ESTROGENS AND PROGESTINS

David S. Loose and George M. Stancel

Estrogens and *progestins* are endogenous hormones that produce numerous physiological actions. In women, these include developmental effects, neuroendocrine actions involved in the control of ovulation, the cyclical preparation of the reproductive tract for fertilization and implantation, and major actions on mineral, carbohydrate, protein, and lipid metabolism. Estrogens also have important actions in males, including effects on bone, spermatogenesis, and behavior.

The biosynthesis, biotransformation, and disposition of estrogens and progestins are well established. Two well-characterized nuclear receptors are present for each hormone. This knowledge provides a firm conceptual basis for understanding the actions of both steroids.

The therapeutic use of estrogens and progestins largely reflects extensions of their physiological activities. The most common uses of these agents are menopausal hormone therapy and contraception in women, but the specific compounds and dosages used in these two settings differ substantially.

Estrogen- and progesterone-receptor antagonists also are available. The main uses of anti-estrogens are treatment of hormone-responsive breast cancer and infertility. Selective estrogen receptor modulators (SERMs) that display tissue-selective agonist or antagonist activities are increasing in number. The main use of anti-progestins has been for medical abortion, but other uses are theoretically possible.

A number of naturally occurring and synthetic environmental chemicals mimic, antagonize, or otherwise affect the actions of estrogens in experimental test systems. The precise effect of these agents on humans is unknown, but this is an area of active investigation. Cancer chemotherapeutic strategies based on blockade of estrogen- and/or progesterone-receptor functions are considered in further detail in Chapter 51. Complementary therapeutic strategies based on suppression of gonadotropin secretion by

long-acting gonadotropin-releasing hormone agonists are discussed in Chapter 55.

History. The hormonal nature of the ovarian control of the female reproductive system was firmly established in 1900 by Knauer when he found that ovarian transplants prevented the symptoms of gonadectomy, and by Halban, who showed that normal sexual development and function occurred when glands were transplanted. In 1923, Allen and Doisy devised a bioassay for ovarian extracts based upon the vaginal smear of the rat. Frank and associates in 1925 detected an active sex principle in the blood of sows in estrus, and Loewe and Lange discovered in 1926 that a female sex hormone varied in the urine of women throughout the menstrual cycle. The excretion of estrogen in the urine during pregnancy also was reported by Zondek in 1928 and enabled Butenandt and Doisy in 1929 to crystallize an active substance.

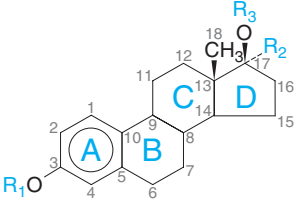

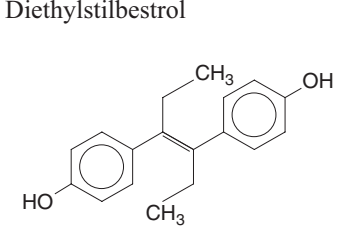

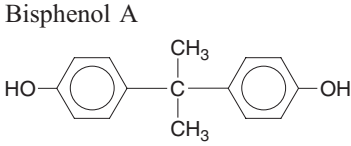

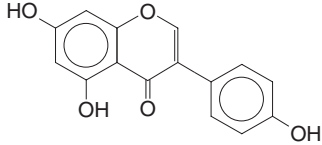

Early investigations indicated that the ovary secretes two substances. Beard had postulated in 1897 that the corpus luteum serves a necessary function during pregnancy, and Fraenkel showed in 1903 that destruction of the corpora lutea in pregnant rabbits caused abortion. Several groups then isolated progesterone from mammalian corpora lutea in the 1930s.

In the early 1960s, pioneering studies by Jensen and colleagues suggested the presence of intracellular receptors for estrogens in target tissues. This was the first demonstration of receptors of the steroid/thyroid superfamily and provided techniques to identify receptors for the other steroid hormones. A second estrogen receptor was identified in 1996 and termed *estrogen receptor β* (ER β) to distinguish it from the receptor identified by Jensen and others, termed *estrogen receptor α* (ER α). Two protein isoforms, A and B, of the progesterone receptor arise from a single gene by transcription initiation from different promoters. (*Note:* For the primary literature references about the history of this subject, consult the ninth and tenth editions of this volume.)

ESTROGENS

Chemistry. Many steroidal and nonsteroidal compounds, some of which are shown in Table 57–1 and Figure 57–1, possess estrogenic activity. The most potent naturally occurring estrogen in humans, for

both ER α - and β -mediated actions, is 17 β -estradiol, followed by estrone and estriol. Each contains a phenolic A ring with a hydroxyl group at carbon 3, and a β -OH or ketone in position 17 of ring D.

The phenolic A ring is the principal structural feature responsible for selective, high-affinity binding to both receptors. Most alkyl substitutions on the A ring impair binding, but substitutions on ring C or D may be tolerated. Ethinyl substitutions at the C17 position greatly increase oral potency by inhibiting first-pass hepatic metabolism. Models for the ligand-binding sites of both estrogen receptors have been determined from structure–activity relationships (Harrington *et al.*, 2003) and structural analysis (Pike *et al.*, 2000).

Diethylstilbestrol (DES), which is structurally similar to estradiol when viewed in the *trans* conformation, binds with high affinity to both estrogen receptors and is as potent as estradiol in most assays, but has a much longer half-life. DES no longer has widespread use, but it was important historically as an inexpensive, orally active estrogen.

Selective ligands for ER α and ER β are available for experimental studies but are not yet used therapeutically (Harrington *et al.*, 2003).

Nonsteroidal compounds with estrogenic or anti-estrogenic activity—including flavones, isoflavones (*e.g.*, genistein), and coumestan derivatives—occur in plants and fungi. Synthetic agents—including

pesticides (*e.g.*, *p,p'*-DDT), plasticizers (*e.g.*, bisphenol A), and a variety of other industrial chemicals (*e.g.*, polychlorinated biphenyls)—also have hormonal or antihormonal activity. While their affinity is relatively weak, their large number, bioaccumulation, and persistence in the environment have raised concerns about their potential toxicity in humans and wildlife (Mäkelä *et al.*, 1999). Over-the-counter and prescription preparations containing naturally occurring, estrogenlike compounds from plants (*i.e.*, phytoestrogens) now are available (Fitzpatrick, 2003).

Biosynthesis. Steroidal estrogens arise from androstenedione or testosterone (Figure 57-1) by aromatization of the A ring. The reaction is catalyzed by a cytochrome P450 monooxygenase enzyme complex (aromatase or CYP19) that uses NADPH and molecular oxygen as co-substrates. A ubiquitous flavoprotein, NADPH–cytochrome P450 reductase, also is essential. Both proteins are localized in the endoplasmic reticulum of ovarian granulosa cells, testicular Sertoli and Leydig cells, adipose stroma, placental syncytiotrophoblasts, preimplantation blastocysts, bone, various brain regions, and many other tissues (Simpson *et al.*, 2002).

The ovaries are the principal source of circulating estrogen in premenopausal women, with estradiol being the main secretory product. Gonadotropins, acting via receptors that couple to the G_s -

Figure 57-1. The biosynthetic pathway for the estrogens.

adenylyl cyclase–cyclic AMP pathway, increase the activities of aromatase and the cholesterol side-chain cleavage enzyme and facilitate the transport of cholesterol (the precursor of all steroids) into the mitochondria of cells that synthesize steroids. The ovary contains a form of 17 β -hydroxysteroid dehydrogenase (type I) that favors the production of testosterone and estradiol from androstenedione and estrone, respectively. However, in the liver, another form of this enzyme (type II) favors oxidation of circulating estradiol to estrone (Peltoketo *et al.*, 1999), and both of these steroids are then converted to estriol (Figure 57-1). All three of these estrogens are excreted in the urine along with their glucuronide and sulfate conjugates.

In postmenopausal women, the principal source of circulating estrogen is adipose tissue stroma, where estrone is synthesized from dehydroepiandrosterone secreted by the adrenals. In men, estrogens are produced by the testes, but extragonadal production by aromatization of circulating C19 steroids (*e.g.*, androstenedione and dehydroepiandrosterone) accounts for most circulating estrogens. Thus, the level of estrogens is regulated in part by the availability of androgenic precursors (Simpson, 2003).

Estrogenic effects most often have been attributed to circulating hormones, but locally produced estrogens also may have important actions (Simpson *et al.*, 2002). For example, estrogens may be produced from androgens by the actions of aromatase or from estrogen conjugates by hydrolysis. Such local production of estrogens could play a causal role in the development of certain diseases such as breast cancer, since mammary tumors contain both aromatase and hydrolytic enzymes. Estrogens also may be produced from androgens *via* aromatase in the central nervous system (CNS) and other

tissues and exert local effects near their production site (*e.g.*, in bone they affect bone mineral density).

The placenta uses fetal dehydroepiandrosterone and its 16 α -hydroxyl derivative to produce large amounts of estrone and estriol. Human urine during pregnancy is thus an abundant source of natural estrogens, and pregnant mare's urine is the source of *conjugated equine estrogens*, which have been widely used therapeutically for many years.

Physiological and Pharmacological Actions

Developmental Actions. Estrogens are largely responsible for pubertal changes in girls and secondary sexual characteristics. They cause growth and development of the vagina, uterus, and fallopian tubes, and contribute to breast enlargement. They also contribute to molding the body contours, shaping the skeleton, and causing the pubertal growth spurt of the long bones and epiphyseal closure. Growth of axillary and pubic hair, pigmentation of the genital region, and the regional pigmentation of the nipples and areolae that occur after the first trimester of pregnancy are also estrogenic actions. Androgens may also play a secondary role in female sexual development (*see* Chapter 58).

Estrogens appear to play important developmental roles in males. In boys, estrogen deficiency diminishes the puber-

Figure 57-2. Neuroendocrine control of gonadotropin secretion in females. The hypothalamic pulse generator located in the arcuate nucleus of the hypothalamus functions as a neuronal “clock” that fires at regular hourly intervals (A). This results in the periodic release of gonadotropin-releasing hormone (GnRH) from GnRH-containing neurons into the hypothalamic-pituitary portal vasculature (B). GnRH neurons (B) receive inhibitory input from opioid, dopamine, and GABA neurons and stimulatory input from noradrenergic neurons (NE, norepinephrine). The pulses of GnRH trigger the intermittent release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from pituitary gonadotropes (C), resulting in the pulsatile plasma profile (D). FSH and LH regulate ovarian production of estrogen and progesterone, which exert feedback controls (E). (See text and Figure 57-3 for additional details.)

tal growth spurt and delays skeletal maturation and epiphyseal closure so that linear growth continues into adulthood. Estrogen deficiency in men leads to elevated gonadotropins, macroorchidism, and increased testosterone levels and also may affect carbohydrate and lipid metabolism and fertility in some individuals (Grumbach and Auchus, 1999).

Neuroendocrine Control of the Menstrual Cycle. A neuroendocrine cascade involving the hypothalamus, pituitary, and ovaries controls the menstrual cycle (Figure 57-2). A neuronal oscillator or “clock” in the hypothalamus fires

at intervals that coincide with bursts of gonadotropin-releasing hormone (GnRH) release into the hypothalamic-pituitary portal vasculature (see Chapter 55). GnRH interacts with its cognate receptor on pituitary gonadotropes to cause release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The frequency of the GnRH pulses, which varies in the different phases of the menstrual cycle (see below), controls the relative synthesis of the unique β subunits of FSH and LH.

The gonadotropins (LH and FSH) regulate the growth and maturation of the graafian follicle in the ovary and the ovar-

ian production of estrogen and progesterone, which exert feedback regulation on the pituitary and hypothalamus.

Because the release of GnRH is intermittent, LH and FSH secretion is pulsatile. The pulse *frequency* is determined by the neural “clock” (Figure 57–2), termed the *hypothalamic GnRH pulse generator* (Knobil, 1981), but the amount of gonadotropin released in each pulse (*i.e.*, the pulse *amplitude*) is largely controlled by the actions of estrogens and progesterone on the pituitary. The intermittent, *pulsatile* nature of hormone release is essential for the maintenance of normal ovulatory menstrual cycles, since constant infusion of GnRH results in a cessation of gonadotropin release and ovarian steroid production (*see* Chapter 55). The pulse generator resides in the arcuate nucleus of the hypothalamus, which also contains the highest concentration of GnRH neurons; considerable evidence suggests that these GnRH neurons collectively form the pulse generator.

The precise mechanism that regulates the timing of GnRH release (*i.e.*, pulse frequency) is unclear, but these cells appear to have an intrinsic ability to release GnRH episodically. The overall pattern of GnRH release likely is regulated by the interplay of intrinsic mechanism(s) and extrinsic synaptic inputs from opioid, catecholamine, and GABAergic neurons (Figure 57–2). Ovarian steroids, primarily progesterone, regulate the frequency of GnRH release, but the cellular and molecular mechanisms of this regulation are not well established. Some GnRH cells appear to contain immunoreactive steroid receptors. Some nerve cells that synapse with GnRH neurons contain steroid receptors, and neighboring glial cells also may contain estrogen and progesterone receptors. Steroids may thus directly and indirectly modulate GnRH neuronal function.

At puberty the pulse generator is activated and establishes cyclic profiles of pituitary and ovarian hormones. While the mechanism of activation is not entirely established, it may involve increases in circulating IGF-1 and leptin levels, the latter acting to inhibit neuropeptide Y (NPY) in the arcuate nucleus to relieve an inhibitory effect on GnRH neurons.

Figure 57–3 provides a schematic diagram of the profiles of gonadotropin and gonadal steroid levels in the menstrual cycle. The “average” plasma levels of LH throughout the cycle are shown in panel A of Figure 57–3; inserts illustrate the pulsatile patterns of LH during the proliferative and secretory phases in more detail. The average LH levels are similar throughout the early (follicular) and late (luteal) phases of the cycle, but the frequency and amplitude of the LH pulses are quite different in the two phases. This characteristic pattern of hormone secretions results from complex positive and negative feedback mechanisms (Hotchkiss and Knobil, 1994).

In the early follicular phase of the cycle: (1) the pulse generator produces bursts of neuronal activity with a frequency of about one per hour that correspond with pulses of GnRH secretion; (2) these

cause a corresponding pulsatile release of LH and FSH from pituitary gonadotropes; and (3) FSH in particular causes the graafian follicle to mature and secrete estrogen. The effects of estrogens on the pituitary are inhibitory at this time and cause the amount of LH and FSH released from the pituitary to decline (*i.e.*, the amplitude of the LH pulse decreases), so gonadotropin levels gradually fall, as seen in Figure 57–3. Inhibin, produced by the ovary, also exerts a negative feedback to selectively decrease serum FSH at this time (*see* Chapter 55). Activin and follistatin, two other peptides released from the ovary, may also regulate FSH production and secretion to a lesser extent, although their levels do not vary appreciably during the menstrual cycle.

At mid-cycle, serum estradiol rises above a threshold level of 150 to 200 pg/ml for approximately 36 hours. This sustained elevation of estrogen no longer inhibits gonadotropin release but exerts a brief positive feedback effect on the pituitary to trigger the preovulatory surge of LH and FSH. This effect primarily involves a change in pituitary responsiveness to GnRH. In some species, estrogens may also exert a positive effect on hypothalamic neurons that contributes to a mid-cycle “surge” of GnRH release; this is not yet established in humans. Progesterone may contribute to the mid-cycle LH surge.

The mid-cycle surge in gonadotropins stimulates follicular rupture and ovulation within 1 to 2 days. The ruptured follicle then develops into the corpus luteum, which produces large amounts of progesterone and lesser amounts of estrogen under the influence of LH during the second half of the cycle. In the absence of pregnancy, the corpus luteum ceases to function, steroid levels drop, and menstruation occurs. When steroid levels drop, the pulse generator reverts to a firing pattern characteristic of the follicular phase, the entire system then resets, and a new ovarian cycle occurs.

Regulation of the frequency and amplitude of gonadotropin secretions by steroids may be summarized as follows: Estrogens act primarily on the pituitary to control the amplitude of gonadotropin pulses, and may also contribute to the amplitude of GnRH pulses secreted by the hypothalamus.

In the follicular phase of the cycle, estrogens inhibit gonadotropin release, but then have a brief mid-cycle stimulatory action that increases the amount released and causes the LH surge. Progesterone, acting on the hypothalamus, exerts the predominant control of the frequency of LH release. It decreases the firing rate of the hypothalamic pulse generator, an action thought to be mediated largely *via* inhibitory opioid neurons (containing progesterone receptors) that synapse with GnRH neurons. Progesterone also exerts a direct effect on the pituitary to oppose the inhibitory actions of estrogens and thus enhance the amount of LH released (*i.e.*, to increase the amplitude of the LH pulses). These steroid feedback effects, coupled with the intrinsic activity of the hypothalamic GnRH pulse generator, lead to relatively frequent LH pulses of small amplitude in the follicular phase of the cycle, and less frequent pulses of larger amplitude in the luteal phase. Studies in knockout mice indicate that ER α (Hewitt and Korach, 2003) and the progesterone receptor PR-A (Conneely *et al.*, 2002) mediate the major actions of estrogens and progestins, respectively, on the hypothalamic-pituitary axis.

In males, testosterone regulates the hypothalamic-pituitary-gonadal axis at both the hypothalamic and pituitary levels, and its negative feedback effect is mediated to a substantial degree by estrogen formed *via* aromatization. Thus, exogenous estrogen administration decreases LH and testosterone levels in men, and anti-estrogens such as *clomiphene* cause an elevation of serum LH, which can be used to evaluate the male reproductive axis.

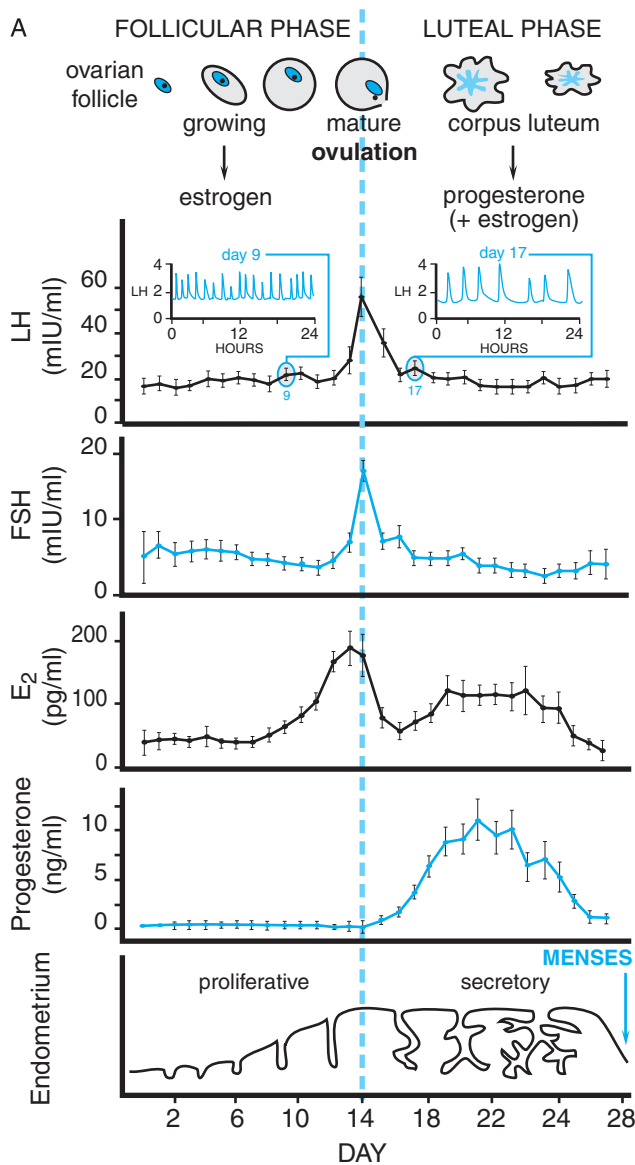

Figure 57-3. Hormonal relationships of the human menstrual cycle. A. Average daily values of LH, FSH, estradiol (E_2), and progesterone in plasma samples from women exhibiting normal 28-day menstrual cycles. Changes in the ovarian follicle (top) and endometrium (bottom) also are illustrated schematically.

Frequent plasma sampling reveals pulsatile patterns of gonadotropin release. Characteristic profiles are illustrated schematically for the follicular phase (day 9, inset on left) and luteal phase (day 17, inset on right). Both the frequency (number of pulses per hour) and amplitude (extent of change of hormone release) of pulses vary throughout the cycle. (Redrawn with permission from Thorneycroft *et al.*, 1971).

B. Major regulatory effects of ovarian steroids on hypothalamic-pituitary function. Estrogen decreases the amount of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) released (*i.e.*, gonadotropin pulse amplitude) during most of the cycle and triggers a surge of LH release only at mid-cycle. Progesterone decreases the frequency of GnRH release from the hypothalamus and thus decreases the frequency of plasma gonadotropin pulses. Progesterone also increases the amount of LH released (*i.e.*, the pulse amplitude) during the luteal phase of the cycle.

When the ovaries are removed or cease to function, there is overproduction of FSH and LH, which are excreted in the urine. Measurement of urinary or plasma LH is valuable to assess pituitary function and the effectiveness of therapeutic doses of estrogen. Although FSH levels will also decline upon estrogen administration, they do not return to normal, secondary to production of inhibin by the ovary (*see* Chapter 55). Consequently, the measurement of FSH levels as a means to monitor the effectiveness of hormone therapy is not clinically useful. Additional features of the regulation of gonadotropin secretion and actions are discussed in Chapters 55 and 58.

Effects of Cyclical Gonadal Steroids on the Reproductive Tract.

The cyclical changes in estrogen and progesterone production by the ovaries regulate corresponding events in the fallopian tubes, uterus, cervix, and vagina. Physiologically, these changes prepare the uterus for implantation, and the proper timing of events in these tissues is essential for pregnancy. If pregnancy does not occur, the endometrium is shed as the menstrual discharge.

The uterus is composed of an endometrium and a myometrium. The endometrium contains an epithelium lining the uterine cavity and an underlying stroma; the myometrium is the smooth muscle component responsible for uterine contractions. These cell layers, the fallopian tubes, cervix, and vagina display a characteristic set of responses to both estrogens and progestins. The changes typically associated with menstruation occur largely in the endometrium (Figure 57-3).

The luminal surface of the endometrium is a layer of simple columnar epithelial secretory and ciliated cells that is continuous with the openings of numerous glands that extend through the underlying stroma to the myometrial border. Fertilization normally occurs in the fallopian tubes, so ovulation, transport of the fertilized ovum through the fallopian tube, and preparation of the endometrial surface must be temporally coordinated for successful implantation.

The endometrial stroma is a highly cellular connective-tissue layer containing a variety of blood vessels that undergo cyclic changes associated with menstruation. The predominant cells are fibroblasts, but macrophages, lymphocytes, and other resident and migratory cell types also are present.

Menstruation marks the start of the menstrual cycle. During the follicular (or proliferative) phase of the cycle, estrogen begins the rebuilding of the endometrium by stimulating proliferation and differentiation. Numerous mitoses become visible, the thickness of the layer increases, and characteristic changes occur in the glands and blood vessels. In rodent models, ER α mediates the uterotropic effects of estrogens (Hewitt and Korach, 2003). The overall endometrial response involves estrogen- and progesterone-mediated expression of peptide growth factors and receptors, cell cycle genes, and other regulatory signals. An important response to estrogen in the endometrium and other tissues is induction of the progesterone receptor (PR), which enables cells to respond to this hormone during the second half of the cycle.

In the luteal (or secretory) phase of the cycle, elevated progesterone limits the proliferative effect of estrogens on the endometrium by stimulating differentiation. Major effects include stimulation of epithelial secretions important for implantation of the blastocyst and the characteristic growth of the endometrial blood vessels seen at this time. These effects are mediated by PR-A in animal models (Conneely *et al.*, 2002). Progesterone is thus important in preparation for implantation and for the changes that take place in the uterus at the implantation site (*i.e.*, the decidual response). There is a narrow “window of implantation,” spanning days 19 to 24 of the endometrial cycle, when the epithelial cells of the endometrium are receptive to blastocyst implantation. Since endometrial status is regulated by estrogens and progestins, the efficacy of some contraceptives may be due in part to production of an endometrial surface that is not receptive to implantation. If pregnancy does not occur, the corpus luteum regresses due to lack of continued LH secretion, estrogen and progesterone levels fall, and the endometrium is shed (Figure 57–3).

If implantation occurs, human chorionic gonadotropin (hCG) (*see* Chapter 55), produced initially by the trophoblast and later by the placenta, interacts with the LH receptor of the corpus luteum to maintain steroid hormone synthesis during the early stages of pregnancy. In later stages the placenta itself becomes the major site of estrogen and progesterone synthesis.

Estrogens and progesterone have important effects on the fallopian tube, myometrium, and cervix. In the fallopian tube, estrogens stimulate proliferation and differentiation, whereas progesterone inhibits these processes. Also, estrogens increase and progesterone decreases tubal muscular contractility, which affects transit time of the ovum to the uterus. Estrogens increase the amount of cervical mucus and its water content to facilitate sperm penetration of the cervix, whereas progesterone generally has opposite effects. Estrogens favor rhythmic contractions of the uterine myometrium, while progesterone diminishes contractions. These effects are physiologically important and may also play a role in the action of some contraceptives.

Metabolic Effects. Estrogens affect many tissues and have many metabolic actions in human beings and animals. It is not clear in all cases if effects result directly from hormone actions on the tissue in question or secondarily from actions at other sites. Many nonreproductive tissues, including bone, vascular endothelium, liver, CNS, immune system, gastrointestinal tract, and heart, express low levels of both estrogen receptors, and the ratio of ER α to ER β varies in a cell-specific manner. Many metabolic effects of estrogens result directly from receptor-mediated events in affected organs. The effects of estrogens on selected aspects of mineral, lipid, carbohydrate, and protein metabolism are particularly important for understanding their pharmacological actions.

It long has been recognized that estrogens have positive effects on bone mass (reviewed by Riggs *et al.*, 2002). Bone is continuously remodeled at sites called “bone-remodeling units” by the resorptive action of osteoclasts and the bone-forming action of osteoblasts (*see* Chapter 61). Maintenance of total bone mass requires equal rates of formation and resorption as occurs in early adulthood (18 to 40 years); thereafter resorption predominates. Osteoclasts and osteoblasts express both ER α and ER β , with the former apparently playing a greater role. Bone also expresses both androgen and progesterone receptors. Based on animal models, the actions of ER α predominate in bone. Estrogens directly regulate osteoblasts and increase the synthesis of type I collagen, osteocalcin, osteopontin, osteonectin, alkaline phosphatase, and other markers of differentiated osteoblasts. Estrogens also increase osteocyte survival by inhibiting apoptosis. However, the major effect of estrogens is to decrease the number and activity of osteoclasts. Much of the action of estrogens on osteoclasts appears to be mediated by altering cytokine (both paracrine and autocrine) signals from osteoblasts. Estrogens decrease osteoblast and stromal cell production of the osteoclast-stimulating cytokines interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)- α and increase the production of insulin-like growth factor (IGF)-1, bone morphogenic protein (BMP)-6, and transforming growth factor (TGF)- β , which are anti-resorptive (reviewed by Spelsberg *et al.*, 1999). Estrogens also increase osteoblast production of the cytokine osteoprotegerin (OPG), a soluble non-membrane-bound member of the TNF superfamily (*see* Chapter 61). OPG acts as a “decoy” receptor that antagonizes the binding of OPG-ligand (OPG-L) to its receptor (termed RANK, or receptor activator of NF- κ B) and prevents the differentiation of osteoclast precursors to mature osteoclasts. Estrogens increase osteoclast apoptosis, either directly or by increasing OPG. Estrogens have anti-apoptotic effects on both osteoblasts and osteocytes in animal models, and this

action may be mediated by nongenomic mechanisms (Kousteni *et al.*, 2002). Estrogens affect bone growth and epiphyseal closure in both sexes. The importance of estrogen in the male skeleton is illustrated by a man with a completely defective ER who had osteoporosis, unfused epiphyses, increased bone turnover, and delayed bone age (Smith *et al.*, 1994), and by the observation that male idiopathic osteoporosis is associated with reduced ER α expression in both osteocytes and osteoblasts (Braidman *et al.*, 2000).

Estrogens have many effects on lipid metabolism; of major interest are their effects on serum lipoprotein and triglyceride levels (Walsh *et al.*, 1994). In general, estrogens slightly elevate serum triglycerides and slightly reduce total serum cholesterol levels. More important, they increase HDL levels and decrease the levels of LDL and Lp(a) (*see* Chapter 35). This beneficial alteration of the ratio of HDL to LDL is an attractive effect of estrogen therapy in postmenopausal women; however, the conclusion from two large clinical trials—the Heart and Estrogen/progestin Replacement Study, or HERS (Hulley *et al.*, 1998), and the Women’s Health Initiative or WHI (Rossouw *et al.*, 2002; Anderson *et al.*, 2004)—is that estrogen-progestin or estrogen-only regimens *do not provide any protection from cardiovascular disease*. The presence of estrogen receptors in the liver suggests that the beneficial effects of estrogen on lipoprotein metabolism are due partly to direct hepatic actions, but other sites of action cannot be excluded. Estrogens also alter bile composition by increasing cholesterol secretion and decreasing bile acid secretion. This leads to increased saturation of bile with cholesterol and appears to be the basis for increased gallstone formation in some women receiving estrogens. The decline in bile acid biosynthesis may contribute to the decreased incidence of colon cancer in women receiving combined estrogen-progestin treatment.

Estrogen alone slightly decreases fasting levels of glucose and insulin but does not have major effects on carbohydrate metabolism. Some older studies of combined oral contraceptives (which contained higher levels of both estrogens and progestins than contraceptives do today) suggested that estrogens might impair glucose tolerance, but it is uncertain whether these effects were due to the progestin or the estrogen component of those oral contraceptives.

Estrogens affect many serum proteins, particularly those involved in hormone binding and clotting cascades. In general, estrogens increase plasma levels of cortisol-binding globulin, thyroxine-binding globulin, and sex hormone-binding globulin (SHBG), which binds both androgens and estrogens.

Estrogens alter a number of metabolic pathways that affect the cardiovascular system (Mendelsohn and Karas, 1999). Systemic effects include changes in lipoprotein metabolism and in hepatic production of plasma proteins. Estrogens cause a small increase in coagulation factors II, VII, IX, X, and XII, and decrease the anticoagulation factors protein C, protein S, and antithrombin III (*see* Chapter 54). Fibrinolytic pathways also are affected, and several studies of women treated with estrogen alone or estrogen with a progestin have demonstrated decreased levels of plasminogen-activator inhibitor protein-1 (PAI-1) with a concomitant increase in fibrinolysis (Koh *et al.*, 1997). Thus, estrogens increase both coagulation and fibrinolytic pathways, and imbalance in these two opposing activities may cause adverse effects. At relatively high concentrations, estrogens have antioxidant activity and may inhibit the oxidation of LDL by affecting superoxide dismutase. Long-term administration of estrogen is associated with decreased plasma renin, angiotensin-converting enzyme, and endothelin-1; expression of the AT₁ receptor for angiotensin II is also decreased. Estrogen actions on the vascular wall include increased production of NO, which occurs within minutes *via* a mechanism involving activation of Akt (also known as protein kinase B) (Simoncini *et al.*, 2000), and induction of inducible NO synthase and increased production of prostacyclin. All of these changes promote vasodilation. Estrogens also promote endothelial cell growth while inhibiting the proliferation of vascular smooth muscle cells.

Estrogen Receptors

Estrogens exert their effects by interaction with receptors that are members of the superfamily of nuclear receptors. The two estrogen receptor genes are located on separate chromosomes: ESR1 encodes ER α , and ESR2 encodes ER β . Both ERs are estrogen-dependent nuclear transcription factors that have different tissue distributions and transcriptional regulatory effects on a wide number of target genes (reviewed by Hanstein *et al.*, 2004). Ligands that discriminate between ER α and ER β have been developed (Harrington *et al.*, 2003) but are not yet in clinical use. Both ER α and ER β exist as multiple mRNA isoforms due to differential promoter use and alternative splicing (reviewed by Kos *et al.*, 2001; Lewandowski *et al.*, 2002). The two human ERs are 44% identical in overall amino-acid sequence and share the domain structure common to members of this family. The estrogen receptor is divided into six functional domains: the NH₂-terminal A/B domain contains the activation function-1 (AF-1) segment, which can activate transcription independently of ligand; the

highly conserved C domain comprises the DNA-binding domain, which contains 4 cysteines arranged in 2 zinc fingers; the D domain, frequently called the “hinge region,” contains the nuclear localization signal; and the E/F domain has multiple functions, including ligand binding, dimerization, and ligand-dependent transactivation, mediated by the AF-2 domain. There are significant differences between the two receptor isoforms in the ligand-binding domains and in both transactivation domains. Human ER β does not appear to contain a functional AF-1 domain. The receptors appear to have different biological functions and respond differently to various estrogenic compounds (Kuiper *et al.*, 1997). However, their high homology in the DNA-binding domains suggests that both receptors recognize similar DNA sequences and hence regulate many of the same target genes.

ER α , the first discovered, is expressed most abundantly in the female reproductive tract—especially the uterus, vagina, and ovaries—as well as in the mammary gland, the hypothalamus, endothelial cells, and vascular smooth muscle. ER β is expressed most highly in the prostate and ovaries, with lower expression in lung, brain, bone, and vasculature. Many cells express both ER α and ER β , which can form either homo- or heterodimers. When co-expressed, in many cases ER β inhibits ER α -mediated transcriptional activation (Hall and McDonnell, 1999). Polymorphic variants of ER have been identified, but attempts to correlate specific polymorphisms with the frequency of breast cancer (Han *et al.*, 2003), bone mass (Vandevyver *et al.*, 1999; Kurabayashi *et al.*, 2004), endometrial cancer (Weiderpass *et al.*, 2000), or cardiovascular disease (Herrington and Howard, 2003) have led to contradictory results.

Mechanism of Action

Both estrogen receptors (ERs) are ligand-activated transcription factors that increase or decrease the transcription of target genes (Figure 57–4). After entering the cell by passive diffusion through the plasma membrane, the hormone binds to an ER in the nucleus. In the nucleus, the ER is present as an inactive monomer bound to heat-shock proteins, and upon binding estrogen, a change in ER conformation dissociates the heat-shock proteins and causes receptor dimerization, which increases the affinity and the rate of receptor binding to DNA (Cheskis *et al.*, 1997). Homodimers of ER α or ER β and ER α /ER β heterodimers can be produced depending on the receptor complement in a given cell. The concept of ligand-mediated changes in ER conformation is central to understanding the mechanism of action of estrogen agonists and antagonists. The ER dimer binds to estrogen response elements (EREs), typically located in the promoter region of target genes with the consensus sequence GGTCANNNT-GACC, but several similar sequences can act as estrogen

response elements in a promoter-specific context. The type of ERE with which ERs interact also regulates the three-dimensional structure of the activated receptor (Hall *et al.*, 2002).

The ER/DNA complex recruits a cascade of co-activator and other proteins to the promoter region of target genes (Figure 57–4B). There are three families of proteins that interact with ERs. The first of these has the ability to modify nucleosome structure either in an ATP-dependent manner, like SWI/Snf, or by histone methyl-transferase (HMT) activity, as in proteins such as PRMT1. The second family comprises the p160/SRC proteins and includes SRC-1 (steroid-receptor co-activator-1), SRC-2, and SRC-3. The third family includes p300/CBP (cyclic AMP response-element binding protein), co-activators that are targets of several signal transduction cascades and may integrate function among diverse pathways and the basal transcriptional apparatus. Agonist-bound ERs appear initially to recruit SWI/Snf and HMT members that modify nucleosome structure and facilitate the subsequent recruitment of p160 members and p300 proteins (Metivier *et al.*, 2003). The co-activators and p300 proteins have histone acetylase (HAT) activity. Acetylation of histones further alters chromatin structure in the promoter region of target genes and allows the proteins that make up the general transcription apparatus to assemble and initiate transcription.

Interaction of ERs with antagonists also promotes dimerization and DNA binding. However, an antagonist produces a conformation of ER that is different from the agonist-occupied receptor (Wijayaratne *et al.*, 1999; Smith and O'Malley, 2004). The antagonist-induced conformation facilitates binding of co-repressors such as NcoR/SMRT (nuclear hormone receptor co-repressor/silencing mediator of retinoid and thyroid receptors) (Figure 57–4C). The co-repressor/ER complex then further recruits other proteins with histone deacetylase activity such as HDAC1. Deacetylation of histones alters chromatin conformation and reduces the ability of the general transcription apparatus to form initiation complexes.

Besides co-activators and co-repressors, both ER α and ER β can interact physically with other transcription factors such as Sp1 (Saville *et al.*, 2000) or AP-1 (Paeck *et al.*, 1997), and these protein-protein interactions provide an alternate mechanism of action. In these circumstances, ER-ligand complexes interact with Sp1 or AP-1 that is already bound to its specific regulatory element, such that the ER complex does not interact directly with an ERE. This may explain how estrogens are able to regulate genes that lack a consensus ERE. Responses to agonists and antagonists mediated by these protein-protein interactions also are ER isoform- and promoter-specific. For example, 17β -estradiol induces transcription of a target gene controlled by an AP-1 site in the presence of an ER α /AP-1 complex, but inhibits transcription in the presence of an ER β /AP-1

Figure 57-4. Molecular mechanism of action of nuclear estrogen receptor. **A.** Unliganded estrogen receptor (ER) exists as a monomer within the nucleus. **B.** Agonists such as 17β -estradiol (E) bind to the ER and cause a ligand-directed change in conformation that facilitates dimerization and interaction with specific estrogen response element (ERE) sequences in DNA. The ER-DNA complex recruits co-activators such as SWI/SNF that modify chromatin structure, and co-activators such as steroid-receptor co-activator-1 (SRC-1) that has histone acetyltransferase (HAT) activity that further alters chromatin structure. This remodeling facilitates the exchange of the recruited proteins such that other co-activators (e.g., p300 and the TRAP complex) associate on the target gene promoter and proteins that comprise the general transcription apparatus (GTA) are recruited, with subsequent synthesis of mRNA. **C.** Antagonists such as tamoxifen (T) also bind to the ER but produce a different receptor conformation. The antagonist-induced conformation also facilitates dimerization and interaction with DNA, but a different set of proteins called co-repressors, such as nuclear-hormone receptor co-repressor (NcoR), are recruited to the complex. NcoR further recruits proteins such as histone deacetylase I (HDAC1) that act on histone proteins to stabilize nucleosome structure and prevent interaction with the GTA.

complex. Conversely, anti-estrogens are potent activators of ER β /AP-1 but not of ER α /AP-1 complexes.

Other signaling systems may activate nuclear ER by ligand-independent mechanisms. Phosphorylation of ER α at serine 118 by MAP kinase activates the receptor (Kato *et al.*, 1995). Similarly, PI-3-kinase-activated Akt directly phosphorylates ER α , causing ligand-independent activation of estrogen-target genes (Simoncini *et al.*, 2000). This provides a means of cross-talk between membrane-bound receptor pathways (*i.e.*, EGF/IGF-1) that activate MAPK and the nuclear ER. In a reciprocal fashion ER may interact directly with members of the Src-Shc/Erk signaling pathway. Activation of Erk by the novel ER and androgen receptor (AR) agonist estren is thought to be responsible for the anti-apoptotic action of this drug in bone (reviewed in Manolagas *et al.*, 2002).

Several studies have suggested that some estrogen receptors are located on the plasma membrane of cells. It appears that this form of the ER is encoded by the same gene that encodes ER α , but it is

transported to the plasma membrane, mainly in caveolae (reviewed by Zhu and Smart, 2003). These membrane-localized ERs mediate the rapid activation of some proteins such as MAPK, which is phosphorylated in several cell types within 5 to 10 minutes of 17β -estradiol addition (Endoh *et al.*, 1997), or the rapid increase in cyclic AMP caused by the hormone (Aronica and Katzenellenbogen, 1993). The finding that MAPK is activated by estradiol provides an additional level of cross-talk with growth factors, such as IGF-1 and EGF, that activate this kinase pathway.

Absorption, Fate, and Elimination

Various estrogens are available for oral, parenteral, transdermal, or topical administration (Table 57-1). Given the lipophilic nature of estrogens, absorption generally is good with the appropriate preparation. Aqueous or oil-

based esters of estradiol and estrone are available for intramuscular injection, ranging in frequency from every several days to once per month. Transdermal patches that are changed once or twice weekly deliver estradiol continuously through the skin. Preparations are available for topical use in the vagina or creams applied to the skin. For many uses, preparations are available as an estrogen alone or in combination with a progestin.

Oral administration is common and may utilize estradiol, conjugated estrogens, esters of estrone and other estrogens, and *ethinyl estradiol*. A special micronized preparation of estradiol (ESTRACE, others) that yields a large surface for rapid absorption is required for oral administration, although high doses must be used because absolute bioavailability remains low due to first-pass metabolism (Fotherby, 1996). Ethinyl estradiol is used orally, as the ethinyl substitution in the C17 position inhibits first-pass hepatic metabolism. Other common oral preparations contain conjugated equine estrogens (PREMARIN), which are primarily the sulfate esters of estrone, equilin, and other naturally occurring compounds; *esterified esters*; or mixtures of conjugated estrogens prepared from plant-derived sources (CENESTIN). These are hydrolyzed by enzymes present in the lower gut that remove the charged sulfate groups and allow absorption of estrogen across the intestinal epithelium. In another oral preparation, *estropipate* (ORTHO-EST, OGEN), estrone is solubilized as the sulfate and stabilized with piperazine. Due largely to differences in metabolism, the potencies of various oral preparations differ widely; ethinyl estradiol, for example, is much more potent than conjugated estrogens.

A number of foodstuffs and plant-derived products, largely from soy, are available as nonprescription items and often are touted as providing benefits similar to those from compounds with established estrogenic activity. These products may contain flavonoids such as genistein (Table 57–1), which display estrogenic activity in laboratory tests, albeit generally much less than that of estradiol. In theory, these preparations could produce appreciable estrogenic effects, but their efficacy at relevant doses has not been established in human trials (Mäkelä *et al.*, 1999; Fitzpatrick, 2003).

Administration of estradiol *via* transdermal patches (ESTRADERM, VIVELLE, ALORA, CLIMARA, others) provides slow, sustained release of the hormone, systemic distribution, and more constant blood levels than oral dosing. Estradiol is also available as a topical cream (ESTRASORB) that is applied to the upper thigh and calf, or as a gel (ESTROGEL) that is applied once daily to the arm. The transdermal route does not lead to the high level of the drug that enters the liver *via* the portal circulation after oral administration, and is thus expected to minimize hepatic effects of estrogens (*e.g.*, on hepatic protein synthesis, lipoprotein profiles, and triglyceride levels).

Other preparations are available for intramuscular injection. When dissolved in oil and injected, esters of estradiol are well absorbed. The aryl and alkyl esters of estradiol become less polar as the size of the substituents increases; correspondingly, the rate of absorption of oily preparations is progressively slowed, and the duration of action can be prolonged. A single therapeutic dose of compounds such as *estradiol valerate* (DELESTROGEN) or *estradiol cypionate* (DEPO-ESTRADIOL) may be absorbed over several weeks following a single intramuscular injection. Suspensions containing estrone or a combination of esters (primarily estrone and equilin sulfates) also may be given *via* intramuscular injection.

Preparations of estradiol and conjugated estrogen creams are available for topical administration to the vagina. These are effective locally, but systemic effects also are possible due to significant absorption. A 3-month vaginal ring (ESTRING, FEMRING) may be used for slow release of estradiol, and tablets are also available for vaginal use (VAGIFEM).

Estradiol, ethinyl estradiol, and other estrogens are extensively bound to plasma proteins. Estradiol and other naturally occurring estrogens are bound mainly to sex hormone-binding globulin (SHBG) and to a lesser degree to serum albumin. In contrast, ethinyl estradiol is bound extensively to serum albumin but not SHBG. Due to their size and lipophilic nature, unbound estrogens distribute rapidly and extensively.

Variations in estradiol metabolism occur and depend upon the stage of the menstrual cycle, menopausal status, and several genetic polymorphisms (Herrington and Klein, 2001). In general, the hormone undergoes rapid hepatic biotransformation, with a plasma half-life measured in minutes. Estradiol is converted primarily by 17 β -hydroxysteroid dehydrogenase to estrone, which undergoes conversion by 16 α -hydroxylation and 17-keto reduction to estriol, the major urinary metabolite. A variety of sulfate and glucuronide conjugates also are excreted in the urine. Lesser amounts of estrone or estradiol are oxidized to the 2-hydroxycatechols by CYP3A4 in the liver and by CYP1A in extrahepatic tissues or to 4-hydroxycatechols by CYP1B1 in extrahepatic sites, with the 2-hydroxycatechol being formed to a greater extent. The 2- and 4-hydroxycatechols are largely inactivated by catechol-*O*-methyl transferases (COMTs). However, smaller amounts may be converted by CYP- or peroxidase-catalyzed reactions to yield semiquinones or quinones that are capable of forming DNA adducts or of generating (*via* redox cycling) reactive oxygen species that could oxidize DNA bases (Yue *et al.*, 2003).

Estrogens also undergo enterohepatic recirculation *via* (1) sulfate and glucuronide conjugation in the liver, (2) biliary secretion of the conjugates into the intestine, and (3) hydrolysis in the gut (largely by bacterial enzymes) followed by reabsorption.

Many other drugs and environmental agents (*e.g.*, cigarette smoke) act as inducers or inhibitors of the various enzymes that metabolize estrogens, and thus have the potential to alter their clearance. Consideration of the impact of these factors on efficacy and untoward effects is increasingly important with the decreased doses of estrogens currently employed for both menopausal hormone therapy and contraception.

Ethinyl estradiol is cleared much more slowly than is estradiol due to decreased hepatic metabolism, and the elimination-phase half-life in various studies ranges from 13 to 27 hours. Unlike estradiol, the primary route of biotransformation of ethinyl estradiol is *via* 2-hydroxylation and subsequent formation of the corresponding 2- and 3-methyl ethers. *Mestranol*, another semisynthetic estrogen and a component of some combination oral contraceptives, is the 3-methyl ether of ethinyl estradiol. In the body it undergoes rapid hepatic demethylation to ethinyl estradiol, which is its active form (Fotherby, 1996).

Untoward Responses

Estrogens are highly efficacious, but they do carry a number of risks as well. Many concerns arose initially from studies of early oral contraceptives, which contained high doses of estrogens, but the amount of estrogens (and pro-

gestins) in oral contraceptives has been markedly decreased, which has significantly diminished the risks associated with their use. Nevertheless, major concerns about the use of estrogens remain today, especially regarding cancer, thromboembolic disease, increased risk of cardiovascular disease, altered cognition, changes in carbohydrate and lipid metabolism, hypertension, gallbladder disease, nausea, migraine, changes in mood, and several lesser side effects.

