugs, concentrations, and doses recommended are the same as for infiltration anesthesia. The advantage of field block anesthesia is that less drug can be used to provide a greater area of anesthesia than when infiltration anesthesia is used. Knowledge of the relevant neuroanatomy obviously is essential for successful field block anesthesia.

Nerve Block Anesthesia

Injection of a solution of a local anesthetic into or about individual peripheral nerves or nerve plexuses produces even greater areas of anesthesia than do the techniques described above. Blockade of mixed peripheral nerves and nerve plexuses also usually anesthetizes somatic motor nerves, producing skeletal muscle relaxation, which is essential for some surgical procedures. The areas of sensory and motor block usually start several centimeters distal to the site of injection. Brachial plexus blocks are particularly useful for procedures on the upper extremity and shoulder. Intercostal nerve blocks are effective for anesthesia and relaxation of the anterior abdominal wall. Cervical plexus block is appropriate for surgery of the neck.

Sciatic and femoral nerve blocks are useful for surgery distal to the knee. Other useful nerve blocks prior to surgical procedures include blocks of individual nerves at the wrist and at the ankle, blocks of individual nerves such as the median or ulnar at the elbow, and blocks of sensory cranial nerves.

There are four major determinants of the onset of sensory anesthesia following injection near a nerve. These are the proximity of the injection to the nerve, concentration and volume of drug, the degree of ionization of the drug, and time. Local anesthetic is never intentionally injected into the nerve, as this would be painful and could cause nerve damage. Instead, the anesthetic agent is deposited as close to the nerve as possible. Thus the local anesthetic must diffuse from the site of injection into the nerve, where it acts. The rate of diffusion is determined chiefly by the concentration of the drug, its degree of ionization (ionized local anesthetic diffuses more slowly), its hydrophobicity, and the physical characteristics of the tissue surrounding the nerve. Higher concentrations of local anesthetic will provide a more rapid onset of peripheral nerve block. The utility of higher concentrations, however, is limited by systemic toxicity and by direct neural toxicity of concentrated local anesthetic solutions. For a given concentration, local anesthetics with lower pK_a values tend to have a more rapid onset of action because more drug is uncharged at neutral pH. For example, the onset of action of lidocaine occurs in about 3 minutes; 35% of lidocaine is in the basic form at pH 7.4. In contrast, the onset of action of bupivacaine requires about 15 minutes; only 5% to 10% of bupivacaine is uncharged at this pH. Increased hydrophobicity might be expected to speed onset by increased penetration into nerve tissue. However, it also will increase binding in tissue lipids. Furthermore, the more hydrophobic local anesthetics also are more potent (and toxic) and thus must be used at lower concentrations, decreasing the concentration gradient for diffusion. Tissue factors also play a role in determining the rate of onset of anesthetic effects. The amount of connective tissue that must be penetrated can be significant in a nerve plexus compared to isolated nerves and can slow or even prevent adequate diffusion of local anesthetic to the nerve fibers.

Duration of nerve block anesthesia depends on the physical characteristics of the local anesthetic used and the presence or absence of vasoconstrictors. Especially important physical characteristics are lipid solubility and protein binding. Local anesthetics can be broadly divided into three categories: those with a short (20 to 45 minutes) duration of action in mixed peripheral nerves, such as procaine; those with an intermediate (60 to 120 minutes) duration of action, such as lidocaine and mepivacaine; and those with a long (400 to 450 minutes) duration of action, such as bupivacaine, ropivacaine, and tetracaine. Block duration of the intermediate-acting local anesthetics such as lidocaine can be prolonged by the addition of epinephrine (5 $\mu\text{g}/\text{ml}$). The degree of block prolongation in peripheral nerves following the addition of epinephrine appears to be related to the intrinsic vasodilatory properties of the local anesthetic and thus is most pronounced with lidocaine.

The types of nerve fibers that are blocked when a local anesthetic is injected about a mixed peripheral nerve depend on the concentration of drug used, nerve-fiber size, internodal distance, and frequency and pattern of nerve-impulse transmission (see above). Anatomical factors are similarly important. A mixed peripheral nerve or nerve trunk consists of individual nerves surrounded by an investing epineurium. The vascular supply usually is centrally located. When a local anesthetic is deposited about a peripheral nerve, it diffuses from the outer surface toward the core along a concentration gradient (DeJong, 1994; Winnie *et al.*, 1977). Consequently, nerves in the

outer mantle of the mixed nerve are blocked first. These fibers usually are distributed to more proximal anatomical structures than are those situated near the core of the mixed nerve and often are motor. If the volume and concentration of local anesthetic solution deposited about the nerve are adequate, the local anesthetic eventually will diffuse inward in amounts adequate to block even the most centrally located fibers. Lesser amounts of drug will block only nerves in the mantle and the smaller and more sensitive central fibers. Furthermore, since removal of local anesthetics occurs primarily in the core of a mixed nerve or nerve trunk, where the vascular supply is located, the duration of blockade of centrally located nerves is shorter than that of more peripherally situated fibers.

The choice of local anesthetic and the amount and concentration administered are determined by the nerves and the types of fibers to be blocked, the required duration of anesthesia, and the size and health of the patient. For blocks of 2 to 4 hours, lidocaine (1% to 1.5%) can be used in the amounts recommended above (see "Infiltration Anesthesia"). Mepivacaine (up to 7 mg/kg of a 1% to 2% solution) provides anesthesia that lasts about as long as that from lidocaine. Bupivacaine (2 to 3 mg/kg of a 0.25% to 0.375% solution) can be used when a longer duration of action is required. Addition of 5 $\mu\text{g}/\text{ml}$ epinephrine slows systemic absorption and therefore prolongs duration and lowers the plasma concentration of the intermediate-acting local anesthetics.

Peak plasma concentrations of local anesthetics depend on the amount injected, the physical characteristics of the local anesthetic, whether epinephrine is used, the rate of blood flow to the site of injection, and the surface area exposed to local anesthetic. This is of particular importance in the safe application of nerve block anesthesia, since the potential for systemic reactions is related to peak free serum concentrations. For example, peak concentrations of lidocaine in blood following injection of 400 mg without epinephrine for intercostal nerve blocks average 7 $\mu\text{g}/\text{ml}$; the same amount of lidocaine used for block of the brachial plexus results in peak concentrations in blood of approximately 3 $\mu\text{g}/\text{ml}$ (Covino and Vassallo, 1976). Therefore, the amount of local anesthetic that can be injected must be adjusted according to the anatomical site of the nerve(s) to be blocked to minimize untoward effects. Addition of epinephrine can decrease peak plasma concentrations by 20% to 30%. Multiple nerve blocks (*e.g.*, intercostal block) or blocks performed in vascular regions require reduction in the amount of anesthetic that can be given safely, because the surface area for absorption or the rate of absorption is increased.

Intravenous Regional Anesthesia (Bier's Block)

This technique relies on using the vasculature to bring the local anesthetic solution to the nerve trunks and endings. In this technique, an extremity is exsanguinated with an Esmarch (elastic) bandage, and a proximally located tourniquet is inflated to 100 to 150 mm Hg above the systolic blood pressure. The Esmarch bandage is removed, and the local anesthetic is injected into a previously cannulated vein. Typically, complete anesthesia of the limb ensues within 5 to 10 minutes. Pain from the tourniquet and the potential for ischemic nerve injury limits tourniquet inflation to 2 hours or less. However, the tourniquet should remain inflated for at least 15 to 30 minutes to prevent toxic amounts of local anesthetic from entering the circulation following deflation. Lidocaine, 40 to 50 ml (0.5 ml/kg in children) of a 0.5% solution without epinephrine is the drug of choice for this technique. For intravenous regional anesthesia in adults using a 0.5% solution without epinephrine, the dose

administered should not exceed 4 mg/kg. A few clinicians prefer prilocaine (0.5%) over lidocaine because of its higher therapeutic index. The attractiveness of this technique lies in its simplicity. Its primary disadvantages are that it can be used only for a few anatomical regions, sensation (*i.e.*, pain) returns quickly after tourniquet deflation, and premature release or failure of the tourniquet can produce toxic levels of local anesthetic (*e.g.*, 50 ml of 0.5% lidocaine contains 250 mg of lidocaine). For the last reason and because their longer durations of action offer no advantages, the more cardiotoxic local anesthetics, bupivacaine and etidocaine, are not recommended for this technique. Intravenous regional anesthesia is used most often for surgery of the forearm and hand, but can be adapted for the foot and distal leg.

Spinal Anesthesia

Spinal anesthesia follows the injection of local anesthetic into the cerebrospinal fluid (CSF) in the lumbar space. For a number of reasons, including the ability to produce anesthesia of a considerable fraction of the body with a dose of local anesthetic that produces negligible plasma levels, spinal anesthesia remains one of the most popular forms of anesthesia. In most adults, the spinal cord terminates above the second lumbar vertebra; between that point and the termination of the thecal sac in the sacrum, the lumbar and sacral roots are bathed in CSF. Thus, in this region there is a relatively large volume of CSF within which to inject drug, thereby minimizing the potential for direct nerve trauma.

A brief discussion of the physiological effects of spinal anesthesia relating to the pharmacology of the local anesthetics used is presented here. See more specialized texts (*e.g.*, Cousins and Bridenbaugh, 1998) for additional details.