Concern about Carcinogenic Actions. The possibility of developing cancer is probably the major concern for the use of estrogens and oral contraceptives. Early studies established that estrogens can induce tumors of the breast, uterus, testis, bone, kidney, and several other tissues in various animal species. These early studies disseminated a fear of cancer resulting from estrogen use.

In later reports (Greenwald *et al.*, 1971; Herbst *et al.*, 1971), an increased incidence of vaginal and cervical adenocarcinoma was noted in female offspring of mothers who had taken diethylstilbestrol (DES) during the first trimester of pregnancy. The incidence of clear-cell vaginal and cervical adenocarcinoma in women who were exposed to DES *in utero* was 0.01% to 0.1% (Food and Drug Administration, 1985); these findings established for the first time that developmental exposure to estrogens was associated with an increase in a human cancer. Estrogen use during pregnancy also can increase the incidence of nonmalignant genital abnormalities in both male and female offspring. Thus, pregnant patients should not be given estrogens because of the possibility of such reproductive tract toxicities.

Other studies established that the use of unopposed estrogen for hormone treatment in postmenopausal women increases the risk of endometrial carcinoma by five- to fifteenfold (Shapiro *et al.*, 1985). This increased risk can be prevented if a progestin is co-administered with the estrogen (Pike *et al.*, 1997), and this is now standard practice.

The association between estrogen and/or estrogen-progestin use and breast cancer continues to be of great concern and debate. The results of two very large, randomized, clinical trials of estrogen-progestin and estrogen-only (*i.e.*, the two arms of The Women's Health Initiative or WHI) use in postmenopausal women have clearly established a small but significant increase in the risk of breast cancer, apparently due to the medroxyprogesterone (Rossouw *et al.*, 2002; Anderson *et al.*, 2004). In the WHI study, an estrogen-progestin combination increased the total risk of breast cancer by 24%; the absolute increase in attributable cases of disease was 6 per 1000 women and required 3 or more years of treatment. In women without a uterus who received estrogen alone, the relative risk of breast cancer was actually decreased by 23%, and the decrease only narrowly missed reaching statistical significance.

The Million Women Study (MWS) in the United Kingdom was a cohort study rather than a clinical trial (Beral *et al.*, 2003). It surveyed over one million women, about half receiving some type of hormone treatment and half had never used them. Those receiving an estrogen-progestin combination had an increased relative risk of invasive breast cancer of 2, and those receiving estrogen alone had an increased relative risk of 1.3, but the increase in actual attributable cases of the disease was again small.

Both the WHI and MWS data are thus consistent with earlier studies indicating that the progestin component (*e.g.*, medroxyprogesterone) in hormone-replacement therapy plays a major role in this increased risk of breast cancer (Schairer *et al.*, 2000; Ross *et al.*,

2000). Importantly, although long-term data have not accumulated for the WHI trials, the available data suggest that the excess risk of breast cancer associated with menopausal hormone use appears to abate 5 years after discontinuing therapy.

Historically, the carcinogenic actions of estrogens were thought to be related to their trophic effects. An increase in cell proliferation would be expected to cause an increase in spontaneous errors associated with DNA replication, and estrogens would then enhance the growth of clones with mutations introduced by this or other mechanisms (*e.g.*, chemical carcinogens). More recently, another mechanism has been proposed. If catechol estrogens, especially the 4-hydroxycatechols, are converted to semiquinones or quinones prior to "inactivation" by COMT, these products, or reactive oxygen species generated during subsequent biotransformations, may cause direct chemical damage to DNA bases (Yue *et al.*, 2003). In this regard, CYP1B1, which has specific estrogen-4-hydroxylase activity, is present in tissues such as uterus, breast, ovary, and prostate, which often give rise to hormone-responsive cancers (Yue *et al.*, 2003).

Metabolic and Cardiovascular Effects. Although they may slightly elevate plasma triglycerides, estrogens themselves generally have favorable overall effects on plasma lipoprotein profiles. However, as noted in a later section dealing with hormone-replacement regimens, progestins may reduce the favorable actions of estrogens. In contrast, estrogens do increase cholesterol levels in bile and cause a relative two- to threefold increase in gallbladder disease. Currently prescribed doses of estrogens do not increase the risk of hypertension.

A number of observational studies, clinical trials using intermediate markers of cardiovascular disease, and numerous animal studies suggested that estrogen therapy in postmenopausal women would reduce the risk of cardiovascular disease by 35% to 50% (Manson and Martin, 2001). However, two recent randomized clinical trials have not found such protection. The Heart and Estrogen/progestin Replacement Study, or HERS (Hulley *et al.*, 1998), followed women with established coronary heart disease (CHD) and found that estrogen plus a progestin increased the relative risk of nonfatal myocardial infarction or CHD death within 1 year of treatment, and found no overall change in 5 years. The HERS II follow-up (Grady *et al.*, 2002) found no overall change in the incidence of CHD after 6.8 years of the treatment. A similar conclusion was reached in the WHI trials for women *without* existing CHD treated with an estrogen plus progestin (Rossouw *et al.*, 2002). These studies establish unequivocally that the estrogen-progestin combination used does not protect against CHD. However, only conjugated equine estrogens (CEE) or CEE plus medroxyprogesterone acetate (MPA) were examined in these studies, and only a single dose was used in a relatively old patient population (*e.g.*, average age approximately 60 years). It thus remains unclear whether these conclusions can be globally extended to other preparations, doses, and patient populations (*e.g.*, women closer to age 50 who typically initiate hormone therapy for relief of vasomotor symptoms).

It is clear, however, that oral estrogens increase the risk of thromboembolic disease in healthy women and in women with pre-existing cardiovascular disease (Grady *et al.*, 2000). The increase in absolute risk is small but significant. In the WHI, for example, an estrogen-progestin combination led to an increase in 8 attributable cases of stroke per 10,000 women and a similar increase in pulmonary embolism (Rossouw *et al.*, 2002).

Effects on Cognition. Several retrospective studies had suggested that estrogens had beneficial effects on cognition and delayed the

onset of Alzheimer's disease (Green and Simpkins, 2000). However, the Women's Health Initiative Memory Study (WHIMS) of a group of women aged 65 or older (Shumaker *et al.*, 2003) found that estrogen-progestin therapy was associated with a doubling in the number of women diagnosed with probable dementia, and no benefit of hormone treatment on global cognitive function was observed (Rapp *et al.*, 2003). Women in the estrogen-only arm also showed a comparable decrease in cognitive function (Espeland *et al.*, 2004), implicating estrogens in these cognitive changes.

Other Potential Untoward Effects. Nausea and vomiting are an initial reaction to estrogen therapy in some women, but these effects may disappear with time and may be minimized by taking estrogens with food or just prior to sleeping. Fullness and tenderness of the breasts and edema may occur but sometimes can be diminished by lowering the dose. A more serious concern is that estrogens may cause severe migraine in some women. Estrogens also may reactivate or exacerbate endometriosis.

Therapeutic Uses

The two major uses of estrogens are as components of combination oral contraceptives (*see* below) and for menopausal hormone therapy (MHT). The pharmacological considerations for their use and the specific drugs and doses used differ in these settings. Historically, conjugated estrogens have been the most common agents for postmenopausal use (0.625 mg/day most often used). In contrast, most combination oral contraceptives in current use employ 20 to 35 μg /day of ethinyl estradiol. These preparations differ widely in their oral potencies; *e.g.*, a dose of 0.625 mg of conjugated estrogens generally is considered equivalent to 5 to 10 μg of ethinyl estradiol. Thus, the "effective" dose of estrogen used for MHT is less than that in oral contraceptives when one considers potency. Furthermore, in the last two decades the doses of estrogens employed in both settings have decreased substantially. The untoward effects of the 20- to 35- μg doses now commonly used thus have a lower incidence and severity than those reported in older studies (*e.g.*, with oral contraceptives that contained 50 to 150 μg of ethinyl estradiol or mestranol).

Menopausal Hormone Therapy. The established benefits of estrogen therapy in postmenopausal women include amelioration of vasomotor symptoms and the prevention of bone fractures and urogenital atrophy.

Vasomotor Symptoms. The decline in ovarian function at menopause is associated with vasomotor symptoms in most women. The characteristic hot flashes may alternate with chilly sensations, inappropriate sweating, and (less commonly) paresthesias. Treatment with estrogen is specific and is the most efficacious pharmacotherapy for these symptoms (Belchetz, 1994). If estrogen is contraindicated or otherwise undesirable, other options may be considered.

Medroxyprogesterone acetate (discussed in the later section on progestins) may provide some relief of vasomotor symptoms for certain patients, and the α_2 adrenergic agonist *clonidine* diminishes vasomotor symptoms in some women, presumably by blocking the CNS outflow that regulates blood flow to cutaneous vessels. In many women, hot flashes diminish within several years; when prescribed for this purpose the dose and duration of estrogen use should thus be the minimum necessary to provide relief.

Osteoporosis. Osteoporosis is a disorder of the skeleton associated with the loss of bone mass (*see* Chapter 61). The result is thinning and weakening of the bones and an increased incidence of fractures, particularly compression fractures of the vertebrae and minimal-trauma fractures of the hip and wrist. The frequency and severity of these fractures and their associated complications (*e.g.*, death and permanent disability) are a major public health problem, especially as the population continues to age. Osteoporosis is an indication for estrogen therapy, which clearly is efficacious in decreasing the incidence of fractures. However, because of the risks associated with estrogen use, first-line use of other drugs should be carefully considered (*see* Chapter 61). Nevertheless, it is important to note that the majority of fractures in the postmenopausal period occur in women without a prior history of osteoporosis, and estrogens are the most efficacious agents available for prevention of fractures at all sites in such women (Rosouw *et al.*, 2002; Anderson *et al.*, 2004).

The primary mechanism by which estrogens act is to decrease bone resorption; consequently, estrogens are more effective at preventing rather than restoring bone loss (Prince *et al.*, 1991; Belchetz, 1994). Estrogens are most effective if treatment is initiated before significant bone loss occurs, and their maximal beneficial effects require continuous use; bone loss resumes when treatment is discontinued. An appropriate diet with adequate intake of Ca^{2+} and vitamin D and weight-bearing exercise enhance the effects of estrogen treatment. Public health efforts to improve diet and exercise patterns in girls and young women also are rational approaches to increase bone mass.

Vaginal Dryness and Urogenital Atrophy. Loss of tissue lining the vagina or bladder leads to a variety of symptoms in many postmenopausal women (Robinson and Cardozo, 2003). These include dryness and itching of the vagina, dyspareunia, swelling of tissues in the genital region, pain during urination, a need to urinate urgently or often, and sudden or unexpected urinary incontinence. When estrogens are being used solely for relief of vulvar and vaginal atrophy, local administration as a vaginal cream, ring device, or tablets may be considered.

Cardiovascular Disease. The incidence of cardiovascular disease is low in premenopausal women, rising rapidly after menopause, and epidemiological studies consistently showed an association between estrogen use and reduced cardiovascular disease in postmenopausal women. Furthermore, estrogens produce a favorable lipoprotein profile, promote vasodilation, inhibit the response to vascular injury, and reduce atherosclerosis. Studies such as these led to the widespread use of estrogen for prevention of cardiovascular disease in postmenopausal women (Mendelsohn and Karas, 1999). As discussed above, several randomized, prospective studies (Rosouw *et al.*, 2002; Grady *et al.*, 2002) unexpectedly indicated that the incidence of heart disease and stroke in older postmenopausal women treated with conjugated estrogens and a progestin was initially increased, although the trend reversed with time. While it is not clear if similar results would occur with different drugs/doses or in different patient populations (Turgeon *et al.*, 2004), estrogens (alone or in combination with a progestin) should *not* be used for the treatment or prevention of cardiovascular disease.

Other Therapeutic Effects. Many other changes occur in postmenopausal women, including a general thinning of the skin; changes in the urethra, vulva, and external genitalia; and a variety of changes including headache, fatigue, and difficulty concentrating, many of which may be due to the chronic lack of sleep created by hot flashes and other vasomotor symptoms. Estrogen replacement may help alleviate or lessen some of these *via* direct actions (e.g., improvement of vasomotor symptoms) or secondary effects resulting in an improved feeling of well-being (Belchetz, 1994).

The Women's Health Initiative also demonstrated that a conjugated estrogen in combination with a progestin reduces the risk of colon cancer by roughly one-half in postmenopausal women (Rossouw *et al.*, 2002).

Menopausal Hormone Regimens. In the 1960s and 1970s there was an increase in *estrogen-replacement therapy*, or ERT (*i.e.*, estrogens alone), in postmenopausal women, primarily to reduce vasomotor symptoms, vaginitis, and osteoporosis. About 1980, epidemiological studies indicated that this treatment increased the incidence of endometrial carcinoma. This led to the use of *hormone-replacement therapy*, or HRT, that includes a progestin to limit estrogen-related endometrial hyperplasia. While the actions of progesterone on the endometrium are complex, its effects on estrogen-induced hyperplasia may involve a decrease in estrogen receptor content, increased local conversion of estradiol to the less potent estrone *via* the induction of 17 β -hydroxysteroid dehydrogenase in the tissue, and/or the conversion of the endometrium from a proliferative to a secretory state. "Hormone-replacement" therapy (now generally referred to as "menopausal hormone" therapy) with both an estrogen and progestin now is recommended for postmenopausal women with a uterus (Belchetz, 1994). For women who have undergone a hysterectomy, endometrial carcinoma is not a concern, and estrogen alone avoids the possible deleterious effects of progestins previously discussed.

Conjugated estrogens and medroxyprogesterone acetate (MPA) historically have been used most commonly in menopausal hormone regimens, although estradiol, estrone, and estriol have been used as estrogens, and *norethindrone*, *norgestimate*, *levonorgestrel*, *norethisterone*, and *progesterone* also have been widely used (especially in Europe). Various "continuous" or "cyclic" regimens have been used; the latter regimens include drug-free days. An example of a cyclic regimen is as follows: (1) administration of an estrogen for 25 days; (2) the addition of MPA for the last 12 to 14 days of estrogen treatment; and (3) 5 to 6 days with no hormone treatment, during which withdrawal bleeding normally occurs due to breakdown and shedding of the endometrium. Continuous administration of combined estrogen plus progestin does not lead to regular, recurrent endometrial shedding, but may cause intermittent spotting or bleeding, especially in the first year of use. Other regimens include a progestin intermittently (e.g., every third month), but the long-term endometrial safety of these regimens remains to be firmly established. PREMPRO (conjugated estrogens plus MPA given as a fixed dose daily) and PREMPHASE (conjugated estrogens given for 28 days plus MPA given for 14 out of

28 days) are widely used combination formulations. Other combination products available in the United States are FEMHRT (ethinyl estradiol plus *norethindrone acetate*), ACTIVELLA (estradiol plus *norethindrone*), and PREFEST (estradiol and *norgestimate*). Doses and regimens are usually adjusted empirically based on control of symptoms, patient acceptance of bleeding patterns, and/or other untoward effects.

Another pharmacological consideration is the route of estrogen administration. Oral administration exposes the liver to higher concentrations of estrogens than transdermal administration. Either route effectively relieves vasomotor symptoms and protects against bone loss. Oral but not transdermal estrogen may increase SHBG, other binding globulins, and angiotensinogen; the oral route might be expected to cause greater increases in the cholesterol content of the bile. Transdermal estrogen appears to cause smaller beneficial changes in LDL and HDL profiles (approximately 50% of those seen with the oral route) (Walsh *et al.*, 1994), but may be preferred in women with hypertriglyceridemia.

Tibolone (LIVIAL) is widely used in Europe for treatment of vasomotor symptoms and prevention of osteoporosis but is not currently approved in the United States. The parent compound itself is devoid of activity, but it is metabolized in a tissue-selective manner to three metabolites that have predominantly estrogenic, progestogenic, and androgenic activities. The drug appears to increase bone mineral density and decrease vasomotor symptoms without stimulating the endometrium, but its effects on fractures, breast cancer, and long-term outcomes remain to be established (Modelska and Cummings, 2002).

Regardless of the specific agent or regimen, menopausal hormone therapy with estrogens should use the lowest dose and shortest duration necessary to achieve an appropriate therapeutic goal.

Estrogen Treatment in the Failure of Ovarian Development. In several conditions (e.g., Turner's syndrome), the ovaries do not develop and puberty does not occur. Therapy with estrogen at the appropriate time replicates the events of puberty, and androgens (*see* Chapter 58) and/or growth hormone (*see* Chapter 55) may be used concomitantly to promote normal growth. While estrogens and androgens promote bone growth, they also accelerate epiphyseal fusion, and their premature use can thus result in a shorter ultimate height.

SELECTIVE ESTROGEN RECEPTOR MODULATORS (SERMS) AND ANTI-ESTROGENS

In the past, estrogen pharmacology was based on a simple model of an agonist binding to a single ER that subsequently affected transcription by the same molecular mechanism in all target tissues, and of antagonists that acted by simple competition with agonists for binding. This simple concept is no longer valid. By altering the conformation of the two different ERs and thereby changing interactions with co-activators and co-repressors in a cell- and promoter-specific context, ligands may have a broad spectrum of activities from purely anti-estrogenic in all tissues, to partially estrogenic in some tissues with anti-estrogenic or no activities in others, to purely estrogenic activities in all tissues. The elu-

cidation of these concepts has been a major breakthrough in estrogen pharmacology and should permit the rational design of drugs with very selective patterns of estrogenic activity (Smith and O'Malley, 2004).

SERMs: Tamoxifen, Raloxifene, and Toremifene. Selective estrogen receptor modulators, or SERMs, are compounds with tissue-selective actions. The pharmacological goal of these drugs is to produce beneficial estrogenic actions in certain tissues (*e.g.*, bone, brain, and liver) during postmenopausal hormone therapy, but antagonist activity in tissues such as breast and endometrium, where estrogenic actions (*e.g.*, carcinogenesis) might be deleterious. Currently approved drugs in the United States in this class are *tamoxifen citrate* (NOLVADEX, OTHERS), *raloxifene hydrochloride* (EVISTA), and *toremifene* (FARESTON), which is chemically related and has similar actions to tamoxifen. Tamoxifen and toremifene are used for treatment of breast cancer, and raloxifene is used primarily for prevention and treatment of osteoporosis.

Anti-estrogens: Clomiphene and Fulvestrant. These compounds are distinguished from the SERMs in that they are pure antagonists in all tissues studied. Clomiphene (CLOMID, SEROPHENE, others) is approved for the treatment of infertility in anovulatory women, and *fulvestrant* (FASLODEX, ICI 182,780) is used for the treatment of breast cancer in women with disease progression after tamoxifen.

Chemistry. The structures of the *trans*-isomer of tamoxifen, and of raloxifene, *trans*-clomiphene (enclomiphene), and fulvestrant are as follows:

Tamoxifen is a triphenylethylene with the same stilbene nucleus as diethylstilbestrol; compounds of this class display a variety of estrogenic and anti-estrogenic activities. In general, the *trans* conformations have anti-estrogenic activity, whereas the *cis* conformations display estrogenic activity. However, the pharmacological activity of the *trans* compound depends on the species, target tissue, and gene. Hepatic metabolism produces primarily *N*-desmethyltamoxifen, which has affinity for ER comparable to that of tamoxifen, and lesser amounts of the highly active 4-hydroxy metabolite, which has a 25 to 50 times higher affinity for both ER α and ER β than does tamoxifen (Kuiper *et al.*, 1997). Tamoxifen is marketed as the pure *trans*-isomer. Toremifene is a triphenylethylene with a chlorine substitution at the R2 position.

Raloxifene is a polyhydroxylated nonsteroidal compound with a benzothiopyran core. Raloxifene binds with high affinity for both ER α and ER β (Kuiper *et al.*, 1997).

Clomiphene citrate is a triphenylethylene; its two isomers, zuclomiphene (*cis*-clomiphene) and enclomiphene (*trans*-clomiphene), are a weak estrogen agonist and a potent antagonist, respectively. Clomiphene binds to both ER α and ER β , but the individual isomers have not been examined (Kuiper *et al.*, 1997).

Fulvestrant is a 7 α -alkylamide derivative of estradiol that interacts with both ER α and ER β (Van Den Bemd *et al.*, 1999).

Pharmacological Effects

Tamoxifen exhibits anti-estrogenic, estrogenic, or mixed activity depending on the species and target gene measured. In clinical tests or laboratory studies with human cells, the drug's activity depends on the tissue and endpoint measured. For example, tamoxifen inhibits the proliferation of cultured human breast cancer cells and reduces tumor size and number in women (reviewed in Jaiyesimi *et al.*, 1995), and yet it stimulates proliferation of endometrial cells and causes endometrial thickening (Lahti *et al.*, 1993). The drug has an antiresorptive effect on bone, and in humans it decreases total cholesterol, LDL, and lipoprotein (a), but does not increase HDL and triglycerides (Love *et al.*, 1994). Tamoxifen treatment causes a two- to threefold increase in the relative risk of deep vein thrombosis and pulmonary embolism and a roughly twofold increase in endometrial carcinoma (Smith, 2003). Tamoxifen produces hot flashes and other adverse effects, including cataracts and nausea. Due to its agonist activity in bone, it does not increase the incidence of fractures when used in this setting.

Raloxifene is an estrogen agonist in bone, where it exerts an antiresorptive effect. It reduces the number of vertebral fractures by up to 50% in a dose-dependent manner (Delmas *et al.*, 1997; Ettinger *et al.*, 1999). The drug also acts as an estrogen agonist in reducing total cholesterol and LDL, but it does not increase HDL or normalize plasminogen-activator inhibitor 1 in postmenopausal women (Walsh *et al.*, 1998). Raloxifene does not cause proliferation or thickening of the endometrium. Preclinical studies indicate that raloxifene has an antiproliferative effect on ER-positive breast tumors and on proliferation of ER-positive breast cancer cell lines (Hol *et al.*, 1997) and significantly reduces the risk of ER-positive but not ER-negative breast cancer (Cummings *et al.*, 1999). Raloxifene does not alleviate the vasomotor symptoms associated with menopause. Adverse effects include hot flashes and leg cramps and a threefold increase in deep vein thrombosis and pulmonary embolism (Cummings *et al.*, 1999).

Initial animal studies with clomiphene showed slight estrogenic activity and moderate anti-estrogenic activity, but the most striking effect was the inhibition of pituitary gonadotropes. In contrast, the most prominent effect in women was enlargement of the ovaries, and the drug induced ovulation in many patients with amenorrhea, polycystic ovarian syndrome, and dysfunctional bleeding with anovulatory cycles. This is the basis for clomiphene's major pharmacological use: to induce ovulation in women with a functional hypothalamic-hypophyseal-ovarian system and adequate endogenous estrogen production. In some cases, clomiphene is used in conjunction with human gonadotropins (*see* Chapter 55) to induce ovulation.

Fulvestrant and its less potent forerunner ICI 164,384 have been purely anti-estrogenic in studies to date. *In vitro*, fulvestrant was more potent than 4-hydroxytamoxifen (DeFriend *et al.*, 1994) in inhibiting proliferation of breast cancer cells, and in clinical trials it is efficacious in treating tamoxifen-resistant breast cancers (Robertson *et al.*, 2003).

All of these agents bind to the ligand-binding pocket of both ER α and ER β and competitively block estradiol binding. However, the conformation of the ligand-bound ERs is different with different ligands (Smith and O'Malley, 2004), and this has two important mechanistic consequences. The distinct ER-ligand conformations recruit different co-activators and co-repressors onto the promoter of a target gene by differential protein-protein interactions at the receptor surface. The tissue-specific actions of SERMs thus can be explained in part by the distinct conformation of the ER when occupied by different ligands, in combination with different co-activator and co-repressor levels in different cell types that together affect the nature of ER complexes formed in a tissue-selective fashion.

The conformation of ERs, especially in the AF-2 domain, determines whether a co-activator or a co-repressor will be recruited to the ER-DNA complex (Smith and O'Malley, 2004). While 17 β -estradiol induces a conformation that recruits co-activators to the receptor, tamoxifen induces a conformation that permits the recruitment of the co-repressor to both ER α and ER β . The agonist activity of tamoxifen seen in tissues such as the endometrium is mediated by the ligand-independent AF-1 transactivation domain of ER α ; since ER β does not contain a functional AF-1 domain, tamoxifen does not activate ER β (McInerney *et al.*, 1998).

Raloxifene acts as a partial agonist in bone but does not stimulate endometrial proliferation in postmenopausal women. Presumably this is due to some combination of differential expression of transcription factors in the two tissues and the effects of this SERM on ER conformation. Raloxifene induces a configuration in ER α that is distinct from that of tamoxifen-ER β (Tamrazi *et al.*, 2003), suggesting that a different set of co-activators/co-repressors may interact with ER-raloxifene compared to ER-tamoxifen.

Clomiphene increases gonadotropin secretion and stimulates ovulation. It increases the amplitude of LH and FSH pulses without changing pulse frequency (Kettel *et al.*, 1993). This suggests that the drug is acting largely at the pituitary level to block inhibitory actions of estrogen on gonadotropin release from the gland, and/or is somehow causing the hypothalamus to release larger amounts of GnRH per pulse.

Fulvestrant binds to ER α and ER β with a high affinity comparable to estradiol, but represses transactivation. It also increases dramatically the intracellular proteolytic degradation of ER α , while apparently protecting ER β from degradation (Van Den Bemd *et al.*, 1999). This effect on ER α protein levels may explain its efficacy in tamoxifen-resistant breast cancer.

Absorption, Fate, and Excretion

Tamoxifen is given orally, and peak plasma levels are reached within 4 to 7 hours after treatment. This drug displays two elimination phases with half-lives of 7 to 14 hours and 4 to 11 days. Due to the prolonged half-life, 3 to 4 weeks of treatment are required to reach steady-state plasma levels. The parent drug is converted largely to metabolites within 4 to 6 hours after oral administration. Tamoxifen is metabolized in humans by multiple hepatic CYPs, some of which it also induces (Sridar *et al.*, 2002). In human beings and other species, 4-hydroxytamoxifen is produced *via* hepatic metabolism, and this compound is considerably more potent than the parent drug as an anti-estrogen. The major route of elimination from the body involves *N*-demethylation and deamination. The drug undergoes enterohepatic circulation, and excretion is primarily in the feces as conjugates of the deaminated metabolite.

Raloxifene is adsorbed rapidly after oral administration and has an absolute bioavailability of about 2%. The drug has a half-life of about 28 hours and is eliminated primarily in the feces after hepatic glucuronidation; it does not appear to undergo significant biotransformation by CYPs.

Clomiphene is well absorbed following oral administration, and the drug and its metabolites are eliminated primarily in the feces and to a lesser extent in the urine. The long plasma half-life (5 to 7 days) is due largely to plasma-protein binding, enterohepatic circulation, and accumulation in fatty tissues. Other active metabolites with long half-lives also may be produced.

Fulvestrant is administered monthly by intramuscular depot injections. Plasma concentrations reach maximal levels in 7 days and are maintained for a month. Numerous metabolites are formed

in vivo, possibly by pathways similar to endogenous estrogen metabolism, but the drug is eliminated primarily (90%) *via* the feces in humans.

Therapeutic Uses

Breast Cancer. Tamoxifen is highly efficacious in the treatment of breast cancer. It is used alone for palliation of advanced breast cancer in women with ER-positive tumors, and it is now indicated as the hormonal treatment of choice for both early and advanced breast cancer in women of all ages (Jaiyesimi *et al.*, 1995). Response rates are approximately 50% in women with ER-positive tumors and 70% for ER- and PR-positive tumors. Tamoxifen increases disease-free survival and overall survival; treatment for 5 years reduces cancer recurrence by 50% and death by 27% and is more efficacious than shorter 1- to 2-year treatment periods. Tamoxifen reduces the risk of developing contralateral breast cancer and is approved for primary prevention of breast cancer in women at high risk, in whom it causes a 50% decrease in the development of new tumors. Prophylactic treatment should be limited to 5 years, as effectiveness decreases thereafter. The most frequent side effect is hot flashes. Tamoxifen has estrogenic activity in the uterus, increases the risk of endometrial cancer by two- to threefold, and also causes a comparable increase in the risk of thromboembolic disease that leads to serious risks for women receiving anti-coagulant therapy (Smith, 2003).

Toremifene has therapeutic actions similar to tamoxifen, and fulvestrant may be efficacious in women who become resistant to tamoxifen. Untoward effects of fulvestrant include hot flashes, GI symptoms, headache, back pain, and pharyngitis.

Osteoporosis. Raloxifene reduces the rate of bone loss and may increase bone mass at certain sites. In a large clinical trial, raloxifene increased spinal bone mineral density by more than 2% and reduced the rate of vertebral fractures by 30% to 50%, but did not significantly reduce nonvertebral fractures (Ettinger *et al.*, 1999; Delmas *et al.*, 2002). Raloxifene does not appear to increase the risk of developing endometrial cancer. The drug has beneficial actions on lipoprotein metabolism, reducing both total cholesterol and LDL; however, HDL is not increased. Adverse effects include hot flashes, deep vein thrombosis, and leg cramps.

Infertility. Clomiphene is used primarily for treatment of female infertility due to anovulation. By increasing gonadotropin levels, primarily FSH, it enhances follicular recruitment. It is relatively inexpensive, orally active, and

requires less extensive monitoring than do other treatment protocols. However, the drug may exhibit untoward effects, including ovarian hyperstimulation, increased incidence of multiple births, ovarian cysts, hot flashes, and blurred vision. In addition, clomiphene-induced cycles have a relatively high incidence of luteal phase dysfunction due to inadequate progesterone production, and prolonged use (*e.g.*, 12 or more cycles) may increase the risk of ovarian cancer. The drug should not be administered to pregnant women due to reports of teratogenicity in animals, but there is no evidence of this when the drug has been used to induce ovulation. Clomiphene also may be used to evaluate the male reproductive system, since testosterone feedback on the hypothalamus and pituitary is mediated to a large degree by estrogens formed from aromatization of the androgen.

Experimental SERM-Estrogen Combinations. There is considerable interest in menopausal hormone therapy using combinations of a pure estrogen agonist (*e.g.*, estradiol) with a SERM that has predominantly antagonist activity in the breast and endometrium, but does not distribute to the CNS. The strategy is to obtain the beneficial actions of the agonist (*e.g.*, prevention of hot flashes and bone loss), while the SERM blocks unwanted agonist action at peripheral sites (*e.g.*, proliferative effects in breast and endometrium), but does not enter the brain to cause hot flashes. Animal studies have been encouraging (Labrie *et al.*, 2003), but clinical efficacy and safety of this approach remain to be established.

Estrogen-Synthesis Inhibitors

Several agents can be used to block estrogen biosynthesis. Continual administration of GnRH agonists prevents ovarian synthesis of estrogens but not their peripheral synthesis from adrenal androgens (*see* Chapter 55). *Aminoglutethimide* inhibits aromatase activity, but its use is limited by lack of selectivity (*see* Chapters 51 and 59).

The recognition that locally produced, as well as circulating, estrogens may play a significant role in breast cancer has greatly stimulated interest in the use of aromatase inhibitors to selectively block production of estrogens (*see* Chapter 51). Both steroidal (*e.g.*, *formestane* and *exemestane* [AROMASIN]) and nonsteroidal agents (*e.g.*, *anastrozole* [ARIMIDEX], *letrozole* [FEMARA], and *vorozole*) are available. Steroidal, or type I, agents are substrate analogs that act as suicide inhibitors to irreversibly inactivate aromatase, while the nonsteroidal, or type II, agents interact reversibly with the heme groups of CYPs (Haynes *et al.*, 2003). Exemestane, letrozole, and anastrozole are current-

ly approved in the United States for the treatment of breast cancer. The structures of exemestane and anastrozole are as follows:

As discussed in Chapter 51, these agents may be used as first-line treatment of breast cancer or as second-line drugs after tamoxifen. They are highly efficacious and actually superior to tamoxifen in some adjuvant settings (Coombes *et al.*, 2004), but unlike tamoxifen, they do not increase the risk of uterine cancer or venous thromboembolism. Because they dramatically reduce circulating as well as local levels of estrogens, they produce hot flashes. Their potential long-term effects on bone and plasma lipids remain to be established.

There is also great interest in the potential use of aromatase inhibitors for the chemoprevention of breast cancer. These agents decrease estrogen levels and thus block hormonal effects as tumor promoters (*i.e.*, by stimulating cell proliferation), but would also prevent actions of locally produced estrogens to initiate tumors (*i.e.*, *via* formation of DNA-adducts). This would provide a theoretical advantage over tamoxifen, which would only be expected to decrease actions of estrogens as tumor promoters.

PROGESTINS

Compounds with biological activities similar to those of progesterone have been variously referred to in the literature as progestins, progestational agents, progestagens, progestogens, gestagens, or gestogens. The progestins (Figure 57–5) include the naturally occurring hormone progesterone, 17 α -acetoxyprogesterone derivatives in the

pregnane series, 19-nortestosterone derivatives (estranses), and *norgestrel* and related compounds in the gonane series. Medroxyprogesterone acetate (MPA) and *megestrol acetate* are C21 steroids with selective activity very similar to that of progesterone itself. MPA and oral micronized progesterone are widely used with estrogens for menopausal hormone therapy and other situations in which a selective progestational effect is desired, and a depot form of MPA is used as a long-acting injectable contraceptive. The 19-nortestosterone derivatives were developed for use as progestins in oral contraceptives, and while their predominant activity is progestational, they exhibit androgenic and other activities. The gonanes are a more recently developed series of “19-nor” compounds, containing an ethyl rather than a methyl substituent in the 13-position, and they have diminished androgenic activity. These two classes of 19-nortestosterone derivatives are the progestational components of all oral and some long-acting injectable contraceptives.

Agents Similar to Progesterone (Pregnanes)

Agents Similar to 19-Nortestosterone (Estranses)

Agents Similar to Norgestrel (Gonanes)

Figure 57–5. Structural features of various progestins.

History. Corner and Allen originally isolated a hormone in 1933 from the corpora lutea of sows and named it “progesterin.” The next year, several European groups independently isolated the crystalline compound and called it “luteo-sterone,” unaware of the previous name. This difference in nomenclature was resolved in 1935 at a garden party in London given by Sir Henry Dale, who helped persuade all parties that the name “progesterone” was a suitable compromise.

Two major advances overcame the early difficulties and astronomical expense of obtaining progesterone from animal sources. The first was the synthesis of progesterone by Russel Marker from the plant product diosgenin in the 1940s, which provided relatively inexpensive and highly pure product. The second was the synthesis of 19-nor compounds, the first orally active progestins, in the early 1950s by Carl Djerassi, who synthesized norethindrone at Syntex, and Frank Colton, who synthesized the isomer *norethynodrel* at Searle. These advances led to the development of effective oral contraceptives.

Chemistry. Unlike the ER, which requires a phenolic A ring for high-affinity binding, the progesterone receptor (PR) favors a Δ^4 -3-one A-ring structure in an inverted 1β , 2α -conformation (Duax *et al.*, 1988). Other steroid hormone receptors also bind this nonphenolic A-ring structure, although the optimal conformation differs from that for the PR. Thus, some synthetic progestins (especially the 19-nor compounds) display limited binding to glucocorticoid, androgen, and mineralocorticoid receptors, a property that probably accounts for some of their nonprogestational activities. The spectrum of activities of these compounds is highly dependent upon specific substituent groups, especially the nature of the C17 substituent in the D ring, the presence of a C19 methyl group, and the presence of an ethyl group at position C13.

One major class of agents is similar to progesterone and its metabolite 17α -hydroxyprogesterone (Figure 57–5). Compounds such as hydroxyprogesterone caproate have progestational activity but must be used parenterally due to first-pass hepatic metabolism. However, further substitutions at the 6-position of the B ring yield orally active compounds such as medroxyprogesterone acetate and megestrol acetate with selective progestational activity.

The second major class of agents is 19-nor testosterone derivatives. These testosterone derivatives, lacking the C19 methyl group, display primarily progestational rather than androgenic activity. An ethinyl substituent at C17 decreases hepatic metabolism and yields orally active 19-nortestosterone analogs such as norethindrone, norethindrone acetate, norethynodrel, and *ethynodiol diacetate*. The activity of the latter three compounds is due primarily to their rapid *in vivo* conversion to norethindrone. These compounds are less selective than the 17α -hydroxyprogesterone derivatives mentioned above and have varying degrees of androgenic activity, and to a lesser extent, estrogenic and anti-estrogenic activities.

Replacement of the 13-methyl group of norethindrone with a 13-ethyl substituent yields the gonane *norgestrel*, which is a more potent progestin than the parent compound but has less androgenic activity. Norgestrel is a racemic mixture of an inactive dextrorotatory isomer and the active levorotatory isomer, levonorgestrel. Preparations containing half as much levonorgestrel as norgestrel thus have equivalent pharmacological activity. Other gonanes—including norgestimate, *desogestrel*, and *gestodene* (not available in the United States)—are reported to have very little if any androgenic activity at therapeutic doses (Rebar and Zeserson, 1991).

Newer steroidal progestins include the gonane *dienogest*; 19-nor-progestin derivatives (*e.g.*, *nomegestrol*, *nestorone*, and *trimegestone*), which have increased selectivity for the progesterone

receptor and less androgenic activity than estranes; and the spironolactone derivative *drospirenone*, which is used in a combination oral contraceptive. Like spironolactone, drospirenone is also a mineralocorticoid receptor antagonist. In addition, efforts are currently underway to develop novel, nonsteroidal progestins, as these may have less affinity for other steroid receptors.

Synthesis and Secretion. Progesterone is secreted by the ovary, mainly from the corpus luteum, during the second half of the menstrual cycle (Figure 57–3). The stimulatory effect of LH on progesterone synthesis and secretion is mediated by a receptor that couples to the G_s -adenylyl cyclase–cyclic AMP pathway (*see* Chapter 55).

After fertilization, the trophoblast secretes hCG into the maternal circulation to sustain the corpus luteum. During the second or third month of pregnancy, the developing placenta begins to secrete estrogen and progesterone in collaboration with the fetal adrenal glands, and thereafter the corpus luteum is not essential to continued gestation. Estrogen and progesterone continue to be secreted in large amounts by the placenta up to the time of delivery.

Physiological and Pharmacological Actions

Neuroendocrine Actions. As discussed previously, progesterone produced in the luteal phase of the cycle has several physiological effects including decreasing the frequency of GnRH pulses, which is the major mechanism of action of progestin-containing contraceptives.

Reproductive Tract. Progesterone decreases estrogen-driven endometrial proliferation and leads to the development of a secretory endometrium (Figure 57–3), and the abrupt decline in progesterone at the end of the cycle is the main determinant of the onset of menstruation. If the duration of the luteal phase is artificially lengthened, either by sustaining luteal function or by treatment with progesterone, decidual changes in the endometrial stroma similar to those seen in early pregnancy can be induced. Under normal circumstances, estrogen antecedes and accompanies progesterone in its action upon the endometrium and is essential to the development of the normal menstrual pattern.

Progesterone also influences the endocervical glands, and the abundant watery secretion of the estrogen-stimulated structures is changed to a scant, viscid material. As noted previously, these and other effects of progestins decrease penetration of the cervix by sperm.

The estrogen-induced maturation of the human vaginal epithelium is modified toward the condition of pregnancy by the action of progesterone, a change that can be detected in cytological alterations in the vaginal smear. If the quantity of estrogen concurrently acting is known to be adequate, or if it is assured by giving estrogen, the cytological response to a progestin can be used to evaluate its progestational potency.

Progesterone is very important for the maintenance of pregnancy. Progesterone suppresses menstruation and uterine contractility, but other effects also may be important. These effects to maintain pregnancy led to the historical use of progestins to prevent threatened abortion. However, such treatment is of questionable benefit, probably because spontaneous abortion infrequently results from diminished progesterone. Based on a recent report that premature labor in high-risk mothers was diminished by weekly intramuscular administration of *17-hydroxyprogesterone* (DELALUTIN), this indication is being re-evaluated (Meis *et al.*, 2003).

Mammary Gland. Development of the mammary gland requires both estrogen and progesterone. During pregnancy and to a minor degree during the luteal phase of the cycle, progesterone, acting with estrogen, brings about a proliferation of the acini of the mammary gland. Toward the end of pregnancy, the acini fill with secretions and the vasculature of the gland notably increases; however, only after the levels of estrogen and progesterone decrease at parturition does lactation begin.

During the normal menstrual cycle, mitotic activity in the breast epithelium is very low in the follicular phase and then peaks in the luteal phase. This pattern is due to progesterone, which triggers a *single* round of mitotic activity in the mammary epithelium. This effect is transient, however, and continued exposure to the hormone is rapidly followed by arrest of growth of the epithelial cells. As described above, progesterone may be responsible for the increased risk of breast cancer associated with estrogen-progestin use in postmenopausal women (Anderson *et al.*, 2004; Ros-souw *et al.*, 2002).

CNS Effects. During a normal menstrual cycle, an increase in basal body temperature of about 0.6°C (1°F) may be noted at mid-cycle; this correlates with ovulation. This increase is due to progesterone, but the exact mechanism of this effect is unknown. Progesterone also increases the ventilatory response of the respiratory centers to carbon dioxide and leads to reduced arterial and alveolar PCO₂ in the luteal phase of the menstrual cycle and during pregnancy. Progesterone also may have depressant and hypnotic actions in the CNS, possibly accounting for reports of drowsiness after hormone administration. This potential untoward effect may be abrogated by giving progesterone preparations at bedtime, which may even help some patients sleep.

Metabolic Effects. Progestins have numerous metabolic actions. Progesterone itself increases basal insulin levels

and the rise in insulin after carbohydrate ingestion, but it does not normally alter glucose tolerance. However, long-term administration of more potent progestins, such as norgestrel, may decrease glucose tolerance. Progesterone stimulates lipoprotein lipase activity and seems to enhance fat deposition. Progesterone and analogs such as MPA have been reported to increase LDL and cause either no effects or modest reductions in serum HDL levels. The 19-norprogestins may have more pronounced effects on plasma lipids because of their androgenic activity. In this regard, a large prospective study has shown that MPA decreases the favorable HDL increase caused by conjugated estrogens during postmenopausal hormone replacement, but does not significantly affect the beneficial effect of estrogens to lower LDL. In contrast, micronized progesterone does not significantly affect beneficial estrogen effects on either HDL or LDL profiles (Writing Group for the PEPI Trial, 1995). Progesterone also may diminish the effects of aldosterone in the renal tubule and cause a decrease in sodium reabsorption that may increase mineralocorticoid secretion from the adrenal cortex.

Mechanism of Action

There is a single gene that encodes two isoforms of the progesterone receptor (PR): PR-A and PR-B. The first 164 N-terminal amino acids of PR-B are missing from PR-A; this occurs by use of two distinct estrogen-dependent promoters in the PR gene (Giangrande and McDonnell, 1999). The ratios of the individual isoforms vary in reproductive tissues as a consequence of tissue type, developmental status, and hormone levels. Both PR-A and PR-B have AF-1 and AF-2 transactivation domains, but the longer PR-B also contains an additional AF-3 that contributes to its cell- and promoter-specific activity. Since the ligand-binding domains of the two PR isoforms are identical, there is no difference in ligand binding. In the absence of ligand, PR is present in the nucleus in an inactive monomeric state bound to heat-shock proteins (HSP-90, HSP-70, and p59). Upon binding progesterone, the heat-shock proteins dissociate, and the receptors are phosphorylated and subsequently form dimers (homo- and heterodimers) that bind with high selectivity to PREs (progesterone response elements) located on target genes (Giangrande and McDonnell, 1999). Transcriptional activation by PR occurs primarily *via* recruitment of co-activators such as SRC-1, NcoA-1, or NcoA-2 (Collingwood *et al.*, 1999). The receptor-co-activator complex then favors further interactions with additional proteins such as CBP and p300, which have histone acetylase activity. Histone acetylation causes a remodeling of chromatin that

increases the accessibility of general transcriptional proteins, including RNA polymerase II, to the target promoter. Progesterone antagonists also facilitate receptor dimerization and DNA binding, but, as with ER, the conformation of antagonist-bound PR is different from that of agonist-bound PR. This different conformation favors PR interaction with co-repressors such as NcoR/SMRT, which recruit histone deacetylases. Histone deacetylation increases DNA interaction with nucleosomes and renders a target promoter inaccessible to the general transcription apparatus.

The biological activities of PR-A and PR-B are distinct and depend on the target gene in question. In most cells, PR-B mediates the stimulatory activities of progesterone; PR-A strongly inhibits this action of PR-B (Vegeto *et al.*, 1993) and is also a transcriptional inhibitor of other steroid receptors (McDonnell and Goldman, 1994). Current data suggest that co-activators and co-repressors interact differentially with PR-A and PR-B, *e.g.*, the co-repressor SMRT binds much more tightly to PR-A than to PR-B (Giangrande *et al.*, 2000), and this may account, at least in part, for the differential activities of the two isoforms. Female PR-A knockout mice are infertile, with impaired ovulation and defective decidualization and implantation. Several uterine genes appear to be regulated exclusively by PR-A, including calcitonin and amphiregulin (Mulac-Jericevic *et al.*, 2000), and the antiproliferative effect of progesterone on the estrogen-stimulated endometrium is lost in PR-A knockout mice. In contrast, knockout studies suggest that PR-B is largely responsible for mediating hormone effects in the mammary gland (Mulac-Jericevic *et al.*, 2003).

Certain effects of progesterone, such as increased Ca²⁺ mobilization in sperm, can be seen in as little as 3 minutes (Blackmore, 1999), and these effects are caused by nongenomic mechanisms involving membrane-bound progesterone receptors that are not derived from the gene encoding PR-A/PR-B (Losel *et al.*, 2004). The pharmacological importance of these membrane-bound receptors has not been determined.

Absorption, Fate, and Excretion

Progesterone undergoes rapid first-pass metabolism, but high-dose (*e.g.*, 100 to 200 mg) preparations of micronized progesterone (PROMETRIUM) are available for oral use. Although the absolute bioavailability of these preparations is low (Fotherby, 1996), efficacious plasma levels nevertheless may be obtained. Progesterone also is available in oil solution for injection, as a vaginal gel (CRINONE, PROCHIEVE), and as a slow-release intrauterine device (PROGESTASERT) for contraception.

Esters such as *hydroxyprogesterone caproate* (HYALUTIN) and MPA (DEPO-PROVERA) are available for intramuscular administration, and MPA (PROVERA, others) and megestrol acetate (MEGACE) may be used orally due to decreased hepatic metabolism. The 19-nor steroids have good oral activity because the ethinyl substituent at C17 significantly slows hepatic metabolism. Implants and depot preparations of synthetic progestins are available in many countries for release over very long periods of time (*see* later section on contraceptives).

In the plasma, progesterone is bound by albumin and corticosteroid-binding globulin, but is not appreciably bound to SHBG. 19-Nor compounds, such as norethindrone, norgestrel, and desogestrel, bind

to SHBG and albumin, and esters such as MPA bind primarily to albumin. Total binding of all these synthetic compounds to plasma proteins is extensive, 90% or more, but the proteins involved are compound-specific.

The elimination half-life of progesterone is approximately 5 minutes, and the hormone is metabolized primarily in the liver to hydroxylated metabolites and their sulfate and glucuronide conjugates, which are eliminated in the urine. A major metabolite specific for progesterone is pregnane-3 α , 20 α -diol; its measurement in urine and plasma is used as an index of endogenous progesterone secretion. The synthetic progestins have much longer half-lives, *e.g.*, approximately 7 hours for norethindrone, 16 hours for norgestrel, 12 hours for gestodene, and 24 hours for MPA. The metabolism of synthetic progestins is thought to be primarily hepatic, and elimination is generally *via* the urine as conjugates and various polar metabolites, although their metabolism is not as clearly defined as that of progesterone.

Therapeutic Uses

The two most frequent uses of progestins are for contraception, either alone or with an estrogen (*see* below), and in combination with estrogen for hormone therapy of postmenopausal women (*see* above).

Progestins also are used for secondary amenorrhea, abnormal uterine bleeding in patients without underlying organic pathology (*e.g.*, fibroids or cancer), luteal-phase support to treat infertility, and premature labor. Among the oral progestins used besides MPA in these settings is norethindrone acetate (AYGESTIN). In general, these uses of oral progestins are extensions of the physiological actions of progesterone on the neuroendocrine control of ovarian function and on the endometrium.

Progesterone can be used diagnostically to test for estrogen secretion and for responsiveness of the endometrium. After administration of progesterone to amenorrheic women for 5 to 7 days, withdrawal bleeding will occur if the endometrium has been stimulated by endogenous estrogens. Combinations of estrogens and progestins also can be used to test endometrial responsiveness in patients with amenorrhea.

As described above, progestins are highly efficacious in decreasing the occurrence of endometrial hyperplasia and carcinoma caused by unopposed estrogens; when used in this setting, there appears to be less irregular uterine bleeding with sequential rather than continuous administration. When used to decrease estrogen-induced endometrial hyperplasia, local intrauterine application *via* a hormone-releasing IUD would be a rational approach to prevent untoward effects (*e.g.*, unfavorable lipid profiles and incidence of breast cancer) of systemically administered progestins. Progestins are also used as a palliative measure for metastatic endometrial carcinoma, but adjuvant therapy after surgery does not significantly reduce cancer-related deaths; megestrol acetate is used as a second-line treatment for breast cancer. Megestrol acetate is also used off-label for AIDS-related wasting.

ANTI-PROGESTINS AND PROGESTERONE-RECEPTOR MODULATORS

The first report of an anti-progestin, RU 38486 (often referred to as RU-486) or *mifepristone*, appeared in 1981;

this drug is available for the termination of pregnancy (Christin-Maitre *et al.*, 2000). Anti-progestins also have several other potential applications, including uses as contraceptives, to induce labor, and to treat uterine leiomyomas, endometriosis, meningiomas, and breast cancer (Spitz and Chwalisz, 2000).

Mifepristone

Chemistry. Mifepristone is a derivative of the 19-norprogesterone containing a dimethyl-aminophenol substituent at the 11 β -position. It effectively competes with both progesterone and glucocorticoids for binding to their respective receptors. Mifepristone was initially thought to be a pure anti-progestin; this is its predominant activity in most situations, but it also has some agonist activity. Thus it is now considered a progesterone-receptor modulator (PRM) due to its context-dependent activity.

Other PRMs and pure progesterone antagonists now have been synthesized, and most contain an 11 β -aromatic group. Another widely studied anti-progestin is *onapristone* (or ZK 98299), which is similar in structure to mifepristone but contains a methyl substituent in the 13 α rather than 13 β orientation. More selective progesterone-receptor modulators, such as *asoprisnil*, are being studied experimentally (DeManno *et al.*, 2003). Mifepristone and onapristone have the following structures:

MIFEPRISTONE

ONAPRISTONE

Pharmacological Actions. In the presence of progestins, mifepristone acts as a competitive receptor antagonist for both progesterone receptors. While mifepristone acts primarily as an antagonist *in vivo*, it exhibits some agonist activity in certain *in vivo* and *in vitro* contexts. In contrast, onapristone appears to be a pure progesterone antagonist both *in vivo* and *in vitro*. PR complexes of both compounds antagonize the actions of progesterone-PR complexes and also appear to preferentially recruit corepressors (Leonhardt and Edwards, 2002).

When administered in the early stages of pregnancy, mifepristone causes decidual breakdown by blockade of uter-

ine progesterone receptors. This leads to detachment of the blastocyst, which decreases hCG production. This in turn causes a decrease in progesterone secretion from the corpus luteum, which further accentuates decidual breakdown. Decreased endogenous progesterone coupled with blockade of progesterone receptors in the uterus increases uterine prostaglandin levels and sensitizes the myometrium to their contractile actions. Mifepristone also causes cervical softening, which facilitates expulsion of the detached blastocyst.

Mifepristone can delay or prevent ovulation depending upon the timing and manner of administration. These effects are due largely to actions on the hypothalamus and pituitary rather than the ovary, although the mechanisms are unclear.

If administered for one or several days in the mid- to late luteal phase, mifepristone impairs the development of a secretory endometrium and produces menses. Progesterone-receptor blockade at this time is the pharmacological equivalent of progesterone withdrawal, and bleeding normally ensues within several days and lasts for 1 to 2 weeks after anti-progestin treatment.

Mifepristone also binds to glucocorticoid and androgen receptors and exerts anti-glucocorticoid and anti-androgenic actions. A predominant effect in humans is blockade of the feedback inhibition by cortisol of ACTH secretion from the pituitary, thus increasing both corticotropin and adrenal steroid levels in the plasma (*see* Chapter 59 for further discussion of effects on the hypothalamic-pituitary-adrenal axis). Onapristone also binds to both glucocorticoid and androgen receptors, but has less anti-glucocorticoid activity than does mifepristone.

Absorption, Fate, and Excretion. Mifepristone is orally active with good bioavailability. Peak plasma levels occur within several hours, and the drug is slowly cleared with a plasma half-life of 20 to 40 hours. In plasma, it is bound by α_1 -acid glycoprotein, which contributes to its long half-life. Metabolites are primarily the mono- and di-demethylated products (which are thought to have pharmacological activity) formed *via* CYP3A4-catalyzed reactions, and to a lesser extent, hydroxylated compounds. The drug undergoes hepatic metabolism and enterohepatic circulation, and metabolic products are found predominantly in the feces (Jang and Benet, 1997).

Therapeutic Uses and Prospects. Mifepristone (MIFEPREX), in combination with *misoprostol* or other prostaglandins (*see* below), is available for the termination of early pregnancy. When mifepristone is used to produce a medical abortion, a prostaglandin is given 48 hours after the anti-progestin to further increase myometrial contractions and ensure expulsion of the detached blastocyst. Intramuscular *sulprostone*, intravaginal *gemprost*, and oral *misoprostol* have been used. The success rate with such regimens is >90% among women with pregnancies of 49 days' duration or less. The most severe untoward effect is vaginal bleeding, which most often lasts from 8 to 17 days, but is only rarely (0.1% of patients) severe enough to require blood transfusions. High percentages of women also have experienced abdominal pain and uterine cramps, nausea, vomiting, and diarrhea due to the prostaglandin. Women receiving chronic glucocorticoid therapy should not be given mifepristone because of its anti-glucocorticoid activity, and the drug should be used very cautiously in women who are anemic or receiving anticoagulants. Women over 35 years old with cardiovascular risk factors

should not be given sulprostone because of possible heart failure (Christin-Maitre *et al.*, 2000).

Other investigational or potential uses for mifepristone that are under development include the induction of labor after fetal death; the induction of labor at the end of the third trimester; treatment of endometriosis, leiomyomas, breast cancer, and meningiomas; and as a postcoital or luteal-phase contraceptive (Spitz and Chwalisz, 2000). A major concern about long-term use is the possibility of unopposed estrogenic effects, but this concern could be allayed by further development of selective progesterone-receptor modulators.

HORMONAL CONTRACEPTIVES

Oral contraceptives are among the most widely used agents in the United States and throughout the world and have had a revolutionary impact on global society. For the first time in history, they provided a convenient, affordable, and completely reliable means of contraception for family planning and the avoidance of unplanned pregnancies.

It is important to consider several key points as a prelude to the pharmacology of specific hormonal contraceptives: (1) A variety of agents with substantially different components, doses, and side effects are available and provide real therapeutic options; (2) In addition to contraceptive actions, these agents have substantial health benefits; (3) Because of differences in doses and specific compounds used, it is not appropriate to extrapolate directly untoward effects of hormonal contraceptives to menopausal hormone therapy, or *vice versa*. Oral contraceptives are now extremely effective and have a low incidence of untoward effects for most women.

History. Around the beginning of the twentieth century, a number of European scientists including Beard, Prenant, and Loeb developed the concept that secretions of the corpus luteum suppressed ovulation during pregnancy. The Austrian physiologist Haberlandt then produced temporary sterility in rodents in 1927 by feeding ovarian and placental extracts—a clear example of an oral contraceptive! In 1937 it was shown by Makepeace and colleagues that pure progesterone blocked ovulation in rabbits, and Astwood and Fevold found a similar effect in rats in 1939.

In the 1950s, Pincus, Garcia, and Rock found that progesterone and 19-nor progestins prevented ovulation in women. Ironically, this finding grew out of their attempts to treat infertility with progestins or estrogen-progestin combinations. The initial findings were that either treatment effectively blocked ovulation in the majority of women. However, concern about cancer and other possible side effects of the estrogen they used (*i.e.*, diethylstilbestrol) led to the use of a progestin alone in their studies.

One of the compounds used was norethynodrel, and early batches of this compound were contaminated with a small amount of mestranol. When mestranol was removed, it was noted that treatment with pure norethynodrel led to increased breakthrough bleeding and less consistent inhibition of ovulation. Mestranol was thus re-incorporated into the preparation, and this combination was

employed in the first large-scale clinical trial of combination oral contraceptives.

Clinical studies in the 1950s in Puerto Rico and Haiti established the virtually complete contraceptive success of the norethynodrel-mestranol combination. In late 1959, ENOVID (norethynodrel plus mestranol; no longer marketed in the United States) was the first “Pill” approved by the FDA for use as a contraceptive agent in the United States; this was followed in 1962 by approval for ORTHONOVUM (norethindrone plus mestranol). By 1966 numerous preparations utilizing either mestranol or ethinyl estradiol with a 19-nor progestin were available. In the 1960s, the progestin-only minipill and long-acting injectable preparations were developed and introduced.

Millions of women began using oral contraceptives, and frequent reports of untoward effects began appearing in the 1970s (Kols *et al.*, 1982). The recognition that these side effects were dose-dependent and the realization that estrogens and progestins synergistically inhibited ovulation led to the reduction of doses and the development of so-called low-dose or second-generation contraceptives. The increasing use of biphasic and triphasic preparations throughout the 1980s further reduced steroid dosages; it may be that currently used doses are the lowest that will provide reliable contraception. In the 1990s, the “third-generation” oral contraceptives, containing progestins with reduced androgenic activity (*e.g.*, norgestimate [CYCLEN, ORTHO TRI-CYCLEN LO] and desogestrel [DESOGEN]), became available in the United States after being used in Europe. Products containing gestodene as a progestin with reduced androgenic activity also are available in Europe. Another major development in the 1980s was the widespread realization that oral contraceptives have a number of substantial health benefits. More recently, a variety of contraceptive formulations have become available and now include pills, injections providing 1 or 3 months of contraceptive coverage, skin patches, subcutaneous implants, vaginal rings, and intrauterine devices that release hormones.

Types of Hormonal Contraceptives

Combination Oral Contraceptives. The most frequently used agents in the United States are combination oral contraceptives containing both an estrogen and a progestin. Their theoretical efficacy generally is considered to be 99.9%. Ethinyl estradiol and mestranol are the two estrogens used (with ethinyl estradiol being much more frequently used); several progestins currently are used, with levonorgestrel probably being the most common worldwide. The progestins are 19-nor compounds in the estrane or gonane series, and each has varying degrees of androgenic, estrogenic, and anti-estrogenic activities that may be responsible for some of their side effects. Compounds such as desogestrel and norgestimate are the most recently developed and have less androgenic activity than other 19-nor compounds.

Combination oral contraceptives are available in many formulations. Monophasic, biphasic, or triphasic pills are generally provided in 21-day packs. For the monophasic agents, fixed amounts of the estrogen and progestin are present in each pill, which is taken daily for 21 days, followed by a 7-day “pill-free” period. (Virtually all preparations

come as 28-day packs, with the pills for the last 7 days containing only inert ingredients.) The biphasic and triphasic preparations provide two or three different pills containing varying amounts of active ingredients, to be taken at different times during the 21-day cycle. This reduces the total amount of steroids administered and more closely approximates the estrogen-to-progestin ratios that occur during the menstrual cycle. With these preparations, predictable menstrual bleeding generally occurs during the 7-day “off” period each month. In 2003, the FDA approved a norgestrel–ethinyl estradiol combination (SEASONALE) that is taken continuously for 84 days followed by 7 days of placebo tablets; this reduces menstrual bleeding to once every 13 weeks. Additional options include a once-monthly medroxyprogesterone–estradiol cypionate injectable (LUNELLE), an ethinyl estradiol–*norelgestromin* (the active metabolite of norgestimate) patch (ORTHO EVRA) applied weekly, and an ethinyl estradiol–*etonogestrel* (the active metabolite of desogestrel) flexible vaginal ring (NUVARING) used for 3 weeks (followed by a removal for 1 week that leads to menstrual bleeding).

The estrogen content of current preparations ranges from 20 to 50 μg ; the majority contain 30 to 35 μg . Preparations containing 35 μg or less of an estrogen are generally referred to as “low-dose” or “modern” pills. The dose of progestin is more variable because of differences in potency of the compounds used. For example, monophasic pills currently available in the United States contain 0.4 to 1 mg of norethindrone, 0.1 to 0.15 mg of levonorgestrel, 0.3 to 0.5 mg of norgestrel, 1 mg of ethynodiol diacetate, 0.25 mg of norgestimate, and 0.15 mg of desogestrel, with slightly different dose ranges in biphasic and triphasic preparations. In contrast, most first-generation preparations (circa 1966) contained 50 to 100 μg of an estrogen and 2 to 10 mg of a progestin. These large differences in doses complicate extrapolation of data from early epidemiological studies on the side effects of “high-dose” oral contraceptives to the “low-dose” preparations now used.

Progestin-Only Contraceptives. Several agents are available for progestin-only contraception. They are only slightly less efficacious than combination oral contraceptives, with reports of theoretical efficacy of 99%. Specific preparations include the “minipill”; low doses of progestins (e.g., 350 μg of norethindrone [NOR-QD, MICRONOR] or 75 μg of norgestrel [OVRETTE]) taken daily without interruption; subdermal implants of 216 mg of norgestrel (NOR-PLANT II, JADELLE) for slow release and resultant long-term contraceptive action (e.g., up to 5 years); and crystalline suspensions of medroxyprogesterone acetate (DEPO-PROVERA) for intramuscular injection of 150 mg of drug, which provides effective contraception for 3 months.

An intrauterine device (PROGESTASERT) that releases low amounts of progesterone locally is available for insertion on a yearly basis. Its effectiveness is considered to be 97% to 98%, and contraceptive action probably is due to local effects on the endometrium. Another intrauterine device (MIRENA) releases levonorgestrel for up to 5 years. It inhibits ovulation in some women but is thought to act primarily by producing local effects.

Postcoital or Emergency Contraceptives. High doses of diethylstilbestrol and other estrogens once were used

for postcoital contraception (the “morning-after pill”) but never received FDA approval for this indication. The FDA has now approved two preparations for postcoital contraception. PLAN-B is two doses of the “minipill” (0.75 mg levonorgestrel per pill) separated by 12 hours. PREVEN is two 2-pill doses of a high-dose oral contraceptive (0.25 mg of levonorgestrel and 0.05 mg of ethinyl estradiol per pill) separated by 12 hours. This is sometimes referred to as the “Yuzpe” method after the Canadian physician who pioneered its use. The FDA also has declared other products with the same or very similar composition safe and effective for use as emergency contraceptive pills.

The first dose of such preparations should be taken anytime within 72 hours after intercourse, and this should be followed 12 hours later by a second dose. This treatment reduces the risk of pregnancy following unprotected intercourse by approximately 60% for the Yuzpe method and 80% for levonorgestrel alone. With either preparation, effectiveness appears to increase the sooner after intercourse the pills are taken (Task Force on Postovulatory Methods of Fertility Regulation, 1998).

Mechanism of Action

Combination Oral Contraceptives. Combination oral contraceptives act by preventing ovulation (Lobo and Stanczyk, 1994). Direct measurements of plasma hormone levels indicate that LH and FSH levels are suppressed, a mid-cycle surge of LH is absent, endogenous steroid levels are diminished, and ovulation does not occur. While either component alone can be shown to exert these effects in certain situations, the combination synergistically decreases plasma gonadotropin levels and suppresses ovulation more consistently than either alone.

Given the multiple actions of estrogens and progestins on the hypothalamic-pituitary-ovarian axis during the menstrual cycle and the extraordinary efficacy of these agents, several effects probably contribute to the blockade of ovulation.

Hypothalamic actions of steroids play a major role in the mechanism of oral contraceptive action. Progesterone clearly diminishes the frequency of GnRH pulses. Since the proper frequency of LH pulses is essential for ovulation, this effect of progesterone likely plays a major role in the contraceptive action of these agents. In monkeys and women with normal menstrual cycles, estrogens do not affect the frequency of the pulse generator. However, in the prolonged absence of a menstrual cycle (e.g., in ovariectomized monkeys and postmenopausal women; Hotchkiss and Knobil, 1994), estrogens markedly diminish pulse-generator frequency, and progesterone enhances this effect. In theory, this hypothalamic effect of estrogens could come into play when oral contraceptives are used for extended time periods.

Multiple pituitary effects of both estrogen and progestin components are thus likely to contribute to oral contraceptive action. Oral

contraceptives seem likely to decrease pituitary responsiveness to GnRH. Estrogens also suppress FSH release from the pituitary during the follicular phase of the menstrual cycle, and this effect seems likely to contribute to the lack of follicular development in oral contraceptive users. Pharmacologically, the progestin component may also inhibit the estrogen-induced LH surge at mid-cycle. Other effects may contribute to a minor extent to the extraordinary efficacy of oral contraceptives. Transit of sperm, the egg, and fertilized ovum are important to establish pregnancy, and steroids are likely to affect transport in the fallopian tube. In the cervix, progestin effects also are likely to produce a thick, viscous mucus to reduce sperm penetration and in the endometrium to produce a state that is not receptive to implantation. However, it is difficult to assess quantitatively the contributions of these effects because the drugs block ovulation so effectively.

Progestin-Only Contraceptives. Progestin-only pills and levonorgestrel implants are highly efficacious but block ovulation in only 60% to 80% of cycles. Their effectiveness is thus thought to be due largely to a thickening of cervical mucus, which decreases sperm penetration, and to endometrial alterations that impair implantation; such local effects account for the efficacy of intrauterine devices that release progestins. Depot injections of MPA are thought to exert similar effects, but they also yield plasma levels of drug high enough to prevent ovulation in virtually all patients, presumably by decreasing the frequency of GnRH pulses.

Emergency Contraceptive Pills. Multiple mechanisms are likely to contribute to the efficacy of these agents, but their precise contributions are unknown (Glasier, 1997). Some studies have shown that ovulation is inhibited or delayed, but additional mechanisms thought to play a role include alterations in endometrial receptivity for implantation; interference with functions of the corpus luteum that maintain pregnancy; production of a cervical mucus that decreases sperm penetration; alterations in tubular transport of sperm, egg, or embryo; or effects on fertilization. However, emergency contraceptives do not interrupt pregnancy after implantation.

Untoward Effects

Combination Oral Contraceptives. Shortly after the introduction of oral contraceptives, reports of adverse side effects associated with their use began to appear. Many of the side effects were found to be dose dependent, and this led to the development of current low-dose preparations. Untoward effects of early hormonal contraceptives fell into several major categories: adverse cardiovascular effects, including hypertension, myocardial infarction, hemorrhagic or ischemic stroke, and venous thrombosis and embolism; breast, hepatocellular, and cervical cancers; and a number of endocrine and metabolic effects. The current consensus is that low-dose preparations pose minimal health risks in women who have no predisposing

risk factors, and these drugs also provide many beneficial health effects (Burkman *et al.*, 2004).

Cardiovascular Effects. The question of cardiovascular side effects has been re-examined for the newer low-dose oral contraceptives (Sherif, 1999; Burkman *et al.*, 2004). For nonsmokers without other risk factors such as hypertension or diabetes, there is no significant increase in the risk of myocardial infarction or stroke. There is a 28% increase in relative risk for venous thromboembolism, but the estimated absolute increase is very small because the incidence of these events in women without other predisposing factors is low (*e.g.*, roughly half that associated with the risk of venous thromboembolism in pregnancy). Nevertheless, the risk is significantly increased in women who smoke or have other factors that predispose to thrombosis or thromboembolism (Castelli, 1999). Early high-dose combination oral contraceptives caused hypertension in 4% to 5% of normotensive women and increased blood pressure in 10% to 15% of those with pre-existing hypertension. This incidence is much lower with newer, low-dose preparations, and most reported changes in blood pressure are not significant. The cardiovascular risk associated with oral contraceptive use does not appear to persist after use is discontinued. As noted previously, estrogens increase serum HDL and decrease LDL levels, and progestins tend to have the opposite effect. Recent studies of several low-dose preparations have not found significant change in total serum cholesterol or lipoprotein profiles, although slight increases in triglycerides have been reported.

Cancer. Given the growth-promoting effects of estrogens, there has been a long-standing concern that oral contraceptives might increase the incidence of endometrial, cervical, ovarian, breast, and other cancers. These concerns were further heightened in the late 1960s by reports of endometrial changes caused by sequential oral contraceptives, which have since been removed from the market in the United States. However, it is now clear that there is *not* a widespread association between oral contraceptive use and cancer (Westhoff, 1999; Burkman *et al.*, 2004).

Recent epidemiological evidence suggests that combined oral contraceptive use may increase the risk of cervical cancer by about twofold, but only in long-term users (>5 years) with persistent human papilloma virus infection (Moodley, 2004).

There have been reports of increases in the incidence of hepatic adenoma and hepatocellular carcinoma in oral contraceptive users. Current estimates indicate that there is about a doubling in the risk of liver cancer after 4 to 8 years of use. However, these are rare cancers and the absolute increases are small.

The major present concern about the carcinogenic effects of oral contraceptives is focused on breast cancer. Numerous studies have dealt with this issue, and the following general picture has emerged. The risk of breast cancer in women of childbearing age is very low, and current oral contraceptive users in this group have only a very small increase in relative risk of 1.1 to 1.2, depending on other variables. This small increase is not substantially affected by duration of use, dose or type of component, age at first use, or parity. Importantly, 10 years after discontinuation of oral contraceptive use, there is no difference in breast cancer incidence between past users and never users. In addition, breast cancers diagnosed in women who have ever used oral contraceptives are more likely to be localized to the breast and thus easier to treat, *i.e.*, are less likely to have spread to other sites (Westhoff, 1999). Thus, overall there is no significant difference in the cumulative risk of breast cancer between those

who have ever used oral contraceptives and those who have never used them.

Combination oral contraceptives do *not* increase the incidence of endometrial cancer, but actually cause a 50% decrease in the incidence of this disease, which lasts 15 years after the pills are stopped. This is thought to be due to the inclusion of a progestin, which opposes estrogen-induced proliferation, throughout the entire 21-day cycle of administration. These agents also decrease the incidence of ovarian cancer, and decreased ovarian stimulation by gonadotropins provides a logical basis for this effect. There are accumulating data that oral contraceptive use decreases the risk of colorectal cancer (Fernandez *et al.*, 2001).

Metabolic and Endocrine Effects. The effects of sex steroids on glucose metabolism and insulin sensitivity are complex (Godsland, 1996) and may differ among agents in the same class (*e.g.*, the 19-nor progestins). Early studies with high-dose oral contraceptives generally reported impaired glucose tolerance as demonstrated by increases in fasting glucose and insulin levels and responses to glucose challenge. These effects have decreased as steroid dosages have been lowered, and current low-dose combination contraceptives may even improve insulin sensitivity. Similarly, the high-dose progestins in early oral contraceptives did raise LDL and reduce HDL levels, but modern low-dose preparations do not produce unfavorable lipid profiles (Sherif, 1999). There also have been periodic reports that oral contraceptives increase the incidence of gallbladder disease, but any such effect appears to be weak and limited to current or very long-term users (Burkman, 2004).

The estrogenic component of oral contraceptives may increase hepatic synthesis of a number of serum proteins, including those that bind thyroid hormones, glucocorticoids, and sex steroids. While physiological feedback mechanisms generally adjust hormone synthesis to maintain normal “free” hormone levels, these changes can affect the interpretation of endocrine function tests that measure *total* plasma hormone levels, and may necessitate dose adjustment in patients receiving thyroid-hormone replacement.

The ethinyl estradiol present in oral contraceptives appears to cause a dose-dependent increase in several serum factors known to increase coagulation. However, in healthy women who do not smoke, there also is an increase in fibrinolytic activity, which exerts a counter effect so that overall there is a minimal effect on hemostatic balance. In women who smoke, however, this compensatory effect is diminished, which may shift the hemostatic profile toward a hypercoagulable condition (Fruzzetti, 1999).

Miscellaneous Effects. Nausea, edema, and mild headache occur in some individuals, and more severe migraine headaches may be precipitated by oral contraceptive use in a smaller fraction of women. Some patients may experience breakthrough bleeding during the 21-day cycle when the active pills are being taken. Withdrawal bleeding may fail to occur in a small fraction of women during the 7-day “off” period, thus causing confusion about a possible pregnancy. Acne and hirsutism are thought to be mediated by the androgenic activity of the 19-nor progestins.

Progestin-Only Contraceptives. Episodes of irregular, unpredictable spotting and breakthrough bleeding are the most frequently encountered untoward effect and the major reason women discontinue use of all three types of progestin-only contraceptives. With time, the incidence of these bleeding episodes decreases, especially with the

long-acting preparations, and amenorrhea becomes common after a year or more of use.

There is no evidence that the progestin-only minipill preparations increase thromboembolic events, which are thought to be related to the estrogenic component of combination preparations; blood pressure does not appear to be elevated, and nausea and breast tenderness do not occur. Acne may be a problem, however, because of the androgenic activity of norethindrone-containing preparations. These preparations may be attractive for nursing mothers because they do not decrease lactation as do products containing estrogens.

Aside from bleeding irregularities, headache is the most commonly reported untoward effect of depot MPA (medroxyprogesterone acetate). Mood changes and weight gain also have been reported, but controlled clinical studies of these effects are not available. It is of more concern that many studies have found decreases in HDL levels and increases in LDL levels and that there have been several reports of decreased bone density. These effects may be due to reduced endogenous estrogens because depot MPA is particularly effective in lowering gonadotropin levels. Numerous human studies have not found any increases in breast, endometrial, cervical, or ovarian cancer in women receiving MPA (Westhoff, 2003). Because of the time required to completely eliminate the drug, the contraceptive effect of this agent may remain for 6 to 12 months after the last injection.

Implants of norethindrone may be associated with infection, local irritation, pain at the insertion site, and rarely, expulsion of the inserts. Headache, weight gain, and mood changes have been reported, and acne is seen in some patients. A number of metabolic studies have been performed in NORPLANT (no longer marketed in the United States) users, and in most cases only minimal changes have been observed in lipid, carbohydrate, and protein metabolism. In women desiring pregnancy, ovulation occurs fairly soon after implant removal, reaching 50% in 3 months and almost 90% within 1 year.

Emergency Contraceptive Pills. Nausea and vomiting are the main untoward effects, with an incidence of roughly 50% and 20%, respectively, for combined estrogen-levonorgestrel combinations and 23% and 6% for levonorgestrel alone (Task Force on Postovulatory Methods of Fertility Regulation, 1998). No changes in clotting factors have been reported for the combined regimen, but based on concerns with combination oral contraceptives, levonorgestrel alone might be considered for women who smoke or have a history of blood clots. *Emergency contraceptive pills are contraindicated in cases of confirmed pregnancy.*

Contraindications

While the use of modern oral contraceptives is considered generally safe in most healthy women, *these agents can contribute to the incidence and severity of certain diseases if other risk factors are present.* The following conditions are thus considered absolute contraindications for combination oral contraceptive use: the presence or history of thromboembolic disease, cerebrovascular disease, myocardial infarction, coronary artery disease, or congenital hyperlipidemia; known or suspected carcinoma of the breast, carcinoma of the female reproductive tract, or other hormone-dependent/responsive neoplasias; abnormal undiagnosed vaginal bleeding; known or suspected pregnancy; and past or present liver tumors or impaired liver function. *The risk of serious cardiovascular side*

effects is particularly marked in women over 35 years of age who smoke heavily (e.g., over 15 cigarettes per day); even low-dose oral contraceptives are contraindicated in such patients.

Several other conditions are relative contraindications and should be considered on an individual basis. These include migraine headaches, hypertension, diabetes mellitus, obstructive jaundice of pregnancy or prior oral contraceptive use, and gallbladder disease. If elective surgery is planned, many physicians recommend discontinuation of oral contraceptives for several weeks to a month to minimize the possibility of thromboembolism after surgery. These agents should be used with care in women with prior gestational diabetes or uterine fibroids, and low-dose pills should generally be used in such cases.

Progestin-only contraceptives are contraindicated in the presence of undiagnosed vaginal bleeding, benign or malignant liver disease, and known or suspected breast cancer. Depot medroxyprogesterone acetate and levonorgestrel inserts are contraindicated in women with a history or predisposition to thrombophlebitis or thromboembolic disorders.

Choice of Contraceptive Preparations

Many preparations that differ substantially in dose and specific components are available, providing the option to select the preparation best suited to each individual. Treatment should generally begin with preparations containing the minimum dose of steroids that provides effective contraceptive coverage. This is typically a pill with 30 to 35 μg of estrogen, but preparations with 20 μg may be adequate for lighter women or those over 40 with perimenopausal symptoms, while a preparation containing 50 μg of estrogen may be required for heavier women. Breakthrough bleeding may occur if the estrogen-to-progestin ratio is too low to produce a stable endometrium, and this may be prevented by switching to a pill with a higher ratio.

In women for whom estrogens are contraindicated or undesirable, progestin-only contraceptives may be an option. The progestin-only minipill may have enhanced effectiveness in several such types of women (e.g., nursing mothers and women over 40, in whom fertility may be decreased).

Another consideration is the concomitant administration of medications that may increase metabolism of estrogens (e.g., *rifampicin*, barbiturates, and *phenytoin*) or reduce their enterohepatic recycling (e.g., tetracyclines and *ampicillin* decrease intestinal bacteria that produce enzymes required for hydrolysis and reuptake of conjugated metabolites). In these situations, a low-dose pill may *not* be 99.9% effective due to increased steroid metabolism.

The choice of a preparation also may be influenced by the specific 19-nor progestin component, since this component may have varying degrees of androgenic and other activities. The androgenic activity of this component may contribute to untoward effects such as weight gain, acne due to increased sebaceous gland secretions, and unfavorable lipoprotein profiles. These side effects are greatly reduced in newer, low-dose contraceptives, but any patients exhibiting such side effects may benefit by switching to pills that contain a progestin with less androgenic activity. Of the progestins commonly found in oral contraceptives, norgestrel is generally considered to have the most androgenic activity; norethindrone and ethynodiol diacetate to have more moderate androgenic activity; and desogestrel, norgestimate, and drospirenone to have the least androgenic activity.

The FDA has approved a triphasic, low-dose combination oral contraceptive (ORTHO TRI-CYCLEN) containing ethinyl estradiol and norgestimate for the treatment of moderate acne vulgaris. Similar

preparations (DEMULEN 1/35, DESOGEN, others) also are effective. The mechanism appears to be a decrease in free plasma testosterone due to an increase in plasma SHBG, since total testosterone levels are unchanged (Redmond *et al.*, 1997).

In summary, for a given individual, both the efficacy and side effects of hormonal contraceptives may vary considerably among preparations. A number of choices are available to counter the development of side effects and improve patient tolerance, both in terms of specific components and routes of administration, without decreasing contraceptive efficacy.

Noncontraceptive Health Benefits

It is generally accepted that combination oral contraceptives have substantial health benefits unrelated to their contraceptive use. Oral contraceptives significantly reduce the incidence of ovarian and endometrial cancer within 6 months of use, and the incidence is decreased 50% after 2 years of use. Depot MPA injections also reduce very substantially the incidence of uterine cancer. Furthermore, this protective effect persists for up to 15 years after oral contraceptive use is discontinued. These agents also decrease the incidence of ovarian cysts and benign fibrocystic breast disease.

Oral contraceptives have major benefits related to menstruation in many women. These include more regular menstruation, reduced menstrual blood loss and less iron-deficiency anemia, and decreased frequency of dysmenorrhea. There also is a decreased incidence of pelvic inflammatory disease and ectopic pregnancies, and endometriosis may be ameliorated. Some women also may obtain these benefits with progestin-only contraceptives. There are suggestions that MPA may improve hematological parameters in women with sickle-cell disease (Cullins, 1996).

There is now a consensus that combination oral contraceptives prevent thousands of deaths, episodes of various diseases, and cases of hospitalization each year in the United States alone. From a purely statistical perspective, fertility regulation by oral contraceptives is substantially safer than pregnancy or childbirth for most women, even without considering the additional health benefits of these agents.

CLINICAL SUMMARY

Estrogens are most commonly used to treat vasomotor disturbances (“hot flashes”) in postmenopausal women. Other important benefits are amelioration of the effects of urogenital atrophy, a decreased incidence of colon cancer, and prevention of bone loss. Estrogens have proven efficacy for prevention of bone fractures at all sites in normal women, although when used solely for this purpose they

should not be considered first-line because of possible untoward side effects including breast cancer, stroke, and coronary heart disease (CHD). Estrogens should *not* be prescribed for treatment or prevention of CHD or other cardiovascular diseases, or to prevent neurodegenerative disease. A variety of preparations, including oral, transdermal, and vaginal, are available. *Regardless of the specific drug(s) selected, treatment should use the minimum dose and duration for the desired therapeutic endpoint.*

In postmenopausal women with an intact uterus, a progestin is included to prevent endometrial cancer. Medroxyprogesterone acetate is frequently used in the United States and micronized progesterone is available; norethindrone and norgestrel/levonorgestrel are also commonly used. As progestins may contribute to untoward effects, especially breast cancer and CHD, women without a uterus are administered estrogen alone. Postmenopausal hormone therapy and contraception are the most frequent uses of progestins.

Tamoxifen, a selective estrogen receptor modulator or SERM, is widely used for the adjuvant treatment of breast cancer and for prophylaxis of the disease in high-risk women, but treatment should be limited to 5 years. The drug is most effective in the treatment of estrogen-receptor positive disease, and untoward effects include hot flashes as well as an increase in blood clots and uterine cancer. Another SERM, raloxifene, is used to prevent osteoporosis and decreases the incidence of vertebral fractures in postmenopausal women. Raloxifene does not increase the risk of uterine cancer, but does increase the incidence of thromboembolic events and hot flashes.

The pure estrogen antagonist fulvestrant is also used to treat breast cancer, especially in patients who become refractory to tamoxifen. Another estrogen antagonist, clomiphene, is used to treat infertility in anovulatory women. Both compounds may cause hot flashes.

Aromatase inhibitors, including letrozole, anastrozole, and exemestane, are also highly effective for the adjuvant treatment of breast cancer, and their prophylactic use is being explored. Untoward effects include hot flashes; potential long-term effects of these agents on osteoporosis and bone fractures remain to be established.

Mifepristone is used therapeutically as an anti-progestin for medical abortion, and is administered with a prostaglandin for this purpose.

Estrogens and progestins are widely used as “combination” contraceptives and are 99% effective in preventing ovulation. These combinations are most often used orally, although transdermal preparations, once-monthly injections, and vaginal rings are available. Ethinyl estradiol (or mestranol) and 19-nor steroids such as norgestrel/

levonorgestrel, norethindrone, or another synthetic progestin are commonly used. The greatest concern with these agents is the risk of stroke or other thromboembolic events; consequently, they should not be used in older women (over 35) who smoke or have other risk factors (*e.g.*, hypertension) for cardiovascular disease.

Several progestin-only contraceptives are available, including low-dose pills, long-lasting (*e.g.*, 3-month) depot injections, and subdermal implants (not available in the United States). These agents are also highly efficacious and exert a number of actions, including decreased frequency of ovulation, and effects on cervical mucus, ovum transport, and implantation. They may be used in nursing mothers and in some women with contraindications for combined estrogen-progestin combinations. The most common untoward effect is unpredictable vaginal bleeding.

A levonorgestrel-only pill and high-dose estrogen-progestin oral contraceptives are available and effective for postcoital or emergency contraception within 72 hours of unprotected intercourse. These preparations are ineffective in cases of established pregnancy and should not be used to terminate pregnancy.

ANDROGENS

Peter J. Snyder

TESTOSTERONE AND OTHER ANDROGENS

Synthesis of Testosterone. In men, testosterone is the principal secreted androgen. The Leydig cells synthesize the majority of testosterone by the pathways shown in Figure 58–1. In women, testosterone also is probably the principal androgen and is synthesized both in the corpus luteum and the adrenal cortex by similar pathways. The testosterone precursors androstenedione and dehydroepiandrosterone are weak androgens that can be converted peripherally to testosterone.

Secretion and Transport of Testosterone. The magnitude of testosterone secretion is greater in men than in women at almost all stages of life, a difference that explains almost all other differences between men and women. In the first trimester *in utero*, the fetal testes begin to secrete testosterone, which is the principal factor in male sexual differentiation, probably stimulated by human chorionic gonadotropin (hCG) from the placenta. By the beginning of the second trimester, the value is close to that of midpuberty, about 250 ng/dl (Figure 58–2) (Dawood and Saxena, 1977; Forest, 1975). Testosterone production then falls by the end of the second trimester, but by birth the value is again about 250 ng/dl (Dawood and Saxena, 1977; Forest, 1975), possibly due to stimulation of the fetal Leydig cells by luteinizing hormone (LH) from the fetal pituitary gland. The testosterone value falls again in the first few days after birth, but it rises and peaks again at about 250 ng/dl at 2 to 3 months after birth and falls to <50 ng/dl by 6 months, where it remains until puberty (Forest, 1975). During puberty, from about age 12 to 17 years, the serum testosterone concentration in males increases to a much greater degree than in females, so that by early adulthood the serum testosterone concentration is 500 to 700 ng/dl in men, compared to 30 to 50 ng/dl in women.

The magnitude of the testosterone concentration in the male is responsible for the pubertal changes that further differentiate men from women. As men age, their serum testosterone concentrations gradually decrease, which may contribute to other effects of aging in men.

LH, secreted by the pituitary gonadotropes (*see* Chapter 55), is the principal stimulus of testosterone secretion in men, perhaps potentiated by follicle-stimulating hormone (FSH), also secreted by gonadotropes. The secretion of LH by gonadotropes is positively regulated by hypothalamic gonadotropin-releasing hormone (GnRH), while testosterone directly inhibits LH secretion in a negative feedback loop (*see* Chapter 55). LH is secreted in pulses, which occur approximately every 2 hours and are greater in magnitude in the morning. The pulsatility appears to result from pulsatile secretion of GnRH from the hypothalamus. Pulsatile administration of GnRH to men who are hypogonadal due to hypothalamic disease results in normal LH pulses and testosterone secretion, but continuous administration does not (Crowley *et al.*, 1985). Testosterone secretion is likewise pulsatile and diurnal, with the highest plasma concentrations occurring at about 8 A.M. and the lowest at about 8 P.M. The morning peaks diminish as men age (Bremner *et al.*, 1983).

In women, LH stimulates the corpus luteum (formed from the follicle after release of the ovum) to secrete testosterone. Under normal circumstances, however, estradiol and progesterone, not testosterone, are the principal inhibitors of LH secretion in women. Sex hormone-binding globulin (SHBG) binds about 40% of circulating testosterone with high affinity. Because of this high affinity, testosterone bound to SHBG is unavailable for biological effects. Albumin binds almost 60% of circulating testosterone with low affinity, leaving approximately 2% unbound or free. In some testosterone assays, the latter two components are considered as “bioavailable” testosterone.

Figure 58–1. Pathway of synthesis of testosterone in the Leydig cells of the testes. In Leydig cells, the 11 and 21 hydroxylases (present in adrenal cortex) are absent but CYP17 (17 α -hydroxylase) is present. Thus, androgens and estrogens are synthesized; corticosterone and cortisol are not formed (see Figure 59–3). Bold arrows indicate favored pathways.

Metabolism of Testosterone to Active and Inactive Compounds. Testosterone has many different effects in tissues. One of the mechanisms by which the varied effects are mediated is the metabolism of testosterone to two other active steroids, dihydrotestosterone and estradiol (Figure 58–3). Some effects of testosterone appear to be mediated by testosterone itself, some by dihydrotestosterone, and others by estradiol.

Figure 58–2. Schematic representation of the serum testosterone concentration from early gestation to old age.

The enzyme 5 α -reductase catalyzes the conversion of testosterone to dihydrotestosterone. Although both testosterone and dihydrotestosterone act *via* the androgen receptor, dihydrotestosterone binds with higher affinity (Wilbert *et al.*, 1983) and activates gene expression more efficiently (Deslypere *et al.*, 1992). As a result, testosterone, acting *via* dihydrotestosterone, is able to have effects in tissues that express 5 α -reductase that it could not have if it were present only as testosterone. Two forms of 5 α -reductase have been identified: type I, which is found predominantly in non-genital skin, liver, and bone, and type II, which is found predominantly in urogenital tissue in men and genital skin in men and women. The effects of dihydrotestosterone in these tissues are described below.

The enzyme complex aromatase (CYP19), which is present in many tissues, especially the liver and adipose tissue, catalyzes the conversion of testosterone to estradiol. This conversion results in approximately 85% of circulating estradiol in men; the remainder is secreted directly by the testes, probably the Leydig cells (MacDonald *et al.*, 1979). The effects of testosterone thought to be mediated *via* estradiol are described below.

Testosterone is metabolized in the liver to androsterone and etiocholanolone (Figure 58–3), which are biologically inactive. Dihydrotestosterone is metabolized to androsterone, androstenedione, and androstenediol.

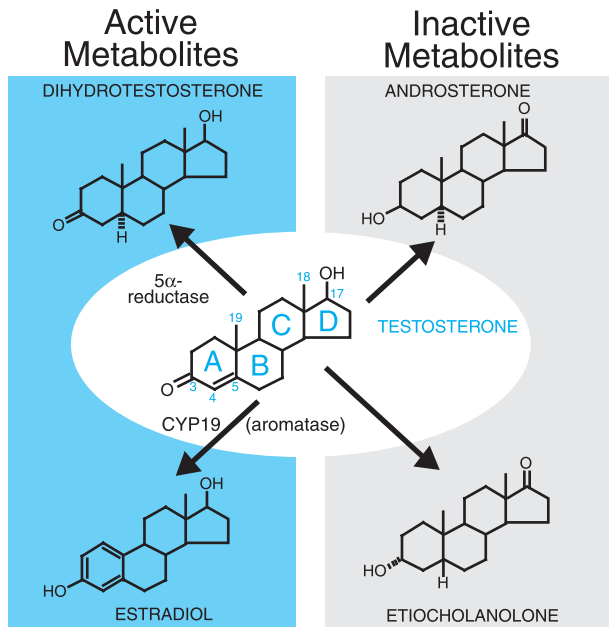

Figure 58–3. Metabolism of testosterone to its major active and inactive metabolites.

Physiological and Pharmacological Effects of Androgens

The biological effects of testosterone can be considered by the receptor it activates and by the tissues in which

effects occur at various stages of life. Testosterone can act as an androgen either directly, by binding to the androgen receptor, or indirectly by conversion to dihydrotestosterone, which binds to the androgen receptor even more avidly than testosterone. Testosterone also can act as an estrogen by conversion to estradiol, which binds to the estrogen receptor (Figure 58–4).

Effects That Occur via the Androgen Receptor. Testosterone and dihydrotestosterone act as androgens via a single androgen receptor (Figure 58–5). The androgen receptor—officially designated NR3A—is a member of the nuclear receptor superfamily (steroid hormone receptors, thyroid hormone receptors, and orphan receptors). The androgen receptor is comprised of an amino-terminal domain, a DNA-binding domain, and a ligand-binding domain. Testosterone and dihydrotestosterone bind to the ligand-binding domain, causing a conformational change in the receptor that allows the ligand-receptor complex to translocate to the nucleus and bind via the DNA-binding domain to androgen response elements on certain responsive genes. The ligand-receptor complex acts as a transcription factor complex and stimulates expression of those genes (Brinkman and Trapman, 2000).

The mechanisms by which androgens have different actions in diverse tissues have become clearer in recent years. One mechanism is the higher affinity with which dihydrotestosterone binds to and activates the androgen

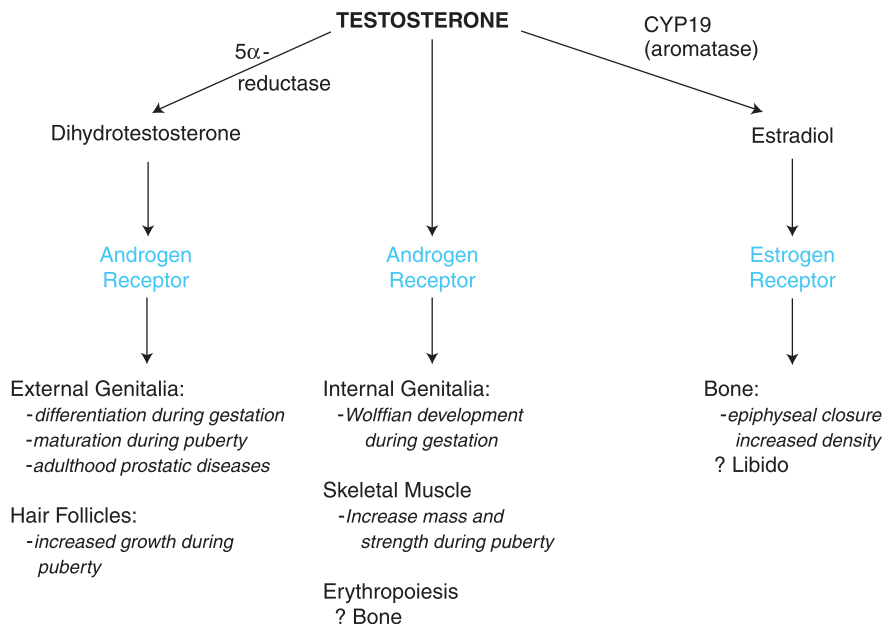

Figure 58–4. Direct effects of testosterone and effects mediated indirectly via dihydrotestosterone or estradiol.