Physiological Effects of Spinal Anesthesia. Most of the physiological side effects of spinal anesthesia are a consequence of the sympathetic blockade produced by local anesthetic block of the sympathetic fibers in the spinal nerve roots. A thorough understanding of these physiological effects is necessary for the safe and successful application of spinal anesthesia. Although some of them may be deleterious and require treatment, others can be beneficial for the patient or can improve operating conditions. Most sympathetic fibers leave the spinal cord between T1 and L2 (*see* Chapter 6, Figure 6–1). Although local anesthetic is injected below these levels in the lumbar portion of the dural sac, cephalad spread of the local anesthetic occurs with all but the smallest volumes injected. This cephalad spread is of considerable importance in the practice of spinal anesthesia and potentially is under the control of numerous variables, of which patient position and baricity (density of the drug relative to the density of the CSF) are the most important (Greene, 1983). The degree of sympathetic block is related to the height of sensory anesthesia; often the level of sympathetic blockade is several spinal segments higher, since the preganglionic sympathetic fibers are more sensitive to low concentrations of local anesthetic. The effects of sympathetic blockade involve both the actions (now partially unopposed) of the parasympathetic nervous system and the response of the unblocked portion of the sympathetic nervous system. Thus, as the level of sympathetic block ascends, the actions of the parasympathetic nervous system are increasingly dominant, and the compensatory mechanisms of the unblocked sympathetic nervous system are diminished. As most sympathetic nerve fibers leave the cord at T1 or below, few additional effects of sympathetic blockade are seen with cervical levels of spinal anesthesia. The con-

sequences of sympathetic blockade will vary among patients as a function of age, physical conditioning, and disease state. Interestingly, sympathetic blockade during spinal anesthesia appears to be inconsequential in healthy children.

Clinically, the most important effects of sympathetic blockade during spinal anesthesia are on the cardiovascular system. At all but the lowest levels of spinal blockade, some vasodilation will occur. Vasodilation is more marked on the venous than on the arterial side of the circulation, resulting in blood pooling in the venous capacitance vessels. This reduction in circulating blood volume is well tolerated at low levels of spinal anesthesia in healthy patients. With an increasing level of block, this effect becomes more marked and venous return becomes gravity-dependent. If venous return decreases too much, cardiac output and organ perfusion decline precipitously. Venous return can be increased by a modest (10° to 15°) head-down tilt or by elevating the legs. At high levels of spinal blockade, the cardiac accelerator fibers, which exit the spinal cord at T1 to T4, will be blocked. This is detrimental in patients dependent on elevated sympathetic tone to maintain cardiac output (*e.g.*, during congestive heart failure or hypovolemia), and it also removes one of the compensatory mechanisms available to maintain organ perfusion during vasodilation. Thus, as the level of spinal block ascends, the rate of cardiovascular compromise can accelerate if not carefully observed and treated. Sudden asystole also can occur, presumably because of loss of sympathetic innervation in the continued presence of parasympathetic activity at the sinoatrial node (Caplan, *et al.*, 1988). In the usual clinical situation, blood pressure serves as a surrogate marker for cardiac output and organ perfusion. Treatment of hypotension usually is warranted when the blood pressure decreases to about 30% of resting values. Therapy is aimed at maintaining brain and cardiac perfusion and oxygenation. To achieve these goals, administration of oxygen, fluid infusion, manipulation of patient position, and the administration of vasoactive drugs are all options. In particular, patients typically are administered a bolus (500 to 1000 ml) of fluid prior to the administration of spinal anesthesia in an attempt to prevent some of the deleterious effects of spinal blockade. Since the usual cause of hypotension is decreased venous return, possibly complicated by decreased heart rate, drugs with preferential vasoconstrictive and chronotropic properties are preferred. For this reason, ephedrine, 5 to 10 mg intravenously, often is the drug of choice. In addition to the use of ephedrine to treat deleterious effects of sympathetic blockade, direct-acting α_1 adrenergic receptor agonists such as phenylephrine (*see* Chapter 10) can be administered either by bolus or continuous infusion.

A beneficial effect of spinal anesthesia partially mediated by the sympathetic nervous system is on the intestine. Sympathetic fibers originating from T5 to L1 inhibit peristalsis; thus, their blockade produces a small, contracted intestine. This, together with a flaccid abdominal musculature, produces excellent operating conditions for some types of bowel surgery. The effects of spinal anesthesia on the respiratory system mostly are mediated by effects on the skeletal musculature. Paralysis of the intercostal muscles will reduce a patient's ability to cough and clear secretions, which may produce dyspnea in patients with bronchitis or emphysema. It should be noted that respiratory arrest during spinal anesthesia is seldom due to paralysis of the phrenic nerves or to toxic levels of local anesthetic in the CSF of the fourth ventricle. It is much more likely to be due to medullary ischemia secondary to hypotension.

Pharmacology of Spinal Anesthesia. Currently in the United States, the drugs most commonly used in spinal anesthesia are lidocaine, tetracaine, and bupivacaine. Procaine occasionally is used for diagnostic

blocks when a short duration of action is desired. The choice of local anesthetic is primarily determined by the desired duration of anesthesia. General guidelines are to use lidocaine for short procedures, bupivacaine for intermediate to long procedures, and tetracaine for long procedures. As mentioned above, the factors contributing to the distribution of local anesthetics in the CSF have received much attention because of their importance in determining the height of block. The most important pharmacological factors include the amount, and possibly the volume, of drug injected and its baricity. The speed of injection of the local anesthesia solution also may affect the height of the block, just as the position of the patient can influence the rate of distribution of the anesthetic agent and the height of blockade achieved (*see below*). For a given preparation of local anesthetic, administration of increasing amounts leads to a fairly predictable increase in the level of block attained. For example, 100 mg of lidocaine, 20 mg of bupivacaine, or 12 mg of tetracaine usually will result in a T4 sensory block. More complete tables of these relationships can be found in standard anesthesiology texts. Epinephrine often is added to spinal anesthetics to increase the duration or intensity of block. Epinephrine's effect on duration of block is dependent on the technique used to measure duration. A commonly used measure of block duration is the length of time it takes for the block to recede by two dermatomes from the maximum height of the block, while a second is the duration of block at some specified level, typically L1. In most studies, addition of 200 μ g of epinephrine to tetracaine solutions prolongs the duration of block by both measures. However, addition of epinephrine to lidocaine or bupivacaine does not affect the first measure of duration, but does prolong the block at lower levels. In different clinical situations, one or the other measure of anesthesia duration may be more relevant, and this must be kept in mind when deciding whether to add epinephrine to spinal local anesthetics. The mechanism of action of vasoconstrictors in prolonging spinal anesthesia is uncertain. It has been hypothesized that these agents decrease spinal cord blood flow, decreasing clearance of local anesthetic from the CSF, but this has not been convincingly demonstrated. Epinephrine and other α adrenergic agonists have been shown to decrease nociceptive transmission in the spinal cord, and studies in genetically modified mice suggest that α_{2A} adrenergic receptors play a principal role in this response (Stone *et al.*, 1997). It is possible that these actions contribute to the effects of epinephrine.

Drug Baricity and Patient Position. The baricity of the local anesthetic injected will determine the direction of migration within the dural sac. Hyperbaric solutions will tend to settle in the dependent portions of the sac, while hypobaric solutions will tend to migrate in the opposite direction. Isobaric solutions usually will stay in the vicinity where they were injected, diffusing slowly in all directions. Consideration of the patient position during and after the performance of the block and the choice of a local anesthetic of the appropriate baricity is crucial for a successful block during some surgical procedures. For example, a saddle (perineal) block is best performed with a hyperbaric anesthetic in the sitting position, with the patient remaining in that position until the anesthetic level has become "fixed." On the other hand, for a saddle block in the prone, jack-knife position, a hypobaric local anesthetic is appropriate. Lidocaine and bupivacaine are marketed in both isobaric and hyperbaric preparations, and if desired, can be diluted with sterile, preservative-free water to make them hypobaric.

Complications of Spinal Anesthesia. Persistent neurological deficits following spinal anesthesia are extremely rare. Thorough evaluation

of a suspected deficit should be performed in collaboration with a neurologist. Neurological sequelae can be both immediate and late. Possible causes include introduction of foreign substances (such as disinfectants or talc) into the subarachnoid space, infection, hematoma, or direct mechanical trauma. Aside from drainage of an abscess or hematoma, treatment usually is ineffective; thus, avoidance and careful attention to detail while performing spinal anesthesia are necessary. High concentrations of local anesthetic can cause irreversible block. After administration, local anesthetic solutions are diluted rapidly, quickly reaching nontoxic concentrations. However, there are several reports of transient or longer-lasting neurological deficits following lidocaine spinal anesthesia, particularly with 5% lidocaine (*i.e.*, 180 mmol) in 7.5% glucose (Hodgson *et al.*, 1999). Spinal anesthesia sometimes is regarded as contraindicated in patients with preexisting disease of the spinal cord. No experimental evidence exists to support this hypothesis. Nonetheless, it is prudent to avoid spinal anesthesia in patients with progressive diseases of the spinal cord. However, spinal anesthesia may be very useful in patients with fixed, chronic spinal cord injury.