Figure 58–5. Structure of the androgen receptor.

receptor compared to testosterone (Deslypere *et al.*, 1992; Wilbert *et al.*, 1983). Another mechanism involves transcription co-factors, both co-activators and co-repressors, which are tissue-specific. At this time, the roles of co-factors are better described for other nuclear receptors than for the androgen receptor (Smith and O'Malley, 2004).

The importance of the androgen receptor is illustrated by the consequences of its mutations. Predictably, mutations that either alter the primary sequence of the protein or cause a single amino-acid substitution in the hormone- or DNA-binding domains result in resistance to the action of testosterone, beginning *in utero* (McPhaul and Griffin, 1999). Male sexual differentiation therefore is incomplete, as is pubertal development.

Another kind of mutation occurs in patients who have spinal and bulbar muscular atrophy, known as Kennedy's disease. These patients have an expansion of the CAG repeat, which codes for glutamine, at the amino terminus of the molecule (Walcott and Mery, 2002). The result is very mild androgen resistance, manifest principally by gynecomastia (Dejager *et al.*, 2002), but progressively severe motor neuron atrophy. The mechanism by which the neuron atrophy occurs is unknown, but similar trinucleotide repeats are associated with a number of other neurological disorders (Masino and Pastore, 2002).

Other kinds of androgen receptor mutations may explain why prostate cancer that is treated by androgen deprivation eventually becomes androgen-independent. Prostate cancer is initially at least partially androgen-sensitive, which is the basis for the initial treatment of metastatic prostate cancer by androgen deprivation. Metastatic prostate cancer often regresses initially in response to this treatment, but then becomes unresponsive to continued deprivation. The androgen receptor not only continues to be expressed in androgen-independent prostate cancer, but its signaling remains active, as indicated by expression of the androgen receptor–dependent prostate-specific antigen. It has been postulated that these observations can be explained by mutations in the androgen receptor gene or changes in androgen receptor co-regulatory proteins (Heinlein and Chang, 2004; Taplin and Balk, 2004).

Effects That Occur via the Estrogen Receptor. The effects of testosterone on at least one tissue are mediated by its conversion to estradiol, catalyzed by the CYP19 enzyme complex (Figures 58–3 and 58–4). In the rare cases in which a male does not express CYP19 (Carani *et al.*, 1997; Morishima *et al.*, 1995) or the estrogen receptor (Smith *et al.*, 1994), the epiphyses do not fuse and long-bone growth continues indefinitely. In addition, the patients are osteoporotic. Administration of estradiol cor-

rects the bone abnormalities in patients with CYP19 deficiency (Bilizekian *et al.*, 1998), but not in those with an estrogen-receptor defect. Because men have larger bones than women, and bone cells express the androgen receptor (Colvard *et al.*, 1989), testosterone also may have an effect on bone *via* the androgen receptor. Administration of estradiol to a man with CYP19 deficiency increased his libido (Carani *et al.*, 1997), suggesting that the effect of testosterone on male libido may be mediated by conversion to estradiol.

Effects of Androgens at Different Stages of Life. In Utero. When the fetal testes, stimulated by human chorionic gonadotropin, begin to secrete testosterone at about the eighth week of gestation, the high local concentration of testosterone around the testes stimulates the nearby wolffian ducts to differentiate into the male internal genitalia: the epididymis, vas deferens, and seminal vesicles. Farther away, in the anlage of the external genitalia, testosterone is converted to dihydrotestosterone, which causes the development of the male external genitalia—the penis, scrotum—and the prostate. The increase in testosterone at the end of gestation may result in further phallic growth.

Infancy. The consequences of the increase in testosterone secretion by the testes during the first few months of life are not yet known.

Puberty. Puberty in the male begins at a mean age of 12 years with an increase in the secretion of FSH and LH from the gonadotropes, stimulated by increased secretion of GnRH from the hypothalamus. The increased secretion of FSH and LH stimulates the testes, so, not surprisingly, the first sign of puberty is an increase in testicular size. The increase in testosterone production by Leydig cells, along with the effect of FSH on the Sertoli cells, stimulates the development of the seminiferous tubules, which eventually produce mature sperm. Increased secretion of testosterone into the systemic circulation affects many tissues simultaneously, and the changes in most of them occur gradually during the course of several years. The phallus enlarges in length and width, the scrotum becomes rugated, and the prostate begins secreting the fluid it contributes to the semen. The skin becomes coarser and oilier due to increased sebum production, which contributes to the development of acne. Sexual hair begins to grow, initially pubic and axillary hair, then hair on the lower legs, and finally other body hair and facial hair. Full development of the latter two may not occur until 10 years after the start of puberty and marks the completion of puberty. Muscle mass and strength increase, especially of the shoulder girdle, and subcutaneous fat decreases. Epiphyseal bone growth accelerates, resulting in the pubertal growth spurt, but epiphyseal maturation leads eventually to a slowing and then cessation of growth. Bones also become thicker. The increase in the mass of muscle and bone results in a pronounced increase in body weight. Erythropoiesis increases, resulting in higher hematocrit and hemoglobin concentrations in men than boys or women. The larynx thickens, resulting in a lower voice. Libido develops.

Other changes may result from the increase in testosterone during puberty. Men tend to have a better sense of spatial relations than do women and to exhibit behavior that differs in some ways from that of women, including being more aggressive.

Adulthood. The serum testosterone concentration and the characteristics of the adult male are largely maintained during early

adulthood and midlife. One change during this time is the gradual development of male pattern baldness, beginning with recession of hair at the temples and the vertex.

Two changes that can occur in the prostate gland during adulthood are of much greater medical significance. One is the gradual development of benign prostatic hyperplasia, which occurs to a variable degree in almost all men, sometimes obstructing urine outflow by compressing the urethra as it passes through the prostate. This development is mediated by the conversion of testosterone to dihydrotestosterone by 5α -reductase II within prostatic cells (Wilson, 1980).

The other change that can occur in the prostate during adulthood is the development of cancer. Although no direct evidence suggests that testosterone causes the disease, prostate cancer is dependent on testosterone, at least to some degree and at some time in its course. This dependency is the basis of treating metastatic prostate cancer by lowering the serum testosterone concentration (Iversen *et al.*, 1990) or by blocking its action.

Senescence. As men age, the serum testosterone concentration gradually declines (Figure 58–2), and the sex hormone-binding globulin concentration gradually increases, so that by age 80, the total testosterone concentration is approximately 80% and the free testosterone is approximately 40% of that present at age 20 (Harman *et al.*, 2001). This fall in serum testosterone could contribute to several other changes that occur with increasing age in men, including decreases in energy, libido, muscle mass (Forbes, 1976) and strength (Murray *et al.*, 1980), and bone mineral density (Riggs *et al.*, 1982). A causal role is suggested by the occurrence of similar changes seen in men who develop hypogonadism due to disease at a younger age, as discussed below.

Consequences of Androgen Deficiency

The consequences of androgen deficiency depend on the stage of life during which the deficiency first occurs and on the degree of the deficiency.

During Fetal Development. Testosterone deficiency in a male fetus during the first trimester *in utero* causes incomplete sexual differentiation. Testosterone deficiency in the first trimester results only from testicular disease, such as deficiency of CYP17 (17α -hydroxylase); deficiency of LH secretion because of pituitary or hypothalamic disease does not result in testosterone deficiency during the first trimester, presumably because Leydig cell secretion of testosterone at that time is regulated by placental hCG. Complete deficiency of testosterone secretion results in entirely female external genitalia; less severe testosterone deficiency results in incomplete virilization of the external genitalia proportionate to the degree of deficiency. Testosterone deficiency at this stage of development also leads to failure of the wolffian ducts to differentiate into the male internal genitalia, such as the vas deferens and seminal vesicles, but the müllerian ducts do not differentiate into the female internal genitalia as long as testes are present and secrete müllerian inhibitory substance. Similar changes occur if testosterone is secreted normally, but its action is

diminished because of an abnormality of the androgen receptor or of 5α -reductase. Abnormalities of the androgen receptor can have quite varied effects. The most severe form results in complete absence of androgen action and a female phenotype; moderately severe forms result in partial virilization of the external genitalia; and the mildest forms permit normal virilization *in utero* and result only in impaired spermatogenesis in adulthood (McPhaul and Griffin, 1999). Abnormal 5α -reductase results in incomplete virilization of the external genitalia *in utero* but normal development of the male internal genitalia, which requires only testosterone (Wilson *et al.*, 1993).

Testosterone deficiency during the third trimester, caused either by a testicular disease or a deficiency of fetal LH secretion, has two known consequences. First, the phallus fails to grow normally. The result, called micropallus, is a common occurrence in boys later discovered to be unable to secrete LH due to abnormalities of GnRH synthesis. Second, the testes fail to descend into the scrotum; this condition, called cryptorchidism, occurs commonly in boys whose LH secretion is subnormal (*see* Chapter 55).

Before Completion of Puberty. When a boy can secrete testosterone normally *in utero* but loses the ability to do so before the anticipated age of puberty, the result is failure to complete puberty. All of the pubertal changes described above, including those of the external genitalia, sexual hair, muscle mass, voice, and behavior, are impaired to a degree proportionate to the abnormality of testosterone secretion. In addition, if growth hormone secretion is normal when testosterone secretion is subnormal during the years of expected puberty, the long bones continue to lengthen because the epiphyses do not close. The result is longer arms and legs relative to the trunk; these proportions are referred to as eunuchoid. Another consequence of subnormal testosterone secretion during the age of expected puberty is enlargement of glandular breast tissue (gynecomastia).

After Completion of Puberty. When testosterone secretion becomes impaired after puberty is completed, regression of the pubertal effects of testosterone depends on both the degree and the duration of testosterone deficiency. When the degree of testosterone deficiency is substantial, libido and energy decrease within a week or two, but other testosterone-dependent characteristics decline more slowly. A clinically detectable decrease in muscle mass in an individual does not occur for several years. A pronounced decrease in hematocrit and hemoglobin will occur within several months. A decrease in bone mineral density probably can be detected by dual-energy x-ray absorptiometry within 2 years, but an increase in fracture incidence would not be likely to occur for many years. A loss of sexual hair takes many years.

In Women. Loss of androgen secretion in women results in a decrease in sexual hair, but not for many years. Androgens may have other important effects in women, and the loss of androgens (especially with the severe loss of ovarian and adrenal androgens that occurs in panhypopituitarism) would result in the loss of these effects. Testosterone preparations that can yield serum testosterone concentrations in the physiological range in women currently are being developed. The availability of such preparations will allow clinical trials to determine if testosterone replacement in androgen-deficient women improves their libido, energy, muscle mass and strength, and bone mineral density.

Therapeutic Androgen Preparations

The need for a creative approach to pharmacotherapy with androgens arises from the fact that ingestion of testosterone is not an effective means of replacing testosterone deficiency. Even though ingested testosterone is readily absorbed into the hepatic circulation, rapid hepatic metabolism ensures that hypogonadal men generally cannot ingest testosterone in sufficient amounts and with sufficient frequency to maintain a normal serum concentration. Therefore most pharmaceutical preparations of androgens are designed to bypass hepatic metabolism of testosterone.

Testosterone Esters. Esterifying a fatty acid to the 17α hydroxyl group of testosterone creates a compound that is even more lipophilic than testosterone itself. When an ester, such as *testosterone enanthate (heptanoate)* (Figure 58–6) or *cypionate (cyclopentylpropionate)* is dissolved in oil and administered intramuscularly every 2 weeks to hypogonadal men, the ester hydrolyzes *in vivo* and results in serum testosterone concentrations that range from higher-than-normal in the first few days after the injection to low-normal just before the next injection (Snyder and Lawrence, 1980) (Figure 58–7). Attempts to decrease the frequency of injections by increasing the amount of each injection result in wider fluctuations and poorer therapeutic outcomes. The undecanoate ester of testosterone (Figure 58–6), when dissolved in oil and ingested orally, is absorbed into the lymphatic circulation, thus bypassing initial hepatic metabolism. *Testosterone undecanoate* in oil also can be injected and produces stable serum testosterone concentrations for a month (Zhang *et al.*, 1998). The undecanoate ester of testosterone is not currently marketed in the United States.

Alkylated Androgens. Adding an alkyl group to the 17α position of testosterone (Figure 58–6) retards hepatic metabolism of the compound. Consequently, 17α -alkylated androgens are androgenic when administered orally;

however, they are less androgenic than testosterone itself, and they cause hepatotoxicity (Cabasso, 1994; Petera *et al.*, 1962), whereas native testosterone does not.

Transdermal Delivery Systems. Recent attempts to avoid the first-pass inactivation of testosterone by the liver have employed novel delivery systems; chemicals called excipients are used to facilitate the absorption of native testosterone across the skin in a controlled fashion. These transdermal preparations provide more stable serum testosterone concentrations than do injections of testosterone esters. The first such preparations were patches, one of which (ANDRODERM) is still available (Dobs *et al.*, 1999). Newer preparations include gels (ANDROGEL, TESTIM) (Marbury *et al.*, 2003; Swerdloff *et al.*, 2000) and a buccal tablet (STRIANT). These preparations produce mean serum testosterone concentrations within the normal range in hypogonadal men (Figure 58–7).

Attempts to Design Selective Androgens

Alkylated Androgens. Decades ago, investigators attempted to synthesize analogs of testosterone that possessed greater anabolic effects than androgenic effects compared to native testosterone. Several compounds appeared to have such differential effects, based on a greater effect on the levator ani muscle compared to the ventral prostate of the rat. These compounds were called anabolic steroids, and most are 17α -alkylated androgens. None of these compounds, however, has been convincingly demonstrated to have such a differential effect in human beings. Nonetheless, they have enjoyed popularity among athletes who seek to enhance their performance, as described below. Another alkylated androgen, 7α -methyl-19-nortestosterone, is poorly converted to dihydrotestosterone (Kumar *et al.*, 1992).

Selective Androgen Receptor Modulators. Stimulated by the development of selective estrogen receptor modulators, which have estrogenic effects in some tissues but not others (*see* Chapter 57), investigators are attempting to develop selective androgen receptor modulators. Indeed, it would be desirable to produce effects of testosterone in some tissues, such as muscle and bone, while avoiding the undesirable effects in other tissues, such as the prostate. Nonsteroidal molecules have been developed that bind to the androgen receptor, and when administered to castrated rats, stimulate the growth of the levator ani more than the prostate (Hanada *et al.*, 2003; Yin *et al.*, 2003). One molecule also improved several properties of bone (Hanada *et al.*, 2003). No human studies have yet been reported.

Therapeutic Uses of Androgens

Male Hypogonadism. The best-established indication for administration of androgens is for the treatment of

Testosterone (HISTERONE, others)

Testosterone Esters

Testosterone enanthate
(DELATESTRYL, others)

Testosterone cypionate
(DEPO-TESTOSTERONE, others)

Testosterone undecanoate
(ANDRIOL)

17 α -Alkylated Androgens

Methyltestosterone
(ORETIN METHYL, others)

Oxandrolone
(OXANDRIN)

Stanozolol
(WINSTROL)

Fluoxymesterone
(HALOTESTIN)

Danazol
(DANOCRINE)

Other

7 α -Methyl-19-nortestosterone

Tetrahydrogestrinone

Figure 58-6. Structures of some androgens available for therapeutic use.

male hypogonadism (testosterone deficiency in men). Any of the transdermal testosterone preparations or testosterone esters described above can be used to treat tes-

tosterone deficiency. Monitoring treatment for beneficial and deleterious effects differs somewhat in adolescents and the elderly from that in other men.

Figure 58-7. Pharmacokinetic profiles of three testosterone preparations during their chronic administration to hypogonadal men. Doses of each were given at time 0. Dashed lines indicate range of normal levels. (A. Adapted from Snyder and Lawrence, 1980; B. Dobs *et al.*, 1999; and C. Swerdloff *et al.*, 2000.)

Monitoring for Efficacy. The goal of testosterone therapy for a hypogonadal man is to mimic as closely as possible the normal serum concentration; therefore, serum testosterone concentration must be monitored during treatment. When the serum testosterone concentration is measured depends on the testosterone preparation used. With transdermal patches (*e.g.*, ANDRODERM), the serum testosterone concentration fluctuates during the 24-hour wearing period, with a peak value 6 to 9 hours after application and a nadir (about 50% of the peak) just before the next patch is applied (Dobs *et al.*, 1999). With testosterone gels, the mean serum testosterone concentration is relatively constant from one application to the next (Marbury *et al.*, 2003; Swerdloff *et al.*, 2000). Occasional random fluctuations can occur, however, so measurements should be repeated for any dose. When the enanthate or cypionate esters of testosterone are administered once every 2 weeks, the serum testosterone concentration measured midway between doses should be normal; if not, the dosage schedule should be adjusted accordingly. If testosterone deficiency results from testicular disease, as indicated by an elevated serum LH concentration, adequacy of testosterone treatment also can be judged indirectly by the normalization of LH within 2 months of treatment initiation (Findlay *et al.*, 1989; Snyder and Lawrence, 1980).

Normalization of the serum testosterone concentration induces normal virilization in prepubertal boys and restores virilization in men who became hypogonadal as adults. Within a few months, and often sooner, libido, energy, and hematocrit return to normal. Within 6 months, muscle mass increases and fat mass decreases. Bone density, however, continues to increase for 2 years (Snyder *et al.*, 2000).

Monitoring for Deleterious Effects. When testosterone itself is administered, as in one of the transdermal preparations or as an ester that is hydrolyzed to testosterone, it has no “side effects” (*i.e.*, no effects that endogenously secreted testosterone does not have), as long as the dose is not excessive. Modified testosterone compounds, such as the 17 α -alkylated androgens, do have undesirable effects even when dosages are targeted at physiologic replacement. Some of these undesirable effects occur shortly after testosterone administration is initiated, whereas others usually do not occur until administration has been continued for many years. Raising the serum testosterone concentration from prepubertal or midpubertal levels to that of an adult male at any age can result in undesirable effects similar to those that occur during puberty, including acne, gynecomastia, and more aggressive sexual behavior. Physiological amounts of testosterone do not appear to affect serum lipids or apolipoproteins. Replacement of physiological levels of testosterone may occasionally have undesirable effects in the presence of concomitant illnesses. For example, stimulation of erythropoiesis would increase the hematocrit from subnormal to normal in a healthy man, but would raise the hematocrit above normal in a man with a predisposition to erythrocytosis, such as in chronic pulmonary disease. Similarly, the mild degree of sodium and water retention seen with testosterone replacement would have no clinical effect in a healthy man, but would exacerbate pre-existing congestive heart failure. If the testosterone dose is excessive, erythrocytosis, and uncommonly, salt and water retention and peripheral edema occur, even in men who have no predisposition to these conditions. When a man’s serum testosterone concentration has been in the normal adult male range for many years, whether from endogenous secretion or exogenous administration, and he is older than 40, he is subject to certain testosterone-dependent diseases, including benign prostatic hyperplasia and prostate cancer.

The principal side effects of the 17 α -alkylated androgens are hepatic, including cholestasis, and uncommonly, peliosis hepatis, blood-filled hepatic cysts. Hepatocellular cancer has been reported rarely. Case reports of cancer regression after androgen cessation suggest a possible causal role, but an etiologic link is unproven. The

17 α -alkylated androgens, especially in large amounts, may lower serum HDL cholesterol.

Monitoring at the Anticipated Time of Puberty.

Administration of testosterone to testosterone-deficient boys at the anticipated time of puberty should be guided by the considerations above, but also by the fact that testosterone accelerates epiphyseal maturation, leading initially to a growth spurt but then to epiphyseal closure and permanent cessation of linear growth. Consequently, the height and growth-hormone status of the boy must be considered. Boys who are short because of growth-hormone deficiency should be treated with growth hormone before their hypogonadism is treated with testosterone.

Male Senescence. Preliminary evidence suggests that increasing the serum testosterone concentration of men whose serum levels are subnormal for no reason other than their age will increase their bone mineral density and lean mass and decrease their fat mass (Amory *et al.*, 2004; Kenny *et al.*, 2001; Snyder *et al.*, 1999a; Snyder *et al.*, 1999b). However, it is entirely uncertain at this time if such treatment will worsen benign prostatic hyperplasia or increase the incidence of clinically detectable prostate cancer.

Female Hypogonadism. It remains to be determined if increasing the serum testosterone concentrations of women whose serum testosterone concentrations are below normal will improve their libido, energy, muscle mass and strength, or bone mineral density.

Enhancement of Athletic Performance. Some athletes take drugs, including androgens, to attempt to improve their performance. Because androgens taken for this purpose usually are taken surreptitiously, information about their possible effects is not as reliable as that for androgens taken for treatment of male hypogonadism.

Kinds of Androgens Used. Virtually all androgens produced for human or veterinary purposes have been taken by athletes. When use by athletes began more than two decades ago, the favored compounds were 17 α -alkylated androgens and other compounds that were thought to have greater anabolic effects than androgen effects relative to testosterone (so-called “anabolic steroids”). Because these compounds can be detected readily by organizations that govern athletic competitions, preparations that increase the serum concentration of testosterone itself, such as the testosterone esters or human chorionic gonadotropin, have increased in popularity. Testosterone precursors, such as androstenedione and dehydroepiandrosterone (DHEA), also have increased in popularity recently because they are considered nutritional supplements and thus are not regulated by national governments or athletic organizations.

A new development in use of androgens by athletes is represented by tetrahydrogestrinone (THG), a potent androgen (Death *et al.*,

2004) that appears to have been designed and synthesized in order to avoid detection by anti-doping laboratories on the basis of its novel structure (Figure 58–6) and rapid metabolism.

Efficacy. There have been few controlled studies of the effects of pharmacological doses of androgens on muscle strength. In one controlled study, 43 normal young men were randomized to one of four groups: strength training with either 600 mg of testosterone enanthate once a week (more than six times the replacement dose) or placebo; or no exercise with either testosterone or placebo. The men who received testosterone experienced an increase in muscle strength compared to those who received placebo, and the men who exercised simultaneously experienced even greater increases (Bhasin *et al.*, 1996). In another study, normal young men were treated with a GnRH analog to reduce endogenous testosterone secretion severely and in a random, blinded fashion, weekly doses of testosterone enanthate from 25 mg to 600 mg. There was a dose-dependent effect of testosterone on muscle strength (Bhasin *et al.*, 2001).

In a double-blind study of androstenedione, men who took 100 mg three times a day for 8 weeks did not experience an increase in muscle strength compared to men who took placebo. Failure of this treatment to increase muscle strength is not surprising, because it also did not increase the mean serum testosterone concentration (King *et al.*, 1999).

Side Effects. All androgens suppress gonadotropin secretion when taken in high doses and thereby suppress endogenous testicular function. This decreases endogenous testosterone and sperm production, resulting in diminished fertility. If administration continues for many years, testicular size may diminish. Testosterone and sperm production usually return to normal within a few months of discontinuation but may take longer. High doses of androgens also cause erythrocytosis (Drinka *et al.*, 1995).

When administered in high doses, androgens that can be converted to estrogens, such as testosterone, cause gynecomastia. Androgens whose A rings have been modified so that they cannot be aromatized, such as dihydrotestosterone, do not cause gynecomastia, even in high doses.

The 17 α -alkylated androgens are the only androgens that cause hepatotoxicity. When administered at high doses, these androgens are more likely than others to affect serum lipid concentrations, specifically to decrease high-density lipoprotein (HDL) cholesterol and increase low-density lipoprotein (LDL) cholesterol. Other side effects have been suggested by many anecdotes but have not been confirmed, including psychological disorders and sudden death due to cardiac disease, possibly related to changes in lipids or to coagulation activation.

Certain side effects occur specifically in women and children. Both experience virilization, including facial and body hirsutism, temporal hair recession in a male pattern, and acne. Boys experience phallic enlargement, and women experience clitoral enlargement. Boys and girls whose epiphyses have not yet closed experience premature closure and stunting of linear growth.

Male Contraception. As discussed above, androgens inhibit LH secretion by the pituitary and thereby decrease endogenous testosterone production. Based on these observations, scientists have tried for more than a decade to use androgens—either alone or in combination with other drugs—as a male contraceptive. Because the concentration of testosterone within the testes, approximately one hundred times that in the peripheral circulation, is necessary for spermatogenesis, suppression of endogenous testosterone production greatly diminishes spermatogenesis. Initial use of testosterone alone, however, required supraphysiologic doses, and addition of GnRH agonists required daily injections. A more promising approach is the combination of a progestin with a physiological dose of testosterone to suppress LH secretion and spermatogenesis,

but provide a normal serum testosterone concentration (Bebb *et al.*, 1996). A recent trial employed injections of testosterone undecanoate with a depot progestin every 2 months (Gu *et al.*, 2004). Another androgen being tested as part of a male contraceptive regimen is 7 α -methyl-19-nortestosterone, a synthetic androgen that cannot be metabolized to dihydrotestosterone (Cummings *et al.*, 1998).

Catabolic and Wasting States. Testosterone, because of its anabolic effects, has been used in attempts to ameliorate catabolic and muscle-wasting states, but this has not been generally effective. One exception is in the treatment of muscle wasting associated with acquired immunodeficiency syndrome (AIDS), which often is accompanied by hypogonadism. Treatment of men with AIDS-related muscle wasting and subnormal serum testosterone concentrations increases their muscle mass and strength (Bhasin *et al.*, 2000).

Angioedema. Chronic androgen treatment of patients with angioedema effectively prevents attacks. The disease is caused by hereditary impairment of C1-esterase inhibitor or acquired development of antibodies against it (Cicardi *et al.*, 1998). The 17 α -alkylated androgens, such as *stanozolol* and *danazol*, stimulate the hepatic synthesis of the esterase inhibitor. In women, virilization is a potential side effect. In children, virilization and premature epiphyseal closure prevent chronic use of androgens for prophylaxis, although they are used occasionally to treat acute episodes.

Blood Dyscrasias. Androgens once were employed to attempt to stimulate erythropoiesis in patients with anemias of various etiologies, but the availability of erythropoietin has supplanted that use. Androgens such as *danazol* still are used occasionally as adjunctive treatment for hemolytic anemia and idiopathic thrombocytopenic purpura that are refractory to first-line agents.

ANTI-ANDROGENS

Because some effects of androgens are undesirable, at least under certain circumstances, agents have been developed specifically to inhibit androgen synthesis or effects. Other drugs, originally developed for different purposes, have been accidentally found to be anti-androgens and now are used intentionally for this indication.

Inhibitors of Testosterone Secretion. Both agonists and antagonists of the GnRH receptor are used to reduce testosterone secretion. Analogs of GnRH effectively inhibit testosterone secretion by inhibiting LH secretion. GnRH “superactive” analogs, given repeatedly, down-regulate the GnRH receptor and are available for treatment of prostate cancer. An extended-release form of the GnRH antagonist *abarelix* (PLENAXIS) is approved for treating prostate cancer (Trachtenberg *et al.*, 2002). Because *abarelix* does not transiently increase sex steroid production, this preparation may be especially useful in prostate cancer patients in whom any stimulus to tumor growth might have serious adverse consequences, such as patients

with spinal cord metastases in whom increased tumor growth could cause paralysis (*see* Chapter 55).

Some antifungal drugs of the imidazole family, such as ketoconazole (*see* Chapter 48), inhibit CYPs and thereby block the synthesis of steroid hormones, including testosterone and cortisol. Because they may induce adrenal insufficiency and are associated with hepatotoxicity, these drugs generally are not used to inhibit androgen synthesis, but sometimes are employed in cases of glucocorticoid excess (*see* Chapter 59).

Inhibitors of Androgen Action

These drugs inhibit the binding of androgens to the androgen receptor or inhibit 5 α -reductase.

Androgen Receptor Antagonists. *Flutamide*, *Bicalutamide*, and *Nilutamide*. These relatively potent androgen receptor antagonists have limited efficacy when used alone because the increased LH secretion stimulates higher serum testosterone concentrations. They are used primarily in conjunction with a GnRH analog in the treatment of metastatic prostate cancer. In this situation, they block the action of adrenal androgens, which are not inhibited by GnRH analogs. Survival rates in groups of patients with metastatic prostate cancer treated with a combination of a GnRH agonist and *flutamide* (EULEXIN), *bicalutamide* (CASODEX), or *nilutamide* (NILANDRON) are similar to one another (Schellhammer *et al.*, 1995) and to survival rates in those treated by castration (Iversen *et al.*, 1990). *Bicalutamide* is replacing *flutamide* for this purpose because it appears to have less hepatotoxicity and is taken once a day instead of three times a day. *Nilutamide* appears to have worse side effects than *flutamide* and *bicalutamide* (Dole and Holdsworth, 1997). *Flutamide* also has been used to treat hirsutism in women, and it appears to be as effective as any other treatment for this purpose (Venturoli *et al.*, 1999). However, the association with hepatotoxicity warrants cautions against its use for this cosmetic purpose.

Spironolactone. *Spironolactone* (ALDACTONE) (see Chapter 28) is an inhibitor of aldosterone that also is a weak antagonist at the androgen receptor and a weak inhibitor of testosterone synthesis, apparently inhibiting CYP17. When used to treat fluid retention or hypertension in men, gynecomastia is a common side effect (Camino-Torres *et al.*, 1977). In part because of this adverse effect, the selective mineralocorticoid receptor antagonist *epleronone* (INSPIRA) recently was launched in the United States. Spironolactone is approved by the FDA for treating hirsutism in women, for which it is moderately effective (Cumming *et al.*, 1982); however, it may cause irregular menses.

Cyproterone Acetate. *Cyproterone acetate* is a progestin and a weak anti-androgen by virtue of binding to the androgen receptor. It is moderately effective in reducing hirsutism alone or in combination with an oral contraceptive (Venturoli *et al.*, 1999), but it is not approved for use in the United States.

5 α -Reductase Inhibitors. *Finasteride* (PROSCAR) is an antagonist of 5 α -reductase, especially type II; *dutasteride* (AVODART) is an antagonist of types I and II; both drugs block the conversion of testosterone to dihydrotestosterone, especially in the male external genitalia. These agents were developed to treat benign prostatic hyperplasia, and they are approved in the United States and many other countries for this purpose. When they are administered to men with moderately severe symptoms due to obstruction of urinary tract outflow, serum and prostatic concentrations of dihydrotestosterone decrease, prostatic volume decreases, and urine flow rate increases (McConnell *et al.*, 1998; Roehrborn *et al.*, 2004; Clark *et al.*, 2004). Impotence is a well-documented, albeit infrequent, side effect of this use, although the mechanism is not understood. Finasteride also is approved for use in the treatment of male pattern baldness under the trade name PROPECIA, even though that effect is presumably mediated *via* type I 5 α -reductase. Finasteride appears to be as effective as flutamide and the combination of estrogen and cyproterone in the treatment of hirsutism (Venturoli *et al.*, 1999).

ADRENOCORTICOTROPIC HORMONE; ADRENOCORTICAL STEROIDS AND THEIR SYNTHETIC ANALOGS; INHIBITORS OF THE SYNTHESIS AND ACTIONS OF ADRENOCORTICAL HORMONES

Bernard P. Schimmer and Keith L. Parker

Adrenocorticotrophic hormone (ACTH, also called corticotropin) and the steroid hormone products of the adrenal cortex are considered together because the major physiological and pharmacological effects of ACTH result from its action to increase the circulating levels of adrenocortical steroids. Synthetic derivatives of ACTH are used principally in the diagnostic assessment of adrenocortical function. Because all known therapeutic effects of ACTH can be achieved with corticosteroids, synthetic steroid hormones generally are used therapeutically instead of ACTH.

Corticosteroids and their biologically active synthetic derivatives differ in their metabolic (glucocorticoid) and electrolyte-regulating (mineralocorticoid) activities. These agents are employed at physiological doses for replacement therapy when endogenous production is impaired. In addition, glucocorticoids potently suppress inflammation, and their use in a variety of inflammatory and autoimmune diseases makes them among the most frequently prescribed classes of drugs. Because they exert effects on almost every organ system, the clinical use of and withdrawal from corticosteroids are complicated by a number of serious side effects, some of which are life-threatening. Therefore, the decision to institute therapy with corticosteroids always requires careful consideration of the relative risks and benefits in each patient.

Agents that inhibit steps in the steroidogenic pathway and thus alter the biosynthesis of adrenocortical steroids are discussed, as are synthetic steroids that inhibit glucocorti-

coid action. Agents that inhibit the action of aldosterone are presented in Chapter 28; agents used to inhibit growth of steroid-dependent tumors are discussed in Chapter 51.

History. Addison described fatal outcomes in patients with adrenal destruction in a presentation to the South London Medical Society in 1849. These studies were soon extended when Brown-Séquard demonstrated that bilateral adrenalectomy was fatal in laboratory animals. It later was shown that the adrenal cortex, rather than the medulla, was essential for survival in these experiments. Further studies demonstrated that the adrenal cortex regulated both carbohydrate metabolism and fluid and electrolyte balance. Studies of the factors that regulated carbohydrate metabolism (termed *glucocorticoids*) culminated with the synthesis of *cortisone*, the first pharmacologically effective glucocorticoid to become readily available. Subsequently, Tate and colleagues isolated and characterized a distinct corticosteroid, *aldosterone*, which potently affected fluid and electrolyte balance and therefore was termed a *mineralocorticoid*. The isolation of distinct corticosteroids that regulated carbohydrate metabolism or fluid and electrolyte balance led to the concept that the adrenal cortex comprises two largely independent units: an outer zone that produces mineralocorticoids and an inner region that synthesizes glucocorticoids and androgen precursors.

Studies of adrenocortical steroids also played a key part in delineating the role of the anterior pituitary in endocrine function. As early as 1912, Cushing described patients with hypercorticism, and later recognized that pituitary basophilism caused the adrenal overactivity, thus establishing the link between the anterior pituitary and adrenal function. These studies led to the purification of ACTH and the determination of its chemical structure. ACTH was further shown to be essential for maintaining the structural integrity and steroidogenic capacity of the inner cortical zones. Harris established the role of the hypothalamus in pituitary control and postulated that

a soluble factor produced by the hypothalamus activated ACTH release. These investigations culminated with the determination of the structure of corticotropin-releasing hormone (CRH), a hypothalamic peptide that regulates secretion of ACTH from the pituitary.

Shortly after synthetic cortisone became available, Hench and colleagues demonstrated its dramatic effect in the treatment of rheumatoid arthritis. These studies set the stage for the clinical use of corticosteroids in a wide variety of diseases, as discussed below.

ADRENOCORTICOTROPIC HORMONE (ACTH; CORTICOTROPIN)

As summarized in Figure 59–1, ACTH is synthesized as part of a larger precursor protein, pro-opiomelanocortin (POMC), and is liberated from the precursor through proteolytic cleavage at dibasic residues by the enzyme prohormone convertase 1 (*see* Chapter 21). Impaired processing of POMC due to a mutation in prohormone convertase 1 has been implicated in the pathogenesis of a human disorder that presents with adrenal insufficiency, childhood obesity, hypogonadotropic hypogonadism, and diabetes. A number of other biologically important peptides, including endorphins, lipotropins, and the melanocyte-stimulating hormones (MSH), also are produced from the same POMC precursor.

Human ACTH is a peptide of 39 amino acids (Figure 59–1). Whereas removal of a single amino acid at the amino terminus considerably impairs biological activity, a number of amino acids can be removed from the carboxyl-terminal end without a marked effect. The structure–activity relationships of ACTH have been studied extensively, and it is believed that a stretch of four basic amino acids at positions 15 to 18 is an important determinant of high-affinity binding to the ACTH receptor, whereas amino acids 6 to 10 are important for receptor activation.

The actions of ACTH and the other melanocortins liberated from POMC are mediated by their specific interactions with five melanocortin receptor (MCR) subtypes comprising a distinct subfamily of G protein–coupled receptors. The well-known effects of MSH on pigmentation result from interactions with the MC1R on melanocytes. MC1Rs also are found on cells of the immune system and are thought to mediate the antiinflammatory effects of α -MSH in experimental models of inflammation. ACTH, which is identical to α -MSH in its first 13 amino acids (Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val), exerts its effects on the adrenal cortex through the MC2R. ACTH has a much higher affinity for the MC2R than for the MC1R; however, under pathological conditions in which ACTH levels are

Figure 59–1. Processing of pro-opiomelanocortin to adrenocorticotrophic hormone and the sequence of adrenocorticotrophic hormone. The pathway by which pro-opiomelanocortin (POMC) is converted to adrenocorticotrophic hormone (ACTH) and other peptides in the anterior pituitary is depicted. The amino acid sequence of human ACTH is shown. The light blue boxes behind the ACTH structure indicate regions identified as important for steroidogenic activity (residues 6–10) and binding to the ACTH receptor (15–18). α -Melanocyte-stimulating hormone also derives from the POMC precursor and contains the first 13 residues of ACTH. LPH, lipotropin; MSH, melanocyte-stimulating hormone; PC1, prohormone convertase 1. For additional information on peptide hormones derived from POMC, *see* Table 55–1.

persistently elevated, such as primary adrenal insufficiency, ACTH can signal through the MC1R and cause hyperpigmentation. Recent studies have defined a key role for α -MSH acting *via* the MC3R and MC4R receptors in the hypothalamic regulation of appetite and body weight (Wardlaw, 2001), and they therefore are the subject of considerable investigation as possible targets for drugs that affect appetite. The role of MC5R is less well defined, but studies in rodents suggest that MSH stimulates LH secretion and triggers aggressive, pheromone-related behavior *via* the MC5R.

Actions on the Adrenal Cortex. Acting *via* MC2R, ACTH stimulates the adrenal cortex to secrete glucocorticoids, mineralocorticoids, and the androgen precursor dehydroepiandrosterone (DHEA) that can be converted peripherally into more potent androgens. The adrenal cortex histologically and functionally can be separated into three zones that produce different steroid products under different regulatory influences. The outer zona glomerulosa secretes the mineralocorticoid aldosterone, the middle zona fasciculata secretes the glucocorticoid cortisol, and the inner zona reticularis secretes DHEA and its sulfated derivative (Figure 59–2).

Figure 59–2. The adrenal cortex contains three anatomically and functionally distinct compartments. The major functional compartments of the adrenal cortex are shown, along with the steroidogenic enzymes that determine the unique profiles of corticosteroid products. Also shown are the predominant physiologic regulators of steroid production: angiotensin II (Ang II) and K⁺ for the zona glomerulosa and ACTH for the zona fasciculata. The physiological regulator(s) of dehydroepiandrosterone (DHEA) production by the zona reticularis are not known, although ACTH acutely increases DHEA biosynthesis.

Cells of the outer zone have receptors for angiotensin II and express aldosterone synthase (CYP11B2), an enzyme that catalyzes the terminal reactions in mineralocorticoid biosynthesis. Although ACTH acutely stimulates mineralocorticoid production by the zona glomerulosa, this zone is regulated predominantly by angiotensin II and extracellular K⁺ (see Chapter 30) and does not undergo atrophy in the absence of ongoing stimulation by the pituitary gland. In the setting of persistently elevated ACTH, mineralocorticoid levels initially increase and then return to normal (a phenomenon termed *ACTH escape*).

In contrast, cells of the zona fasciculata have fewer receptors for angiotensin II and express two enzymes, steroid 17 α -hydroxylase (CYP17) and 11 β -hydroxylase (CYP11B1), which catalyze the production of glucocorticoids. In the zona reticularis, CYP17 carries out a second C 17-20 lyase reaction that converts C 21 corticosteroids to C 19 androgen precursors.

In the absence of the anterior pituitary, the inner zones of the cortex atrophy, and the production of glucocorticoids and adrenal androgens is markedly impaired.

Persistently elevated levels of ACTH, due either to repeated administration of large doses of ACTH or to excessive endogenous production, induce hyperplasia and

hypertrophy of the inner zones of the adrenal cortex, with overproduction of cortisol and adrenal androgens. Adrenal hyperplasia is most marked in congenital disorders of steroidogenesis, in which ACTH levels are continuously elevated as a secondary response to impaired cortisol biosynthesis. There is some debate regarding the relative roles of ACTH versus other POMC-derived peptides in stimulating adrenal growth, but the essential role of the anterior pituitary in maintaining the integrity of the zona fasciculata is indisputable.

Mechanism of Action. ACTH stimulates the synthesis and release of adrenocortical hormones. As specific mechanisms for steroid hormone secretion have not been defined and since steroids do not accumulate appreciably in the gland, it is believed that the actions of ACTH to increase steroid hormone production are mediated predominantly at the level of *de novo* biosynthesis.

ACTH, binding to MC2R, activates the G protein G α_s to stimulate adenylyl cyclase, increase intracellular cyclic AMP content, and activate PKA. Cyclic AMP is an obligatory second messenger for most, if not all, effects of ACTH on steroidogenesis. Mutations in the ACTH receptor are one of the causes of the rare syndrome of familial resistance to ACTH (Clark and Weber, 1998).

Temporally, the response of adrenocortical cells to ACTH has two phases. The acute phase, which occurs within seconds to minutes, largely reflects increased supply of cholesterol substrate to the steroidogenic enzymes. The chronic phase, which occurs over hours to days, results largely from increased transcription of the steroidogenic enzymes. A summary of the pathways of adrenal steroid biosynthesis and the structures of the major steroid intermediates and products of the human adrenal cortex are shown in Figure 59–3. The rate-limiting step in steroid hormone production is the conversion of cholesterol to pregnenolone, a reaction catalyzed by CYP11A1, the cholesterol side-chain cleavage enzyme. Most of the enzymes required for steroid hormone biosynthesis, including CYP11A1, are members of the cytochrome P450 superfamily of mixed-function oxidases that play important roles in the metabolism of xenobiotics such as drugs and environmental pollutants, as well as in the biosynthesis of such endogenous compounds as steroid hormones, vitamin D, bile acids, fatty acids, prostaglandins, and biogenic amines (see Chapter 3). The rate-limiting components in this reaction regulate the mobilization of substrate cholesterol and its delivery to CYP11A1 in the inner mitochondrial matrix.

To ensure an adequate supply of substrate for steroidogenesis, the adrenal cortex uses multiple sources of cholesterol, including: (1) circulating cholesterol and cholesterol esters taken up *via* the low-density lipoprotein and high-density lipoprotein receptor pathways; (2) liberation of cholesterol from endogenous cholesterol ester stores *via* activation of cholesterol esterase; and (3) increased *de novo* biosynthesis.

The mechanisms by which ACTH stimulates the translocation of cholesterol to the inner mitochondrial matrix are not fully defined. A 30,000-dalton phosphoprotein—designated the steroidogenic

Figure 59–3. Pathways of corticosteroid biosynthesis. The steroidogenic pathways used in the biosynthesis of the corticosteroids are shown, along with the structures of the intermediates and products. The pathways that are unique to the zona glomerulosa are shown in blue, whereas those that occur in the inner zona fasciculata and zona reticularis are shown in gray. The zona reticularis does not express 3 β -HSD, and thus preferentially synthesizes DHEA. CYP11A1, cholesterol side-chain cleavage enzyme; 3 β -HSD, 3 β -hydroxysteroid dehydrogenase; CYP17, steroid 17 α -hydroxylase; CYP21, steroid 21-hydroxylase; CYP11B2, aldosterone synthase; CYP11B1, steroid 11 β -hydroxylase.

acute regulatory protein—clearly plays essential roles in cholesterol delivery. Mutations in the gene encoding this phosphoprotein are found in patients with congenital lipid adrenal hyperplasia, a rare congenital disorder in which adrenal cells become engorged with cholesterol deposits secondary to an inability to synthesize any steroid hormones. An important component of the trophic effect of ACTH is the enhanced transcription of genes that encode the individual steroidogenic enzymes, with associated increases in the steroidogenic capacity of the gland. A variety of transcriptional regulators mediate the induction of steroid hydroxylases by ACTH, and concerted mechanisms that coordinate the expression of the different genes have not been defined.

Extra-adrenal Effects of ACTH. In large doses, ACTH causes a number of metabolic changes in adrenalectomized animals, including ketosis, lipolysis, hypoglycemia (immediately after treatment), and resistance to insulin (later after treatment). Because of the large doses of ACTH required, the physiological significance of these extra-adrenal effects is questionable. ACTH also improves learning in experimental animals; this latter effect appears to be non-endocrine and mediated *via* distinct receptors in the central nervous system.

Regulation of ACTH Secretion. Hypothalamic-Pituitary-Adrenal Axis. The rate of glucocorticoid secretion is determined by fluctuations in the release of ACTH by the pituitary corticotropes. These corticotropes, in turn, are regulated by corticotropin-releasing hormone (CRH), a peptide hormone released by CRH neurons of the endocrine hypothalamus. These three organs collectively are referred to as the hypothalamic-pituitary-adrenal (HPA) axis, an integrated system that maintains appropriate levels of glucocorticoids (see Figure 59–4 for a schematic overview). There are three characteristic modes of regulation of the HPA axis: diurnal rhythm in basal steroidogenesis, negative feedback regulation by adrenal corticosteroids, and marked increases in steroidogenesis in response to stress. The diurnal rhythm is entrained by higher neuronal centers in response to sleep-wake cycles, such that levels of ACTH peak in the early morning hours, causing the circulating glucocorticoid levels to peak at approximately 8 A.M. As discussed below, negative feedback regulation occurs at multiple levels of the HPA axis and is the major mechanism that maintains circulating glucocorticoid levels in the appropriate range. Stress can override the normal negative feedback control mechanisms, leading to marked increases in plasma concentrations of glucocorticoids.