A more common sequela following any lumbar puncture, including spinal anesthesia, is a postural headache with classic features. The incidence of headache decreases with increasing age of the patient and decreasing needle diameter. Headache following lumbar puncture must be thoroughly evaluated to exclude serious complications such as meningitis. Treatment usually is conservative, with bed rest and analgesics. If this approach fails, an epidural blood patch with the injection of autologous blood can be performed; this procedure usually is successful in alleviating post-dural puncture headaches, although a second blood patch may be necessary. If two epidural blood patches are ineffective in relieving the headache, the diagnosis of post-dural puncture headache should be reconsidered. Intravenous caffeine (500 mg as the benzoate salt administered over 4 hours) also has been advocated for the treatment of post-dural puncture headache. However, the efficacy of caffeine is less than that of a blood patch, and relief usually is transient.

Evaluation of Spinal Anesthesia. Spinal anesthesia is a safe and effective technique, especially during surgery involving the lower abdomen, the lower extremities, and the perineum. It often is combined with intravenous medication to provide sedation and amnesia. The physiological perturbations associated with low spinal anesthesia often have less potential harm than those associated with general anesthesia. The same does not apply for high spinal anesthesia. The sympathetic blockade that accompanies levels of spinal anesthesia adequate for mid- or upper-abdominal surgery, coupled with the difficulty in achieving visceral analgesia, is such that equally satisfactory and safer operating conditions can be realized by combining the spinal anesthetic with a "light" general anesthetic or by the administration of a general anesthetic and a neuromuscular blocking agent.

Epidural Anesthesia

Epidural anesthesia is administered by injecting local anesthetic into the epidural space—the space bounded by the ligamentum flavum posteriorly, the spinal periosteum laterally, and the dura anteriorly. Epidural anesthesia can be performed in the sacral hiatus (caudal anesthesia) or in the lumbar, thoracic, or cervical regions of the spine. Its current popularity arises from the development of catheters that can be placed into the epidural space, allowing either continuous infusions or repeated bolus administration of local anesthetics. The primary site of action of epidurally administered local

anesthetics is on the spinal nerve roots. However, epidurally administered local anesthetics also may act on the spinal cord and on the paravertebral nerves.

The selection of drugs available for epidural anesthesia is similar to that for major nerve blocks. As for spinal anesthesia, the choice of drugs to be used during epidural anesthesia is dictated primarily by the duration of anesthesia desired. However, when an epidural catheter is placed, short-acting drugs can be administered repeatedly, providing more control over the duration of block. Bupivacaine, 0.5% to 0.75%, is used when a long duration of surgical block is desired. Due to enhanced cardiotoxicity in pregnant patients, the 0.75% solution is not approved for obstetrical use. Lower concentrations—0.25%, 0.125%, or 0.0625%—of bupivacaine, often with 2 $\mu\text{g}/\text{ml}$ of fentanyl added, frequently are used to provide analgesia during labor. They also are useful preparations for providing postoperative analgesia in certain clinical situations. Lidocaine 2% is the most frequently used intermediate-acting epidural local anesthetic. Chloroprocaine, 2% or 3%, provides rapid onset and a very short duration of anesthetic action. However, its use in epidural anesthesia has been clouded by controversy regarding its potential ability to cause neurological complications if the drug is accidentally injected into the subarachnoid space (*see above*). The duration of action of epidurally administered local anesthetics frequently is prolonged, and systemic toxicity decreased, by addition of epinephrine. Addition of epinephrine also makes inadvertent intravascular injection easier to detect and modifies the effect of sympathetic blockade during epidural anesthesia.

For each anesthetic agent, a relationship exists between the volume of local anesthetic injected epidurally and the segmental level of anesthesia achieved. For example, in 20- to 40-year-old, healthy, nonpregnant patients, each 1 to 1.5 ml of 2% lidocaine will give an additional segment of anesthesia. The amount needed decreases with increasing age and also decreases during pregnancy and in children.

The concentration of local anesthetic used determines the type of nerve fibers blocked. The highest concentrations are used when sympathetic, somatic sensory, and somatic motor blockade are required. Intermediate concentrations allow somatic sensory anesthesia without muscle relaxation. Low concentrations will block only preganglionic sympathetic fibers. As an example, with bupivacaine these effects might be achieved with concentrations of 0.5%, 0.25%, and 0.0625%, respectively. The total amounts of drug that can be injected with safety at one time are approximately those mentioned above under “Nerve Block Anesthesia” and “Infiltration Anesthesia.” Performance of epidural anesthesia requires a greater degree of skill than does spinal anesthesia. The technique of epidural anesthesia and the volumes, concentrations, and types of drugs used are described in detail in standard texts on regional anesthesia (*e.g.*, Cousins and Bridenbaugh, 1998).

A significant difference between epidural and spinal anesthesia is that the dose of local anesthetic used can produce high concentrations in blood following absorption from the epidural space. Peak concentrations of lidocaine in blood following injection of 400 mg (without epinephrine) into the lumbar epidural space average 3 to 4 $\mu\text{g}/\text{ml}$; peak concentrations of bupivacaine in blood average 1 $\mu\text{g}/\text{ml}$ after the lumbar epidural injection of 150 mg. Addition of epinephrine (5 $\mu\text{g}/\text{ml}$) decreases peak plasma concentrations by about 25%. Peak blood concentrations are a function of the total dose of drug administered rather than the concentration or volume of solution following epidural injection (Covino and Vassallo, 1976). The risk of inadvertent intravascular injection is increased in epidural anesthesia, as the epidural space contains a rich venous plexus.

Another major difference between epidural and spinal anesthesia is that there is no zone of differential sympathetic blockade with epidural anesthesia; thus, the level of sympathetic block is close to the level of sensory block. Because epidural anesthesia does not result in the zones of differential sympathetic blockade observed during spinal anesthesia, cardiovascular responses to epidural anesthesia might be expected to be less prominent. In practice this is not the case; the potential advantage of epidural anesthesia is offset by the cardiovascular responses to the high concentration of anesthetic in blood that occurs during epidural anesthesia. This is most apparent when, as is often the case, epinephrine is added to the epidural injection. The resulting concentration of epinephrine in blood is sufficient to produce significant β_2 adrenergic receptor-mediated vasodilation. As a consequence, blood pressure decreases, even though cardiac output increases due to the positive inotropic and chronotropic effects of epinephrine (*see Chapter 10*). The result is peripheral hyperperfusion and hypotension. Differences in cardiovascular responses to equal levels of spinal and epidural anesthesia also are observed when a local anesthetic such as lidocaine is used without epinephrine. This may be a consequence of the direct effects of high concentrations of lidocaine on vascular smooth muscle and the heart. The magnitude of the differences in responses to equal sensory levels of spinal and epidural anesthesia varies, however, with the local anesthetic used for the epidural injection (assuming no epinephrine is used). For example, local anesthetics such as bupivacaine, which are highly lipid soluble, are distributed less into the circulation than are less lipid-soluble agents such as lidocaine.

High concentrations of local anesthetics in blood during epidural anesthesia are especially important when this technique is used to control pain during labor and delivery. Local anesthetics cross the placenta, enter the fetal circulation, and at high concentrations may cause depression of the neonate. The extent to which they do so is determined by dosage, acid-base status, the level of protein binding in both maternal and fetal blood, placental blood flow, and solubility of the agent in fetal tissue. These concerns have been lessened by the trend toward using more dilute solutions of bupivacaine for labor analgesia.

Epidural and Intrathecal Opiate Analgesia. Small quantities of opioid injected intrathecally or epidurally produce segmental analgesia (Yaksh and Rudy, 1976). This observation led to the clinical use of spinal and epidural opioids during surgical procedures and for the relief of postoperative and chronic pain (Cousins and Mather, 1984). As with local anesthesia, analgesia is confined to sensory nerves that enter the spinal cord dorsal horn in the vicinity of the injection. Presynaptic opioid receptors inhibit the release of substance P and other neurotransmitters from primary afferents, while postsynaptic opioid receptors decrease the activity of certain dorsal horn neurons in the spinothalamic tracts (Willcockson, *et al.*, 1986; *see also Chapters 6 and 21*). Since conduction in autonomic, sensory, and motor nerves is not affected by the opioids, blood pressure, motor function, and non-nociceptive sensory perception typically are not influenced by spinal opioids. The volume-evoked micturition reflex is inhibited, as manifested by urinary retention. Other side effects include pruritus and nausea and vomiting in susceptible individuals. Delayed respiratory depression and sedation, presumably from cephalad spread of opioid within the CSF, occurs infrequently with the doses of opioids currently used.

Spinally administered opioids by themselves do not provide satisfactory anesthesia for surgical procedures. Thus, opioids have

found the greatest use in the treatment of postoperative and chronic pain. In selected patients, spinal or epidural opioids can provide excellent analgesia following thoracic, abdominal, pelvic, or lower extremity surgery without the side effects associated with high doses of systemically administered opioids. For postoperative analgesia, spinally administered morphine, 0.2 to 0.5 mg, usually will provide 8 to 16 hours of analgesia. Placement of an epidural catheter and repeated boluses or an infusion of opioid permits an increased duration of analgesia. Many opioids have been used epidurally. Morphine, 2 to 6 mg, every 6 hours, commonly is used for bolus injections, while fentanyl, 20 to 50 $\mu\text{g}/\text{hour}$, often combined with bupivacaine, 5 to 20 mg/hour, is used for infusions. For cancer pain, repeated doses of epidural opioids can provide analgesia of several months' duration. The dose of epidural morphine, for example, is far less than the dose of systemically administered morphine that would be required to provide similar analgesia. This reduces the complications that usually accompany the administration of high doses of systemic opioids, particularly sedation and constipation. Unfortunately, as with systemic opioids, tolerance will develop to the analgesic effects of epidural opioids, but this usually can be managed by increasing the dose.