Central Nervous System. The central nervous system integrates a number of positive and negative influences on ACTH secretion that are conveyed by several neurotransmitters (Figure 59–4). These signals converge on the CRH neurons, which are clustered largely in the

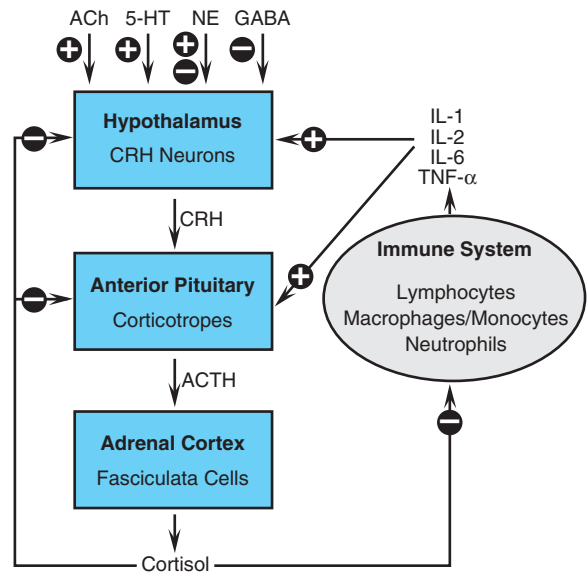

Figure 59–4. Overview of the hypothalamic-pituitary-adrenal (HPA) axis and the immune inflammatory network. Also shown are inputs from higher neuronal centers that regulate CRH secretion. + indicates a positive regulator, – indicates a negative regulator, +/- indicates a mixed effect. parvocellular region of the paraventricular hypothalamic nucleus and make axonal connections to the median eminence of the hypothalamus (see Chapter 12). Following release into the hypophyseal plexus, CRH is transported *via* this portal system to the anterior pituitary, where it binds to specific membrane receptors on corticotropes. Upon CRH binding, the CRH receptor activates the G_s -adenylyl cyclase–cyclic AMP pathway within corticotropes, ultimately stimulating both ACTH biosynthesis and secretion. CRH and CRH-related peptides called urocortins also are produced at other sites, including the amygdala and hindbrain, gut, skin, adrenal gland, adipose tissue, placenta, and other sites in the periphery (Bale and Vale, 2004). The classical CRH receptor, now designated CRF₁ receptor, belongs to the class II family of G protein–coupled receptors that includes receptors for calcitonin, parathyroid hormone, growth hormone–releasing hormone, secretin, glucagon, and glucagon-like peptide. A second CRH receptor, designated CRF₂ receptor, shares 70% homology at the amino-acid level. These two receptors differentially bind CRH and the urocortins, providing a highly complex neural network that modulates the adaptive response to stress. The complex relationships between stress and mood have stimulated considerable interest in the possible use of CRH antagonists in disorders such as anxiety and depression.

Arginine Vasopressin. Arginine vasopressin (AVP) also acts as a secretagogue for corticotropes, significantly potentiating the effects of CRH. Animal studies suggest that the potentiation of CRH action by AVP probably contributes to the full magnitude of the stress response *in vivo*. Like CRH, AVP is produced in the parvocellular neurons of the paraventricular nucleus and secreted into the pituitary

plexus from the median eminence. After binding to V_{1b} receptors, AVP activates the G_q -PLC- IP_3 - Ca^{2+} pathway to enhance the release of ACTH. In contrast to CRH, AVP apparently does not increase ACTH synthesis.

Negative Feedback of Glucocorticoids. Glucocorticoids inhibit ACTH secretion *via* direct and indirect actions on CRH neurons to decrease CRH mRNA levels and CRH release and *via* direct effects on corticotropes. The inhibition of CRH release may be mediated by specific corticosteroid receptors in the hippocampus. At lower cortisol levels, the mineralocorticoid receptor (MR), which has a higher affinity for glucocorticoids and is the predominant form found in the hippocampus, is the major receptor species occupied. As glucocorticoid concentrations rise and exceed the capacity of the MR, the glucocorticoid receptor (GR) also becomes occupied. Both classes of receptor apparently control the basal activity of the HPA axis, whereas feedback inhibition by glucocorticoids predominantly involves the GR.

In the pituitary, glucocorticoids act through the GR to inhibit the release of ACTH from corticotropes and the expression of POMC. These effects are both rapid (occurring within seconds to minutes and possibly mediated by glucocorticoid receptor-independent mechanisms) and delayed (requiring hours and involving changes in gene transcription mediated through the GR).

The Stress Response. Stress overcomes negative feedback regulation of the HPA axis, leading to a marked rise in corticosteroid production. Examples of stress signals include injury, hemorrhage, severe infection, major surgery, hypoglycemia, cold, pain, and fear. Although the precise mechanisms that underlie this stress response and the essential actions played by corticosteroids are not fully defined, it is clear that their increased secretion is vital to maintain homeostasis in these stressful settings. As discussed below, complex interactions between the HPA axis and the immune system may be a fundamental physiological component of this stress response (Sapolsky *et al.*, 2000).

Assays for ACTH. Initially, ACTH levels were assessed by bioassays that measured induced steroid production or the depletion of adrenal ascorbic acid. Radioimmunoassays that subsequently were developed to quantitate ACTH levels in individual patients were not always reproducible and did not clearly differentiate between low and normal levels of ACTH. Immunochemiluminescent assays that use two separate antibodies directed at distinct epitopes on the ACTH molecule now are widely available. These assays increase considerably the ability to differentiate patients with primary hypoadrenalism due to intrinsic adrenal disease, who have high ACTH levels due to the loss of normal glucocorticoid feedback inhibition, from those with secondary forms of hypoadrenalism, due to low ACTH levels resulting from hypothalamic or pituitary disorders. The immunochemiluminescent ACTH assays also are useful in differentiating between ACTH-dependent and ACTH-independent forms of hypercorticism: High ACTH levels are seen when the hypercorticism results from pituitary adenomas (*e.g.*, Cushing's disease) or nonpituitary tumors that secrete ACTH (*e.g.*, the syndrome of ectopic ACTH), whereas low ACTH levels are seen in patients with exces-

sive glucocorticoid production due to primary adrenal disorders. Despite their considerable utility, one problem with the immunoassays for ACTH is that their specificity for intact ACTH can lead to falsely low values in patients with ectopic ACTH secretion; these tumors can secrete aberrantly processed forms of ACTH that have biological activity but do not react in the antibody assays.

Therapeutic Uses and Diagnostic Applications of ACTH. There are anecdotal reports that selected conditions respond better to ACTH than to corticosteroids (*e.g.*, multiple sclerosis), and some clinicians continue to advocate therapy with ACTH. Despite this, ACTH currently has only limited utility as a therapeutic agent. Therapy with ACTH is less predictable and less convenient than therapy with corticosteroids. In addition, ACTH stimulates mineralocorticoid and adrenal androgen secretion and may therefore cause acute retention of salt and water, as well as virilization. While ACTH and the corticosteroids are not pharmacologically equivalent, all proven therapeutic effects of ACTH can be achieved with appropriate doses of corticosteroids with a lower risk of side effects.

Testing the Integrity of the HPA Axis. The major clinical use of ACTH is in testing the integrity of the HPA axis. Other tests used to assess the HPA axis include the insulin tolerance test (*see* Chapter 55) and the metyrapone test (discussed later in this chapter). *Cosyntropin* (CORTROSYN, SYNACTHEN) is a synthetic peptide that corresponds to residues 1 to 24 of human ACTH. At the considerably supraphysiological dose of 250 μ g, cosyntropin maximally stimulates adrenocortical steroidogenesis. In the standard cosyntropin stimulation test, 250 μ g of cosyntropin is administered either intramuscularly or intravenously, with cortisol measured just before administration (baseline) and 30 to 60 minutes after cosyntropin administration. An increase in the circulating cortisol to a level greater than 18 to 20 μ g/dl indicates a normal response. Others also have included an increase of 7 μ g/dl over the baseline value as a positive response, although this is less widely accepted. In patients with pituitary or hypothalamic disease of recent onset or shortly after surgery for pituitary tumors, the standard cosyntropin stimulation test may be misleading, as the duration of ACTH deficiency may have been insufficient to cause significant adrenal atrophy with frank loss of steroidogenic capacity. For these patients, some experts advocate a "low-dose" cosyntropin stimulation test, in which 1 μ g of cosyntropin is administered intravenously, and cortisol is measured just before and 30 minutes after cosyntropin administration; the cutoff for a normal response is the same as that for the standard test. Because cosyntropin is not generally available in a 1- μ g dose, the standard ampule of cosyntropin (250 μ g) is diluted to permit accurate delivery of the 1- μ g challenge dose. Care must be taken to avoid adsorption of the cosyntropin to plastic tubing and to measure the plasma cortisol precisely at 30 minutes after the cosyntropin injection. Although some studies indicate that the low-dose test is more sensitive than the standard 250- μ g test, others report that this test also may fail to detect secondary adrenal insufficiency.

As noted above, primary adrenocortical insufficiency and secondary adrenocortical insufficiency are reliably distinguished using avail-

able sensitive assays for ACTH. Thus, longer-course ACTH stimulation tests rarely are used to differentiate between these disorders.

CRH Stimulation Test. Ovine CRH (*corticotropin* [ACTHREL]) and human CRH are available for diagnostic testing of the HPA axis, with the former used in the United States and the latter preferred in Europe. In patients with documented ACTH-dependent hypercorticism, CRH testing may help differentiate between a pituitary source (*i.e.*, Cushing's disease) and an ectopic source of ACTH. After two baseline blood samples are obtained 15 minutes apart, CRH (1 $\mu\text{g}/\text{kg}$ body weight) is administered intravenously over a 30- to 60-second interval, and peripheral blood samples are obtained at 15, 30, and 60 minutes for ACTH measurement. It is important that the blood samples be handled as recommended for the ACTH assay. At the recommended dose, CRH generally is well tolerated, although flushing may occur, particularly if the dose is administered as a bolus. Patients with Cushing's disease respond to CRH with either a normal or an exaggerated increase in ACTH, whereas ACTH levels do not increase in patients with ectopic sources of ACTH. It should be noted that this test is not perfect: ACTH levels are induced by CRH in occasional patients with ectopic ACTH, whereas approximately 5% to 10% of patients with Cushing's disease fail to respond.

To improve the diagnostic accuracy of the CRH stimulation test, many authorities advocate sampling of blood from the inferior petrosal sinuses and the peripheral circulation after peripheral administration of CRH as above. In this test, an inferior petrosal/peripheral ratio of >2.5 supports a pituitary source of ACTH. When performed by a skilled neuroradiologist, this procedure increases diagnostic accuracy with a tolerable risk of complications from the catheterization procedure (Arnaldi *et al.*, 2003).

Absorption and Fate. ACTH is readily absorbed from parenteral sites. The hormone rapidly disappears from the circulation after intravenous administration; in humans, the half-life in plasma is about 15 minutes, primarily due to rapid enzymatic hydrolysis.

Toxicity of ACTH. Aside from rare hypersensitivity reactions, the toxicity of ACTH is primarily attributable to the increased secretion of corticosteroids. Cosyntropin generally is less antigenic than native ACTH; thus cosyntropin is the preferred agent for clinical use.

ADRENOCORTICAL STEROIDS

The adrenal cortex synthesizes two classes of steroids: the *corticosteroids* (glucocorticoids and mineralocorticoids), which have 21 carbon atoms, and the *androgens*, which have 19 (Figure 59–3). The actions of corticosteroids historically were described as glucocorticoid (carbohydrate metabolism–regulating) and mineralocorticoid (electrolyte balance–regulating), reflecting their preferential activities. In humans, *cortisol* (*hydrocortisone*) is the main glucocorticoid and aldosterone is the main mineralocorticoid. The mechanisms by which glucocorticoid biosynthesis is regulated by ACTH are discussed above, and the regulation of aldosterone production is described in Chapter 30. Table 59–1 shows typical rates of secretion of cortisol and aldosterone, as well as their normal circulat-

Table 59–1

Normal Daily Production Rates and Circulating Levels of the Predominant Corticosteroids

	CORTISOL	ALDOSTERONE
Rate of secretion under optimal conditions	10 mg/day	0.125 mg/day
Concentration in peripheral plasma:		
8 A.M.	16 $\mu\text{g}/100$ ml	0.01 $\mu\text{g}/100$ ml
4 P.M.	4 $\mu\text{g}/100$ ml	0.01 $\mu\text{g}/100$ ml

ing concentrations. Earlier studies had suggested that cortisol was produced at a daily rate of 20 mg, but more recent studies indicate that the actual rate is closer to 10 mg/day.

Although the adrenal cortex is an important source of androgen precursors in women, patients with adrenal insufficiency can be restored to normal life expectancy by replacement therapy with glucocorticoids and mineralocorticoids. Nevertheless, some recent studies have shown that addition of DHEA to the standard replacement regimen in women with adrenal insufficiency improved subjective well-being and sexuality (Allolio and Arlt, 2002). While adrenal androgens are not essential for survival, the levels of dehydroepiandrosterone (DHEA) and its sulfated derivative DHEA-S peak in the third decade of life and decline progressively thereafter. Moreover, patients with a number of chronic diseases have very low DHEA levels, leading some to propose that DHEA treatment might at least partly alleviate the adverse consequences of aging. These findings have prompted considerable discussion about uses of DHEA, which despite the absence of definitive data is widely used as a nutritional supplement for its alleged health benefits.

Physiological Functions and Pharmacological Effects

Physiological Actions. The effects of corticosteroids are numerous and widespread, and include alterations in carbohydrate, protein, and lipid metabolism; maintenance of fluid and electrolyte balance; and preservation of normal function of the cardiovascular system, the immune system, the kidney, skeletal muscle, the endocrine system, and the nervous system. In addition, corticosteroids endow the organism with the capacity to resist such

Table 59–2

†These dose relationships apply only to oral or intravenous administration, as glucocorticoid potencies may differ greatly following intramuscular or intraarticular administration. ‡This agent is not used for glucocorticoid effects.

stressful circumstances as noxious stimuli and environmental changes. In the absence of the adrenal cortex, survival is made possible only by maintaining an optimal environment, including adequate and regular feedings, ingestion of relatively large amounts of sodium chloride, and maintenance of an appropriate environmental temperature; stresses such as infection and trauma in this setting can be life-threatening.

Until recently, corticosteroid effects were viewed as physiological (reflecting actions of corticosteroids at doses corresponding to normal daily production levels) or pharmacological (representing effects seen only at doses exceeding the normal daily production of corticosteroids). More recent concepts suggest that the antiinflammatory and immunosuppressive actions of corticosteroids—one of the major “pharmacological” uses of this class of drugs—also provide a protective mechanism in the physiological setting. Many of the immune mediators associated with the inflammatory response decrease vascular tone and could lead to cardiovascular collapse if unopposed by the adrenal corticosteroids. This hypothesis is supported by the fact that the daily production rate of cortisol can rise at least tenfold in the setting of severe stress. In addition, as discussed below, the pharmacological actions of corticosteroids in different tissues and their physiological effects are mediated by the same receptor. Thus, the various glucocorticoid derivatives used as pharmacological agents generally have side effects on physiological processes that parallel their therapeutic effectiveness.

The actions of corticosteroids are interrelated to those of other hormones. For example, in the absence of lipolytic

hormones, cortisol has virtually no effect on the rate of lipolysis by adipocytes. Likewise, in the absence of glucocorticoids, epinephrine and norepinephrine have only minor effects on lipolysis. Administration of a small dose of glucocorticoid, however, markedly potentiates the lipolytic action of these catecholamines. Those effects of corticosteroids that involve concerted actions with other hormonal regulators are termed *permissive* and most likely reflect steroid-induced changes in protein synthesis that, in turn, modify tissue responsiveness to other hormones.

Corticosteroids are grouped according to their relative potencies in Na⁺ retention, effects on carbohydrate metabolism (*i.e.*, hepatic deposition of glycogen and gluconeogenesis), and antiinflammatory effects. In general, potencies of steroids as judged by their ability to sustain life in adrenalectomized animals closely parallel those determined for Na⁺ retention, while potencies based on effects on glucose metabolism closely parallel those for antiinflammatory effects. The effects on Na⁺ retention and the carbohydrate/antiinflammatory actions are not closely related and reflect selective actions at distinct receptors, as noted above.

Based on these differential potencies, the corticosteroids traditionally are divided into mineralocorticoids and glucocorticoids. Estimates of potencies of representative steroids in these actions are listed in Table 59–2. Some steroids that are classified predominantly as glucocorticoids (*e.g.*, cortisol) also possess modest but significant mineralocorticoid activity and thus may affect fluid and electrolyte handling in the clinical setting. At doses used for replacement therapy in patients with primary adrenal insufficiency (*see* below), the mineralocorticoid effects of

these “glucocorticoids” are insufficient to replace that of aldosterone, and concurrent therapy with a more potent mineralocorticoid generally is needed. In contrast, aldosterone is exceedingly potent with respect to Na⁺ retention, but has only modest potency for effects on carbohydrate metabolism. At normal rates of secretion by the adrenal cortex or in doses that maximally affect electrolyte balance, aldosterone has no significant glucocorticoid activity and thus acts as a pure mineralocorticoid.

General Mechanisms for Corticosteroid Effects. Corticosteroids interact with specific receptor proteins in target tissues to regulate the expression of corticosteroid-responsive genes, thereby changing the levels and array of proteins synthesized by the various target tissues (Figure 59–5). As a consequence of the time required to modulate gene expression and protein synthesis, most effects of corticosteroids are not immediate but become apparent after several hours. This fact is of clinical significance, because a delay generally is seen before beneficial effects of corticosteroid therapy become manifest. Although corticosteroids predominantly act to increase expression of target genes, there are well-documented examples in which glucocorticoids decrease transcription of target genes (De Bosscher *et al.*, 2003), as discussed below. In addition to these genomic effects, some immediate actions of corticosteroids may be mediated by membrane-bound receptors (Norman *et al.*, 2004).

The receptors for corticosteroids are members of the nuclear receptor family of transcription factors that transduce the effects of a diverse array of small, hydrophobic ligands, including the steroid hormones, thyroid hormone, vitamin D, and retinoids. These receptors share two highly conserved domains: a region of approximately 70 amino acids forming two zinc-binding domains, called *zinc fingers*, that are essential for the interaction of the receptor with specific DNA sequences, and a region at the carboxyl terminus that interacts with ligand (the ligand-binding domain).

Although complete loss of glucocorticoid receptor (GR) function apparently is lethal, mutations leading to partial loss of GR function have been identified in rare patients with generalized glucocorticoid resistance (Bray and Cotton, 2003). These patients harbor mutations in the GR that impair glucocorticoid binding and decrease transcriptional activation. As a consequence of these mutations, cortisol levels that normally mediate feedback inhibition fail to suppress the HPA axis completely. In this setting of partial loss of GR function, the HPA axis resets to a higher level to provide compensatory increases in ACTH and cortisol secretion. Because the GR defect is partial, adequate compensation for the end-organ insensitivity can result from the elevated cortisol level, but the excess ACTH secretion also stimulates the production of mineralocorticoids and adrenal androgens. Because the mineralocorticoid receptor (MR) and the androgen receptor are intact, these subjects present with manifestations of mineralocorticoid excess (hypertension and hypokalemic alkalosis) and/or of increased androgen levels (acne, hirsutism, male

Figure 59–5. Intracellular mechanism of action of the glucocorticoid receptor. The figure shows the molecular pathway by which cortisol (labeled S) enters cells and interacts with the glucocorticoid receptor (GR) to change GR conformation (indicated by the change in shape of the GR), induce GR nuclear translocation, and activate transcription of target genes. The example shown is one in which glucocorticoids activate expression of target genes; the expression of certain genes, including pro-opiomelanocortin (POMC) expression by corticotropes, is inhibited by glucocorticoid treatment. CBG, corticosteroid-binding globulin; GR, glucocorticoid receptor; S, steroid hormone; HSP90, the 90-kd heat-shock protein; HSP70, the 70-kd heat-shock protein; IP, the 56-kd immunophilin; GRE, glucocorticoid-response elements in the DNA that are bound by GR, thus providing specificity to induction of gene transcription by glucocorticoids. Within the gene are introns (*unshaded*) and exons (*shaded*); transcription and mRNA processing leads to splicing and removal of introns and assembly of exons into mRNA.

pattern baldness, menstrual irregularities, anovulation, and infertility). In children, the excess adrenal androgens can cause precocious sexual development.

Glucocorticoid Receptor. The GR resides predominantly in the cytoplasm in an inactive form until it binds glucocorticoids (Figure 59–5). Steroid binding results in receptor activation and translocation to the nucleus. The inactive GR is complexed with other proteins, including heat-shock protein (HSP) 90, a member of the heat-shock family of stress-induced proteins; HSP70; and a 56,000-dalton immu-

nophilin, one of the group of intracellular proteins that bind the immunosuppressive agents *cyclosporine* and *tacrolimus* (see Chapter 52 for a discussion of these agents). HSP90, through interactions with the steroid-binding domain, may facilitate folding of the GR into an appropriate conformation that permits ligand binding.

Regulation of Gene Expression by Glucocorticoids. After ligand binding, the GR dissociates from its associated proteins and translocates to the nucleus. There, it interacts with specific DNA sequences within the regulatory regions of affected genes. The short DNA sequences that are recognized by the activated GR are called *glucocorticoid responsive elements* (GREs) and provide specificity to the induction of gene transcription by glucocorticoids. The consensus GRE sequence is an imperfect palindrome (GGTACAnnnTGTTCT, where n is any nucleotide) to which the GR binds as a receptor dimer. The mechanisms by which GR activates transcription are complex and not completely understood, but they involve the interaction of the GR with transcriptional coactivators and with proteins that make up the basal transcription apparatus. Genes that are negatively regulated by glucocorticoids also have been identified. One well-characterized example is the pro-opiomelanocortin gene, whose negative regulation in corticotropes by glucocorticoids is an important part of the negative feedback regulation of the HPA axis. In this case, the GR appears to inhibit transcription by a direct interaction with a GRE in the *POMC* promoter. Other genes negatively regulated by glucocorticoids include genes for cyclooxygenase-2 (COX-2), inducible nitric oxide synthase (NOS2), and inflammatory cytokines.

Although glucocorticoids and the GR are essential for survival, interactions of the GR with specific GREs apparently are not. These conclusions are supported by the findings that genetically engineered mice completely lacking GR function die immediately after birth, whereas mice harboring a mutated GR incapable of binding to DNA are viable. These observations imply that the critical function of GR involves protein–protein interactions with other transcription factors. Indeed, protein–protein interactions have been observed between the GR and the transcription factors NF- κ B and AP-1, which regulate the expression of a number of components of the immune system (De Bosscher *et al.*, 2003). Such interactions repress the expression of genes encoding a number of cytokines—regulatory molecules that play key roles in the immune and inflammatory networks—and enzymes, such as collagenase and stromelysin, that are proposed to play key roles in the joint destruction seen in inflammatory arthritis. Thus, these negative effects on gene expression appear to contribute significantly to the antiinflammatory and immunosuppressive effects of the glucocorticoids.

The recognition that the metabolic effects of glucocorticoids generally are mediated by transcriptional activation, while the anti-inflammatory effects largely are mediated by transrepression, suggests that selective GR ligands may maintain the antiinflammatory actions while lessening the metabolic side effects (Coghlan *et al.*, 2003). Recent reports describe steroidal and nonsteroidal compounds that exhibit antiinflammatory actions but have little effect on blood glucose, suggesting that such selective glucocorticoid agonists may emerge from ongoing research.

Regulation of Gene Expression by Mineralocorticoids. Like the GR, MR also is a ligand-activated transcription factor and binds to a very similar, if not identical, hormone-responsive element. Although its actions have been studied in less detail than the GR, the basic principles of action appear to be similar; in particular, the MR also associates with HSP90 and activates the transcription of discrete sets of genes within target tissues. Studies have not yet identified differences

in the DNA recognition motifs for the GR and the MR that would explain their differential capacities to activate discrete sets of target genes. The GR and MR differ in their ability to inhibit AP-1–mediated gene activation, suggesting that differential interactions with other transcription factors may underlie their distinct effects on cell function. In addition, unlike the GR, the MR has a restricted expression: It is expressed principally in the kidney (distal cortical tubule and cortical collecting duct), colon, salivary glands, sweat glands, and hippocampus.

Aldosterone exerts its effects on Na⁺ and K⁺ homeostasis primarily *via* its actions on the principal cells of the distal renal tubules and collecting ducts, while the effects on H⁺ secretion largely are exerted in the intercalated cells. After binding to the MR, aldosterone initiates a sequence of events that includes the rapid induction of serum- and glucocorticoid-regulated kinase, which in turn phosphorylates and activates amiloride-sensitive epithelial Na⁺ channels in the apical membrane. Thereafter, increased Na⁺ influx stimulates the Na⁺,K⁺-ATPase in the basolateral membrane. In addition to these rapid actions, aldosterone also increases the synthesis of the individual components of these membrane proteins.

Further insights into the roles of the MR and its target genes in fluid and electrolyte balance have emerged from analyses of patients with rare genetic disorders of mineralocorticoid action, such as *pseudohypoaldosteronism* and *pseudoaldosteronism*. Despite elevated levels of mineralocorticoids, patients with pseudohypoaldosteronism present with clinical manifestations suggestive of deficient mineralocorticoid action (*i.e.*, volume depletion, hypotension, hyperkalemia, and metabolic acidosis). Molecular analyses have defined discrete subpopulations of patients with this disorder. One form is an autosomal recessive disease resulting from loss-of-function mutations in genes encoding subunits of the amiloride-sensitive epithelial sodium channel. A second, autosomal dominant form of pseudohypoaldosteronism is caused by mutations in the MR that impair its activity. Pseudoaldosteronism, also termed Liddle's syndrome, is an autosomal dominant disease that results from mutations in subunits of the amiloride-sensitive Na⁺ channel that interfere with its down-regulation. The constitutive activity of this channel leads to hypertension, hypokalemia, and metabolic alkalosis, despite low levels of plasma renin and aldosterone.

Receptor-Independent Mechanism for Corticosteroid Specificity.

The availability of cloned genes encoding the GR and MR led to the surprising finding that aldosterone (a classic mineralocorticoid) and cortisol (generally viewed as predominantly glucocorticoid) binds the MR with equal affinity. This raised the question of how the apparent specificity of the MR for aldosterone was maintained in the face of much higher circulating levels of glucocorticoids. We now know that the type 2 isozyme of 11 β -hydroxysteroid dehydrogenase (11 β HSD2) plays a key role in corticosteroid specificity, particularly in the kidney, colon, and salivary glands (Sandeep and Walker, 2001). This enzyme metabolizes glucocorticoids such as cortisol to receptor-inactive 11-keto derivatives such as cortisone (Figure 59–6). Because its predominant form in physiological settings is the hemiacetal derivative (Figure 59–7), which is resistant to 11 β HSD action, aldosterone escapes this inactivation and maintains mineralocorticoid activity. In the absence of 11 β HSD2, as occurs in an inherited disease called the *syndrome of apparent mineralocorticoid excess*, the MR is swamped by cortisol, leading to severe hypokalemia and mineralocorticoid-related hypertension. A state of mineralocorticoid excess also can be induced by inhibiting 11 β HSD with *glycyrrhizic acid*, a component of licorice implicated in licorice-induced hypertension.

Figure 59–6. Receptor-independent mechanism by which 11 β -hydroxysteroid dehydrogenase confers specificity of corticosteroid action. By converting cortisol, which binds to both the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR), to cortisone, which binds to neither MR nor GR, the type 2 isozyme of 11 β -hydroxysteroid dehydrogenase (11 β -HSD2) protects the MR from the high circulating concentrations of cortisol. This inactivation allows specific responses to aldosterone in sites such as the distal nephron. The reverse reaction is catalyzed by the type 1 isozyme of 11 β -HSD, which converts inactive cortisone to active cortisol in such tissues as liver and fat.

Carbohydrate and Protein Metabolism. Corticosteroids profoundly affect carbohydrate and protein metabolism. Teleologically, these effects of glucocorticoids on intermediary metabolism can be viewed as protecting glucose-

dependent tissues (e.g., the brain and heart) from starvation. They stimulate the liver to form glucose from amino acids and glycerol and to store glucose as liver glycogen. In the periphery, glucocorticoids diminish glucose utilization, increase protein breakdown and the synthesis of glutamine, and activate lipolysis, thereby providing amino acids and glycerol for gluconeogenesis. The net result is to increase blood glucose levels. Because of their effects on glucose metabolism, glucocorticoids can worsen glycemic control in patients with overt diabetes and can precipitate the onset of hyperglycemia in patients who are otherwise predisposed.

The mechanisms by which glucocorticoids inhibit glucose utilization in peripheral tissues are not fully understood. Glucocorticoids decrease glucose uptake in adipose tissue, skin, fibroblasts, thymocytes, and polymorphonuclear leukocytes; these effects are postulated to result from translocation of the glucose transporters from the plasma membrane to an intracellular location. These peripheral effects are associated with a number of catabolic actions, including atrophy of lymphoid tissue, decreased muscle mass, negative nitrogen balance, and thinning of the skin.

Similarly, the mechanisms by which the glucocorticoids promote gluconeogenesis are not fully defined. Amino acids mobilized from a number of tissues in response to glucocorticoids reach the liver and provide substrate for the production of glucose and glycogen. In the liver, glucocorticoids induce the transcription of a number of

Figure 59–7. Structure and nomenclature of corticosteroid products and selected synthetic derivatives. The structure of hydrocortisone is represented in two dimensions. It should be noted that the steroid ring system is not completely planar and that the orientation of the groups attached to the steroid rings is an important determinant of the biological activity. The methyl groups at C18 and C19 and the hydroxyl group at C11 project upward (*forward* in the two-dimensional representation and shown by a solid line connecting the atoms) and are designated β . The hydroxyl at C17 projects below the plane (*behind* in the two-dimensional representation, and represented by the dashed line connecting the atoms) and is designated α .

enzymes involved in gluconeogenesis and amino acid metabolism, including phosphoenolpyruvate carboxykinase (PEPCK), glucose-6-phosphatase, and the bi-functional enzyme fructose-2,6-bisphosphatase. Analyses of the molecular basis for regulation of PEPCK gene expression have identified complex regulatory influences involving an interplay among glucocorticoids, insulin, glucagon, and catecholamines. The effects of these hormones and amines on PEPCK gene expression mirror the complex regulation of gluconeogenesis in the intact organism.

Lipid Metabolism. Two effects of corticosteroids on lipid metabolism are firmly established. The first is the dramatic redistribution of body fat that occurs in settings of endogenous or pharmacologically induced hypercorticism, such as Cushing's syndrome. The other is the permissive facilitation of the lipolytic effect of other agents, such as growth hormone and β adrenergic receptor agonists, resulting in an increase in free fatty acids after glucocorticoid administration. With respect to fat distribution, there is increased fat in the back of the neck ("buffalo hump"), face ("moon facies"), and supraclavicular area, coupled with a loss of fat in the extremities.

One hypothesis for this redistribution is that peripheral and truncal adipocytes differ in their relative sensitivities to insulin and to glucocorticoid-facilitated lipolytic effects, that truncal adipocytes respond predominantly to elevated levels of insulin resulting from glucocorticoid-induced hyperglycemia, whereas peripheral adipocytes are less sensitive to insulin and respond mostly to the glucocorticoid-facilitated effects of other lipolytic hormones. This differential sensitivity may reflect differences in the expression of the type 1 isozyme of 11β HSD that converts inactive cortisone into active cortisol in target tissues (Figure 59–6). Consistent with this idea, overexpression of 11β HSD1 in adipocytes causes obesity in a transgenic mouse model. The potential role of this enzyme in adipocyte function has prompted speculation that 11β HSD1 inhibitors may have a role in the treatment of obesity.

Electrolyte and Water Balance. Aldosterone is by far the most potent endogenous corticosteroid with respect to fluid and electrolyte balance. Thus, electrolyte balance is relatively normal in patients with adrenal insufficiency due to pituitary disease, despite the loss of glucocorticoid production by the inner cortical zones. Mineralocorticoids act on the distal tubules and collecting ducts of the kidney to enhance reabsorption of Na^+ from the tubular fluid; they also increase the urinary excretion of K^+ and H^+ . Conceptually, it is useful to think of aldosterone as stimulating a renal exchange between Na^+ and K^+ or H^+ , although this does not involve a simple 1:1 exchange of cations in the renal tubule.

These actions on electrolyte transport, in the kidney and in other tissues (*e.g.*, colon, salivary glands, and sweat glands), appear to account for the physiological and pharmacological activities that are characteristic of mineralo-

corticoids. Thus, the primary features of hyperaldosteronism are positive Na^+ balance with consequent expansion of extracellular fluid volume, normal or slight increases in plasma Na^+ concentration, hypokalemia, and alkalosis. Mineralocorticoid deficiency, in contrast, leads to Na^+ wasting and contraction of the extracellular fluid volume, hyponatremia, hyperkalemia, and acidosis. Chronically, hyperaldosteronism can cause hypertension, whereas aldosterone deficiency can lead to hypotension and vascular collapse. Because of the effects of mineralocorticoids on electrolyte handling by sweat glands, patients who are adrenal insufficient are especially predisposed to Na^+ loss and volume depletion through excessive sweating in hot environments.

Glucocorticoids also exert effects on fluid and electrolyte balance, largely due to permissive effects on tubular function and actions that maintain glomerular filtration rate. Glucocorticoids play a permissive role in the renal excretion of free water; the ability to excrete a water challenge was used at one time to diagnose adrenal insufficiency. In part, the inability of patients with glucocorticoid deficiency to excrete free water results from the increased secretion of AVP, which stimulates water reabsorption in the kidney.

In addition to their effects on monovalent cations and water, glucocorticoids also exert multiple effects on Ca^{2+} metabolism. Steroids interfere with Ca^{2+} uptake in the gut and increase Ca^{2+} excretion by the kidney. These effects collectively lead to decreased total body Ca^{2+} stores.

Cardiovascular System. The most striking effects of corticosteroids on the cardiovascular system result from mineralocorticoid-induced changes in renal Na^+ excretion, as is evident in primary aldosteronism. The resultant hypertension can lead to a diverse group of adverse effects on the cardiovascular system, including increased atherosclerosis, cerebral hemorrhage, stroke, and hypertensive cardiomyopathy. Consistent with the known actions of mineralocorticoids in the kidney, restriction of dietary Na^+ can lower the blood pressure considerably in mineralocorticoid excess.

Studies also have shown direct effects of aldosterone on the heart and vascular lining; aldosterone induces hypertension and interstitial cardiac fibrosis in animal models. The increased cardiac fibrosis is proposed to result from direct mineralocorticoid actions in the heart rather than from the effect of hypertension, because treatment with spironolactone, a MR antagonist, blocked the fibrosis without altering blood pressure. Similar effects of mineralocorticoids on cardiac fibrosis in human beings may explain, at least in part, the beneficial effects of

spironolactone in patients with congestive heart failure (see Chapter 33).

The second major action of corticosteroids on the cardiovascular system is to enhance vascular reactivity to other vasoactive substances. Hypoadrenalism is associated with reduced response to vasoconstrictors such as norepinephrine and angiotensin II, perhaps due to decreased expression of adrenergic receptors in the vascular wall. Conversely, hypertension is seen in patients with excessive glucocorticoid secretion, occurring in most patients with Cushing's syndrome and in a subset of patients treated with synthetic glucocorticoids (even those lacking any significant mineralocorticoid action).

The underlying mechanisms in glucocorticoid-induced hypertension also are unknown; in hypertension related to the endogenous secretion of cortisol, as seen in patients with Cushing's syndrome, it is not known if the effects are mediated by the GR or MR. Unlike hypertension caused by high aldosterone levels, the hypertension secondary to excess glucocorticoids is generally resistant to Na⁺ restriction.

Skeletal Muscle. Permissive concentrations of corticosteroids are required for the normal function of skeletal muscle, and diminished work capacity is a prominent sign of adrenocortical insufficiency. In patients with Addison's disease, weakness and fatigue are frequent symptoms that may reflect an inadequacy of the circulatory system. Excessive amounts of either glucocorticoids or mineralocorticoids also impair muscle function. In primary aldosteronism, muscle weakness results primarily from hypokalemia rather than from direct effects of mineralocorticoids on skeletal muscle. In contrast, glucocorticoid excess over prolonged periods, either secondary to glucocorticoid therapy or endogenous hypercorticism, causes skeletal muscle wasting. This effect, termed *steroid myopathy*, accounts in part for weakness and fatigue in patients with glucocorticoid excess and is discussed in more detail below.

Central Nervous System. Corticosteroids exert a number of indirect effects on the CNS, through maintenance of blood pressure, plasma glucose concentrations, and electrolyte concentrations. Increasingly, direct effects of corticosteroids on the CNS have been recognized, including effects on mood, behavior, and brain excitability.

Patients with adrenal insufficiency exhibit a diverse array of psychiatric manifestations, including apathy, depression, and irritability; some patients are frankly psychotic. Appropriate replacement therapy corrects these abnormalities. Conversely, glucocorticoid administration can induce multiple CNS reactions. Most patients respond with mood elevation, which may impart a sense of well-being despite the persistence of underlying disease. Some patients

exhibit more pronounced behavioral changes, such as euphoria, insomnia, restlessness, and increased motor activity. A smaller but significant percentage of patients treated with glucocorticoids becomes anxious, depressed, or overtly psychotic. A high incidence of neuroses and psychoses is seen in patients with Cushing's syndrome. These abnormalities usually disappear after cessation of glucocorticoid therapy or treatment of the Cushing's syndrome.

The mechanisms by which corticosteroids affect neuronal activity are unknown, but it has been proposed that steroids produced locally in the brain (termed *neurosteroids*) may regulate neuronal excitability. Studies in rodent models indicated that glucocorticoids deleteriously affect survival and function of hippocampal neurons, and that these changes are associated with diminished memory. In one study, basal cortisol levels in human beings correlated directly with hippocampal atrophy and memory deficits. To the extent that these results are confirmed, they have important prognostic implications for age-related memory decline, and they suggest therapeutic approaches directed at diminishing the negative effects of glucocorticoids on hippocampal neurons with aging.

Formed Elements of Blood. Glucocorticoids exert minor effects on hemoglobin and erythrocyte content of blood, as evidenced by the frequent occurrence of polycythemia in Cushing's syndrome and of normochromic, normocytic anemia in adrenal insufficiency. More profound effects are seen in the setting of autoimmune hemolytic anemia, in which the immunosuppressive effects of glucocorticoids can diminish the self-destruction of erythrocytes.

Corticosteroids also affect circulating white blood cells. Addison's disease is associated with an increased mass of lymphoid tissue and lymphocytosis. In contrast, Cushing's syndrome is characterized by lymphocytopenia and decreased mass of lymphoid tissue. The administration of glucocorticoids leads to a decreased number of circulating lymphocytes, eosinophils, monocytes, and basophils. A single dose of hydrocortisone leads to a decline of these circulating cells within 4 to 6 hours; this effect persists for 24 hours and results from the redistribution of cells away from the periphery rather than from increased destruction. In contrast, glucocorticoids increase circulating polymorphonuclear leukocytes as a result of increased release from the marrow, diminished rate of removal from the circulation, and increased demargination from vascular walls. Finally, certain lymphoid malignancies are destroyed by glucocorticoid treatment, an effect that may relate to the ability of glucocorticoids to activate programmed cell death.

Antiinflammatory and Immunosuppressive Actions. In addition to their effects on lymphocyte number, corticosteroids profoundly alter the immune responses of lymphocytes. These effects are an important facet of the anti-inflammatory and immunosuppressive actions of the glucocorticoids. Glucocorticoids can prevent or suppress

Table 59–3*Effects of Glucocorticoids on Components of Inflammatory/Immune Responses*

CELL TYPE	FACTOR	COMMENTS
Macrophages and monocytes	Arachidonic acid and its metabolites (prostaglandins and leukotrienes) Cytokines, including: interleukin (IL)-1, IL-6, and tumor necrosis factor- α (TNF- α) Acute phase reactants	Mediated by glucocorticoid inhibition of cyclooxygenase-2 and phospholipase A ₂ . Production and release are blocked. The cytokines exert multiple effects on inflammation (<i>e.g.</i> , activation of T cells, stimulation of fibroblast proliferation). These include the third component of complement.
Endothelial cells	Endothelial leukocyte adhesion molecule-1 (ELAM-1) and intracellular adhesion molecule-1 (ICAM-1) Acute phase reactants Cytokines (<i>e.g.</i> , IL-1) Arachidonic acid derivatives	ELAM-1 and ICAM-1 are intracellular adhesion molecules that are critical for leukocyte localization. Same as above, for macrophages and monocytes. Same as above, for macrophages and monocytes. Same as above, for macrophages and monocytes.
Basophils Fibroblasts	Histamine, leukotriene C4 Arachidonic acid metabolites	IgE-dependent release inhibited by glucocorticoids. Same as above for macrophages and monocytes. Glucocorticoids also suppress growth factor-induced DNA synthesis and fibroblast proliferation.
Lymphocytes	Cytokines (IL-1, IL-2, IL-3, IL-6, TNF- α , GM-CSF, interferon- γ)	Same as above for macrophages and monocytes.

inflammation in response to multiple inciting events, including radiant, mechanical, chemical, infectious, and immunological stimuli. Although the use of glucocorticoids as antiinflammatory agents does not address the underlying cause of the disease, the suppression of inflammation is of enormous clinical utility and has made these drugs among the most frequently prescribed agents. Similarly, glucocorticoids are of immense value in treating diseases that result from undesirable immune reactions. These diseases range from conditions that predominantly result from humoral immunity, such as urticaria (*see* Chapter 62), to those that are mediated by cellular immune mechanisms, such as transplantation rejection (*see* Chapter 52). The immunosuppressive and antiinflammatory actions of glucocorticoids are inextricably linked, perhaps because they both involve inhibition of leukocyte functions.

Multiple mechanisms are involved in the suppression of inflammation by glucocorticoids. It is now clear that glucocorticoids inhibit the production by multiple cells of factors that are critical in generating the inflammatory response. As a result, there is decreased release of vasoactive and chemoattractive factors, diminished secretion of lipolytic and proteolytic enzymes, decreased extravasation of leukocytes to areas of injury, and ultimately, decreased fibrosis. Glucocorticoids can also reduce expression of proinflammatory cytokines, such as COX-2 and NOS2. Some of the cell types and mediators that are inhibited by

glucocorticoids are summarized in Table 59–3. The net effect of these actions on various cell types is to diminish markedly the inflammatory response.

The influence of stressful conditions on immune defense mechanisms is well documented, as is the contribution of the HPA axis to the stress response (Sapolsky *et al.*, 2000). This has led to a growing appreciation of the importance of glucocorticoids as physiological modulators of the immune system, where glucocorticoids appear to protect the organism against life-threatening consequences of a full-blown inflammatory response (Chrousos, 1995).

Stresses such as injury, infection, and disease result in the increased production of cytokines, a network of signaling molecules that integrate actions of macrophages/monocytes, T lymphocytes, and B lymphocytes in mounting immune responses. Among these cytokines, interleukin (IL)-1, IL-6, and tumor necrosis factor- α (TNF- α) stimulate the HPA axis, with IL-1 having the broadest range of actions. IL-1 stimulates the release of CRH by hypothalamic neurons, interacts directly with the pituitary to increase the release of ACTH, and may directly stimulate the adrenal gland to produce glucocorticoids. As detailed above, the increased production of glucocorticoids, in turn, profoundly inhibits the immune system at multiple sites. Factors that are inhibited include components of the cytokine network, including interferon- γ (IFN- γ), granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukins (IL-1, IL-2, IL-3, IL-6, IL-8, and IL-12), and TNF- α . Thus, the HPA axis and the immune system are capable of bidirectional interactions in response to stress, and these interactions appear to be important for homeostasis (Chrousos, 1995).

Absorption, Transport, Metabolism, and Excretion

Absorption. Hydrocortisone and numerous congeners, including the synthetic analogs, are orally effective. Certain water-soluble esters of hydrocortisone and its synthetic congeners are administered intravenously to achieve high concentrations of drug rapidly in body fluids. More prolonged effects are obtained by intramuscular injection of suspensions of hydrocortisone, its esters, and congeners. Minor changes in chemical structure may markedly alter the rate of absorption, time of onset of effect, and duration of action.

Glucocorticoids also are absorbed systemically from sites of local administration, such as synovial spaces, the conjunctival sac, skin, and respiratory tract. When administration is prolonged, when the site of application is covered with an occlusive dressing, or when large areas of skin are involved, the absorption may be sufficient to cause systemic effects, including suppression of the HPA axis.

Transport, Metabolism, and Excretion. After absorption, 90% or more of cortisol in plasma is reversibly bound to protein under normal circumstances. Only the fraction of corticosteroid that is unbound can enter cells to mediate corticosteroid effects. Two plasma proteins account for almost all of the steroid-binding capacity: corticosteroid-binding globulin (CBG; also called transcortin), and albumin. CBG is an α -globulin secreted by the liver that has high affinity (estimated association constant of approximately $7.6 \times 10^7 \text{ M}^{-1}$) for steroids but relatively low total binding capacity, whereas albumin, also produced by the liver, has low affinity (estimated association constant of $1 \times 10^3 \text{ M}^{-1}$) but relatively large binding capacity. At normal or low concentrations of corticosteroids, most of the hormone is protein-bound. At higher steroid concentrations, the capacity of protein binding is exceeded, and a greater fraction of the steroid exists in the free state. Corticosteroids compete with each other for binding sites on CBG. CBG has relatively high affinity for cortisol and most of its synthetic congeners and low affinity for aldosterone and glucuronide-conjugated steroid metabolites; thus, greater percentages of these latter steroids are found in the free form.

A special state of physiological hypercorticism occurs during pregnancy. The elevated circulating estrogen levels induce CBG production, and CBG and total plasma cortisol increase severalfold. The physiological significance of these changes remains to be established.

All of the biologically active adrenocortical steroids and their synthetic congeners have a double bond in the

4,5 position and a ketone group at C 3 (Figure 59–7). As a general rule, the metabolism of steroid hormones involves sequential additions of oxygen or hydrogen atoms, followed by conjugation to form water-soluble derivatives. Reduction of the 4,5 double bond occurs at both hepatic and extrahepatic sites, yielding inactive compounds. Subsequent reduction of the 3-ketone substituent to the 3-hydroxyl derivative, forming tetrahydrocortisol, occurs only in the liver. Most of these A ring-reduced steroids are conjugated through the 3-hydroxyl group with sulfate or glucuronide by enzymatic reactions that take place in the liver, and to a lesser extent in the kidney. The resultant sulfate esters and glucuronides are water-soluble and are the predominant forms excreted in urine. Neither biliary nor fecal excretion is of quantitative importance in humans.

Synthetic steroids with an 11-keto substituent, such as cortisone and *prednisone*, must be enzymatically reduced to the corresponding 11 β -hydroxy derivative before they are biologically active. The type 1 isozyme of 11 β -hydroxysteroid dehydrogenase catalyzes this reduction, predominantly in the liver, but also in specialized sites such as adipocytes, bone, eye, and skin. In settings in which this enzymatic activity is impaired, it is prudent to use steroids that do not require enzymatic activation (*e.g.*, hydrocortisone and *prednisolone* rather than cortisone or prednisone). Such settings include severe hepatic failure and patients with the rare condition of cortisone reductase deficiency, who are unable to activate the 11-keto steroids because of a partial loss of 11 β HSD1 activity and a relative deficiency in the enzyme hexose-6-phosphate dehydrogenase, which supplies reducing equivalents to the 11 β -hydroxysteroid dehydrogenase.

Structure–Activity Relationships

Chemical modifications to the cortisol molecule have generated derivatives with greater separations of glucocorticoid and mineralocorticoid activity; for a number of synthetic glucocorticoids, the effects on electrolytes are minimal even at the highest doses used (Table 59–2). In addition, these modifications have led to derivatives with greater potencies and with longer durations of action. A vast array of steroid preparations is available for oral, parenteral, and topical use. Some of these agents are summarized in Table 59–4. None of these currently available derivatives effectively separates antiinflammatory effects from effects on carbohydrate, protein, and fat metabolism, or from suppressive effects on the HPA axis, as discussed above.

The structures of hydrocortisone (cortisol) and some of its major derivatives are shown in Figure 59–7. Changes in chemical structure may alter the specificity and/or potency due to changes in affinity and intrinsic activity at corticosteroid receptors, and alterations in absorption, protein binding, rate of metabolic transformation, rate of excretion, or membrane permeability. The effects of various substitutions on glucocorticoid and mineralocorticoid activity and on duration of action are summarized in Table 59–2. The 4,5 double bond and the 3-keto group on ring A are essential for glucocorticoid and mineralocorticoid activity; an 11 β -hydroxyl group on ring C is required for glucocorticoid activity but not mineralocorticoid activity; a hydroxyl group at C 21 on ring D is present on all natural corti-

Table 59–4

Available Preparations of Adrenocortical Steroids and Their Synthetic Analogs

NONPROPRIETARY NAME (TRADE NAME)	TYPES OF PREPARATIONS	NONPROPRIETARY NAME (TRADE NAME)	TYPES OF PREPARATIONS
Alclometasone dipropionate (ACLOVATE)	Topical	Cortisol (hydrocortisone) valerate (WESTCORT)	Topical
Amcinonide (CYCLOCORT)	Topical	Cortisone acetate (CORTONE ACETATE)	Oral, injectable
Beclomethasone dipropionate (BECLOVENT, VANCERIL, others)	Inhalation	Desonide (DESOWEN, TRIDESILON)	Topical
Betamethasone (CELESTONE)	Oral	Desoximetasone (TOPICORT)	Topical
Betamethasone dipropionate (DIPROSONE, others)	Topical	Dexamethasone (DECADRON, others)	Oral, topical
Betamethasonesodium phosphate (CELESTONE PHOSPHATE, others)	Injectable	Dexamethasone acetate (DECADRON- LA, others)	Injectable
Betamethasonesodium phosphate and acetate (CELESTONE SOLUSPAN)	Injectable	Dexamethasonesodium phosphate (DECADRON PHOSPHATE, HEXADROL PHOSPHATE, others)	Topical, oph- thalmic, otic, injectable
Betamethasone valerate (BETA-VAL, VALISONE, others)	Topical	Diflorasone diacetate (FLORONE, MAXIFLOR)	Topical
Budesonide (PULMICORT, RHINOCORT)	Inhalation	Fludrocortisone acetate* (FLORINEF)	Oral
Clobetasol propionate (TEMOVATE)	Topical	Flunisolide (AEROBID, NASALIDE)	Inhalation
Clocortolone pivalate (CLODERM)	Topical	Fluocinolone acetonide (FLUONID, SYNALAR, others)	Topical
Cortisol (hydrocortisone) (CORTEF, HYDROCORTONE, others)	Topical, enema, otic solutions, oral, injectable	Fluocinonide (LIDEX)	Topical
Cortisol (hydrocortisone) acetate (HYDROCORTONE ACETATE others)	Topical, supposi- tories, rectal foam, injectable	Fluorometholone (FLUOR-OP, FML, LIQUIFILM)	Ophthalmic
Cortisol (hydrocortisone) butyrate (LOCOID)	Topical	Fluorometholone acetate (FLAREX)	Ophthalmic
Cortisol (hydrocortisone) cypionate (CORTEF)	Oral	Flurandrenolide (CORDRAN)	Topical
Cortisol (hydrocortisone) sodium phosphate (HYDROCORTONE PHOSPHATE)	Injectable	Halcinonide (HALOG)	Topical
Cortisol (hydrocortisone) sodium succinate (A-HYDROCORT, SOLU- CORTEF)	Injectable	Medrysone (HMS LIQUIFILM)	Ophthalmic
Mometasone furoate (ELOCON)	Topical	Methylprednisolone (MEDROL)	Oral
Prednisolone (DELTA-CORTEF)	Oral	Methylprednisolone acetate (DEPO-MEDROL, MEDROL ACETATE, others)	Topical, inject- able
Prednisolone acetate (ECONOPRED, others)	Ophthalmic, injectable	Methylprednisolone sodium succi- nate (A-METHAPRED, SOLU-MEDROL)	Injectable
Prednisolone sodium phosphate (PEDIAPRED, others)	Oral, ophthalmic, injectable	Prednisone (DELTASONE, others)	Oral
Prednisolone tebutate (HYDELTRA-T.B.A., others)	Injectable	Triamcinolone (ARISTOCORT, KENACORT)	Oral
		Triamcinolone acetonide (KENALOG, others)	Topical, inhala- tion, injectable
		Triamcinolone diacetate (ARISTOCORT, KENACORT DIACETATE, others)	Oral, injectable
		Triamcinolone hexacetonide (ARISTOSPAN)	Injectable

*Fludrocortisone acetate is intended for use as a mineralocorticoid. *Note:* Topical preparations include agents for application to skin or mucous membranes in creams, solutions, ointments, gels, pastes (for oral lesions), and aerosols; ophthalmic preparations include solutions, suspensions, and ointments; inhalation preparations include agents for nasal or oral inhalation.

corticosteroids and on most of the active synthetic analogs and seems to be an absolute requirement for mineralocorticoid activity, but not for glucocorticoid activity. The 17α -hydroxyl group on ring D is a substituent on cortisol and on all of the currently used synthetic glucocorticoids. While steroids without the 17α -hydroxyl group (e.g., corticosterone) have appreciable glucocorticoid activity, the 17α -hydroxyl group gives optimal potency.

Introduction of an additional double bond in the 1,2 position of ring A, as in prednisolone or prednisone, selectively increases glucocorticoid activity (approximately fourfold compared to hydrocortisone), resulting in an enhanced glucocorticoid/mineralocorticoid potency ratio. This modification also results in compounds that are metabolized more slowly than hydrocortisone.

Fluorination at the 9α position on ring B enhances both glucocorticoid and mineralocorticoid activity, possibly related to an electron-withdrawing effect on the nearby 11β -hydroxyl group. *Fludrocortisone* (9α -fluorocortisol) has enhanced activity at the GR (10 times relative to cortisol) but even greater activity at the MR (125 times relative to cortisol). It is used in mineralocorticoid replacement therapy (see below) and has no appreciable glucocorticoid effect at usual daily doses of 0.05 mg to 0.2 mg. When combined with the 1,2 double bond in ring A and other substitutions at C 16 on ring D (Figure 59–7), the 9α -fluoro derivatives formed (e.g., *triamcinolone*, *dexamethasone*, and *betamethasone*) have marked glucocorticoid activity. The substitutions at C 16 virtually eliminate mineralocorticoid activity.

Other Substitutions. 6α Substitution on ring B has somewhat unpredictable effects. 6α -Methylcortisol has increased glucocorticoid and mineralocorticoid activity, whereas 6α -methylprednisolone has somewhat greater glucocorticoid activity and somewhat less mineralocorticoid activity than prednisolone. A number of modifications convert the glucocorticoids to more lipophilic molecules with enhanced topical/systemic potency ratios. Examples include the introduction of an acetone between hydroxyl groups at C 16 and C 17, esterification of the hydroxyl group with valerate at C 17, esterification of hydroxyl groups with propionate at C 17 and C 21, and substitution of the hydroxyl group at C 21 with chlorine. Other approaches to achieve local glucocorticoid activity while minimizing systemic effects involve the formation of analogs that are rapidly inactivated after absorption; examples include C 21 carboxylate or carbithioate glucocorticoid esters, which are rapidly metabolized to inactive 21-carboxylic acids.

Toxicity of Adrenocortical Steroids

Two categories of toxic effects result from the therapeutic use of corticosteroids: those resulting from withdrawal of steroid therapy and those resulting from continued use at supraphysiological doses. The side effects from both categories are potentially life-threatening and mandate a careful assessment of the risks and benefits in each patient.

Withdrawal of Therapy. The most frequent problem in steroid withdrawal is flare-up of the underlying disease for which steroids were prescribed. There are several other complications associated with steroid withdrawal. The most severe complication of steroid cessation, acute adrenal insufficiency, results from overly rapid withdrawal of

corticosteroids after prolonged therapy has suppressed the HPA axis. The therapeutic approach to acute adrenal insufficiency is detailed below. There is significant variation among patients with respect to the degree and duration of adrenal suppression after glucocorticoid therapy, making it difficult to establish the relative risk in any given patient. Many patients recover from glucocorticoid-induced HPA suppression within several weeks to months; however, in some individuals the time to recovery can be one year or longer.

In an effort to diminish the risk of iatrogenic acute adrenal insufficiency, protocols for discontinuing corticosteroid therapy in patients receiving long-term treatment with corticosteroids have been proposed, generally without rigorous documentation of their efficacy. Patients who have received supraphysiological doses of glucocorticoids for a period of 2 to 4 weeks within the preceding year should be considered to have some degree of HPA impairment in settings of acute stress and should be treated accordingly.

In addition to this most severe form of withdrawal, a characteristic glucocorticoid withdrawal syndrome consists of fever, myalgias, arthralgias, and malaise, which may be difficult to differentiate from some of the underlying diseases for which steroid therapy was instituted. Finally, *pseudotumor cerebri*, a clinical syndrome that includes increased intracranial pressure with papilledema, is a rare condition that sometimes is associated with reduction or withdrawal of corticosteroid therapy.

Continued Use of Supraphysiological Glucocorticoid Doses. Besides the consequences that result from the suppression of the HPA axis, there are a number of other complications that result from prolonged therapy with corticosteroids. These include fluid and electrolyte abnormalities, hypertension, hyperglycemia, increased susceptibility to infection, osteoporosis, myopathy, behavioral disturbances, cataracts, growth arrest, and the characteristic habitus of steroid overdose, including fat redistribution, striae, and ecchymoses.

Fluid and Electrolyte Handling. Alterations in fluid and electrolyte handling can cause hypokalemic alkalosis, edema, and hypertension, particularly in patients with primary hyperaldosteronism secondary to an adrenal adenoma or in patients treated with potent mineralocorticoids. Similarly, hypertension is a relatively common manifestation in patients with endogenous glucocorticoid excess and can even be seen in patients treated with glucocorticoids lacking appreciable mineralocorticoid activity.

Metabolic Changes. The effects of glucocorticoids on intermediary metabolism have been described above. Hyperglycemia with glycosuria usually can be managed with diet and/or insulin, and its occurrence should not be a major factor in the decision to continue corticosteroid therapy or to initiate therapy in diabetic patients.

Immune Responses. Because of their multiple effects to inhibit the immune system and the inflammatory response, glucocorticoid use is associated with an increased susceptibility to infection and a risk for reactivation of latent tuberculosis. In the presence of known infections of some consequence, glucocorticoids should be adminis-

tered only if absolutely necessary and concomitantly with appropriate and effective antimicrobial or antifungal therapy.

Possible Risk of Peptic Ulcers. There is considerable debate about the association between peptic ulcers and glucocorticoid therapy. The possible onset of hemorrhage and perforation in these ulcers and their insidious onset make peptic ulcers serious therapeutic problems (see Chapter 36); estimating the degree of risk from corticosteroids has received much study. Most patients who develop gastrointestinal bleeding while receiving corticosteroids also received nonsteroidal antiinflammatory agents, which are known to promote ulceration, such that the pathogenic role of corticosteroids remains open to debate. Nonetheless, it is prudent to be especially vigilant for peptic ulcer formation in patients receiving therapy with corticosteroids, especially when administered concomitantly with nonsteroidal antiinflammatory drugs.

Myopathy. Myopathy, characterized by weakness of proximal limb muscles, can occur in patients taking large doses of corticosteroids and also is part of the clinical picture in patients with endogenous Cushing's syndrome. It can be of sufficient severity to impair ambulation and is an indication for withdrawal of therapy. Attention also has focused on steroid myopathy of the respiratory muscles in patients with asthma or chronic obstructive pulmonary disease (see Chapter 27); this complication can diminish respiratory function. Recovery from the steroid myopathies may be slow and incomplete.

Behavioral Changes. Behavioral disturbances are common after administration of corticosteroids and in patients who have Cushing's syndrome secondary to endogenous hypercorticism; these disturbances may take many forms, including nervousness, insomnia, changes in mood or psyche, and overt psychosis. Suicidal tendencies are not uncommon. A history of previous psychiatric illness does not preclude the use of steroids in patients for whom they are otherwise indicated. Conversely, the absence of a history of previous psychiatric illness does not guarantee that a given patient will not develop psychiatric disorders while on steroids.

Cataracts. Cataracts are a well-established complication of glucocorticoid therapy and are related to dosage and duration of therapy. Children appear to be particularly at risk. Cessation of therapy may not lead to complete resolution of opacities, and the cataracts may progress despite reduction or cessation of therapy. Patients on long-term glucocorticoid therapy at doses of prednisone of 10 to 15 mg/day or greater should receive periodic slit-lamp examinations to detect glucocorticoid-induced posterior subcapsular cataracts.

Osteoporosis. Osteoporosis, a frequent serious complication of glucocorticoid therapy, occurs in patients of all ages and is related to dosage and duration of therapy (Saag, 2003). A reasonable estimate is that 30% to 50% of all patients who receive chronic glucocorticoid therapy ultimately will develop osteoporotic fractures. Glucocorticoids preferentially affect trabecular bone and the cortical rim of the vertebral bodies; the ribs and vertebrae are the most frequent sites of fracture. Glucocorticoids decrease bone density by multiple mechanisms, including inhibition of gonadal steroid hormones, diminished gastrointestinal absorption of Ca^{2+} , and inhibition of bone formation due to suppressive effects on osteoblasts and stimulation of resorption due to effects on osteoclasts mediated by changes in the production of osteoprotegerin and RANK ligand. In addition, glucocorticoid inhibition of intestinal Ca^{2+} uptake may lead to secondary increases in parathyroid hormone, thereby increasing bone resorption.

The considerable morbidity of glucocorticoid-related osteoporosis has led to efforts to identify patients at risk for fractures and to prevent or reverse bone loss in patients requiring chronic glucocorticoid

therapy. The initiation of glucocorticoid therapy is considered an indication for bone densitometry, preferably with techniques such as dual-energy x-ray absorptiometry of the lumbar spine and hip that most sensitively detect abnormalities in trabecular bone. Because bone loss associated with glucocorticoids predominantly occurs within the first 6 months of therapy, densitometric evaluation and prophylactic measures should be initiated with therapy or shortly thereafter. Most authorities advocate maintaining a Ca^{2+} intake of 1500 mg/day by diet plus Ca^{2+} supplementation and vitamin D intake of 400 IU/day, assuming that these measures do not increase urinary calcium excretion above the normal range. Although gonadal hormone replacement therapy has been widely used in specific groups of patients receiving chronic glucocorticoid therapy, this is the subject of considerable debate based on recently published results from randomized, placebo-controlled trials (see Chapter 57). Recombinant parathyroid hormone recently has received considerable attention as a potential therapy of glucocorticoid-induced osteoporosis.

The most important advance to date in the prevention of glucocorticoid-related osteoporosis is the successful use of bisphosphonates, which have been shown to decrease the decline in bone density and the incidence of fractures in patients receiving glucocorticoid therapy. Additional discussion of these issues is found in Chapters 57 and 61.

Osteonecrosis. Osteonecrosis (also known as avascular or aseptic necrosis) is a relatively common complication of glucocorticoid therapy. The femoral head is affected most frequently, but this process also may affect the humeral head and distal femur. Joint pain and stiffness usually are the earliest symptoms, and this diagnosis should be considered in patients receiving glucocorticoids who abruptly develop hip, shoulder, or knee pain. Although the risk increases with the duration and dose of glucocorticoid therapy, osteonecrosis also can occur when high doses of glucocorticoids are given for short periods of time. Osteonecrosis generally progresses, and most affected patients ultimately require joint replacement.

Regulation of Growth and Development. Growth retardation in children can result from administration of relatively small doses of glucocorticoids. Although the precise mechanism is unknown, there are reports that collagen synthesis and linear growth in these children can be restored by treatment with growth hormone; further studies are needed to define the role of concurrent treatment with growth hormone in this setting. Further studies also are needed to explore the possible effects of exposure to corticosteroids *in utero*. Studies in experimental animals have shown that antenatal exposure to glucocorticoids is clearly linked to cleft palate and altered neuronal development, ultimately resulting in complex behavioral abnormalities. Thus, although the actions of glucocorticoids to promote cellular differentiation play important physiological roles in human development in the neonatal period (e.g., induction of the hepatic gluconeogenic enzymes and surfactant production in the lung), the possibility remains that antenatal steroids can lead to subtle abnormalities in fetal development.

Therapeutic Uses

With the exception of replacement therapy in deficiency states, the use of glucocorticoids largely is empirical. Based on extensive clinical experience, a number of therapeutic principles can be proposed. Given the number and severity of potential side effects, the decision to institute therapy

with glucocorticoids always requires a careful consideration of the relative risks and benefits in each patient. For any disease and in any patient, the appropriate dose to achieve a given therapeutic effect must be determined by trial and error and must be re-evaluated periodically as the activity of the underlying disease changes or as complications of therapy arise. A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to one week), in the absence of specific contraindications, is unlikely to be harmful. As the duration of glucocorticoid therapy is increased beyond one week, there are time- and dose-related increases in the incidence of disabling and potentially lethal effects. Except in patients receiving replacement therapy, glucocorticoids are neither specific nor curative; rather, they are palliative by virtue of their antiinflammatory and immunosuppressive actions. Finally, abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency, which may be fatal.

These principles have several implications for clinical practice. When glucocorticoids are to be given over long periods, the dose must be determined by trial and error and must be the smallest one that will achieve the desired effect. When the therapeutic goal is relief of painful or distressing symptoms not associated with an immediately life-threatening disease, complete relief is not sought, and the steroid dose is reduced gradually until worsening symptoms indicate that the minimal acceptable dose has been found. Where possible, the substitution of other medications, such as nonsteroidal antiinflammatory drugs, may facilitate the tapering process once the initial benefit of glucocorticoid therapy has been achieved. When therapy is directed at a life-threatening disease (*e.g.*, pemphigus or lupus cerebritis), the initial dose should be a large one aimed at achieving rapid control of the crisis. If some benefit is not observed quickly, then the dose should be doubled or tripled. After initial control in a potentially lethal disease, dose reduction should be carried out under conditions that permit frequent, accurate observations of the patient. It is always essential to weigh carefully the relative dangers of therapy and of the disease being treated.

The lack of demonstrated deleterious effects of a single dose of glucocorticoids within the conventional therapeutic range justifies their administration to critically ill patients who may have adrenal insufficiency. If the underlying condition does result from deficiency of glucocorticoids, then a single intravenous injection of a soluble glucocorticoid may prevent immediate death and allow time for a definitive diagnosis to be made. If the underlying disease is not adrenal insufficiency, the single dose will not harm the patient.

In the absence of specific contraindications, short courses of high-dose, systemic glucocorticoids also may be given for diseases that are not life-threatening, but the general rule is that long courses

of therapy at high doses should be reserved for life-threatening disease. In selected settings, as when a patient is threatened with permanent disability, this rule is justifiably violated.

In an attempt to dissociate therapeutic effects from undesirable side effects, various regimens of steroid administration have been utilized. To diminish HPA axis suppression, the intermediate-acting steroid preparations (*e.g.*, prednisone or prednisolone) should be given in the morning as a single dose. Alternate-day therapy with the same glucocorticoids also has been employed, as certain patients obtain adequate therapeutic responses on this regimen. Alternatively, pulse therapy with higher glucocorticoid doses (*e.g.*, doses as high as 1 to 1.5 g/day of methylprednisolone for 3 days) frequently is used to initiate therapy in patients with fulminant, immunologically related disorders such as acute transplantation rejection, necrotizing glomerulonephritis, and lupus nephritis. The benefit of such pulse therapy in long-term maintenance regimens remains to be defined.

Replacement Therapy. Adrenal insufficiency can result from structural or functional lesions of the adrenal cortex (primary adrenal insufficiency or Addison's disease) or from structural or functional lesions of the anterior pituitary or hypothalamus (secondary adrenal insufficiency). In developed countries, primary adrenal insufficiency most frequently is secondary to autoimmune adrenal disease, whereas tuberculous adrenalitis is the most frequent etiology in underdeveloped countries. Other causes include adrenalectomy, bilateral adrenal hemorrhage, neoplastic infiltration of the adrenal glands, acquired immunodeficiency syndrome, inherited disorders of the steroidogenic enzymes, and X-linked adrenoleukodystrophy (Carey, 1997). Secondary adrenal insufficiency resulting from pituitary or hypothalamic dysfunction generally presents in a more insidious manner than does the primary disorder, probably because mineralocorticoid biosynthesis is preserved.

Acute Adrenal Insufficiency. This life-threatening disease is characterized by gastrointestinal symptoms (nausea, vomiting, and abdominal pain), dehydration, hyponatremia, hyperkalemia, weakness, lethargy, and hypotension. It usually is associated with disorders of the adrenal rather than the pituitary or hypothalamus, and sometimes follows abrupt withdrawal of glucocorticoids used at high doses or for prolonged periods.

The immediate management of patients with acute adrenal insufficiency includes intravenous therapy with isotonic sodium chloride solution supplemented with 5% glucose and corticosteroids and appropriate therapy for precipitating causes such as infection, trauma, or hemorrhage. Because cardiovascular function often is reduced in the setting of adrenocortical insufficiency, the patient should be monitored for evidence of volume overload such as rising central venous pressure or pulmonary edema. After an initial intravenous bolus of 100 mg, hydrocortisone (cortisol) should be given by continuous infu-

sion at a rate of 50 to 100 mg every 8 hours. At this dose, which approximates the maximum daily rate of cortisol secretion in response to stress, hydrocortisone alone has sufficient mineralocorticoid activity to meet all requirements. As the patient stabilizes, the hydrocortisone dose may be decreased to 25 mg every 6 to 8 hours. Thereafter, patients are treated in the same fashion as those with chronic adrenal insufficiency (*see* below).

For the treatment of suspected but unconfirmed acute adrenal insufficiency, 4 mg of *dexamethasone sodium phosphate* can be substituted for hydrocortisone, since dexamethasone does not cross-react in the cortisol assay and will not interfere with the measurement of cortisol (either basally or in response to the cosyntropin stimulation test). A failure to respond to cosyntropin in this setting is diagnostic of adrenal insufficiency. Often, a sample for the measurement of plasma ACTH also is obtained, as it will provide information about the underlying etiology if the diagnosis of adrenocortical insufficiency is established.

Chronic Adrenal Insufficiency. Patients with chronic adrenal insufficiency present with many of the same manifestations seen in adrenal crisis, but with lesser severity. These patients require daily treatment with corticosteroids (Coursin and Wood, 2002). Traditional replacement regimens have used hydrocortisone in doses of 20 to 30 mg/day. *Cortisone acetate*, which is inactive until converted to cortisol by 11β HSD, also has been used in doses ranging from 25 to 37.5 mg/day. In an effort to mimic the normal diurnal rhythm of cortisol secretion, these glucocorticoids generally have been given in divided doses, with two-thirds of the dose given in the morning and one-third given in the afternoon. Based on revised estimates of daily cortisol production and clinical studies showing that subtle degrees of glucocorticoid excess can decrease bone density in patients on conventional replacement regimens, many authorities advocate a lower daily hydrocortisone dose of 15 to 20 mg/day divided into either two doses (*e.g.*, 10 to 15 mg on awakening and 5 mg in late afternoon) or three doses (*e.g.*, 10 mg on awakening, 5 mg at lunch, and 5 mg in late afternoon). Others prefer to use intermediate- (*e.g.*, prednisone) or long-acting (*e.g.*, dexamethasone) glucocorticoids, since no regimen employing shorter-acting steroids can reproduce the peak serum glucocorticoid levels that normally occur before awakening in the morning. The superiority of any one of these regimens has not been rigorously demonstrated. Although some patients with primary adrenal insufficiency can be maintained on hydrocortisone and liberal salt intake, most of these patients also require mineralocorticoid replacement; *fludrocortisone acetate* generally is used in doses of 0.05 to 0.2 mg/day. For patients with

secondary adrenal insufficiency, the administration of a glucocorticoid alone is generally adequate, as the zona glomerulosa, which makes mineralocorticoids, is intact. When initiating treatment in patients with panhypopituitarism, it is important to administer glucocorticoids before initiating treatment with thyroid hormone, because the administration of thyroid hormone may precipitate acute adrenal insufficiency by increasing the metabolism of cortisol.

The adequacy of corticosteroid replacement therapy is judged by clinical criteria and biochemical measurements. The subjective well-being of the patient is an important clinical parameter in primary and secondary disease. In primary adrenal insufficiency, the disappearance of hyperpigmentation and the resolution of electrolyte abnormalities are valuable indicators of adequate replacement. Overtreatment may cause manifestations of Cushing's syndrome in adults and decreased linear growth in children. Plasma ACTH levels may be used to monitor therapy in patients with primary adrenal insufficiency; the early-morning ACTH level should not be suppressed, but should be less than 100 pg/ml (20 pmol/L). Although advocated by some endocrinologists, assessments of daily profiles of cortisol based on multiple blood samples or measurements of urinary free cortisol have been used more frequently as research tools than as a routine part of clinical practice.

Standard doses of glucocorticoids often must be adjusted upward in patients who also are taking drugs that increase their metabolic clearance (*e.g.*, phenytoin, barbiturates, or rifampin). Dosage adjustments also are needed to compensate for the stress of intercurrent illness, and proper patient education is essential for the execution of these adjustments. All patients with adrenal insufficiency should wear a medical alert bracelet or tag that lists their diagnosis and carries information about their steroid regimen. During minor illness, the glucocorticoid dose should be doubled. Patients should be instructed to contact their physician if nausea and vomiting preclude the retention of oral medications. The patient and family members should also be trained to administer parenteral dexamethasone (4 mg subcutaneously or intramuscularly) in the event that severe nausea or vomiting precludes the oral administration of medications; they then should seek medical attention immediately. Based largely on empirical data, glucocorticoid doses also are adjusted when patients with adrenal insufficiency undergo either elective or emergency surgery (Axelrod, 2003). In this setting, the doses are designed to approximate or exceed the maximal cortisol secretory rate of 200 mg/day; a standard regimen is hydrocortisone, 100 mg parenterally every 8 hours. Fol-

lowing surgery, the dose is halved each day until it is reduced to routine maintenance levels. Although some data suggest that increases in dose to this degree are not essential for survival even in major surgery, this approach remains the standard clinical practice.

Congenital Adrenal Hyperplasia. This term denotes a group of genetic disorders in which the activity of one of the several enzymes required for the biosynthesis of glucocorticoids is deficient. The impaired production of cortisol and the consequent lack of negative feedback inhibition lead to increased release of ACTH. As a result, other hormonally active steroids that are proximal to the enzymatic block in the steroidogenic pathway are produced in excess. Congenital adrenal hyperplasia (CAH) includes a spectrum of disorders whose precise clinical presentation, laboratory findings, and treatment depend on which of the steroidogenic enzymes is deficient.

In approximately 90% of patients, CAH results from mutations in CYP21, the enzyme that carries out the 21-hydroxylation reaction (Figure 59–3). Clinically, patients are divided into those with classic CAH, who have severe defects in enzymatic activity and first present during childhood, and those with nonclassic CAH, who present after puberty with signs and symptoms of mild androgen excess such as hirsutism, amenorrhea, infertility, and acne. Female patients with classic CAH, if not treated *in utero* with glucocorticoids, frequently are born with virilized external genitalia (female pseudohermaphroditism), which results from elevated production of adrenal androgen precursors at critical stages of sexual differentiation *in utero*. Males appear normal at birth and later may have precocious development of secondary sexual characteristics (isosexual precocious puberty). In both sexes, linear growth is accelerated in childhood, but the adult height is reduced by premature closure of the epiphyses.

In a subset of patients with classical CAH, the enzymatic deficiency is sufficiently severe to compromise aldosterone production. Such patients are unable to conserve Na^+ normally and thus are called “salt wasters.” These patients can present with cardiovascular collapse secondary to volume depletion. In an effort to prevent such life-threatening events, especially in males who appear normal at birth, many centers routinely screen all newborn babies for elevated levels of 17-hydroxyprogesterone, the immediate steroid precursor to the enzymatic block.

All patients with classical CAH require replacement therapy with hydrocortisone or a suitable congener, and those with salt wasting also require mineralocorticoid replacement. The goals of therapy are to restore levels of physiological steroid hormones to the normal range and to suppress ACTH and thereby abrogate the effects of overproduction of adrenal androgens. The typical oral dose of hydrocortisone is approximately 0.6 mg/kg daily in two or three divided doses. The mineralocorticoid used is fludrocortisone acetate (0.05 to 0.2 mg/day). Many experts also administer table salt to infants (one-fifth of a teaspoon dis-

solved in formula daily) until the child is eating solid food. Therapy is guided by gain in weight and height, by plasma levels of 17-hydroxyprogesterone, and by blood pressure. Elevated plasma renin activity suggests that the patient is receiving an inadequate dose of mineralocorticoid. Sudden spurts in linear growth often indicate inadequate pituitary suppression and excessive androgen secretion, whereas growth failure suggests overtreatment with glucocorticoid.

The ability to detect classical CAH (21-hydroxylase deficiency) prenatally has made possible the treatment of affected females with glucocorticoids *in utero*, potentially eliminating the need for genital surgery to correct the virilization of the external genitalia. To effectively suppress fetal adrenal androgen production and consequent virilization, glucocorticoid therapy (*e.g.*, dexamethasone, 20 $\mu\text{g}/\text{kg}$ taken daily orally by mothers at risk) must be initiated before 10 weeks' gestation, before a definitive diagnosis of CAH can be made. The genotype and sex of the fetus then are determined and steroid therapy is stopped if the sex is male or there is at least one wild-type allele for 21-hydroxylase. If genotyping reveals an affected female, steroid therapy is continued until delivery. Potential maternal side effects include hypertension, weight gain, edema, and mood changes. Although exposure to glucocorticoids *in utero* may have developmental consequences, adverse effects of this regimen have not yet been described.

Therapeutic Uses in Nonendocrine Diseases. Outlined below are important uses of glucocorticoids in diseases that do not directly involve the HPA axis. The disorders discussed are not inclusive; rather, they illustrate the principles governing glucocorticoid use in selected diseases for which glucocorticoids are more frequently employed. The dosage of glucocorticoids varies considerably depending on the nature and severity of the underlying disorder. For convenience, approximate doses of a representative glucocorticoid (generally prednisone) are provided. This choice is not an endorsement of one particular glucocorticoid preparation over other congeners but is made for illustrative purposes only.

Rheumatic Disorders. Glucocorticoids are used widely in the treatment of a variety of rheumatic disorders and are a mainstay in the treatment of the more serious inflammatory rheumatic diseases, such as systemic lupus erythematosus, and a variety of vasculitic disorders, such as polyarteritis nodosa, Wegener's granulomatosis, Churg-Strauss syndrome, and giant cell arteritis. For these more serious disorders, the starting dose of glucocorticoids should be sufficient to suppress the disease rapidly and minimize resultant tissue damage. Initially, prednisone (1 mg/kg per day in divided doses) often is used, generally followed by consolidation to a single daily dose, with subsequent tapering to a minimal effective dose as determined by clinical variables.

While they are an important component of treatment of rheumatic diseases, glucocorticoids are often used in conjunction with other immunosuppressive agents such as *cyclophosphamide* and *methotrexate*, which offer better long-term control than steroids alone. The exception is giant cell arteritis, for which glucocorticoids remain superior to other agents. Caution should be exercised in the use of glucocorticoids in some forms of vasculitis (*e.g.*, polyarteritis nodosa), for which underlying infections with hepatitis viruses may play a pathogenetic role. Although glucocorticoids are indicated in these cases, there is at least a theoretical concern that glucocorticoids may complicate the course of the viral infection by suppressing the immune system. To facilitate drug tapering and/or conversion to alternate-day treatment regimens, the intermediate-acting glucocorticoids such as prednisone and methylprednisolone are generally preferred over longer-acting steroids such as dexamethasone.

In rheumatoid arthritis, because of the serious and debilitating side effects associated with chronic use, glucocorticoids are used as temporizing agents for progressive disease that fails to respond to first-line treatments such as physiotherapy and nonsteroidal anti-inflammatory agents. In this case, glucocorticoids provide relief until other, slower-acting anti-rheumatic drugs, such as methotrexate or newer agents targeted at tumor necrosis factor take effect. A typical starting dose is 5 to 10 mg of prednisone per day. In the setting of an acute exacerbation, higher doses of glucocorticoids may be employed (typically 20 to 40 mg/day of prednisone or equivalent), with rapid taper thereafter. Complete relief of symptoms is not sought, and the symptomatic effect of small reductions in dose (decreases of perhaps 1 mg/day of prednisone every 2 to 3 weeks) should be tested frequently, while concurrent therapy with other measures is continued, to maintain the lowest possible prednisone dose. Alternatively, patients with major symptomatology confined to one or a few joints may be treated with intra-articular steroid injections. Depending on joint size, typical doses are 5 to 20 mg of *triamcinolone acetonide* or its equivalent.

In noninflammatory degenerative joint diseases (*e.g.*, osteoarthritis) or in a variety of regional pain syndromes (*e.g.*, tendinitis or bursitis), glucocorticoids may be administered by local injection for the treatment of episodic disease flare-up. It is important to minimize the frequency of local steroid administration whenever possible. In the case of repeated intra-articular injection of steroids, there is a significant incidence of painless joint destruction, resembling Charcot's arthropathy. It is recommended that intra-articular injections be performed with intervals of at least 3 months to minimize complications.

Renal Diseases. Patients with nephrotic syndrome secondary to minimal change disease generally respond well to steroid therapy, and glucocorticoids clearly are the first-line treatment in both adults and children. Initial daily doses of prednisone are 1 to 2 mg/kg for 6 weeks, followed by a gradual tapering of the dose over 6 to 8 weeks, although some nephrologists advocate alternate-day therapy. Objective evidence of response, such as diminished proteinuria, is seen within 2 to 3 weeks in 85% of patients, and more than 95% of patients will have remission within 3 months. Cessation of steroid therapy frequently is complicated by disease relapse, as manifested by recurrent proteinuria. Patients who relapse repeatedly are termed *steroid-resistant* and often are treated with other immunosuppressive drugs such as *azathioprine* or *cyclophosphamide*. Patients with renal disease secondary to systemic lupus erythematosus also are generally given a therapeutic trial of glucocorticoids.

Studies with other forms of renal disease, such as membranous and membranoproliferative glomerulonephritis and focal sclerosis,

have provided conflicting data on the role of glucocorticoids. In clinical practice, patients with these disorders often are given a therapeutic trial of glucocorticoids with careful monitoring of laboratory indices of response. In the case of membranous glomerulonephritis, many nephrologists recommend a trial of alternate-day glucocorticoids for 8 to 10 weeks (*e.g.*, prednisone, 120 mg every other day), followed by a 1- to 2-month period of tapering.

Allergic Disease. The onset of action of glucocorticoids in allergic diseases is delayed, and patients with severe allergic reactions such as anaphylaxis require immediate therapy with epinephrine: for adults, 0.3 to 0.5 ml of a 1:1000 solution intramuscularly or subcutaneously (repeated as often as every 15 minutes for up to three additional doses if necessary). The manifestations of allergic diseases of limited duration—such as hay fever, serum sickness, urticaria, contact dermatitis, drug reactions, bee stings, and angioneurotic edema—can be suppressed by adequate doses of glucocorticoids given as supplements to the primary therapy. In severe disease, intravenous glucocorticoids (methylprednisolone 125 mg intravenously every 6 hours, or equivalent) are appropriate. In less severe disease, antihistamines are the drugs of first choice. In allergic rhinitis, intranasal steroids are now viewed as the drug of choice by many experts.

Bronchial Asthma and Other Pulmonary Conditions. Corticosteroids frequently are used in bronchial asthma (*see* Chapter 27). They sometimes are employed in chronic obstructive pulmonary disease (COPD), particularly when there is some evidence of reversible obstructive disease. Data supporting the efficacy of corticosteroids are much more convincing for bronchial asthma than for COPD. The increased use of corticosteroids in asthma reflects an increased appreciation of the role of inflammation in the immunopathogenesis of this disorder. In severe asthma attacks requiring hospitalization, aggressive treatment with parenteral glucocorticoids is considered essential, even though their onset of action is delayed for 6 to 12 hours. Intravenous administration of 60 to 120 mg of methylprednisolone (or equivalent) every 6 hours is used initially, followed by daily oral doses of prednisone (30 to 60 mg) as the acute attack resolves. The dose then is tapered gradually, with withdrawal planned for 10 days to 2 weeks after initiation of steroid therapy. In general, patients subsequently can be managed on their prior medical regimen.

Less severe, acute exacerbations of asthma (as well as acute flares of COPD) often are treated with brief courses of oral glucocorticoids. In adult patients, 30 to 60 mg of prednisone is administered daily for 5 days; an additional week of therapy at lower doses also may be required. Upon resolution of the acute exacerbation, the glucocorticoids generally can be rapidly tapered without significant deleterious effects. Any suppression of adrenal function usually dissipates within 1 to 2 weeks. In the treatment of severe chronic bronchial asthma (or, less frequently, COPD) that is not controlled by other measures, the long-term administration of glucocorticoids may be necessary. As with other long-term uses of these agents, the lowest effective dose is used, and care must be exercised when withdrawal is attempted. Given the risks of long-term treatment with glucocorticoids, it is especially important to document objective evidence of a response (*e.g.*, an improvement in pulmonary function tests). In addition, these risks dictate that long-term glucocorticoid therapy be reserved for those patients who have failed to respond to adequate regimens of other medications (*see* Chapter 27).

In many patients, inhaled steroids (*e.g.*, *beclomethasone dipropionate* [VANCERIL], *triamcinolone acetonide* [AZMACORT], *fluticasone* [FLOVENT], *flunisolide* [AEROBID], or *budesonide* [PULMICORT])

can either reduce the need for oral corticosteroids or replace them entirely. Many physicians prefer inhaled glucocorticoids over previously recommended oral *theophylline* in the treatment of children with moderately severe asthma, in part because of the behavioral toxicity associated with chronic theophylline administration (see Chapter 27). When used as recommended, inhaled glucocorticoids are effective in reducing bronchial hyperreactivity with less suppression of adrenal function than with oral glucocorticoids. Dysphonia or oropharyngeal candidiasis may develop, but the incidence of such side effects can be reduced substantially by maneuvers that reduce drug deposition in the oral cavity, such as spacers and mouth rinsing. The status of glucocorticoids in asthma therapy is discussed in detail in Chapter 27.

Antenatal glucocorticoids are used frequently in the setting of premature labor, decreasing the incidence of respiratory distress syndrome, intraventricular hemorrhage, and death in babies delivered prematurely. Betamethasone (12 mg intramuscularly every 24 hours for two doses) or dexamethasone (6 mg intramuscularly every 12 hours for four doses) are administered to women with premature labor between 27 and 34 weeks' gestation. Due to evidence of decreased birth weight and adrenal suppression in babies whose mothers were given repeated courses of glucocorticoids, only a single course of glucocorticoids should be administered.

Infectious Diseases. Although the use of immunosuppressive glucocorticoids in infectious diseases may seem paradoxical, there are a limited number of settings in which they are indicated in the therapy of specific infectious pathogens. One dramatic example of such beneficial effects is seen in AIDS patients with *Pneumocystis carinii* pneumonia and moderate to severe hypoxia; addition of glucocorticoids to the antibiotic regimen increases oxygenation and lowers the incidence of respiratory failure and mortality. Similarly, glucocorticoids clearly decrease the incidence of long-term neurological impairment associated with *Haemophilus influenzae* type b meningitis in infants and children 2 months of age or older.

A long-standing controversy in medicine is the use of glucocorticoids in septic shock (Annane and Cavaillon, 2003). Although studies initially suggested a benefit from the routine administration of glucocorticoids to subjects with septic shock associated with gram-negative bacteremia, subsequent studies showed that glucocorticoid therapy in supraphysiologic doses was actually associated with increased mortality. Several recent trials have shown benefit in subjects treated early in their course with intermediate doses of glucocorticoids (e.g., 100 mg hydrocortisone every 8 hours). Of note, in one multicenter, randomized, placebo-controlled trial, beneficial effects were seen only in subjects who failed to increase their serum cortisol level by $>9 \mu\text{g}/\text{dl}$ during the rapid cosyntropin stimulation test. To the extent that these results are confirmed, they suggest that glucocorticoid therapy may be beneficial in septic shock, presumably by damping the effects of cytokines that are induced by the disease.

Ocular Diseases. Ocular pharmacology, including some consideration of the use of glucocorticoids, is discussed in Chapter 63. Glucocorticoids frequently are used to suppress inflammation in the eye and can preserve sight when used properly. They are administered topically for diseases of the outer eye and anterior segment and attain therapeutic concentrations in the aqueous humor after instillation into the conjunctival cul-de-sac. For diseases of the posterior segment, systemic administration is required. Generally, ocular use of glucocorticoids should be supervised by an ophthalmologist.

A typical prescription is 0.1% dexamethasone sodium phosphate solution (ophthalmic), 2 drops in the conjunctival sac every 4 hours

while awake, and 0.05% dexamethasone sodium phosphate ointment (ophthalmic) at bedtime. For inflammation of the posterior segment, typical doses are 30 mg of prednisone or equivalent per day, administered orally in divided doses.

Topical glucocorticoid therapy frequently increases intraocular pressure in normal eyes and exacerbates intraocular hypertension in patients with antecedent glaucoma. The glaucoma is not always reversible on cessation of glucocorticoid therapy. Intraocular pressure should be monitored when glucocorticoids are applied to the eye for more than 2 weeks.

Topical administration of glucocorticoids to patients with bacterial, viral, or fungal conjunctivitis can mask evidence of progression of the infection until sight is irreversibly lost. Glucocorticoids are contraindicated in herpes simplex keratitis, because progression of the disease may lead to irreversible clouding of the cornea. Topical steroids should not be used in treating mechanical lacerations and abrasions of the eye because they delay healing and promote the development and spread of infection.

Skin Diseases. Glucocorticoids are remarkably efficacious in the treatment of a wide variety of inflammatory dermatoses. As a result, a large number of different preparations and concentrations of topical glucocorticoids of varying potencies are available. A typical regimen for an eczematous eruption is 1% hydrocortisone ointment applied locally twice daily. Effectiveness is enhanced by application of the topical steroid under an occlusive film, such as plastic wrap; unfortunately, the risk of systemic absorption also is increased by occlusive dressings, and this can be a significant problem when the more potent glucocorticoids are applied to inflamed skin. Glucocorticoids are administered systemically for severe episodes of acute dermatologic disorders and for exacerbations of chronic disorders. The dose in these settings is usually 40 mg/day of prednisone. Systemic steroid administration can be lifesaving in pemphigus, which may require daily doses of up to 120 mg of prednisone. Further discussion of the treatment of skin diseases is given in Chapter 62.

Gastrointestinal Diseases. Glucocorticoid therapy is indicated in selected patients with inflammatory bowel disease (chronic ulcerative colitis and Crohn's disease; see Chapter 38). Patients who fail to respond to more conservative management (i.e., rest, diet, and *sulfasalazine*) may benefit from glucocorticoids; steroids are most useful for acute exacerbations. In mild ulcerative colitis, hydrocortisone (100 mg) can be administered as a retention enema with beneficial effects. In more severe acute exacerbations, oral prednisone (10 to 30 mg/day) frequently is employed. For severely ill patients—with fever, anorexia, anemia, and impaired nutritional status—larger doses should be used (40 to 60 mg prednisone per day). Major complications of ulcerative colitis or Crohn's disease may occur despite glucocorticoid therapy, and glucocorticoids may mask signs and symptoms of complications such as intestinal perforation and peritonitis.

Budesonide, a highly potent synthetic glucocorticoid that is inactivated by first-pass hepatic metabolism, reportedly has diminished systemic side effects commonly associated with glucocorticoids. Oral administration of budesonide in delayed-release capsules (ENTOCORT, 9 mg/day) facilitates drug delivery to the ileum and ascending colon; the drug also has been used as a retention enema in the treatment of ulcerative colitis.

Hepatic Diseases. The use of corticosteroids in hepatic disease has been highly controversial. Glucocorticoids clearly are of benefit in autoimmune hepatitis, where as many as 80% of patients show histological remission when treated with prednisone (40 to 60 mg daily initially, with tapering to a maintenance dose of 7.5 to

10 mg daily after serum transaminase levels fall). The role of corticosteroids in alcoholic liver disease is not fully defined; the most recent studies, including meta-analysis of previously published reports, suggest a beneficial role of prednisolone (40 mg/day for 4 weeks) in patients with severe disease indicators (*e.g.*, hepatic encephalopathy) without active gastrointestinal bleeding. Further studies are needed to confirm or refute the role of steroids in this setting. In the setting of severe hepatic disease, prednisolone should be used instead of prednisone, which requires hepatic conversion to be active.

Malignancies. Glucocorticoids are used in the chemotherapy of acute lymphocytic leukemia and lymphomas because of their antilymphocytic effects. Most commonly, glucocorticoids are one component of combination chemotherapy administered under scheduled protocols. Further discussion of the chemotherapy of malignant disease is given in Chapter 51. Glucocorticoids once were frequently employed in the setting of hypercalcemia of malignancy, but more effective agents, such as the bisphosphonates, now are the preferred therapy.

Cerebral Edema. Corticosteroids are of value in the reduction or prevention of cerebral edema associated with parasites and neoplasms, especially those that are metastatic. Although corticosteroids are frequently used for the treatment of cerebral edema caused by trauma or cerebrovascular accidents, controlled clinical trials do not support their use in these settings.

Miscellaneous Diseases and Conditions. Sarcoidosis. Sarcoidosis is treated with corticosteroids (approximately 1 mg/kg per day of prednisone, or equivalent dose of alternative steroids) to induce remission. Maintenance doses, which often are required for long periods of time, may be as low as 10 mg/day of prednisone. These patients, like all patients who require chronic glucocorticoid therapy at doses exceeding the normal daily production rate, are at increased risk for secondary tuberculosis; therefore, patients with a positive tuberculin reaction or other evidence of tuberculosis should receive prophylactic antituberculosis therapy.

Thrombocytopenia. In thrombocytopenia, prednisone (0.5 mg/kg) is used to decrease the bleeding tendency. In more severe cases, and for initiation of treatment of idiopathic thrombocytopenia, daily doses of prednisone (1 to 1.5 mg/kg) are employed. Patients with refractory idiopathic thrombocytopenia may respond to pulsed, high-dose glucocorticoid therapy.

Autoimmune Destruction of Erythrocytes. Patients with autoimmune destruction of erythrocytes (*i.e.*, hemolytic anemia with a positive Coombs test) are treated with prednisone (1 mg/kg per day). In the setting of severe hemolysis, higher doses may be used, with tapering as the anemia improves. Small maintenance doses may be required for several months in patients who respond.