THERAPEUTIC GASES

Oxygen, Carbon Dioxide, Nitric Oxide, and Helium

Brett A. Simon, Eric J. Moody, and Roger A. Johns

OXYGEN

Oxygen (O_2) is essential for animal existence. Hypoxia is a life-threatening condition in which oxygen delivery is inadequate to meet the metabolic demands of the tissues. Since oxygen delivery is the product of blood flow and oxygen content, hypoxia may result from alterations in tissue perfusion, decreased oxygen tension in the blood, or decreased oxygen-carrying capacity. In addition, hypoxia may result from restricted oxygen transport from the microvasculature to cells or impaired utilization within the cell. Irrespective of cause, an inadequate supply of oxygen ultimately results in the cessation of aerobic metabolism and oxidative phosphorylation, depletion of high-energy compounds, cellular dysfunction, and death.

History. Soon after Priestley's discovery of oxygen in 1772 and Lavoisier's elucidation of its role in respiration, Beddoes introduced oxygen therapy with his 1794 publication entitled "Considerations on the Medicinal Use and Production of Factitious Airs." Beddoes, overcome with enthusiasm for his project, treated all kinds of diseases with oxygen, including such diverse conditions as scrofula, leprosy, and paralysis. Such indiscriminate therapeutic applications naturally led to many failures, and Beddoes died a disconsolate man. The pioneer investigations of Haldane, Hill, Barcroft, Krogh, L. J. Henderson, and Y. Henderson provided a sound physiological basis for oxygen therapy (Sackner, 1974). Although Paul Bert had studied therapeutic aspects of hyperbaric oxygen in 1870 and identified oxygen toxicity, the use of oxygen at pressures above one atmosphere for therapeutic purposes did not begin until the 1950s.

Normal Oxygenation

Oxygen makes up 21% of air, which at sea level represents a partial pressure of 21 kPa (158 mmHg). While the fraction (percentage) of oxygen remains constant regardless of atmospheric pressure, the partial pressure of oxygen (PO_2) decreases with lower atmospheric

pressure. Since the partial pressure drives the diffusion of oxygen, ascent to elevated altitude reduces the uptake and delivery of oxygen to the tissues. Conversely, increases in atmospheric pressure (e.g., hyperbaric therapy or breathing at depth) raise the PO_2 in inspired air and increase gas uptake. As the air is delivered to the distal airways and alveoli, the PO_2 decreases by dilution with carbon dioxide and water vapor and by uptake into the blood. Under ideal conditions, when ventilation and perfusion are well matched, the alveolar PO_2 will be approximately 14.6 kPa (110 mmHg). The corresponding alveolar partial pressures of water and carbon dioxide are 6.2 kPa (47 mmHg) and 5.3 kPa (40 mmHg), respectively. Under normal conditions, there is complete equilibration of alveolar gas and capillary blood, and the PO_2 in end-capillary blood is typically within a fraction of a kilopascal of that in the alveoli. In some diseases, the diffusion barrier for gas transport may be increased, or, during exercise, when high cardiac output reduces capillary transit time, full equilibration may not occur, and the alveolar-end-capillary PO_2 gradient may be increased.

The PO_2 in arterial blood, however, is further reduced by venous admixture (shunt), the addition of mixed venous blood from the pulmonary artery, which has a PO_2 of approximately 5.3 kPa (40 mmHg). Together, the diffusional barrier, ventilation-perfusion mismatches, and the shunt fraction are the major causes of the alveolar-to-arterial oxygen gradient, which is normally 1.3 to 1.6 kPa (10 to 12 mmHg) when air is breathed and 4.0 to 6.6 kPa (30 to 50 mmHg) when 100% oxygen is breathed.

Oxygen is delivered to the tissue capillary beds by the circulation and again follows a gradient out of the blood and into cells. Tissue extraction of oxygen typically reduces the PO_2 of venous blood by an additional 7.3 kPa (55 mmHg). Although the PO_2 at the site of cellular oxygen utilization—the mitochondria—is not known, oxidative phosphorylation can continue at a PO_2 of only a few millimeters of mercury (Robiolio *et al.*, 1989).

In the blood, oxygen is carried primarily in chemical combination with hemoglobin and is to a small extent dissolved in solution. The quantity of oxygen combined with hemoglobin depends on the PO_2 , as illustrated by the sigmoidal oxyhemoglobin dissociation curve (Figure 15-1). Hemoglobin is about 98% saturated with oxygen when air is breathed under normal circumstances, and it binds 1.3 ml of oxygen per gram when fully saturated. The steep slope of this curve with falling PO_2 facilitates unloading of oxygen from

Figure 15-1. Oxyhemoglobin dissociation curve for whole blood. The relationship between PO_2 and hemoglobin (Hb) saturation is shown. The P_{50} , or the PO_2 resulting in 50% saturation, is indicated as well. An increase in temperature or a decrease in pH (as in working muscle) shifts this relationship to the right, reducing the hemoglobin saturation at the same PO_2 and thus aiding in the delivery of oxygen to the tissues.

hemoglobin at the tissue level and reloading when desaturated mixed venous blood arrives at the lung. Shifting of the curve to the right with increasing temperature, increasing PCO_2 , and decreasing pH, as is found in metabolically active tissues, lowers the oxygen saturation for the same PO_2 and thus delivers additional oxygen where and when it is most needed. However, the flattening of the curve with higher PO_2 indicates that increasing blood PO_2 by inspiring oxygen-enriched mixtures can increase the amount of oxygen carried by hemoglobin only minimally. Further increases in blood oxygen content can occur only by increasing the amount of oxygen dissolved in plasma. Because of the low solubility of oxygen (0.226 mL/L per kilopascal or 0.03 mL/L per millimeter of mercury at $37^\circ C$), breathing 100% oxygen can increase the amount of oxygen dissolved in blood by only 15 mL/L, less than one-third of normal metabolic demands. However, if the inspired PO_2 is increased to 3 atm (304 kPa) in a hyperbaric chamber, the amount of dissolved oxygen is sufficient to meet normal metabolic demands even in the absence of hemoglobin (Table 15-1).

Oxygen Deprivation

An understanding of the causes and effects of oxygen deficiency is necessary for the rational therapeutic use of the gas. *Hypoxia* is the term used to denote insufficient oxygenation of the tissues. *Hypoxemia* generally implies a failure of the respiratory system to oxygenate arterial blood.

Pulmonary Mechanisms of Hypoxemia. Classically, there are five causes of hypoxemia: low inspired oxygen fraction (FI_{O_2}), increased diffusion barrier, hypoventilation, ventilation-perfusion (\dot{V}/\dot{Q}) mismatch, and shunt or venous admixture.

Low FI_{O_2} is a cause of hypoxemia only at high altitude or in the event of equipment failure, such as a gas blender malfunction or a mislabeled compressed-gas tank. An increase in the barrier to diffusion of oxygen within the lung is rarely a cause of hypoxemia in a resting subject, except in end-stage parenchymal lung disease. Both these problems may be alleviated with administration of supplemental oxygen, the former by definition and the latter by increasing the gradient driving diffusion.

Hypoventilation causes hypoxemia by reducing the alveolar PO_2 in proportion to the buildup of carbon dioxide in the alveoli. During hypoventilation, there is decreased delivery of oxygen to the alveoli, whereas its removal by the blood remains the same, causing its alveolar concentration to fall. The opposite occurs with carbon dioxide. This is described by the alveolar gas equation: $PA_{O_2} = PI_{O_2} - (PA_{CO_2}/R)$, where PA_{O_2} and PA_{CO_2} are the alveolar partial pressures of oxygen and carbon dioxide, PI_{O_2} is the partial pressure of oxygen in the inspired gas, and R the respiratory quotient. Under normal conditions, breathing room air at sea level (corrected for the partial pressure of water vapor), the PI_{O_2} is about 20 kPa (150 mmHg), the PA_{CO_2} about 5.3 kPa (40 mmHg), R is 0.8, and thus the PA_{O_2} is normally around 13.3 kPa (100 mmHg). It would require substantial hypoventilation, with the PA_{CO_2} rising to over 9.8 kPa (72 mmHg), to cause the PA_{O_2} to fall below 7.8 kPa (60 mmHg). This cause of hypoxemia is readily prevented by administration of even small amounts of supplemental O_2 .