Organ Transplantation. In organ transplantation, high doses of prednisone (50 to 100 mg) are given at the time of transplant surgery, in conjunction with other immunosuppressive agents, and most patients are kept on a maintenance regimen that includes lower doses of glucocorticoids (*see* Chapter 52). Of note, success rates for islet transplantation in type 1 diabetes mellitus have increased considerably following the use of immunosuppressive regimens that do not include glucocorticoids.

Spinal Cord Injury. Multicenter trials have shown significant decreases in neurological defects in patients with acute spinal cord injury treated within 8 hours of injury with large doses of methylprednisolone (30 mg/kg initially followed by an infusion of 5.4 mg/kg per hour for 23 hours). The ability of corticosteroids at these high doses to decrease neurological injury may reflect inhibition

of free radical-mediated cellular injury, as occurs following ischemia and reperfusion.

Diagnostic Applications of Adrenocortical Steroids

In addition to their therapeutic uses, glucocorticoids also are used for diagnostic purposes. To determine if patients with clinical manifestations suggestive of hypercortisolism have biochemical evidence of increased cortisol biosynthesis, an overnight dexamethasone test has been devised. Patients are given 1 mg of dexamethasone orally at 11 P.M., and cortisol is measured at 8 A.M. the following morning. Suppression of plasma cortisol to less than 1.8 $\mu\text{g}/\text{dl}$ suggests strongly that the patient does not have Cushing's syndrome (Arnaldi *et al.*, 2003).

The formal dexamethasone suppression test is used in the differential diagnosis of biochemically documented Cushing's syndrome. Following determination of baseline cortisol levels for 48 hours, dexamethasone (0.5 mg every 6 hours) is administered orally for 48 hours. This dose markedly suppresses cortisol levels in normal subjects, including those who have nonspecific elevations of cortisol due to obesity or stress, but does not suppress levels in patients with Cushing's syndrome. In the high-dose phase of the test, dexamethasone is administered orally at 2 mg every 6 hours for 48 hours. Patients with pituitary-dependent Cushing's syndrome (*i.e.*, Cushing's disease) generally respond with decreased cortisol levels. In contrast, patients with ectopic production of ACTH or with adrenocortical tumors generally do not exhibit decreased cortisol levels. Despite these generalities, dexamethasone may suppress cortisol levels in some patients with ectopic ACTH production, particularly with tumors such as bronchial carcinoids, and many experts prefer to use inferior petrosal sinus sampling after CRH administration to make this distinction.

INHIBITORS OF THE BIOSYNTHESIS AND ACTION OF ADRENOCORTICAL STEROIDS

Five pharmacologic agents are useful inhibitors of adrenocortical secretion. *Mitotane* (o,p'-DDD), an adrenocorticolytic agent, is discussed in Chapter 51. The other inhibitors of steroid hormone biosynthesis—*metyrapone*, *aminoglutethimide*, *ketoconazole*, and *trilostane*—are discussed here. Metyrapone, aminoglutethimide, and ketoconazole inhibit cytochrome P450 enzymes involved in adrenocorticosteroid biosynthesis. Differential selectivity of these agents for the different steroid hydroxylases provides some degree of specificity to their actions. Trilostane is a competitive inhibitor of the conversion of pregnenolone to progesterone, a reaction catalyzed by 3β -hydroxysteroid dehydrogenase. In addition, agents that act as glucocorticoid receptor antagonists (anti-glucocorticoids) are discussed here (mineralocorticoid antagonists are discussed in Chapter 28). All of these agents pose the common risk of precipitating acute adrenal insufficiency; thus, they must be used in appropriate doses, and the status of the patient's HPA axis must be carefully monitored.

Aminoglutethimide. Aminoglutethimide (α -ethyl-*p*-aminophenyl-glutarimide; CYTADREN) primarily inhibits CYP11A1, which catalyzes the initial and rate-limiting step in the biosynthesis of all physiological steroids. As a result, the production of all classes of steroid hormones is impaired. Aminoglutethimide also inhibits CYP11B1 and the enzyme aromatase, which converts androgens to estrogens. Aminoglutethimide has been used to decrease hypersecretion of cortisol in patients with Cushing's syndrome secondary to autonomous adrenal tumors and hypersecretion associated with ectopic production of ACTH. Because of its actions to inhibit aromatase, aminoglutethimide also has been evaluated as a therapeutic agent for the treatment of hormonally responsive tumors such as prostate and breast cancer, although more effective agents such as *tamoxifen* and the aromatase inhibitors are preferred. Dose-dependent gastrointestinal and neurological side effects are relatively common, as is a transient, maculopapular rash. The usual dose is 250 mg every 6 hours, with gradual increases of 250 mg per day at 1- to 2-week intervals until the desired biochemical effect is achieved, side effects prohibit further increases, or a daily dose of 2 g is reached. Because aminoglutethimide can cause frank adrenal insufficiency, glucocorticoid replacement therapy is necessary, and mineralocorticoid supplements also may be indicated. Aminoglutethimide accelerates the metabolism of dexamethasone, and this steroid therefore should not be used for glucocorticoid replacement in this setting.

Ketoconazole. Ketoconazole (NIZORAL) is an antifungal agent, and this remains its most important clinical role (*see* Chapter 48). In doses higher than those employed in antifungal therapy, it is an effective inhibitor of adrenal and gonadal steroidogenesis, primarily because of its inhibition of the activity of CYP17 (17 α -hydroxylase). At even higher doses, ketoconazole also inhibits CYP11A1, effectively blocking steroidogenesis in all primary steroidogenic tissues. Ketoconazole is the most effective inhibitor of steroid hormone biosynthesis in patients with Cushing's disease. In most cases, a dosage regimen of 600 to 800 mg/day (in two divided doses) is required, and some patients may require up to 1200 mg/day given in two to three doses. Side effects include hepatic dysfunction, which ranges from asymptomatic elevations of transaminase levels to severe hepatic injury. The potential of ketoconazole to interact with CYP isoforms can lead to drug interactions of serious consequence (*see* Chapter 3). Further studies are needed to define the precise role of ketoconazole in the medical management of patients with excessive steroid

hormonal production, and the FDA has not approved this indication for ketoconazole use.

Metyrapone. Metyrapone (METOPIRONE) is a relatively selective inhibitor of CYP11B1 (11 β -hydroxylase), which converts 11-deoxycortisol to cortisol in the terminal reaction of the glucocorticoid biosynthetic pathway. Because of this inhibition, the biosynthesis of cortisol is markedly impaired, and the levels of steroid precursors (*e.g.*, 11-deoxycortisol) are markedly increased. Although the biosynthesis of aldosterone also is impaired, the elevated levels of 11-deoxycortisol sustain mineralocorticoid-dependent functions. In a diagnostic test of the entire HPA axis, metyrapone (30 mg/kg, maximum dose of 3 g) is administered orally with a snack at midnight, and plasma cortisol and 11-deoxycortisol are measured at 8 A.M. the next morning. A plasma cortisol of less than 8 μ g/dl validates adequate inhibition of CYP11B1; in this setting, an 11-deoxycortisol level of less than 7 μ g/dl is highly suggestive of impaired hypothalamic-pituitary-adrenal function. An abnormal response does not identify the site of the defect—hypothalamic CRH release, ACTH production, or adrenal biosynthetic capacity could be impaired. Some authorities avoid overnight metyrapone testing in outpatients thought to have a reasonable probability of impaired HPA function, as there is some risk of precipitating acute adrenal insufficiency. Others believe that the ability to assess the entire HPA axis with a relatively easy test justifies the use of metyrapone testing in outpatients.

Metyrapone also is used to diagnose patients with Cushing's syndrome who respond equivocally to the formal dexamethasone suppression test. Those with pituitary-dependent Cushing's syndrome exhibit a normal response, whereas those patients with ectopic secretion of ACTH exhibit no changes in ACTH or 11-deoxycortisol levels.

Therapeutically, metyrapone has been used to treat the hypercorticism resulting from either adrenal neoplasms or tumors producing ACTH ectopically. Maximal suppression of steroidogenesis requires doses of 4 g/day. More frequently, metyrapone is used as adjunctive therapy in patients who have received pituitary irradiation or in combination with other agents that inhibit steroidogenesis. In this setting, a dose of 500 to 750 mg three or four times daily is employed. The use of metyrapone in the treatment of Cushing's syndrome secondary to pituitary hypersecretion of ACTH is more controversial. Chronic administration of metyrapone can cause hirsutism, which results from increased synthesis of adrenal androgens upstream from the enzymatic block, and hypertension, which results from elevated levels of 11-deoxycortisol. Other side effects include nausea, headache, sedation, and rash.

Metyrapone is not available from pharmacy sources in the United States, but can be obtained directly from Novartis for compassionate use.

ANTI-GLUCOCORTICOIDS

The progesterone receptor antagonist *mifepristone* [RU-486; (11 β -4-dimethylaminophenyl)-17 β -hydroxy-7 α -(propyl-1-ynyl)estra-4,9-dien-3-one] has received considerable attention because of its use as an antiprogesteragen that can terminate early pregnancy (*see* Chapter 57). At higher doses, mifepristone also inhibits the GR, blocking feedback regulation of the HPA axis and secondarily increasing endogenous ACTH and cortisol levels. Because of its abili-

ty to inhibit glucocorticoid action, mifepristone also has been studied as a potential therapeutic agent in patients with hypercorticism, although it currently can be recommended only for patients with inoperable causes of cortisol excess that have not responded to other agents.

CLINICAL SUMMARY

Glucocorticoids are administered in multiple formulations (*e.g.*, oral, parenteral, and topical) for disorders that share an inflammatory or immunological basis. Except in patients receiving replacement therapy for adrenal insufficiency, glucocorticoids are neither specific nor curative, but rather are palliative because of their antiinflammatory and immunosuppressive actions. Given the number and severity of potential side effects, the decision to institute therapy with glucocorticoids always requires a careful consideration of the relative risks and benefits in each patient. After therapy is initiated, the minimal dose needed to achieve a given therapeutic effect must be determined by trial and error and must be re-evaluated periodically as the activity of the underlying disease changes or as complications of therapy arise. A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to 1 week) is unlikely to cause harm in the absence of specific contraindications. As the duration of glucocorticoid therapy increases beyond 1 week, adverse effects increase in a time- and dose-related manner. Finally, abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency due to suppression of the HPA axis, which may be fatal.

INSULIN, ORAL HYPOGLYCEMIC AGENTS, AND THE PHARMACOLOGY OF THE ENDOCRINE PANCREAS

Stephen N. Davis

INSULIN

In recent years, developed nations have witnessed an explosive increase in the prevalence of diabetes mellitus (DM) predominantly related to lifestyle changes and the resulting surge in obesity. The metabolic consequences of prolonged hyperglycemia and dyslipidemia, including accelerated atherosclerosis, chronic kidney disease, and blindness, pose an enormous burden on patients with diabetes mellitus and on the public health system. Improvements in our understanding of the pathogenesis of diabetes and its complications and in the therapy and prevention of diabetes are critical to meeting this health care challenge.

History. Few events in the history of medicine are more dramatic than the discovery of insulin. Although the discovery is appropriately attributed to Banting and Best, others provided important observations and techniques that made it possible. In 1869, a German medical student, Paul Langerhans, noted that the pancreas contains two distinct groups of cells—the acinar cells, which secrete digestive enzymes, and cells that are clustered in islands, or islets, which he suggested served a second function. Direct evidence for this function came in 1889, when Minkowski and von Mering showed that pancreatectomized dogs exhibit a syndrome similar to diabetes mellitus in humans.

There were numerous attempts to extract the pancreatic substance responsible for regulating blood glucose. In the early 1900s, Gurg Zuelzer, an internist in Berlin, attempted to treat a dying diabetic patient with extracts of pancreas. Although the patient improved temporarily, he sank back into a coma and died when the supply of extract was exhausted. E.L. Scott, a student at the University of Chicago, made another early attempt to isolate an active principle in 1911. Using alcoholic extracts of the pancreas (not so dif-

ferent from those eventually used by Banting and Best), Scott treated several diabetic dogs with encouraging results; however, he lacked clear measures of control of blood glucose concentrations, and his professor considered the experiments inconclusive at best. Between 1916 and 1920, the Romanian physiologist Nicolas Paulesco found that injections of pancreatic extracts reduced urinary sugar and ketones in diabetic dogs. Although he published the results of his experiments, their significance was fully appreciated only years later.

Unaware of much of this work, Frederick Banting, a young Canadian surgeon, convinced J.J.R. Macleod, a professor of physiology in Toronto, to allow him access to a laboratory to search for the antidiabetic principle of the pancreas. Banting assumed that the islets secreted insulin but that the hormone was destroyed by proteolytic digestion prior to or during extraction. Together with Charles Best, a fourth-year medical student, he attempted to overcome the problem by ligating the pancreatic ducts. The acinar tissue degenerated, leaving the islets undisturbed; the remaining tissue then was extracted with ethanol and acid. Banting and Best thus obtained a pancreatic extract that decreased the concentration of blood glucose in diabetic dogs.

The first patient to receive the active extracts prepared by Banting and Best was Leonard Thompson, aged 14. He presented at the Toronto General Hospital with a blood glucose level of 500 mg/dl (28 mM). Despite rigid control of his diet (450 kcal/day), he continued to excrete large quantities of glucose, and without insulin, the most likely outcome would be death after a few months. The administration of Banting and Best's extracts reduced the plasma concentration and urinary excretion of glucose. Daily injections were given. Glucose excretion was reduced from over 100 to as little as 7.5 g/day, and the patient demonstrated marked clinical improvement. Thus replacement therapy with the newly discovered hormone, insulin, had interrupted what was clearly an otherwise fatal metabolic disorder. Banting and Best faced many trials and tribulations during the subsequent year. It was difficult to obtain active extracts reproducibly. This led to a greater involvement of Macleod; Banting also sought help from J.B. Collip, a chemist with expertise in extraction and purification of epinephrine. Stable extracts eventually were

Figure 60–1. Human proinsulin and its conversion to insulin. The amino acid sequence of human proinsulin is shown. By proteolytic cleavage, four basic amino acids (residues 31, 32, 64, and 65) and the connecting peptide are removed, converting proinsulin to insulin. The sites of action of the endopeptidases PC2 and PC3 are shown.

obtained, and patients in many parts of North America soon were being treated with insulin from porcine and bovine sources. Now, as a result of recombinant DNA technology, human insulin is used for therapy.

The Nobel Prize in medicine and physiology was awarded to Banting and Macleod with remarkable rapidity in 1923, and a furor over credit followed immediately. Banting announced that he would share his prize with Best; Macleod did the same with Collip.

Chemistry. Insulin was purified and crystallized by Abel within a few years of its discovery. Sanger established the amino acid sequence of insulin in 1960, the protein was synthesized in 1963, and Hodgkin and coworkers elucidated insulin's three-dimensional structure in 1972. Insulin was the hormone for which Yalow and Berson first developed the radioimmunoassay (Kahn and Roth, 2004).

The β (or B) cells of pancreatic islets synthesize insulin from a single-chain precursor of 110 amino acids termed *preproinsulin*. After translocation through the membrane of the rough endoplasmic reticulum, the 24-amino-acid N-terminal signal peptide of preproinsulin is cleaved rapidly to form proinsulin (Figure 60–1). Thereafter, proinsulin folds, and the disulfide bonds form. During conversion of human proinsulin to insulin, four basic amino acids and the remaining connector or C peptide are removed by proteolysis. This gives rise to the A and B peptide chains of the insulin molecule, which contains one intrasubunit and two intersubunit disulfide bonds. The A chain usually is composed of 21 amino acid residues, and the B

chain has 30; the molecular mass is thus about 5734 daltons. Although the amino acid sequence of insulin has been highly conserved in evolution, there are significant variations that account for differences in both biological potency and immunogenicity (De Meyts, 1994). There is a single insulin gene and a single protein product in most species. However, rats and mice have two genes that encode insulin and synthesize two molecules that differ at two amino acid residues in the B chain.

The crystal structure reveals that the two chains of insulin form a highly ordered structure with α -helical regions in each of the chains. The isolated chains of insulin are inactive. In solution, insulin can exist as a monomer, dimer, or hexamer. Two molecules of Zn^{2+} are coordinated in the hexamer, and this form of insulin presumably is stored in the granules of the pancreatic β cell. It is believed that Zn^{2+} has a functional role in the hexamer formation and that this process facilitates the conversion of proinsulin to insulin and storage of the hormone. Traditional insulin is hexameric in most of the highly concentrated preparations used for therapy. When the hormone is absorbed and the concentration falls to physiological levels (nanomolar), the hormone dissociates into monomers, and the monomer is most likely the biologically active form of insulin. Monomeric insulin is now available for therapy.

Substantial information about the structure–activity relationship of insulin has been obtained by study of insulins purified from a wide variety of species and by modification of the molecule. A dozen invariant residues in the A and B chains form a surface that interacts with the insulin receptor (Figure 60–2). These residues—

Figure 60–2. Model of the three-dimensional structure of insulin. The shaded area indicates the receptor-binding face of the insulin molecule.

Gly^{A1}, Glu^{A4}, Gln^{A5}, Tyr^{A19}, Asn^{A21}, Val^{B12}, Tyr^{B16}, Gly^{B23}, Phe^{B24}, Phe^{B25}, and Tyr^{B26}—overlap with domains that also are involved in insulin dimerization (De Meyts, 1994). The Leu^{A13} and Leu^{B17} residues may form part of a second binding surface. Insulin binds to surfaces located at the N- and C-terminal regions of the α subunit of the receptor, including a cysteine-rich region in the receptor α chain. In most cases, the affinity of insulin for the insulin receptor correlates closely with its potency for eliciting effects on glucose metabolism. Human, bovine, and porcine insulins are equipotent; South American guinea pig insulin is much less potent, whereas certain avian insulins are significantly more so.

Insulin is a member of a family of related peptides termed *insulinlike growth factors* (IGFs). The two IGFs (IGF-1 and IGF-2) have molecular masses of about 7500 daltons and structures that are homologous to that of proinsulin. However, the short equivalents of the C peptide in proinsulin are not removed from the IGFs. In contrast with insulin, the IGFs are produced in many tissues, and they may serve a more important function in the regulation of growth than in the regulation of metabolism. These peptides, particularly IGF-1, are the presumed mediators of the action of growth hormone, and they originally were called *somatomedins*. The uterine hormone *relaxin* also may be a distant relative of this family of polypeptides, although the relaxin receptor clearly is distinct from those for insulin and IGF-1.

The receptors for insulin and IGF-1 are also closely related (Nakae *et al.*, 2001). Thus, insulin can bind to the receptor for IGF-1 with low affinity and *vice versa*. The growth-promoting actions of insulin appear to be mediated in part through the IGF-1 receptor, and there may be discordance between the metabolic potency of an insulin analog and its ability to promote growth. For example, proinsulin has only 2% of the metabolic potency of insulin *in vitro*, but it is half as potent as insulin in stimulating mitogenesis.

Synthesis, Secretion, Distribution, and Degradation of Insulin

Insulin Production. The molecular and cellular events involved in the synthesis, storage, and secretion of insulin

by the β cell and ultimate degradation of the hormone by its target tissues have been studied in great detail and have served as a model for study of other cell types in the pancreatic islet. The islet of Langerhans is composed of four types of cells, each of which synthesizes and secretes a distinct polypeptide hormone: insulin in the β (B) cell, *glucagon* in the α (A) cell, *somatostatin* in the δ (D) cell, and pancreatic polypeptide in the PP or F cell. The β cells make up 60% to 80% of the islet and form its central core. The α , δ , and F cells form a discontinuous mantle, one to three cells thick, around this core.

The cells in the islet are connected by tight junctions that allow small molecules to pass and facilitate coordinated control of groups of cells. Arterioles enter the islets and branch into a glomerularlike capillary mass in the β -cell core. Capillaries then pass to the rim of the islet and coalesce into collecting venules. Blood flows in the islet from the β cells to α and δ cells. Thus, the β cell is the primary glucose sensor for the islet, and the other cell types presumably are exposed to particularly high concentrations of insulin.

As noted earlier, insulin is synthesized as a single-chain precursor in which the A and B chains are connected by the C peptide. The initial translation product, proinsulin, contains a sequence of 24 primarily hydrophobic amino acid residues attached to the N terminus of the B chain. This signal sequence is required for the association and penetration of nascent proinsulin into the lumen of the rough endoplasmic reticulum. This sequence is cleaved rapidly, and proinsulin is then transported in small vesicles to the Golgi complex. Here, proinsulin is packaged into secretory granules along with the enzyme(s) responsible for its conversion to insulin.

The conversion of proinsulin to insulin begins in the Golgi complex, continues in the secretory granules, and is nearly complete at the time of secretion. Thus, equimolar amounts of C peptide and insulin are released into the circulation. The C peptide has no known biological function but serves as a useful index of insulin secretion in distinguishing between patients with factitious insulin injection and insulin-producing tumors. Small quantities of proinsulin and des-31,32 proinsulin also are released from β cells. This presumably reflects either exocytosis of granules in which the conversion of proinsulin to insulin is not complete or secretion by another pathway. Since the half-life of proinsulin in the circulation is much longer than that of insulin, up to 20% of immunoreactive insulin in plasma is, in reality, proinsulin and intermediates.

Two distinct Ca²⁺-dependent endopeptidases, which are found in the islet cell granules and in other neuroendocrine cells, are responsible for the conversion of proinsulin to insulin. These endopeptidases, PC2 and PC3, have catalytic domains related to that of subtilisin and cleave at Lys–Arg or Arg–Arg sequences (Steiner *et al.*, 1996). PC2 selectively cleaves at the C peptide–A chain junction (Figure 60–1). PC3 preferentially cleaves at the C peptide–B chain junction but has some action at the A chain junction as well. Although there are at least two other members of the family of endopeptidases (PC1 and furin), PC2 and PC3 appear to be the enzymes responsible for processing proinsulin to insulin.

Regulation of Insulin Secretion. Insulin secretion is a tightly regulated process designed to provide stable concentrations of glucose in blood during both fasting and feeding. This regulation is achieved by the coordinated interplay of various nutrients, gastrointestinal hormones, pancreatic hormones, and autonomic neurotransmitters. Glu-

cose, amino acids, fatty acids, and ketone bodies promote the secretion of insulin. The islets of Langerhans are richly innervated by both adrenergic and cholinergic nerves. Stimulation of α_2 adrenergic receptors inhibits insulin secretion, whereas β_2 adrenergic receptor agonists and vagal nerve stimulation enhance release. In general, any condition that activates the sympathetic branch of the autonomic nervous system (such as hypoxia, hypoglycemia, exercise, hypothermia, surgery, or severe burns) suppresses the secretion of insulin by stimulation of α_2 adrenergic receptors. Predictably, α_2 adrenergic receptor antagonists increase basal concentrations of insulin in plasma, and β_2 adrenergic receptor antagonists decrease them.

Glucose is the principal stimulus to insulin secretion in human beings and is an essential permissive factor for the actions of many other secretagogues (Matschinsky, 1996). The sugar is more effective in provoking insulin secretion when taken orally than when administered intravenously because the ingestion of glucose (or food) induces the release of gastrointestinal hormones and stimulates vagal activity. Several gastrointestinal hormones promote the secretion of insulin. The most potent of these are gastrointestinal inhibitory peptide (GIP) and glucagonlike peptide 1 (GLP-1). Insulin release also is stimulated by gastrin, secretin, cholecystokinin, vasoactive intestinal peptide, gastrin-releasing peptide, and enteroglucagon.

When evoked by glucose, insulin secretion is biphasic: The first phase reaches a peak after 1 to 2 minutes and is short-lived; the second phase has a delayed onset but a longer duration.

Recent research has provided an outline of how glucose stimulates insulin secretion. Basically, the resting β cell is hyperpolarized, and its depolarization leads to the secretion of insulin. A rising plasma glucose concentration initiates a series of events that leads to depolarization. Glucose enters the β cell by facilitated transport, which is mediated by GLUT2, a specific subtype of glucose transporter, whereupon the sugar is phosphorylated to glucose-6-phosphate (G-6-P) by glucokinase. The increase in oxidizable substrate (glucose and G-6-P) enhances adenosine triphosphate (ATP) production, thereby increasing the ATP-adenosine diphosphate (ADP) ratio and inhibiting an ATP-sensitive K^+ channel. This decrease in K^+ conductance causes E_m to rise, opening a voltage-sensitive Ca^{2+} channel.

Intracellular Ca^{2+} acts as the insulin secretagogue, as it does for the secretion of many vesicular products. The influx of Ca^{2+} also activates several phospholipases, leading to the production of eicosanoids and IP_3 and the mobilization of intracellular Ca^{2+} stores.

The ATP-sensitive K^+ channel in insulin-secreting cells is an octamer composed of four Kir 6.2 and four SUR1 subunits. Both types of subunits contain nucleotide-binding domains; Kir 6.2 appears to mediate the inhibitory response to ATP; SUR1 binds ADP, the channel activator *diazoxide*, and the channel inhibitors (and promoters of insulin secretion) sulfonylureas and meglitinide. Mutations in the channel proteins can lead to altered insulin secretion (see Proks *et al.*, 2004).

Elevation of free Ca^{2+} concentrations also occurs in response to stimulation of phospholipase C by acetylcholine and cholecystokinin and by hormones that increase intracellular concentrations of cyclic AMP. In the β cell, G protein-coupled receptors (GPCRs) for glucagon, GIP, and GLP-1 couple to G_s to stimulate adenylyl cyclase; somatostatin and α_2 adrenergic receptor agonists couple to G_i to reduce cellular cyclic adenosine monophosphate (AMP) production.

The hexokinase involved in this process is a specific isoform, glucokinase, whose expression is limited primarily to cells and tissues involved in the regulation of glucose metabolism, such as the liver and pancreatic cells. Its relatively high K_m (10 to 20 mM) gives it an important regulatory role at physiological concentrations of

glucose. The capacity of sugars to undergo phosphorylation and subsequent glycolysis correlates closely with their ability to stimulate insulin release. The role of glucokinase as a glucose sensor was inferred from the association of mutations of the glucokinase gene with a form of maturity-onset diabetes of the young (MODY2; *see below*), a rare genetic form of diabetes. These mutations, which compromise the ability of glucokinase to phosphorylate glucose, raise the threshold for glucose-stimulated insulin release.

Most of the nutrients and hormones that stimulate insulin secretion also enhance its biosynthesis. Although there is a close correlation between the two processes, some factors affect one pathway but not the other. For example, lowering extracellular concentrations of Ca^{2+} inhibits secretion of insulin without affecting biosynthesis.

There usually is a reciprocal relationship between the rates of secretion of insulin and glucagon from the pancreatic islet. This reciprocity reflects both the influence of insulin on the α cell and the level of glucose and other substrates (*see below*). In addition, somatostatin, a third islet cell hormone, can modulate the secretion of both hormones (*see below*). Glucagon stimulates the release of somatostatin, which may suppress the secretion of insulin but is not a major physiological influence. Since the blood supply in the islet flows from the β -cell core to the α and δ cells, insulin can inhibit glucagon release in a paracrine manner, but somatostatin must pass through the circulation to reach the α and β cells. Thus, while insulin affects the secretion of glucagon and pancreatic polypeptide, the paracrine of islet somatostatin is not clear.

Distribution and Degradation of Insulin. Insulin circulates in blood as the free monomer, and its volume of distribution approximates the volume of extracellular fluid. Under fasting conditions, the pancreas secretes about 40 μ g (1 unit) of insulin per hour into the portal vein to achieve a concentration of insulin in portal blood of 2 to 4 ng/ml (50 to 100 μ units/ml) and in the peripheral circulation of 0.5 ng/ml (12 μ units/ml) or about 0.1 nM. After ingestion of a meal, there is a rapid rise in the concentration of insulin in portal blood, followed by a parallel but smaller rise in the peripheral circulation. A goal of insulin therapy is to mimic this pattern, but this is difficult to achieve with subcutaneous injections.

The half-life of insulin in plasma is about 5 to 6 minutes in normal subjects and patients with uncomplicated diabetes. This value may be increased in diabetics who develop anti-insulin antibodies. The half-life of proinsulin is longer than that of insulin (about 17 minutes), and this protein usually accounts for about 10% of the immunoreactive "insulin" in plasma. In patients with insulinoma, the percentage of proinsulin in the circulation usually is increased and may be as much as 80% of immunoreactivity. Since proinsulin is only about 2% as potent as insulin, the biologically effective concentration of insulin is somewhat lower than estimated by immunoassay. C peptide is secreted in equimolar amounts with insulin; however, its molar concentration in plasma is higher because of its lower hepatic clearance and considerably longer half-life

(about 30 minutes). C peptide serves as a marker for acute insulin secretion.

Degradation of insulin occurs primarily in liver, kidney, and muscle (Duckworth, 1988). About 50% of the insulin that reaches the liver *via* the portal vein is destroyed and never reaches the general circulation. Insulin is filtered by the renal glomeruli and is reabsorbed by the tubules, which also degrade it. Severe impairment of renal function appears to affect the rate of disappearance of circulating insulin to a greater extent than does hepatic disease. Hepatic degradation of insulin operates near its maximal capacity and cannot compensate for diminished renal breakdown of the hormone. Peripheral tissues such as fat also inactivate insulin, but this is of less significance quantitatively.

Proteolytic degradation of insulin in the liver occurs primarily after internalization of the hormone and its receptor and, to a lesser extent, at the cell surface. The primary pathway for internalization is receptor-mediated endocytosis. The complex of insulin and its receptor is internalized into small vesicles termed *endosomes*, where degradation is initiated (Duckworth, 1988). Some insulin also is delivered to lysosomes for degradation.

The extent to which internalized insulin is degraded by the cell varies considerably with the cell type. In hepatocytes, over 50% of the internalized insulin is degraded, whereas most internalized insulin is released intact from endothelial cells. In the latter case, this finding appears to be related to the role of these cells in transcytosis of insulin molecules from the intravascular to the extracellular space. Transcytosis has an important role in the delivery of insulin to its target cells in tissues where endothelial cells form tight junctions, including skeletal muscle and adipose tissue.

Several enzymes have been implicated in insulin degradation. The primary insulin-degrading enzyme is a thiol metalloproteinase. It is localized primarily in hepatocytes, but immunologically related molecules also have been found in muscle, kidney, and brain (Duckworth, 1988). Most insulin-degrading enzyme activity appears to be cytosolic, raising the question of how the internalized vesicular insulin becomes associated with the degrading enzyme, although this activity also has been found in endosomes. A second insulin-degrading enzyme also has been described (Authier *et al.*, 1994), but the relative roles of these enzymes have not been established. Insulin-degrading enzyme also may have a role in the degradation of other hormones, including glucagon.

Cellular Actions of Insulin. Insulin elicits a remarkable array of biological responses. The important target tissues for regulation of glucose homeostasis by insulin are liver, muscle, and fat, but insulin exerts potent regulatory effects on other cell types as well. Insulin is the primary hormone responsible for controlling the uptake, use, and storage of cellular nutrients. Insulin's anabolic actions include the stimulation of intracellular use and storage of glucose, amino acids, and fatty acids, whereas it inhibits catabolic processes such as the breakdown of glycogen, fat, and protein. It accomplishes these general purposes by stimulating the

transport of substrates and ions into cells, promoting the translocation of proteins between cellular compartments, activating and inactivating specific enzymes, and changing the amounts of proteins by altering the rates of gene transcription and specific mRNA translation (Figure 60–3).

Some effects of insulin occur within seconds or minutes, including the activation of glucose and ion transport systems, the covalent modification (*i.e.*, phosphorylation or dephosphorylation) of enzymes, and some effects on gene transcription (*i.e.*, inhibition of the phosphoenolpyruvate carboxykinase gene) (O'Brien and Granner, 1996). Other effects, such as those on protein synthesis and gene transcription, may take a few hours. Effects of insulin on cell proliferation and differentiation may take days. It is not clear whether these kinetic differences result from the use of different mechanistic pathways or from the intrinsic kinetics of the various processes.

Regulation of Glucose Transport. Stimulation of glucose transport into muscle and adipose tissue is a crucial component of the physiological response to insulin. Glucose enters cells by facilitated diffusion through one of a family of glucose transporters. Five of these (GLUT1 through GLUT5) are thought to be involved in Na⁺-independent facilitated diffusion of glucose into cells (Shepherd and Kahn, 1999). The glucose transporters are integral membrane glycoproteins with molecular masses of about 50,000 daltons, and each has 12 membrane-spanning α -helical domains. Insulin stimulates glucose transport at least in part by promoting translocation of intracellular vesicles that contain the GLUT4 and GLUT1 glucose transporters to the plasma membrane (Figure 60–3). This effect is reversible; the transporters return to the intracellular pool on removal of insulin. Faulty regulation of this process may contribute to the pathophysiology of type 2 DM (Shepherd and Kahn, 1999).

Regulation of Glucose Metabolism. The facilitated diffusion of glucose into cells along a downhill gradient is ensured by glucose phosphorylation. This enzymatic reaction, the conversion of glucose to glucose-6-phosphate (G-6-P), is accomplished by one of a family of hexokinases. Like the glucose transporters described earlier, the four hexokinases (I through IV) are distributed differently in tissues, and two are regulated by insulin. Hexokinase IV, a 50,000-dalton enzyme more commonly known as *glucokinase*, is found in association with GLUT2 in liver and pancreatic β cells. There is one glucokinase gene, but different first exons and promoters are employed in the two tissues (Printz *et al.*, 1993). The liver glucokinase gene is regulated by insulin. Hexokinase II, a 100,000-dalton enzyme, is found in associa-

Figure 60–3. Pathways of insulin signaling. The binding of insulin to its plasma membrane receptor activates a cascade of downstream signaling events. Insulin binding activates the intrinsic tyrosine kinase activity of the receptor dimer, resulting in the tyrosine phosphorylation (Y-P) of the receptor's β subunits and a small number of specific substrates (light blue shapes): the Insulin Receptor Substrate (IRS) proteins, Gab-1 and SHC; within the membrane, a caveolar pool of insulin receptor phosphorylates caveolin (Cav), APS, and Cbl. These tyrosine-phosphorylated proteins interact with signaling cascades via SH2 and SH3 domains to mediate the effects of insulin, with specific effects of insulin resulting from each pathway. In target tissues such as skeletal muscle and adipocytes, a key event is the translocation of the GLUT4 glucose transporter from intracellular vesicles to the plasma membrane; this translocation is stimulated by both the caveolar and non-caveolar pathways. In the non-caveolar pathway, the activation of PI3K is crucial, and PKB/Akt (anchored at the membrane by PIP3) and/or an atypical form of PKC is involved. In the caveolar pathway, the caveolar protein flotillin localizes the signaling complex to the caveola; the signaling pathway involves series of SH2 domain interactions that add the adaptor protein CrkII, the guanine nucleotide exchange protein C3G, and small GTP-binding protein, TC10. The pathways are inactivated by specific phosphoprotein phosphatases (eg, PTB1B) and possibly by actions of ser/thr protein kinases. In addition to the actions shown, insulin also stimulates the plasma membrane Na^+, K^+ -ATPase by a mechanism that is still being elucidated; the result is an increase in pump activity and a net accumulation of K^+ in the cell. Abbreviations: APS, adaptor protein with PH and SH2 domains; CAP, Cbl associated protein; CrkII, chicken tumor virus regulator of kinase II; GLUT4, glucose transporter 4; Gab-1, Grb-2 associated binder; MAP kinase, mitogen-activated protein kinase; PDK, phosphoinositide-dependent kinase; PI3 kinase, phosphatidylinositol-3-kinase; PIP3, phosphatidylinositol trisphosphate; PKB, protein kinase B (also called Akt); aPKC, atypical isoform of protein kinase C; Y, tyrosine residue; Y-P, phosphorylated tyrosine residue.

tion with GLUT4 in skeletal and cardiac muscle and in adipose tissue. Like GLUT4, hexokinase II is regulated transcriptionally by insulin.

G-6-P is a branch-point substrate that can enter several pathways. Thus, following isomerization to G-1-P, G-6-P can be stored as glycogen (insulin enhances the activity of glycogen synthase); G-6-P can enter the glycolytic pathway (leading to ATP production); and G-6-P can also enter the pentose phosphate pathway (providing NADPH for reductive syntheses, for the xenobiotic metabolizing activities of CYPs, and for maintenance of reduced glutathione). Effects of insulin on cellular metabolic enzymes are myriad and generally are mediated via the activities of protein kinases and phosphoprotein phosphatases that are enhanced following insulin treatment. Figure 60–3 shows the initial signaling events following the binding of insulin to its membrane receptor.

Regulation of Gene Transcription. A major action of insulin is the regulation of transcription of specific genes. More than a hundred genes are known to be regulated by insulin (O'Brien and Granner, 1996), although the mechanisms of regulation are still being worked out. As an example, insulin inhibits the transcription of phosphoenolpyruvate carboxykinase, contributing to insulin's inhibition of gluconeogenesis; this effect of insulin may explain why the liver overproduces glucose in the insulin-resistant state that is characteristic of type 2 DM.

The Insulin Receptor. Insulin initiates its actions by binding to a cell-surface receptor. Such receptors are present in virtually all mammalian cells, including not only the classic targets for insulin action (*i.e.*, liver, muscle, and fat) but also such nonclassic targets as circulating

blood cells, neurons, and gonadal cells. The number of receptors varies from as few as 40 per cell on erythrocytes to 300,000 per cell on adipocytes and hepatocytes.

The insulin receptor is a large transmembrane glycoprotein composed of two 135,000-dalton α subunits (719 or 731 amino acids, depending on whether a 12-amino-acid insertion has occurred through alternate RNA splicing) and two 95,000-dalton β subunits (620 amino acids); the subunits are linked by disulfide bonds to form a β - α - α - β heterotetramer (Figure 60–3) (Virkamäki *et al.*, 1999). Both subunits are derived from a single-chain precursor molecule that contains the entire sequence of the α and β subunits separated by a processing site consisting of four basic amino acid residues. The α subunits are entirely extracellular and contain the insulin-binding domain (*see above*), whereas the β subunits are transmembrane proteins that possess tyrosine protein kinase activity. After insulin is bound, receptors aggregate and are internalized rapidly. Since bivalent (but not monovalent) anti-insulin receptor antibodies cross-link adjacent receptors and mimic the rapid actions of insulin, it has been suggested that receptor dimerization is essential for signal transduction. After internalization, the receptor may be degraded or recycled back to the cell surface.

Tyrosine Phosphorylation and the Insulin Action Cascade. Receptors for insulin and IGF-1 belong to the family of receptor tyrosine kinases, in common with many growth factor receptors.

The activated receptors undergo autophosphorylation, which seems to activate their tyrosine kinase activity toward other substrates, principally the four insulin receptor substrates IRS-1 through 4 and Shc (White, 2002). The tyrosine phosphorylated IRS proteins direct the recruitment of signaling cascades *via* the interaction of SH2 domains with phosphotyrosines, recruiting such proteins as SHP2, Grb2, and SOS and resulting in the activation of MAP kinases and PI_3 -kinase, which transduce many of insulin's cellular effects.

Insulin signaling is complicated by the fact that the IGF-1 receptor resembles the insulin receptor and uses similar signaling pathways; furthermore, the two receptors bind each other's ligand, albeit with lower affinity. In addition, IGF-1 and insulin-receptor heterodimers can combine to form hybrid heterotetramers.

The tyrosine kinase activity of the insulin receptor is required for signal transduction. Mutation of the insulin receptor with modification of the ATP-binding site or replacement of the tyrosine residues at major sites of autophosphorylation decreases both insulin-stimulated kinase activity and the cellular response to insulin. An insulin receptor incapable of autophosphorylation is biologically inert. A polymorphism in the human IRS-1, G972R, is associated with insulin resistance and increased risk of type 2 DM; this polymorphic IRS-1 appears to act as an inhibitor of the insulin-receptor tyrosine kinase (McGettrick *et al.*, 2005). In intact cells, the insulin receptor also is phosphorylated on serine and threonine residues, presumably by protein kinase C (PKC) and protein kinase A (PKA). Such phosphorylation inhibits the tyrosine kinase activity of the insulin receptor.

Diabetes Mellitus and the Physiological Effects of Insulin

Diabetes mellitus (DM) consists of a group of syndromes characterized by hyperglycemia; altered metabo-

lism of lipids, carbohydrates, and proteins; and an increased risk of complications from vascular disease. Most patients can be classified clinically as having either type 1 or type 2 DM (Expert Committee on the Diagnosis and Treatment of Diabetes Mellitus, 2003). DM or carbohydrate intolerance also is associated with certain other conditions or syndromes (Table 60–1). Criteria for the diagnosis of DM have been proposed by several medical organizations. The American Diabetes Association (ADA) criteria include symptoms of DM (*e.g.*, polyuria, polydipsia, and unexplained weight loss) and a random plasma glucose concentration of greater than 200 mg/dl (11.1 mM), a fasting plasma glucose concentration of greater than 126 mg/dl (7 mM), or a plasma glucose concentration of greater than 200 mg/dl (11 mM) 2 hours after the ingestion of an oral glucose load (Expert Committee on the Diagnosis and Treatment of Diabetes Mellitus, 2003).

The incidence of each type of diabetes varies widely throughout the world. In the United States, about 5% to 10% of all diabetic patients have type 1 DM, with an incidence of 18 per 100,000 inhabitants per year. A similar incidence is found in the United Kingdom. The incidence of type 1 DM in Europe varies with latitude. The highest rates occur in northern Europe (Finland, 43 per 100,000) and the lowest in the south (France and Italy, 8 per 100,000). The one exception to this rule is the small island of Sardinia, close to Italy, which has an incidence of 30 per 100,000. However, even the relatively low incidence rates of type 1 DM in southern Europe are far higher than the rates in Japan (1 per 100,000 inhabitants).

The vast majority of diabetic patients have type 2 DM. In the United States, about 90% of all diabetic patients have type 2 DM. Incidence rates of type 2 DM increase with age, with a mean rate of about 440 per 100,000 per year by the sixth decade in males in the United States. Ethnicity within a country also can influence the incidence of type 2 DM; the mean rate in African-American males is 540 per 100,000, and that in Pima Indians is about 5000 per 100,000. Unlike those for type 1 DM, the incidence rates for type 2 DM are lower in northern Europe (100 to 250 per 100,000) than in the south (800 per 100,000). Although prevalence data exist for type 2 DM, these numbers almost certainly are underestimates because 33% of all cases are undiagnosed.

There are more than 125 million persons with diabetes in the world today, and by 2010, this number is expected to approach 220 million (Amos *et al.*, 1997). Both type 1 and type 2 DM are increasing in frequency. The reason for the increase of type 1 DM is not known. The genetic basis for type 2 DM cannot change in such a short time; thus other contributing factors, including increasing age, obesity, sedentary lifestyle, and low birth weight, must account for this dramatic increase. In addition, type 2 DM is being diagnosed with remarkable frequency in preadolescents and adolescents. Up to 45% of newly diagnosed children and adolescents have type 2 DM.

In certain tropical countries, the most common cause of diabetes is chronic pancreatitis associated with nutritional or toxic factors (a form of secondary diabetes). Very rarely, diabetes results from point mutations in the insulin gene (Chan *et al.*, 1987). Amino acid substi-

Table 60–1
Different Forms of Diabetes Mellitus

General—genetic and other factors not precisely defined

Type 1 diabetes mellitus (formerly called insulin-dependent diabetes mellitus)

Autoimmune type 1 diabetes mellitus (type 1A)

Non-autoimmune or idiopathic type 1 diabetes mellitus (type 1B)

Type 2 diabetes mellitus (formerly called non-insulin-dependent diabetes mellitus)

Specific—defined gene mutations

Maturity-onset diabetes of youth (MODY)

MODY 1 hepatic nuclear factor 4 α (*HNF4A*) gene mutations

MODY 2 glucokinase (*GCK*) gene mutations

MODY 3 hepatic nuclear factor 1 α (*TCF1*) gene mutations

MODY 4 insulin promoter factor 1 (*IPF1*) gene mutations

MODY 5 hepatic nuclear factor 1 β (*HNF1 β*) gene mutations

MODY 6 neurogenic differentiation 1 (*NEUROD1*) gene mutation

MODY X unidentified gene mutation(s)

Maternally inherited diabetes and deafness (MIDD)

Mitochondrial leucine tRNA gene mutations

Insulin gene mutations

Insulin receptor gene mutations

Diabetes secondary to pancreatic disease

Chronic pancreatitis

Surgery

Tropical diabetes (chronic pancreatitis associated with nutritional and/or toxic factors)

Diabetes secondary to other endocrinopathies

Cushing's disease

Glucocorticoid administration

Acromegaly

Diabetes secondary to immune suppression

Diabetes associated with genetic syndromes; e.g.,

Prader-Willi syndrome

Diabetes associated with drug therapy (see Table 60–5)

tions from such mutations may result in insulins with lower potency or may alter the processing of proinsulin to insulin (see above). Other single-gene mutations cause the several types of MODY (Hattersley, 1998) and maternally inherited diabetes and deafness (van den Ouweland *et al.*, 1992) (Table 60–1).

There are genetic and environmental components that affect the risk of developing either type 1 or type 2 DM. A positive family history of type 2 DM is predictive for the disease. Studies of identical twins show 70% to 80% concordance for developing type 2 DM. Furthermore, there is a high prevalence of type 2 DM in offspring of parents with the disease (up to 70%) as well as in siblings of affected individuals. Persons more than 20% over their ideal body weight also have a greater risk of developing type 2 DM. In fact, 80% to 90% of type 2 DM subjects in the United States are obese. Certain ethnic groups have a higher incidence of type 2 DM (*e.g.*, American Indians, African-Americans, Hispanics, and Polynesian Islanders). In addition, previously identified impaired glucose tolerance, gestational diabetes, hypertension, or significant hyperlipidemia is associated with an increased risk of type 2 DM. These data suggest a strong genetic basis for type 2 DM, but the genetic mechanism(s) involved are not known. A pancreatic β -cell defect and a reduction in tissue sensitivity to insulin both are required before overt type 2 DM is apparent. However, type 2 DM is an extremely heterogeneous disease, and it is likely that a number of different genes are involved. In addition, environmental factors may play a role. Type 2 DM thus is a multifactorial disease. Any combination of genetic and environmental factors that exceeds a threshold can result in type 2 DM. The genetic basis for type 2 DM in a small subset of patients has been established. MODY2 is a rare disorder that is inherited as an autosomal dominant trait and is caused by mutations of the glucokinase gene. Because of decreased glucokinase activity, these patients have an increased glycemic threshold for insulin release that results in persistent mild hyperglycemia. This and other rare genetic forms of MODY are quite distinct from the usual type 2 DM (Table 60–1).