Shunt and \dot{V}/\dot{Q} mismatch are related causes of hypoxemia but with an important distinction in their responses to supplemental oxygen. Optimal gas exchange occurs when blood flow (\dot{Q}) and ventilation (\dot{V}) are matched quantitatively. However, regional variations in \dot{V}/\dot{Q} matching typically exist within the lung, particularly in the presence of lung disease. As ventilation increases relative to blood flow, the alveolar PO_2 (PA_{O_2}) increases; because of the flat shape of the oxyhemoglobin dissociation curve at high PO_2 (Figure 15-1), this increased PA_{O_2} does not contribute much to the oxygen content of the blood. Conversely, as the \dot{V}/\dot{Q} ratio falls and perfusion increases relative to ventilation, the PA_{O_2} of the blood leaving these regions falls relative to regions with better matched ventilation and perfusion. Since the oxyhemoglobin dissociation curve is steep at these lower PO_2 values, the oxygen saturation and content of the pulmonary

Table 15-1*The Carriage of Oxygen in Blood**

ARTERIAL PO ₂ , kPa (mmHg)	Arterial O ₂ Content (ml O ₂ /liter)			MIXED VENOUS PO ₂ , kPa (mmHg)	Mixed Venous O ₂ Content (ml O ₂ /liter)			EXAMPLES
	DISSOLVED	BOUND TO HEMOGLOBIN	TOTAL		DISSOLVED	BOUND TO HEMOGLOBIN	TOTAL	
4.0 (30)	0.9	109	109.9	2.7 (20)	0.6	59	59.6	High altitude; respiratory failure breathing air

9.0 (300)	9.0	195	204	5.9 (44)	1.3	153	154.3	Normal person breathing 50% O ₂
79.7 (600)	18	196	214	6.5 (49)	1.5	163	164.5	Normal person breathing 100% O ₂
239 (1800)	54	196	250	20.0 (150)	4.5	196	200.5	Normal person breathing hyperbaric O ₂

*This table illustrates the carriage of oxygen in the blood under a variety of circumstances. As arterial O₂ tension increases, the amount of dissolved O₂ increases in direct proportion to the PO₂, but the amount of oxygen bound to hemoglobin reaches a maximum of 196 ml O₂/liter (100% saturation of hemoglobin at 15 g/dl). Further increases in O₂ content require increases in dissolved oxygen. At 100% inspired O₂, dissolved O₂ still provides only a small fraction of total demand. Hyperbaric oxygen therapy is required to increase the amount of dissolved oxygen to supply all or a large part of metabolic requirements. Note that, during hyperbaric oxygen therapy, the hemoglobin in the mixed venous blood remains fully saturated with O₂. The figures in this table are approximate and are based on the assumptions of 15 g/dl hemoglobin, 50 ml O₂/liter whole-body oxygen extraction, and constant cardiac output. When severe anemia is present, arterial PO₂ remains the same, but arterial content is lower; oxygen extraction continues, resulting in lower O₂ content and tension in mixed venous blood. Similarly, as cardiac output falls significantly, the same oxygen extraction occurs from a smaller volume of blood and results in lower mixed venous oxygen content and tension.

venous blood falls significantly. At the extreme of low \dot{V}/\dot{Q} ratios, there is no ventilation to a perfused region, and a pure shunt results; thus the blood leaving the region has the same low PO_2 and high PA_{CO_2} as mixed venous blood.

The deleterious effect of \dot{V}/\dot{Q} mismatch on arterial oxygenation is a direct result of the asymmetry of the oxyhemoglobin dissociation curve. Adding supplemental oxygen generally will make up for the fall in PA_{O_2} in low \dot{V}/\dot{Q} units and thereby improve arterial oxygenation. However, since there is no ventilation to units with pure shunt, supplemental oxygen will not be effective in reversing hypoxemia from this cause. Because of the steep oxyhemoglobin dissociation curve at low PO_2 , even moderate amounts of pure shunt will cause significant hypoxemia despite oxygen therapy (Figure 15–2). For the same reason, factors that decrease mixed venous PO_2 , such as decreased cardiac output or increased oxygen consumption, enhance the hypoxic effects of \dot{V}/\dot{Q} mismatch and shunt.

Nonpulmonary Causes of Hypoxia. In addition to failure of the respiratory system to oxygenate the blood adequately, a number of other factors can contribute to

Figure 15–2. Effect of shunt on arterial oxygenation. The iso-shunt diagram shows the effect of changing inspired oxygen concentration on arterial oxygenation in the presence of different amounts of pure shunt. As shunt fraction increases, even an inspired oxygen fraction ($F_{I_{O_2}}$) of 1.0 is ineffective at increasing the arterial PO_2 . This estimation assumes hemoglobin (Hb) from 10 to 14 g/dl, arterial PCO_2 of 3.3 to 5.3 kPa (25 to 40 mmHg), and an arterial–venous (a–v) O_2 content difference of 5 ml/100 ml. Redrawn from Benatar *et al.*, 1973, with permission.

hypoxia at the tissue level. These may be divided into categories of oxygen delivery and oxygen utilization. Oxygen delivery decreases globally when cardiac output falls or locally when regional blood flow is compromised, such as from a vascular occlusion (*e.g.*, stenosis, thrombosis, or microvascular occlusion) or increased downstream pressure (*e.g.*, compartment syndrome, venous stasis, or venous hypertension). Decreased oxygen-carrying capacity of the blood likewise will reduce oxygen delivery, such as occurs with anemia, carbon monoxide poisoning, or hemoglobinopathy. Finally, hypoxia may occur when transport of oxygen from the capillaries to the tissues is decreased (edema) or utilization of the oxygen by the cells is impaired (cyanide toxicity).

Effects of Hypoxia. There has been a considerable increase in our understanding of the cellular and biochemical changes that occur after acute and chronic hypoxia. Regardless of the cause, hypoxia produces a marked alteration in gene expression, mediated in part by hypoxia-inducible factor-1 α (Semenza, 2003). Ultimately, hypoxia results in the cessation of aerobic metabolism, exhaustion of high-energy intracellular stores, cellular dysfunction, and death. The time course of cellular demise depends on the tissue's relative metabolic requirements, oxygen and energy stores, and anaerobic capacity. Survival times (the time from the onset of circulatory arrest to significant organ dysfunction) range from 1 minute in the cerebral cortex to around 5 minutes in the heart and 10 minutes in the kidneys and liver, with the potential for some degree of recovery if reperfused. Revival times (the duration of hypoxia beyond which recovery is no longer possible) are approximately four to five times longer. Less severe degrees of hypoxia have progressive physiological effects on different organ systems (Nunn, 2000b).

Respiratory System. Hypoxia stimulates the carotid and aortic baroreceptors to cause increases in both the rate and depth of ventilation. Minute volume almost doubles when normal individuals inspire gas with a PO_2 of 6.6 kPa (50 mmHg). Dyspnea is not always experienced with simple hypoxia but occurs when the respiratory minute volume approaches half the maximal breathing capacity; this may occur with minimum exertion in patients in whom maximal breathing capacity is reduced by lung disease. In general, little warning precedes the loss of consciousness resulting from hypoxia.

Cardiovascular System. Hypoxia causes reflex activation of the sympathetic nervous system *via* both autonomic and humoral mechanisms, resulting in tachycardia and increased cardiac output. Peripheral vascular resistance, however, decreases primarily *via* local autoregulatory

mechanisms, with the net result that blood pressure generally is maintained unless hypoxia is prolonged or severe. In contrast to the systemic circulation, hypoxia causes pulmonary vasoconstriction and hypertension, an extension of the normal regional vascular response that matches perfusion with ventilation to optimize gas exchange in the lung (hypoxic pulmonary vasoconstriction).

Central Nervous System (CNS). The CNS is least able to tolerate hypoxia. Hypoxia is manifest initially by decreased intellectual capacity and impaired judgment and psychomotor ability. This state progresses to confusion and restlessness and ultimately to stupor, coma, and death as the arterial PO_2 decreases below 4 to 5.3 kPa (30 to 40 mmHg). Victims often are unaware of this progression.

Cellular and Metabolic Effects. When the mitochondrial PO_2 falls below about 0.13 kPa (1 mmHg), aerobic metabolism stops, and the less efficient anaerobic pathways of glycolysis become responsible for the production of cellular energy. End products of anaerobic metabolism, such as lactic acid, are released into the circulation in measurable quantities. Energy-dependent ion pumps slow, and transmembrane ion gradients dissipate. Intracellular concentrations of Na^+ , Ca^{2+} , and H^+ increase, finally leading to cell death. The time course of cellular demise depends on the relative metabolic demands, oxygen storage capacity, and anaerobic capacity of the individual organs. Restoration of perfusion and oxygenation prior to hypoxic cell death paradoxically can result in an accelerated form of cell injury (ischemia–reperfusion syndrome), which is thought to result from the generation of highly reactive oxygen free radicals (McCord, 1985).

Adaptation to Hypoxia. Long-term hypoxia results in adaptive physiological changes; these have been studied most thoroughly in persons exposed to high altitude. Adaptations include increased numbers of pulmonary alveoli, increased concentrations of hemoglobin in blood and myoglobin in muscle, and a decreased ventilatory response to hypoxia. Short-term exposure to high altitude produces similar adaptive changes. In susceptible individuals, however, acute exposure to high altitude may produce *acute mountain sickness*, a syndrome characterized by headache, nausea, dyspnea, sleep disturbances, and impaired judgment progressing to pulmonary and cerebral edema (Johnson and Rock, 1988). Mountain sickness is treated with supplemental oxygen, descent to lower altitude, or an increase in ambient pressure. Diuretics (*carbonic anhydrase inhibitors*) and steroids also may be helpful. The syndrome usually can be avoided by a slow ascent to altitude, permitting time for adaptation to occur.

Certain aspects of fetal and newborn physiology are strongly reminiscent of adaptation mechanisms found in hypoxia-tolerant animals (Mortola, 1999; Singer, 1999), including shifts in the oxyhemoglobin dissociation curve (fetal hemoglobin), reductions in metabolic rate and body temperature (hibernation-like mode), reductions in heart rate and circulatory redistribution (as in diving mammals), and redirection of energy utilization from growth to maintenance

metabolism. These adaptations probably account for the relative tolerance of the fetus and neonate to both chronic (uterine insufficiency) and short-term hypoxia.

Oxygen Inhalation

Physiological Effects of Oxygen Inhalation. Oxygen inhalation is used primarily to reverse or prevent the development of hypoxia; other consequences usually are minor. However, when oxygen is breathed in excessive amounts or for prolonged periods, secondary physiological changes and toxic effects can occur.

Respiratory System. Inhalation of oxygen at 1 atm or above causes a small degree of respiratory depression in normal subjects, presumably as a result of loss of tonic chemoreceptor activity. However, ventilation typically increases within a few minutes of oxygen inhalation because of a paradoxical increase in the tension of carbon dioxide in tissues. This increase results from the increased concentration of oxyhemoglobin in venous blood, which causes less efficient removal of carbon dioxide from the tissues (Plewes and Farhi, 1983).

In a small number of patients whose respiratory center is depressed by long-term retention of carbon dioxide, injury, or drugs, ventilation is maintained largely by stimulation of carotid and aortic chemoreceptors, commonly referred to as the *hypoxic drive*. The provision of too much oxygen can depress this drive, resulting in respiratory acidosis. In these cases, supplemental oxygen should be titrated carefully to ensure adequate arterial saturation. If hypoventilation results, then mechanical ventilatory support with or without tracheal intubation should be provided.

Expansion of poorly ventilated alveoli is maintained in part by the nitrogen content of alveolar gas; nitrogen is poorly soluble and thus remains in the airspaces while oxygen is absorbed. High oxygen concentrations delivered to poorly ventilated lung regions dilute the nitrogen content and can promote absorption atelectasis, occasionally resulting in an increase in shunt and a paradoxical worsening of hypoxemia after a period of oxygen administration.

Cardiovascular System. Aside from reversing the effects of hypoxia, the physiological consequences of oxygen inhalation on the cardiovascular system are of little significance. Heart rate and cardiac output are slightly reduced when 100% oxygen is breathed; blood pressure changes little. While pulmonary arterial pressure changes little in normal subjects with oxygen inhalation, elevated pulmonary artery pressures in patients living at high altitude who have chronic hypoxic pulmonary hypertension may reverse with oxygen therapy or return to sea level. In particular, in neonates with congenital heart disease and left-to-right shunting of cardiac output, oxygen supplementation must be reg-

ulated carefully because of the risk of further reducing pulmonary vascular resistance and increasing pulmonary blood flow.

Metabolism. Inhalation of 100% oxygen does not produce detectable changes in oxygen consumption, carbon dioxide production, respiratory quotient, or glucose utilization.

Oxygen Administration

Oxygen is supplied as a compressed gas in steel cylinders, and a purity of 99% is referred to as *medical grade*. Most hospitals have oxygen piped from insulated liquid oxygen containers to areas of frequent use. For safety, oxygen cylinders and piping are color-coded (green in the United States), and some form of mechanical indexing of valve connections is used to prevent the connection of other gases to oxygen systems. Oxygen concentrators, which employ molecular sieve, membrane, or electrochemical technologies, are available for low-flow home use. Such systems produce 30% to 95% oxygen depending on the flow rate.

Oxygen is delivered by inhalation except during extracorporeal circulation, when it is dissolved directly into the circulating blood. Only a closed delivery system with an airtight seal to the patient's airway and complete separation of inspired from expired gases can precisely control FI_{O_2} . In all other systems, the actual delivered FI_{O_2} will depend on the ventilatory pattern (*i.e.*, rate, tidal volume, inspiratory–expiratory time ratio, and inspiratory flow) and delivery system characteristics.

Low-Flow Systems. Low-flow systems, in which the oxygen flow is lower than the inspiratory flow rate, have a limited ability to raise the FI_{O_2} because they depend on entrained room air to make up the balance of the inspired gas. The FI_{O_2} of these systems is extremely sensitive to small changes in the ventilatory pattern. Devices such as face tents are used primarily for delivering humidified gases to patients and cannot be relied on to provide predictable amounts of supplemental oxygen. Nasal cannulae—small, flexible prongs that sit just inside each naris—deliver oxygen at 1 to 6 L/min. The nasopharynx acts as a reservoir for storing the oxygen, and patients may breathe through either the mouth or nose as long as the nasal passages remain patent. These devices typically deliver 24% to 28% FI_{O_2} at 2 to 3 L/min. Up to 40% FI_{O_2} is possible at higher flow rates, although this is poorly tolerated for more than brief periods because of mucosal drying. The simple facemask, a clear plastic mask with side holes for clearance of expiratory gas and inspiratory air entrainment, is used when higher concentrations of oxygen delivered without tight control are desired. The maximum FI_{O_2} of a facemask can be increased from around 60% at 6 to 15 L/min to greater than 85% by adding a 600- to 1000-ml reservoir bag. With this partial rebreathing mask, most of the inspired volume is drawn from the reservoir, avoiding dilution by entrainment of room air.

High-Flow Systems. The most commonly used high-flow oxygen delivery device is the Venturi mask, which uses a specially designed mask insert to entrain room air reliably in a fixed ratio and thus provides a relatively constant FI_{O_2} at relatively high flow rates. Typically, each insert is designed to operate at a specific oxygen flow rate, and different inserts are required to change the FI_{O_2} . Lower delivered FI_{O_2} values use greater entrainment ratios, resulting in higher total (oxygen plus entrained air) flows to the patient, ranging from 80 L/min for 24% FI_{O_2} to 40 L/min at 50% FI_{O_2} . While these flow rates are much higher than those obtained with low-flow devices, they still may be lower than the peak inspiratory flows for patients in respiratory distress, and thus the actual delivered oxygen concentration may be lower than the nominal value. Oxygen nebulizers, another type of Venturi device, provide patients with humidified oxygen at 35% to 100% FI_{O_2} at high flow rates. Finally, oxygen blenders provide high inspired oxygen concentrations at very high flow rates. These devices mix high-pressure compressed air and oxygen to achieve any concentration of oxygen from 21% to 100% at flow rates of up to 100 L/min. These same blenders are used to provide control of FI_{O_2} for ventilators, CPAP/BiPAP machines, oxygenators, and other devices with similar requirements. Again, despite the high flows, the delivery of high FI_{O_2} to an individual patient also depends on maintaining a tight-fitting seal to the airway and/or the use of reservoirs to minimize entrainment of diluting room air.

Monitoring of Oxygenation. Monitoring and titration are required to meet the therapeutic goal of oxygen therapy and to avoid complications and side effects. Although cyanosis is a physical finding of substantial clinical importance, it is not an early, sensitive, or reliable index of oxygenation. Cyanosis appears when about 5 g/dl of deoxyhemoglobin is present in arterial blood, representing an oxygen saturation of about 67% when a normal amount of hemoglobin (15 g/dl) is present. However, when anemia lowers the hemoglobin to 10 g/dl, then cyanosis does not appear until the arterial blood saturation has decreased to 50%. Invasive approaches for monitoring oxygenation include intermittent laboratory analysis of arterial or mixed venous blood gases and placement of intravascular cannulae capable of continuous measurement of oxygen tension. The latter method, which relies on fiberoptic oximetry, is used frequently for the continuous measurement of mixed venous hemoglobin saturation as an index of tissue extraction of oxygen, usually in critically ill patients.

Noninvasive monitoring of arterial oxygen saturation now is widely available from transcutaneous pulse oximetry, in which oxygen saturation is measured from the differential absorption of light by oxyhemoglobin and deoxyhemoglobin and the arterial saturation determined from the pulsatile component of this signal. Application is simple, and calibration is not required. Because pulse oximetry measures hemoglobin saturation and not PO_2 , it is not sensitive to increases in PO_2 that exceed levels required to saturate the blood fully. However, pulse oximetry is very useful for monitoring the adequacy of oxygenation during procedures requiring sedation or anesthesia, rapid evaluation and monitoring of potentially compromised patients, and titrating oxygen therapy in situations where toxicity from oxygen or side effects of excess oxygen are of concern.

Complications of Oxygen Therapy. Administration of supplemental oxygen is not without potential complications. In addition to the potential to promote absorption atelectasis and depress ventilation (discussed earlier), high flows of dry oxygen can dry out and irritate mucosal surfaces of the airway and the eyes, as well as decrease mucociliary transport and clearance of secretions. Humidified oxy-

gen thus should be used when prolonged therapy (>1 hour) is required. Finally, any oxygen-enriched atmosphere constitutes a fire hazard, and appropriate precautions must be taken both in the operating room and for patients on oxygen at home.

It is important to realize that hypoxemia still can occur despite the administration of supplemental oxygen. Furthermore, when supplemental oxygen is administered, desaturation occurs at a later time after airway obstruction or hypoventilation, potentially delaying the detection of these critical events. Therefore, whether or not oxygen is administered to a patient at risk for these problems, it is essential that both oxygen saturation and adequacy of ventilation be assessed frequently.

Therapeutic Uses of Oxygen

Correction of Hypoxia. As stated earlier, the primary therapeutic use of oxygen is to correct hypoxia. However, hypoxia is most commonly a manifestation of an underlying disease, and administration of oxygen thus should be viewed as a symptomatic or temporizing therapy. Efforts must be directed at correcting the cause of the hypoxia. For example, airway obstruction is unlikely to respond to an increase in inspired oxygen tension without relief of the obstruction. More important, while hypoxemia owing to hypoventilation after a narcotic overdose can be improved with supplemental oxygen administration, the patient remains at risk for respiratory failure if ventilation is not increased through stimulation, narcotic reversal, or mechanical ventilation. The hypoxia that results from most pulmonary diseases can be alleviated at least partially by administration of oxygen, thereby allowing time for definitive therapy to reverse the primary process. Thus, administration of oxygen is a basic and important treatment to be used in all forms of hypoxia, with the understanding that the response will vary in a way that generally is predictable from knowledge of the underlying pathophysiological processes.

Reduction of Partial Pressure of an Inert Gas. Since nitrogen constitutes some 79% of ambient air, it also is the predominant gas in most gas-filled spaces in the body. In certain situations, such as bowel distension from obstruction or ileus, intravascular air embolism, or pneumothorax, it is desirable to reduce the volume of these air-filled spaces. Since nitrogen is relatively insoluble, inhalation of high concentrations of oxygen (and thus low concentrations of nitrogen) rapidly lowers the total-body partial pressure of nitrogen and provides a substantial gradient for the removal of nitrogen from gas spaces. Administration of oxygen for air embolism is additionally beneficial because it also helps to relieve the localized hypoxia distal to the embolic vascular obstruction. In the case of *decompression sickness*, or *bends*, lowering of inert gas tension in blood and tissues by oxygen inhalation prior to or during a barometric decompression can reduce the degree of supersaturation that occurs after decompression so that bubbles do not form. If bubbles do form in either tissues or the vasculature, administration of oxygen is based on the same rationale as that described for gas embolism.

Hyperbaric Oxygen Therapy. Oxygen is administered at greater than atmospheric pressure for a number of conditions when 100% oxygen at 1 atm is insufficient (Buras, 2000; Shank and Muth, 2000; Myers, 2000). To achieve concentrations of greater than 1 atm, a hyperbaric chamber must be used. These chambers range from small, single-person units to multiroom establishments that may include complex medical equipment. Smaller, one-person chambers typically are pressurized with oxygen, whereas larger ones are pres-

surized with air, and a patient must wear a mask to receive the oxygen at the increased pressure. The larger chambers are more suitable for critically ill patients who require ventilation, monitoring, and constant attendance. Any chamber must be built to withstand pressures that may range from 200 to 600 kPa (2 to 6 atm), although inhaled oxygen tension that exceeds 300 kPa (3 atm) rarely is used (see Oxygen Toxicity, below).

Hyperbaric oxygen therapy has two components: increased hydrostatic pressure and increased oxygen pressure. Both factors are necessary for the treatment of decompression sickness and air embolism. The hydrostatic pressure reduces bubble volume, and the absence of inspired nitrogen increases the gradient for elimination of nitrogen and reduces hypoxia in downstream tissues. Increased oxygen pressure at the tissue level is the primary therapeutic goal for most of the other indications for hyperbaric oxygen. For example, even a small increase in PO_2 in previously ischemic areas may enhance the bactericidal activity of leukocytes and increase angiogenesis. Thus, repetitive brief exposures to hyperbaric oxygen are a useful adjunct in the treatment of chronic refractory osteomyelitis, osteoradionecrosis, or crush injury or for the recovery of compromised skin, tissue grafts, or flaps. Furthermore, increased oxygen tension itself can be bacteriostatic; the spread of infection with *Clostridium perfringens* and production of toxin by the bacteria are slowed when oxygen tensions exceed 33 kPa (250 mmHg), justifying the early use of hyperbaric oxygen in clostridial myonecrosis (gas gangrene).

Hyperbaric oxygen also is useful in selected instances of generalized hypoxia. In CO poisoning, hemoglobin (Hb) and myoglobin become unavailable for O_2 binding because of the high affinity of these proteins for CO. This affinity is ~250 times greater than the affinity for O_2 ; thus, an alveolar concentration of CO = 0.4 mm Hg (1/250th that of alveolar O_2 , which is ~100 mm Hg), will compete equally with O_2 for binding sites on Hb. A high PO_2 facilitates competition of O_2 for Hb binding sites as CO is exchanged in the alveoli; i.e., the high PO_2 increases the probability that O_2 rather than CO will bind to Hb once CO dissociates. In addition, hyperbaric O_2 will increase the availability of dissolved O_2 in the blood (see Table 15-1). In a randomized clinical trial (Weaver *et al.*, 2002), hyperbaric oxygen decreased the incidence of long- and short-term neurological sequelae after CO intoxication. The occasional use of hyperbaric oxygen in cyanide poisoning has a similar rationale. Hyperbaric oxygen also may be useful in severe short-term anemia because sufficient oxygen can be dissolved in the plasma at 3 atm to meet metabolic needs. However, such treatment must be limited because oxygen toxicity depends on increased PO_2 , not on the oxygen content of the blood.

Hyperbaric oxygen therapy has been used in such diverse conditions as multiple sclerosis, traumatic spinal cord injury, cerebrovascular accidents, bone grafts and fractures, and leprosy; however, data from well-controlled clinical trials are not sufficient to justify these uses.

Oxygen Toxicity

Oxygen is used in cellular energy production and is crucial for cellular metabolism. However, oxygen also may have deleterious actions at the cellular level. Oxygen toxicity probably results from increased production of hydrogen peroxide and reactive agents such as superoxide anion, singlet oxygen, and hydroxyl radicals (Carraway and Piantadosi, 1999) that attack and damage lipids, proteins, and other macromolecules, especially those in biological mem-

branes. A number of factors limit the toxicity of oxygen-derived reactive agents, including enzymes such as superoxide dismutase, glutathione peroxidase, and catalase, which scavenge toxic oxygen by-products, and reducing agents such as iron, glutathione, and ascorbate. These factors, however, are insufficient to limit the destructive actions of oxygen when patients are exposed to high concentrations over an extended time period. Tissues show differential sensitivity to oxygen toxicity, which is likely the result of differences in both their production of reactive compounds and their protective mechanisms.

Respiratory Tract. The pulmonary system is usually the first to exhibit toxicity, a function of its continuous exposure to the highest oxygen tensions in the body. Subtle changes in pulmonary function can occur within 8 to 12 hours of exposure to 100% oxygen (Sackner *et al.*, 1975). Increases in capillary permeability, which will increase the alveolar/arterial oxygen gradient and ultimately lead to further hypoxemia, and decreased pulmonary function can be seen after only 18 hours of exposure (Davis *et al.*, 1983; Clark, 1988). Serious injury and death, however, require much longer exposures. Pulmonary damage is directly related to the inspired oxygen tension, and concentrations of less than 0.5 atm appear to be safe over long time periods. The capillary endothelium is the most sensitive tissue of the lung. Endothelial injury results in loss of surface area from interstitial edema and leaks into the alveoli (Crapo *et al.*, 1980).

Decreases of inspired oxygen concentrations remain the cornerstone of therapy for oxygen toxicity. Modest decreases in toxicity also have been observed in animals treated with antioxidant enzymes (White *et al.*, 1989). Tolerance also may play a role in protection from oxygen toxicity; animals exposed briefly to high oxygen tensions are subsequently more resistant to toxicity (Kravetz *et al.*, 1980; Coursin *et al.*, 1987). Sensitivity in human beings also can be altered by preexposure to both high and low oxygen concentrations (Hendricks *et al.*, 1977; Clark, 1988). These studies strongly suggest that changes in alveolar surfactant and cellular levels of antioxidant enzymes play a role in protection from oxygen toxicity.

Retina. Retrolental fibroplasia can occur when neonates are exposed to increased oxygen tensions (Betts *et al.*, 1977). These changes can progress to blindness and are likely caused by angiogenesis (Kushner *et al.*, 1977; Ashton, 1979). The incidence of this disorder has decreased with an improved appreciation of the issues and avoidance of excessive inspired oxygen concentrations. Adults do not seem to develop the disease.

Central Nervous System. CNS problems are rare, and toxicity occurs only under hyperbaric conditions where exposure exceeds 200 kPa (2 atm). Symptoms include seizures and visual changes, which resolve when oxygen tension is returned to normal. These problems are a further reason to replace oxygen with helium under hyperbaric conditions (*see below*).

CARBON DIOXIDE

Transfer and Elimination of Carbon Dioxide

Carbon dioxide (CO₂) is produced by the body's metabolism at approximately the same rate as oxygen consumption. At rest, this value is about 3 ml/kg per minute, but it may increase dramatically with heavy exercise. Carbon dioxide diffuses readily from the cells into the bloodstream, where it is carried partly as bicarbonate ion (HCO₃⁻), partly in chemical combination with hemoglobin and plasma proteins, and partly in solution at a partial pressure of about 6 kPa (46 mmHg) in mixed venous blood. Carbon dioxide is transported to the lung, where it is normally exhaled at the same rate at which it is produced, leaving a partial pressure of about 5.2 kPa (40 mmHg) in the alveoli and in arterial blood. An increase in PCO₂ results in a respiratory acidosis and may be due to decreased ventilation or the inhalation of carbon dioxide, whereas an increase in ventilation results in decreased PCO₂ and a respiratory alkalosis. Since carbon dioxide is freely diffusible, the changes in blood PCO₂ and pH soon are reflected by intracellular changes in PCO₂ and pH.

Effects of Carbon Dioxide

Alterations in PCO₂ and pH have widespread effects in the body, particularly on respiration, circulation, and the CNS. More complete discussions of these and other effects are found in textbooks of physiology (*see Nunn, 2000a*).

Respiration. Carbon dioxide is a rapid, potent stimulus to ventilation in direct proportion to the inspired carbon dioxide. Inhalation of 10% carbon dioxide can produce minute volumes of 75 L/min in normal individuals. Carbon dioxide acts at multiple sites to stimulate ventilation. Respiratory integration areas in the brainstem are acted on by impulses from medullary and peripheral arterial chemoreceptors. The mechanism by which carbon dioxide acts on these receptors probably involves changes in pH (Nattie, 1999). Elevated PCO₂ causes bronchodilation, whereas hypocarbia causes constriction of airway smooth muscle; these responses may play a role in matching pulmonary ventilation and perfusion (Duane *et al.*, 1979).

Circulation. The circulatory effects of carbon dioxide result from the combination of its direct local effects and its centrally mediated effects on the autonomic nervous system. The direct effect of carbon dioxide on the heart, diminished contractility, results from pH changes (van den Bos *et al.*, 1979). The direct effect on systemic blood vessels results in vasodilation. Carbon dioxide causes widespread activation of the sympathetic nervous system and an increase in the plasma concentrations of epinephrine, norepinephrine, angiotensin, and other vasoactive peptides (Staszewska-Barczak and Dusing, 1981). The results of sympathetic nervous system activation generally are opposite to the local effects of carbon dioxide. The sympathetic effects consist of increases in cardiac contractility, heart rate, and vasoconstriction (*see* Chapter 10).

The balance of opposing local and sympathetic effects, therefore, determines the total circulatory response to carbon dioxide. The net effect of carbon dioxide inhalation is an increase in cardiac output, heart rate, and blood pressure. In blood vessels, however, the direct vasodilating actions of carbon dioxide appear more important, and total peripheral resistance decreases when the PCO_2 is increased. Carbon dioxide also is a potent coronary vasodilator. Cardiac arrhythmias associated with increased PCO_2 are due to the release of catecholamines.

Hypocarbica results in opposite effects: decreased blood pressure and vasoconstriction in skin, intestine, brain, kidney, and heart. These actions are exploited clinically in the use of hyperventilation to diminish intracranial hypertension.

Central Nervous System. Hypercarbia depresses the excitability of the cerebral cortex and increases the cutaneous pain threshold through a central action. This central depression has therapeutic importance. For example, in patients who are hypoventilating from narcotics or anesthetics, increasing PCO_2 may result in further CNS depression, which in turn may worsen the respiratory depression. This positive-feedback cycle can be deadly. The inhalation of high concentrations of carbon dioxide (about 50%) produces marked cortical and subcortical depression of a type similar to that produced by anesthetic agents. Under certain circumstances, inspired carbon dioxide (25% to 30%) can result in subcortical activation and seizures.

Methods of Administration

Carbon dioxide is marketed in gray metal cylinders as the pure gas or as carbon dioxide mixed with oxygen. It usually is administered at a concentration of 5% to 10% in combination with oxygen by means of a facemask. Another method for the temporary administration of carbon dioxide is by rebreathing, *e.g.*, from an anesthesia breathing circuit when the soda lime canister is bypassed or from something as simple as a paper bag. A potential safety issue exists in that tanks containing carbon dioxide plus oxygen are the same color as those containing 100% carbon dioxide. When tanks containing carbon dioxide and oxygen have been used inadvertently where a fire hazard exists (*e.g.*, in the presence of electrocautery during laparoscopic surgery), explosions and fires have resulted.

Therapeutic Uses

Inhalation of carbon dioxide is used less commonly today than in the past because there are now more effective treatments for most indications. Inhalation of carbon dioxide has been used during anesthesia to increase the speed of induction and emergence from inhalational anesthesia by increasing minute ventilation and cerebral

blood flow. However, this technique results in some degree of respiratory acidosis. Hypocarbica, with its attendant respiratory alkalosis, still has some uses in anesthesia. It constricts cerebral vessels, decreasing brain size slightly, and thus may facilitate the performance of neurosurgical operations. Although carbon dioxide stimulates respiration, it is not useful in situations where respiratory depression has resulted in hypercarbia or acidosis because further depression results.

A common use of carbon dioxide is for insufflation during endoscopic procedures (*e.g.*, laparoscopic surgery) because it is highly soluble and does not support combustion. Any inadvertent gas emboli thus are dissolved and eliminated more easily *via* the respiratory system.

Recently, carbon dioxide has been shown to be helpful during open cardiac surgery, where it is used to flood the surgical field. Because of its density, carbon dioxide displaces the air surrounding the open heart so that any gas bubbles trapped in the heart are carbon dioxide rather than insoluble nitrogen (Nadolny and Svensson, 2000). For the same reasons, CO_2 is used to de-bubble cardiopulmonary bypass and extracorporeal membrane oxygenation (ECMO) circuits. It also can be used to adjust pH during bypass procedures when a patient is cooled.

NITRIC OXIDE

Nitric oxide (NO), a free-radical gas long known as an air pollutant and a potential toxin, is an endogenous cell-signaling molecule of great physiological importance. As knowledge of the important actions of NO has evolved, interest in the use of NO as a therapeutic agent has grown.

Endogenous NO is produced from L-arginine by a family of enzymes called *NO synthases*. NO is both an intracellular and a cell-cell messenger implicated in a wide range of physiological and pathophysiological events in numerous cell types, including the cardiovascular, immune, and nervous systems. NO activates the soluble guanyl cyclase, increasing cellular cyclic GMP (*see* Chapter 1). In the vasculature, basal release of NO produced by endothelial cells is a primary determinant of resting vascular tone; NO causes vasodilation when synthesized in response to shear stress or a variety of vasodilating agents (*see* Chapter 32). It also inhibits platelet aggregation and adhesion. Impaired NO production has been implicated in diseases such as atherosclerosis, hypertension, cerebral and coronary vasospasm, and ischemia-reperfusion injury. In the immune system, NO serves as an effector of macrophage-induced cytotoxicity, and overproduction of NO is a mediator of inflammation. In neurons, NO acts as a mediator of long-term potentiation, cytotoxicity resulting from *N*-methyl-D-aspartate (NMDA), and non-adrenergic noncholinergic neurotransmission; NO has been implicated in mediating central nociceptive pathways (*see* Chapter 6).

The physiology and pathophysiology of endogenous NO have been reviewed extensively (Nathan, 2004; Ignarro and Napoli, 2005).

Therapeutic Use of NO

Inhalation of NO gas has received considerable therapeutic attention owing to its ability to dilate selectively the pulmonary vasculature with minimal systemic cardiovascular effects (Stuedel *et al.*, 1999). The lack of effect of inhaled NO on the systemic circulation is due to its strong binding to and inactivation by oxyhemoglobin on exposure to the pulmonary circulation. Ventilation–perfusion matching is preserved or improved by NO because inhaled NO is distributed only to ventilated areas of the lung and dilates only those vessels directly adjacent to the ventilated alveoli. Thus, inhaled NO will decrease elevated pulmonary artery pressure and pulmonary vascular resistance and often improve oxygenation (Stuedel *et al.*, 1999; Haddad *et al.*, 2000).

Owing to its selective pulmonary vasodilating action, inhaled NO is being studied as a potential therapeutic agent for numerous diseases associated with increased pulmonary vascular resistance. Therapeutic trials of inhaled NO in a wide range of such conditions have confirmed its ability to decrease pulmonary vascular resistance and often increase oxygenation, but in all but a few cases these trials have yet to demonstrate long-term improvement in terms of morbidity or mortality (Dellinger, 1999; Cheifetz, 2000). Inhaled NO has been approved by the FDA only for use in newborns with persistent pulmonary hypertension and has become the first-line therapy for this disease (Hwang *et al.*, 2004; Mourani *et al.*, 2004). In this disease state, NO inhalation has been shown to reduce significantly the necessity for extracorporeal membrane oxygenation, although overall mortality has been unchanged (Kinsella *et al.*, 1997; Roberts *et al.*, 1997). Notably, numerous trials of inhaled NO in adult and pediatric acute respiratory distress syndrome, as well as a recent meta-analysis, have failed to demonstrate an impact on outcome (Dellinger, 1999; Cheifetz, 2000; Sokol *et al.*, 2003). Several small studies and case reports have suggested potential benefits of inhaled NO in a variety of conditions, including weaning from cardiopulmonary bypass in adult and congenital heart disease patients, primary pulmonary hypertension, pulmonary embolism, acute chest syndrome in sickle-cell patients, congenital diaphragmatic hernia, high-altitude pulmonary edema, and lung transplantation (Stuedel *et al.*, 1999; Haddad *et al.*, 2000; Tanus-Santos and Theodorakis, 2002). Larger prospective, randomized studies either have not yet been performed or have failed to confirm any

changes in outcome. Outside of clinical investigation, therapeutic use and benefit of inhaled NO presently are limited to newborns with persistent pulmonary hypertension.

Diagnostic Uses of NO

Inhaled NO also is used in several diagnostic applications. Inhaled NO can be used during cardiac catheterization to evaluate safely and selectively the pulmonary vasodilating capacity of patients with heart failure and infants with congenital heart disease. Inhaled NO also is used to determine the diffusion capacity (DL) across the alveolar–capillary unit. NO is more effective than carbon dioxide in this regard because of its greater affinity for hemoglobin and its higher water solubility at body temperature (Stuedel *et al.*, 1999; Haddad *et al.*, 2000).