With type 1 DM, the concordance rate for identical twins is only 25% to 50%; this suggests that environmental as well as genetic influences have an important role in the disease. However, the known genetic factors in type 1 DM relate to the genes that control the immune response. There is considerable evidence that type 1 DM involves an autoimmune attack on the pancreatic β cell. Antibodies to islet cell antigens are detected in up to 80% of patients with type 1 DM shortly after diagnosis or even prior to the onset of clinical disease. The antibodies are directed at both cytoplasmic and membrane-bound antigens and include islet cell antibodies and antibodies directed against insulin (IAAs), glutamic acid decarboxylase-65 and -67 (GAD-65 and -67), heat-shock protein 65 (HSP-65), and tyrosine phosphatase-like protein (IA-2 or IA-2B).

Although these autoantibodies are correlated with the clinical expression of type 1 DM, it is controversial whether they can predict the development of clinical diabetes. Most prospective studies designed to determine if type 1 DM can be predicted on the basis of antibodies have been performed in healthy first-degree relatives of diabetic patients. These studies have determined that the presence of IAAs confers only a small risk for the development of type 1 DM. On the other hand, the presence of high-titer islet-cell antibodies (ICAs) and GAD antibodies or ICAs combined with IAAs confers a very high risk for the development of type 1 DM in first-degree relatives (Verge *et al.*, 1996).

Since most of the studies aimed at predicting the development of type 1 DM have been carried out in first-degree relatives of diabetic patients, it is not known whether the occurrence of ICAs in individuals from the general population confers a similar risk for development of clinical diabetes. Most available data indicate that the presence of ICAs in individuals from the general population is

associated with a lower risk of developing type 1 DM. However, as in first-degree relatives of type 1 DM patients, it may be that the presence of more than one form of autoantibody in individuals from the general population is a more powerful predictor of the development of clinical diabetes. Individuals with type 1 DM also tend to have antibodies directed toward other endocrine tissues, including the adrenal, parathyroid, and thyroid glands, and have an increased incidence of other autoimmune diseases.

Type 1 DM is associated with specific human leukocyte antigen (HLA) alleles, especially at the B and DR loci (Florez *et al.*, 2003). Approximately 90% of patients with type 1 DM are positive for HLA-DR3 or -DR4, as compared with only 40% of the general population. Compound heterozygotes appear to be at particular risk. In contrast, the haplotype HLA-DR2 appears to be negatively associated with the occurrence of the disease. A polymorphism of the HLA-DQ β chain at position 57 correlates even more closely with susceptibility to diabetes (Todd *et al.*, 1987). Type 1 DM is associated with alleles coding for alanine, valine, or serine at position 57 in the HLA-DQ β chain, whereas aspartic acid in this position is negatively correlated with the disease in Caucasians. These findings implicate both humoral and cell-mediated immune mechanisms in the etiology of type 1 DM.

The trigger for the immune response remains unknown. The identification of triggering agents is difficult because autoimmune destruction of pancreatic β cells may occur over a period of many months or several years before the onset of overt disease. In about 10% of new cases of type 1 DM, there is no evidence of autoimmune insulinitis (Imagawa *et al.*, 2000). The ADA and the World Health Organization (WHO) therefore subdivide this disease into autoimmune (1A) and idiopathic (1B) subtypes. Whatever the causes, the final result in type 1 DM is an extensive and selective loss of pancreatic β cells and a state of absolute insulin deficiency.

The situation in type 2 DM is not so clear-cut. Most studies indicate that there is reduced β -cell mass in type 2 DM patients. Obesity, duration of diabetes, and prevailing hyperglycemia potentially can confound interpretation of data, but studies that have controlled for these variables have reported an approximately 50% reduction in β -cell volume in type 2 DM patients compared with nondiabetic control subjects. Owing to the heterogeneous nature of type 2 DM, mean 24-hour plasma concentrations of insulin in patients have been reported to vary from low to even normal relative to values in control subjects. Of note, standard insulin radioimmunoassays detect proinsulin and processing intermediates. Studies in which specific insulin and proinsulin assays have been used (Temple *et al.*, 1989) have revealed that “true” insulin values in “hyperinsulinemic” type 2 DM patients are either no greater or distinctly less than values in control subjects. Therefore, increased amounts of proinsulin have confounded the appreciation of subnormal insulin levels in type 2 DM patients. Furthermore, even apparently “normal” values of plasma insulin in a hyperglycemic type 2 DM patient are considerably reduced relative to the insulin levels that would be observed in a similarly hyperglycemic nondiabetic individual.

In healthy persons, the contribution of proinsulin to basal immunoreactive insulin levels is low. Proinsulin intermediates make up about 10% of the total immunoreactive insulin in the portal vein. However, owing to its long half-life (about 44 minutes) and tenfold slower metabolic clearance, proinsulin and intermediates make up about 20% of circulating immunoreactive insulin. This amount is physiologically trivial because proinsulin has only

about 5% of the metabolic effect of insulin (Davis *et al.*, 1991). Nevertheless, plasma proinsulinlike molecules are increased in type 2 DM to about 20% or more of total immunoreactive insulin. Furthermore, proinsulin levels increase in response to any β -cell stimulation.

Type 2 DM also is associated with several distinct defects in insulin secretion. At diagnosis, virtually all persons with type 2 DM have a profound defect in first-phase insulin secretion in response to an intravenous glucose challenge. The responses to other secretagogues (*e.g.*, isoproterenol or arginine) are preserved, although there is less potentiation by glucose. Some of these β -cell abnormalities in type 2 DM may be secondary to desensitization by chronic hyperglycemia. The relationship between fasting glycemia and insulinemia in type 2 DM subjects is complex. Patients who have fasting blood glucose levels of 6 to 10 mM (108 to 180 mg/dl) have fasting and stimulated insulin values equal to those of euglycemic control subjects. More severely hyperglycemic subjects are frankly hypoinsulinemic.

Virtually all forms of DM are caused by a decrease in the circulating concentration of insulin (insulin deficiency) and a decrease in the response of peripheral tissues to insulin (insulin resistance). These abnormalities lead to alterations in the metabolism of carbohydrates, lipids, ketones, and amino acids; the central feature of the syndrome is hyperglycemia (Figure 60–4).

Insulin lowers the concentration of glucose in blood by inhibiting hepatic glucose production and by stimu-

Figure 60–4. Overview of insulin action. Insulin stimulates glucose storage in the liver as glycogen and in adipose tissue as triglycerides and amino acid storage in muscle as protein; it also promotes utilization of glucose in muscle for energy. These pathways, which also are enhanced by feeding, are indicated by the solid blue arrows. Insulin inhibits the breakdown of triglycerides, glycogen, and protein and the conversion of amino acids to glucose (gluconeogenesis), as indicated by the white arrows. These pathways are increased during fasting and in diabetic states. The conversion of amino acids to glucose and of glucose to fatty acids occurs primarily in the liver.

Table 60–2

Hypoglycemic Actions of Insulin

LIVER	MUSCLE	ADIPOSE TISSUE
Inhibits hepatic glucose production (decreases gluconeogenesis and glycogenolysis)	Stimulates glucose uptake	Stimulates glucose uptake (amount is small compared to muscle)
Stimulates hepatic glucose uptake	Inhibits flow of gluconeogenic precursors to the liver (<i>e.g.</i> , alanine, lactate, and pyruvate)	Inhibits flow of gluconeogenic precursor to liver (glycerol) and reduces energy substrate for hepatic gluconeogenesis (nonesterified fatty acids)

lating the uptake and metabolism of glucose by muscle and adipose tissue (Table 60–2). These two important effects occur at different concentrations of insulin. Production of glucose is inhibited half maximally by an insulin concentration of about 20 μ units/ml, whereas glucose utilization is stimulated half maximally at about 50 μ units/ml.

In both types of diabetes, glucagon (the levels of which are elevated in untreated patients) opposes the hepatic effects of insulin by stimulating glycogenolysis and gluconeogenesis, but it has relatively little effect on peripheral utilization of glucose. Thus, in the diabetic patient with insulin deficiency or insulin resistance and hyperglucagonemia, there is an increase in hepatic glucose production, a decrease in peripheral glucose uptake, and a decrease in the conversion of glucose to glycogen in the liver (DeFronzo *et al.*, 1992).

Alterations in secretion of insulin and glucagon also profoundly affect lipid, ketone, and protein metabolism. At concentrations below those required to stimulate glucose uptake, insulin inhibits the hormone-sensitive lipase in adipose tissue and thus inhibits the hydrolysis of triglyceride stores. This counteracts the lipolytic action of catecholamines, cortisol, and growth hormone and reduces the concentrations of glycerol (a substrate for gluconeogenesis) and free fatty acids (a substrate for production of ketone bodies and a necessary fuel for gluconeogenesis). These actions of insulin are deficient in the diabetic patient, leading to increased gluconeogenesis and ketogenesis.

The liver produces ketone bodies by oxidation of free fatty acids to acetyl CoA, which then is converted to acetoacetate and β -hydroxybutyrate. The initial step in fatty acid oxidation is transport of the fatty acid into the mitochondria. This involves the interconversion of the

coenzyme A (CoA) and carnitine esters of fatty acids by the enzyme acylcarnitine transferase. The activity of this enzyme is inhibited by intramitochondrial malonyl CoA, one of the products of fatty acid synthesis. Under normal conditions, insulin inhibits lipolysis, stimulates fatty acid synthesis (thereby increasing the concentration of malonyl CoA), and decreases the hepatic concentration of carnitine; these factors all decrease the production of ketone bodies. Conversely, glucagon stimulates ketone body production by increasing fatty acid oxidation and decreasing concentrations of malonyl CoA. In the diabetic patient, particularly the patient with type 1 DM, the consequences of insulin deficiency and glucagon excess provide a hormonal milieu that favors ketogenesis and, in the absence of appropriate treatment, may lead to ketonemia and acidosis.

Insulin also enhances the transcription of lipoprotein lipase in the capillary endothelium. This enzyme hydrolyzes triglycerides present in very low density lipoproteins (VLDL) and chylomicrons, resulting in release of intermediate-density lipoprotein (IDL) particles (*see* Chapter 35). The IDL particles are converted by the liver to the more cholesterol-rich low-density lipoproteins (LDL). Thus, in the untreated or undertreated diabetic patient, hypertriglyceridemia and hypercholesterolemia often occur. In addition, deficiency of insulin may be associated with increased production of VLDL.

The important role of insulin in protein metabolism usually is evident clinically only in diabetic patients with persistently poor control of their disease. Insulin stimulates amino acid uptake and protein synthesis and inhibits protein degradation in muscle and other tissues; it thus causes a decrease in the circulating concentrations of most amino acids. Glutamine and alanine are the major amino

acid precursors for gluconeogenesis. Insulin lowers alanine concentrations during hyperinsulinemic euglycemic conditions. The rate of appearance of alanine is maintained in part by the enhanced rate of transamination of pyruvate to alanine. However, alanine utilization greatly exceeds production (owing to increased hepatic uptake and fractional extraction of the amino acid), and this results in a fall of peripheral alanine levels. In poorly controlled diabetics, there is increased conversion of alanine to glucose, contributing to the enhanced rate of gluconeogenesis. The increased conversion of amino acids to glucose also results in increased production and excretion of urea and ammonia. In addition, there are increased circulating concentrations of branched-chain amino acids as a result of increased proteolysis, decreased protein synthesis, and increased release of branched-chain amino acids from the liver.

A nearly pathognomonic feature of diabetes mellitus is thickening of the capillary basement membrane and other vascular changes that occur during the course of the disease. The cumulative effect is progressive narrowing of the vessel lumina, causing inadequate perfusion of critical regions of certain organs. The matrix is expanded in many vessel walls, in the basement membrane of the retina, and in the mesangial cells of the renal glomerulus (McMillan, 1997). Cellular proliferation in many large vessels further contributes to luminal narrowing. These pathological changes contribute to some of the major complications of diabetes, including premature atherosclerosis, intercapillary glomerulosclerosis, retinopathy, neuropathy, and ulceration and gangrene of the extremities.

It is hypothesized that the factor responsible for the development of most complications of diabetes is the prolonged exposure of tissues to elevated concentrations of glucose. Prolonged hyperglycemia results in the formation of advanced glycation end products (Beisswenger *et al.*, 1995). These macromolecules are thought to induce many of the vascular abnormalities that result in the complications of diabetes (Brownlee, 1995). The results from the Diabetes Control and Complications Trial (DCCT) definitively answered this question: Most diabetic complications arise from prolonged exposure of tissue to elevated glucose concentrations.

The DCCT (DCCT Research Group, 1993) was a multicenter, randomized clinical trial designed to compare intensive and conventional diabetes therapies with regard to their effects on the development and progression of the early vascular and neurologic complications of type 1 DM. The intensive therapy regimen was designed to achieve blood glucose values as close to the normal range as possible with three or more daily insulin injections or with an external insulin pump. Conventional therapy consisted of one or two insulin

injections daily. Two groups of patients were studied to answer separate but related questions. The first question was whether or not intensive therapy could prevent the development of diabetic complications such as retinopathy, nephropathy, and neuropathy (primary prevention). The second was whether or not intensive therapy could slow the progression of existing complications of diabetes (secondary intervention).

In the primary prevention group, intensive therapy reduced the mean risk for the development of retinopathy by 76% compared with conventional therapy. In the secondary intervention group, intensive therapy slowed the progression of retinopathy by 54%. Intensive therapy reduced the risk of nephropathy by 34% in the primary prevention group and by 43% in the secondary intervention group. Similarly, neuropathy was reduced by about 60% in both the primary prevention and secondary intervention groups. Intensive therapy reduced the development of hypercholesterolemia by 34% overall. Because of the relative youth of the patients, it was predicted that the detection of treatment-related differences in rates of macrovascular events would be unlikely. However, intensive therapy reduced the risk of macrovascular disease by 41% in the combined groups. These results established unequivocally that improving day-to-day glycemic control in type 1 DM patients can reduce and slow the development of diabetic complications dramatically. A follow-up study showed that the reduction in the risk of progressive retinopathy and nephropathy persists for at least 4 years, even if tight glycemic control was not maintained (DCCT Research Group, 2000).

A serious complication of intensive therapy was an increased incidence of severe hypoglycemia. Patients receiving intensive therapy had a threefold greater incidence of severe hypoglycemia (blood glucose concentration below 50 mg/dl or 2.8 mM and needing external resuscitative assistance) and hypoglycemic coma than did conventionally treated subjects. Therefore, the present guidelines for treatment given by the ADA include a contraindication for implementing tight metabolic control in infants younger than 2 years old and an extreme caution in children between 2 and 7 years of age because hypoglycemia may impair brain development. Older patients with significant arteriosclerosis also may be vulnerable to permanent injury from hypoglycemia.

The DCCT was performed in relatively young type 1 DM patients. The question was asked whether intensive therapy would provide similar benefits to typical middle-aged or elderly patients with type 2 DM. The results of the DCCT indeed also apply to patients with type 2 DM (U.K. Prospective Diabetes Study Group, 1998a, 1998b). The eye, kidney, and nerve abnormalities appear similar in type 1 and type 2 DM, and it is likely that the same or similar underlying mechanisms of disease apply. However, because of a higher prevalence of macrovascular disease, older patients with type 2 DM may be more vulnerable to serious consequences of hypoglycemia. Thus, as is the case for everyone with diabetes, treatment of type 2 DM patients must be tailored to the individual. Nevertheless, the results of the DCCT and U.K. Prospective Diabetes Study (UKPDS) suggest that many otherwise healthy patients with type 2 DM should attempt to achieve tight metabolic control.

The toxic effects of hyperglycemia may be the result of accumulation of non-enzymatically glycosylated products and osmotically active sugar alcohols such as sorbitol in tissues; the effects of glucose on cellular metabolism also may be responsible (Brownlee, 1995). The covalent reac-

tion of glucose with hemoglobin provides a convenient method to determine an integrated index of the glycemic state. Hemoglobin undergoes glycosylation on its amino-terminal valine residue to form the glucosyl valine adduct of hemoglobin, termed *hemoglobin A_{1c}* (Brownlee, 1995). The half-life of the modified hemoglobin is equal to that of the erythrocyte (about 120 days). Since the amount of glycosylated protein formed is proportional to the glucose concentration and the time of exposure of the protein to glucose, the concentration of hemoglobin A_{1c} in the circulation reflects the severity of the glycemic state over an extended period (4 to 12 weeks) prior to sampling. Thus a rise in hemoglobin A_{1c} from 5% to 10% suggests a prolonged doubling of the mean blood glucose concentration. Although this assay is used widely, measurement of the glycosylation of proteins with somewhat shorter survival times (*e.g.*, albumin) also has proven useful in the management of pregnant diabetic patients.

Glycosylated products accumulate in tissues and eventually may form cross-linked proteins termed *advanced glycosylation end products* (Beisswenger *et al.*, 1995). Such nonenzymatic glycosylation may be directly responsible for expansion of the vascular matrix and the vascular complications of diabetes. This process also may explain the modified cellular proliferative activity in vascular lesions of diabetic patients because macrophages appear to have receptors for advanced glycosylation end products. Binding of such proteins to macrophages in these lesions may stimulate the production of cytokines such as tumor necrosis factor α and interleukin 1 (IL-1), which, in turn, induce degradative and proliferative cascades in mesenchymal and endothelial cells, respectively.

Other explanations for the toxic manifestations of hyperglycemia may exist. Intracellular glucose is reduced to its corresponding sugar alcohol, sorbitol, by the enzyme aldose reductase, and the rate of production of sorbitol is determined by the ambient glucose concentration. This is particularly true in tissues such as the lens, retina, arterial wall, and Schwann cells of peripheral nerves. In diabetic human beings and rodents, these tissues have increased intracellular concentrations of sorbitol, which may contribute to an increased osmotic effect and tissue damage. Inhibitors of aldose reductase currently are being evaluated for treatment of diabetic neuropathy and retinopathy. The results of studies with these agents thus far have been somewhat conflicting and inconclusive (reviewed by Frank, 1994).

In neural tissue and perhaps in other tissues, glucose competes with myoinositol for transport into cells. Reduc-

tion of cellular concentrations of myoinositol may contribute to altered nerve function and neuropathy. Hyperglycemia also may enhance the *de novo* synthesis of diacylglycerol, which could facilitate persistent activation of protein kinase C.

Insulin Therapy

Insulin is the mainstay for treatment of virtually all type 1 DM and many type 2 DM patients. When necessary, insulin may be administered intravenously or intramuscularly; however, long-term treatment relies predominantly on subcutaneous injection of the hormone. Subcutaneous administration of insulin differs from physiological secretion of insulin in at least two major ways: The kinetics do not reproduce the normal rapid rise and decline of insulin secretion in response to ingestion of nutrients, and the insulin diffuses into the peripheral circulation instead of being released into the portal circulation; the direct effect of secreted insulin on hepatic metabolic processes thus is eliminated. Nonetheless, when such treatment is performed carefully, considerable success is achieved.

Preparations of insulin can be classified according to their duration of action into short, intermediate, and long acting and by their species of origin—human or porcine. Human insulin (HUMULIN, NOVOLIN) is now widely available as a result of its recombinant production. Porcine insulin differs from human insulin by one amino acid (alanine instead of threonine at the carboxy terminal of the B chain, *i.e.*, in position B30). Prior to the mid-1970s, commercially available insulin preparations contained proinsulin or glucagonlike substances, pancreatic polypeptide, somatostatin, and vasoactive intestinal peptides. These contaminants were avoided with the advent of monocomponent porcine insulins. During the late 1970s, intense work was carried out on the development of biosynthetic human insulin. During the last decade, human insulin rapidly has become the standard form of therapy, and beef insulin products have been discontinued in the United States.

The physicochemical properties of human and porcine insulins differ owing to their different amino acid sequences. Human insulin, produced using recombinant DNA technology, is more soluble than porcine insulin in aqueous solution owing to the presence of threonine (instead of alanine), with its extra hydroxyl group. The vast majority of preparations now are supplied at neutral pH, which improves stability and permits storage for several days at a time at room temperature.

Table 60–3
Properties of Currently Available Insulin Preparations

TYPE	APPEARANCE	ADDED PROTEIN	ZINC CONTENT, mg/100 units	BUFFER*	Action, Hours [†]		
					ONSET	PEAK	DURATION
Rapid							
Regular soluble (crystalline)	Clear	None	0.01–0.04	None	0.5–0.7	1.5–4	5–8
Lispro	Clear	None	0.02	Phosphate	0.25	0.5–1.5	2–5

Glargine	Clear	None	0.03	None	2–5	5–24	18–24

*Most insulin preparations are supplied at pH 7.2–7.4. Glargine is supplied at a pH of 4.0. †These are approximate figures. There is considerable variation from patient to patient and from time to time in a given patient.

Unitage. For therapeutic purposes, doses and concentrations of insulin are expressed in units. This tradition dates to the time when preparations of the hormone were impure, and it was necessary to standardize them by bioassay. One unit of insulin is equal to the amount required to reduce the concentration of blood glucose in a fasting rabbit to 45 mg/dl (2.5 mM). The current international standard is a mixture of bovine and porcine insulins and contains 24 units/mg. Homogeneous preparations of human insulin contain between 25 and 30 units/mg. Almost all commercial preparations of insulin are supplied in solution or suspension at a concentration of 100 units/ml, which is about 3.6 mg insulin per milliliter (0.6 mM). Insulin also is available in a more concentrated solution (500 units/ml) for patients who are resistant to the hormone.

Classification of Insulins. *Short- and rapid-acting insulins* are solutions of *regular, crystalline zinc insulin (insulin injection)* dissolved usually in a buffer at neutral pH. These preparations have the most rapid onset of action but the shortest duration (Table 60–3). Short-acting insulin (*i.e.*, regular or soluble) usually should be injected 30 to 45 minutes before meals. Regular insulin also may be given intravenously or intramuscularly. After intravenous injection, there is a rapid fall in the blood glucose concentration, which usually reaches a nadir in 20 to 30 minutes. In the absence of a sustained infusion of insulin, the hormone is cleared rapidly, and counter-regulatory hormones (*e.g.*, glucagon, epinephrine, norepinephrine, cortisol, and growth hormone) restore plasma glucose to baseline in 2 to 3 hours. In the absence of a normal counter-regulatory response (*e.g.*, in diabetic patients with autonomic neuropathy), plasma glucose will remain suppressed

for many hours following an insulin bolus of 0.15 units/kg because the cellular actions of insulin are prolonged far beyond its clearance from plasma. Intravenous infusions of insulin are useful in patients with ketoacidosis or when requirements for insulin may change rapidly, such as during the perioperative period, during labor and delivery, and in intensive care situations (*see* below).

When metabolic conditions are stable, regular insulin usually is given subcutaneously in combination with an intermediate- or long-acting preparation. Short-acting insulin is the only form of the hormone that can be used in subcutaneous infusion pumps. Special buffered formulations of regular insulin have been made for the latter purpose that are less likely to crystallize in the tubing during the slow infusion associated with this type of therapy.

The native insulin monomers are associated as hexamers in currently available insulin preparations. These hexamers slow the absorption and reduce postprandial peaks of subcutaneously injected insulin. These pharmacokinetics stimulated the development of short-acting insulin analogs that retain a monomeric or dimeric configuration. A number of compounds have been investigated, and two, insulin *lispro* (HUMALOG) and insulin *aspart* (NOVOLOG), are available for clinical use (Hirsch, 2005). These analogs are absorbed three times more rapidly from subcutaneous sites than is human insulin. Consequently, there is a more rapid increase in plasma insulin concentrations and an earlier hypoglycemic response. Injection of the analogs 15 minutes before a meal affords glycemic control similar to that from an injection of human insulin given 30 minutes before the meal. The first commercially available short-acting analog was human insulin *lispro*. This analog is identical to human insulin except at positions B28 and B29, where the sequence of the two residues has been

reversed to match the sequence in IGF-1, which does not self-associate. Like regular insulin, lispro exists as a hexamer in commercially available formulations. Unlike regular insulin, lispro dissociates into monomers almost instantaneously following injection. This property results in the characteristic rapid absorption and shorter duration of action compared with regular insulin. Two therapeutic advantages have emerged with lispro as compared with regular insulin. First, the prevalence of hypoglycemia is reduced by 20% to 30% with lispro; second, glucose control, as assessed by hemoglobin A_{1c}, is modestly but significantly improved (0.3% to 0.5%) with lispro as compared with regular insulin.

Insulin aspart is formed by the replacement of proline at B28 with aspartic acid. This reduces self-association to that observed with lispro. Like lispro, insulin aspart dissociates rapidly into monomers following injection. Comparison of a single subcutaneous dose of aspart and lispro in a group of type 1 DM patients revealed similar plasma insulin profiles. In clinical trials, insulin aspart and insulin lispro have had similar effects on glucose control and hypoglycemia frequency, with lower rates of nocturnal hypoglycemia as compared with regular insulin (reviewed by Hirsh, 2005).

A third rapid-acting insulin analog called insulin *glulysine* has been approved for clinical use in the United States. In this compound, glutamic acid replaces lysine at B29, and lysine replaces asparagine at B23. Similar to the other two available rapid-acting analogs, this causes a reduction in self-association and rapid dissociation into active monomers. The time-action profile of insulin glulysine is similar to that of insulin aspart and lispro. Similar to insulin aspart, glulysine has been approved by the Food and Drug Administration (FDA) for continuous subcutaneous insulin infusion (CSII) pump use. Owing to their rapid onset, the fast-acting insulin analogs all may be injected immediately before or after a meal, which may confer considerable clinical advantages. Many individuals with diabetes consume smaller amounts of food than originally planned. This, in the presence of a previously injected dose of insulin that was based on a larger meal, could result in postprandial hypoglycemia. Thus, in patients who have gastroparesis or loss of appetite, injection of a rapid-acting analog postprandially, based on the amount of food actually consumed, may provide smoother glycemic control.

Clinical trials of inhaled insulin are underway in a number of countries. Early results demonstrate that inhaled insulin and short-acting subcutaneously-injected insulin provide similar postprandial glycemic control in patients with type 1 and type 2 DM. Patient satisfaction is uniformly high with inhaled insulin, and the prevalence of hypoglycemia is no higher (and may even be reduced) compared with regular (soluble) insulin. Smoking increases and asthma decreases absorption of inhaled insulin. Long-term safety data are awaited before registration approval of the compound will be given.

Intermediate-acting insulins are formulated to dissolve more gradually when administered subcutaneously; thus their durations of action are longer. The two preparations used most frequently are *neutral protamine Hagedorn (NPH) insulin (isophane insulin suspension)* and *lente insulin (insulin zinc suspension)*. NPH insulin is a suspension of insulin in a complex with zinc and protamine in a phosphate buffer. Lente insulin is a mixture of crystallized (ultralente) and amorphous (semilente) insulins in an acetate buffer, which minimizes the solubility of insulin. The pharmacokinetic properties of human intermediate-acting insulins are slightly different from those of porcine preparations. Human insulins have a

more rapid onset and shorter duration of action than do porcine insulins. This difference may be related to the more hydrophobic nature of human insulin, or human and porcine insulins may interact differently with protamine and zinc crystals. This difference may create a problem with optimal timing for evening therapy; human insulin preparations taken before dinner may not have a duration of action sufficient to prevent hyperglycemia by morning. It should be noted that there is no evidence that lente or NPH insulin has different pharmacodynamic effects when used in combination with regular (soluble) insulin in a twice-a-day dosage regimen. Intermediate-acting insulins usually are given either once a day before breakfast or twice a day. In patients with type 2 DM, intermediate-acting insulin given at bedtime may help normalize fasting blood glucose. When lente insulin is mixed with regular insulin, some of the regular insulin may form a complex with the protamine or Zn²⁺ after several hours, and this may slow the absorption of the fast-acting insulin. NPH insulin does not retard the action of regular insulin when the two are mixed vigorously by the patient or when they are available commercially as a mixture (Davis *et al.*, 1991) (*see below*).

Ultralente insulin (extended insulin zinc suspension) and protamine zinc insulin suspension are long-acting insulins; they have a slower onset and a prolonged peak of action. These insulins have been advocated to provide a low basal concentration of insulin throughout the day. The long half-life of ultralente insulin makes it difficult to determine the optimal dosage because several days of treatment are required before a steady-state concentration of circulating insulin is achieved. Doses given once or twice daily are adjusted according to the fasting blood glucose concentration. Protamine zinc insulin is used rarely today because of its very unpredictable and prolonged course of action, and it is no longer available in the United States. Preparations of insulin that are available for clinical use in the United States are shown in Table 60-4.

In the vast majority of patients, insulin-replacement therapy includes intermediate- or long-acting insulin. A search for the ideal intermediate-acting insulin identified *human proinsulin (HPI)* as a promising candidate. Animal studies using *porcine proinsulin* indicated that the compound was a soluble intermediate-acting insulin agonist that had a greater suppressive effect on hepatic glucose production than on stimulation of peripheral glucose disposal. This profile of action appeared favorable for clinical use in diabetic subjects because unrestrained hepatic glucose production is a hallmark of the disease, and a liver-specific insulin would tend to reduce peripheral hyperinsulinemia and the attendant risk of hypoglycemia. Early studies with HPI in human beings confirmed its relatively specific action on hepatocytes and demonstrated that its duration of action was similar to that of NPH insulin. Preliminary results from clinical trials, however, indicated that HPI conferred no additional benefit over currently available human insulins, and all clinical studies soon were suspended because of a high incidence of myocardial infarction in HPI-treated subjects.

The pharmacokinetic limitations of ultralente insulin have prompted efforts to develop an insulin analog that does not have a significant peak in its action. Considerable research has been directed to the development of such a product. Insulin *glargine (LANTUS)* is the first long-acting analog of human insulin to be approved for clinical use in the United States and Europe. Insulin glargine is produced following two alterations of human insulin (Hirsch, 2005). Two arginine residues are added to the C terminus of the B chain, and an asparagine molecule in position A21 on the A chain is

replaced with glycine. Glargine is a clear solution with a pH of 4.0. This pH stabilizes the insulin hexamer and results in a prolonged and predictable absorption from subcutaneous tissues. Owing to insulin glargine's acidic pH, it cannot be mixed with currently available short-acting insulin preparations (*i.e.*, regular insulin, aspart, or lispro) that are formulated at a neutral pH. In clinical studies, insulin glargine results in less hypoglycemia, has a sustained "peakless" absorption profile, and provides a better once-daily 24-hour insulin coverage than ultralente or NPH insulin. Glargine may be administered at any time during the day with equivalent efficacy and no difference in the frequency of hypoglycemic episodes. Glargine does not accumulate after several injections. A recent study has demonstrated that duration of action remains at approximately 24 hours and intersubject variability actually improves after seven as compared to one injection.

Insulin glargine can be combined with various oral antihyperglycemic agents (*see* below) to effectively lower plasma glucose levels. Combination of glargine with *sulfonylureas* and/or *metformin* can reduce both fasting (basal) and postprandial glucose levels. It should be noted that the use of a long-acting basal insulin alone will not control postprandial glucose elevations in insulin-deficient type 1 or type 2 DM. Glargine has been shown in clinical studies to normalize fasting (postabsorptive) glucose levels following once-daily administration in patients with type 2 DM.

Rarely, splitting the dose of glargine may be needed in very lean, insulin-sensitive type 1 DM patients in order to achieve good fasting (basal) glucose levels. Unlike traditional insulin preparations that are absorbed more rapidly from the abdomen than from the arm or leg, the site of administration does not influence the time-action profile of glargine. Similarly, exercise does not influence glargine's unique absorption kinetics, even when the insulin is injected into a working limb. Glargine binds with a slightly greater affinity to IGF-1 receptors as compared with human insulin. However, this slightly increased binding is still approximately two log scales lower than that of IGF-1. The deterioration of retinopathy in a few patients with type 2 DM in early clinical studies with glargine led to a concern that it might be involved in the development of retinopathy. However, none of the patients had optic disc swelling, which is pathognomonic of IGF-1 effects, suggesting that the finding was probably due to the well-recognized "glucose reentry phenomenon" that occurs with improvement of glycemic control rather than the insulin *per se*.

Other approaches to prolong the action of soluble insulin analogs are under investigation. One approach is the addition of a saturated fatty acid to the ϵ amino group of LysB29, yielding a myristoylated insulin called *insulin detemir* (Hirsch, 2005).

When insulin detemir is injected subcutaneously, it binds to albumin *via* its fatty acid chain. Clinical studies in patients with type 1 DM have demonstrated that when insulin detemir is administered twice a day, it has a smoother time-action profile and a reduced prevalence of hypoglycemia as compared with NPH insulin. Additional clinical studies are currently in progress with the aim of submitting insulin detemir for registration in the United States.

The wide variability in the kinetics of insulin action between and even within individuals must be emphasized. The time to peak hypoglycemic effect and insulin levels can vary by 50%. This variability is caused, at least in part, by large variations in the rate of subcutaneous absorption and often has been said to be more noticeable with the intermediate- and long-acting insulins. However, the administration of regular insulin can result in similar variability. When this variability is coupled with normal variations in diet and exercise, it is sometimes surprising how many patients do achieve good control of blood glucose concentrations.

Indications and Goals for Therapy. Subcutaneous administration of insulin is the primary treatment for all patients with type 1 DM, for patients with type 2 DM that is not controlled adequately by diet and/or oral hypoglycemic agents, and for patients with postpancreatectomy diabetes or gestational diabetes (American Diabetes Association, 1999). In addition, insulin is critical for the management of diabetic ketoacidosis, and it has an important role in the treatment of hyperglycemic, nonketotic coma and in the perioperative management of both type 1 and type 2 DM. In all cases, the goal is to normalize not only blood glucose but also all aspects of metabolism; the latter is difficult to achieve. Optimal treatment requires a coordinated approach to diet, exercise, and the administration of insulin. A brief overview of the principles of therapy is given below. (For a more detailed description, *see* LeRoith *et al.*, 2000.)

Near-normoglycemia can be attained in patients with multiple daily doses of insulin or with infusion pump therapy. The goal is to achieve a fasting blood glucose concentration of between 90 and 120 mg/dl (5 to 6.7 mM) and a 2-hour postprandial value below 150 mg/dl (8.3 mM). Goal hemoglobin A_{1C} values should be below 7% and are advocated by some authorities to be below 6.5%. In less disciplined patients, or in those with defective responses of counter-regulatory hormones, it may be necessary to accept higher fasting [*e.g.*, 140 mg/dl (7.8 mM)] and 2-hour postprandial [*e.g.*, 200 to 250 mg/dl (11.1 to 13.9 mM)] blood glucose concentrations.

Daily Requirements. Insulin production by a normal, thin, healthy person is between 18 and 40 units/day or about 0.2 to 0.5 units/kg of body weight per day. About half this amount is secreted in the basal state and about half in response to meals. Thus, basal secretion is about 0.5 to 1 units/h; after an oral glucose load, insulin secretion may increase to 6 units/h. In nondiabetic, obese, and insulin-resistant individuals, insulin secretion may be increased fourfold or more. Insulin is secreted into the portal circulation, and about 50% is destroyed by the liver before reaching the systemic circulation.

In a mixed population of type 1 DM patients, the average dose of insulin is usually 0.6 to 0.7 units/kg body weight per day, with a range of 0.2 to 1 units/kg per day. Obese patients generally require more (about 2 units/kg per day) because of resistance of peripheral tissues to insulin. Patients who require less insulin than 0.5 units/kg per day may have some endogenous production of insulin or may be more sensitive to the hormone because of good physical conditioning. As in nondiabetics, the daily requirement for insulin can be divided into basal and postprandial needs. The basal dose suppresses lipolysis, proteolysis, and hepatic glucose production; it is usually 40% to 60% of the total daily dose. The dose necessary for disposition of nutrients after meals usually is given before meals. Insulin often has been administered as a single daily dose of intermediate-acting insulin, alone or in combination with regular insulin. This is rarely sufficient to achieve true euglycemia; since hyperglycemia is the major determinant of long-term complications of diabetes, more complex regimens that include combinations of intermediate- or long-acting insulins with regular insulin are used to reach this goal.

A number of commonly used dosage regimens that include mixtures of insulin given in two or three daily injections are depicted in Figure 60–5 (LeRoith *et al.*, 2000). The most frequently used is the so-called split-mixed regimen involving the prebreakfast and presupper injection of a mixture of regular and intermediate-acting insulins (Figure 60–5A). When the presupper NPH or lente insulin is not sufficient to control hyperglycemia throughout the night, the evening dose may be divided into a presupper dose of regular insulin followed by NPH or lente insulin at bedtime (Figure 60–5B). Both normal and diabetic individuals have an increased requirement for insulin in the early morning; this is termed the *dawn phenomenon* and makes the kinetics and timing of the evening dose of insulin extremely important.

An alternative regimen that is gaining widespread use involves multiple daily injections consisting of basal administration of long-acting insulin (*e.g.*, insulin glargine) either before breakfast or at bedtime and prandial injections of a short-acting insulin (Figure

60–5C). This method is called *basal/bolus* and is very similar to the pattern of insulin administration achieved with a subcutaneous infusion pump (Figure 60–5E). Following the successful demonstration that intensive glycemic control can reduce the risk of micro- and macrovascular complications in patients with type 2 DM, there has been increased interest in using insulin earlier in the treatment of these patients. Data from the UKPDS indicate that 50% of relative β -cell insulin secretory capacity is lost for every 6 years of type 2 DM. This progressive insulin deficiency as type 2 DM progresses makes it increasingly difficult to achieve tight glycemic control (hemoglobin A_{1C} < 7.0%) with oral antihyperglycemic agents. One way to improve control in this setting is to introduce basal-acting insulin in combination with oral hypoglycemic agents. The exact combination of therapies should be guided by the β -cell secretory reserve in each patient. Thus, in an individual with some exogenous insulin secretory capacity (*i.e.*, a measurable circulating C peptide level), combining an oral insulin secretagogue (*see* below) with basal insulin may provide smooth and efficient glycemic control. The addition of a second oral agent, such as an insulin sensitizer (*see* below), either alone or in combination with an oral insulin secretagogue, also may provide good therapeutic results. This combination allows the oral agents to provide postprandial glycemic control while the basal insulin provides the foundation for normalizing fasting or “basal” glucose levels.

In all patients, careful monitoring of therapeutic end points directs the insulin dose used. This approach is facilitated by the use of home glucose monitors and measurements of hemoglobin A_{1C}. Special care must be taken when the patient has other underlying diseases, deficiencies in other endocrine systems (*e.g.*, adrenocortical or pituitary failure), or substantial resistance to insulin.

Factors That Affect Insulin Absorption. The degree of control of plasma glucose may be modified by changes in insulin absorption, factors that alter insulin action, diet, exercise, and other factors. Factors that determine the rate of absorption of insulin after subcutaneous administration include the site of injection, the type of insulin, subcutaneous blood flow, smoking, regional muscular activity at the site of the injection, the volume and concentration of the injected insulin, and depth of injection (insulin has a more rapid onset of action if delivered intramuscularly rather than subcutaneously).

When insulin is injected subcutaneously, there can be an initial “lag phase” followed by a slow but steadily increasing rate of absorption. The initial lag phase almost disappears when a reduced concentration or volume of insulin is injected.

Insulin usually is injected into the subcutaneous tissues of the abdomen, buttock, anterior thigh, or dorsal arm. Absorption is usually most rapid from the abdominal wall, followed by the arm, buttock, and thigh. Rotation of insulin injection sites traditionally has been advocated to avoid lipohypertrophy or lipoatrophy, although these conditions are less likely to occur with highly purified preparations of insulin. If a patient is willing to inject into the abdomen, injections can be rotated

Figure 60–5. Common multidose insulin regimens. *A.* Typical split-mixed regimen consisting of twice-daily injections of a mixture of regular (regular/lispro/aspart) and intermediate-acting (NPH or lente) insulin. *B.* A variation in which the evening dose of intermediate-acting insulin is delayed until bedtime to increase the amount of insulin available the next morning. *C.* A regimen that incorporates ultralente or glargine insulin. *D.* A variation that includes premeal short-acting insulin with intermediate-acting insulin at breakfast and bedtime. *E.* Patterns of insulin administration with a regimen of continuous subcutaneous insulin infusion.

throughout the entire area, thereby eliminating the injection site as a cause of variability in the rate of absorption. The abdomen currently is the preferred site of injection in the morning because insulin is absorbed about 20% to 30% faster from that site than from the arm. If the patient refuses to inject into the abdominal area, it is preferable to select a consistent injection site for each component of insulin treatment (*e.g.*, prebreakfast dose into the thigh, evening dose into the arm).

Several other factors may affect the absorption of insulin. In a small group of patients, subcutaneous degradation of insulin has been observed, and this has necessitated the injection of large amounts of insulin for adequate metabolic control. Increased subcutaneous blood flow (brought about by massage, hot baths, or exercise) increases the rate of absorption. In the upright posture, subcutaneous blood flow diminishes considerably in the legs and to a lesser extent in the abdominal

wall. An altered volume or concentration of injected insulin affects the rate of absorption and the duration of action. When regular insulin is mixed with lente insulin, some of the regular insulin becomes modified, causing a partial loss of the rapidly acting component. This problem is even more severe if regular insulin is mixed with ultralente insulin. Injections of mixtures of insulin preparations thus should be made without delay. There is less delay in absorption of regular insulin when it is mixed with NPH insulin. Stable, mixed combinations of NPH and regular insulin in proportions of 50:50, 60:40, 70:30, and 80:20, respectively, are available commercially; in the United States, only the 70:30 and 50:50 combinations are available. Combinations of lispro protamine-Lispro (75/25, HUMALOG MIX) and aspart protamine-aspart (70/30, NOVOLOG MIX) are also available in the United States (Table 60–4). “Pen devices” containing prefilled regular, lispro, NPH, glargine, or premixed regular-NPH, lispro protamine-lispro, or aspart protamine-aspart combinations have proven to be popular with many diabetic patients.

Jet injector systems that enable patients to receive subcutaneous insulin “injections” without a needle are available. These devices are rather expensive and cumbersome but are preferred by some patients. Dispersal of insulin throughout an area of subcutaneous tissue theoretically should increase the rate of absorption of both regular and intermediate-acting insulins; however, this result has not always been observed.

Subcutaneous insulin administration results in anti-insulin IgG antibody formation. Older, impure preparations of animal insulins were far more antigenic than the more recent purified porcine and recombinant human preparations. It is disputed whether chronic therapy with human insulin reduces antibody production compared with monocomponent porcine insulin. Regardless, it is clear that human insulin is immunogenic. In the vast majority of patients receiving insulin treatment, circulating anti-insulin antibodies do not alter the pharmacokinetics of the injected hormone.

In rare patients who have a high titers of anti-insulin antibodies, the kinetics of action of regular insulin may resemble those of an intermediate-acting insulin, which itself may become longer acting. Such effects could lead to increased postprandial hyperglycemia (owing to decreased action of regular insulin) but nighttime hypoglycemia (owing to the prolonged action of intermediate insulin).

IgG antibodies can cross the placenta, raising the possibility that anti-insulin antibodies could cause fetal hyperglycemia by neutralizing fetal insulin. On the other hand, fetal or neonatal hypoglycemia could result from the undesirable and unpredictable release of insulin from insulin-antibody complexes. Switching from bovine/porcine to monocomponent insulin preparations has been shown to reduce anti-insulin antibodies, leading to the recommendation that only human insulin be used during pregnancy.

Continuous Subcutaneous Insulin Infusion. A number of pumps are available for continuous subcutaneous

insulin infusion (CSII) therapy. CSII, or “pump,” therapy is not suitable for all patients because it demands considerable attention, especially during the initial phases of treatment. However, for patients interested in intensive insulin therapy, a pump may be an attractive alternative to several daily injections. Most modern pumps provide a constant basal infusion of insulin and have the option of different infusion rates during the day and night to help avoid the dawn phenomenon and bolus injections that are programmed according to the size and nature of a meal.

Pump therapy presents some unique problems. Since all the insulin used is short acting and there is a minimal amount of insulin in the subcutaneous pool at any given time, insulin deficiency and ketoacidosis may develop rapidly if therapy is interrupted accidentally. Although modern pumps have warning devices that detect changes in line pressure, mechanical problems such as pump failure, dislodgement of the needle, aggregation of insulin in the infusion line, or accidental kinking of the infusion catheter may occur. There also is a possibility of subcutaneous abscesses and cellulitis. Selection of the most appropriate patients is extremely important for success with pump therapy. Offsetting these potential problems, pump therapy is capable of producing a more physiological profile of insulin replacement during exercise (where insulin production is decreased) and therefore less hypoglycemia than do traditional subcutaneous insulin injections.

Adverse Reactions. Hypoglycemia. The most common adverse reaction to insulin is hypoglycemia. This may result from an inappropriately large dose, from a mismatch between the time of peak delivery of insulin and food intake, or from superimposition of additional factors that increase sensitivity to insulin (*e.g.*, adrenal or pituitary insufficiency) or that increase insulin-independent glucose uptake (*e.g.*, exercise). The more vigorous the attempt to achieve euglycemia, the more frequent are the episodes of hypoglycemia. In the DCCT, the incidence of severe hypoglycemic reactions was three times higher in the intensive insulin therapy group than in the conventional therapy group (DCCT Research Group, 1993). Milder but significant hypoglycemic episodes were much more common than were severe reactions, and their frequency also increased with intensive therapy. Hypoglycemia is the major risk that always must be weighed against benefits of intensive therapy.

There is a hierarchy of physiological responses to hypoglycemia. The first response is a reduction of endogenous insulin secretion, which occurs at a plasma

glucose level of about 70 mg/dl (3.9 mM); thereafter, the counter-regulatory hormones—epinephrine, glucagon, growth hormone, cortisol, and norepinephrine—are released. Symptoms of hypoglycemia are first discerned at a plasma glucose level of 60 to 80 mg/dl (3.3 to 4.4 mM). Sweating, hunger, paresthesias, palpitations, tremor, and anxiety, principally of autonomic origin, usually are seen first. Difficulty in concentrating, confusion, weakness, drowsiness, a feeling of warmth, dizziness, blurred vision, and loss of consciousness (*i.e.*, the *neuroglycopenic symptoms*) usually occur at lower plasma glucose levels than do autonomic symptoms. In a normal individual, plasma glucose levels are tightly regulated, and it is only under rare conditions that hypoglycemia occurs.

Glucagon and epinephrine are the predominant counter-regulatory hormones in acute hypoglycemia in newly diagnosed type 1 DM patients and normal subjects. In patients with type 1 DM of longer duration, the glucagon secretory response to hypoglycemia becomes deficient, but effective glucose counter-regulation still occurs because epinephrine plays a compensatory role. Patients with type 1 DM thus become dependent on epinephrine for counter-regulation, and if this mechanism becomes deficient, the incidence of severe hypoglycemia increases. This occurs in patients with diabetes of long duration who have autonomic neuropathy. The absence of both glucagon and epinephrine can lead to prolonged hypoglycemia, particularly during the night, when some individuals can have extremely low plasma glucose levels for several hours. Severe hypoglycemia can lead to convulsions and coma.

In addition to autonomic neuropathy, several related syndromes of defective counter-regulation contribute to the increased incidence of severe hypoglycemia in intensively treated type 1 DM patients. These include hypoglycemic unawareness, altered thresholds for release of counter-regulatory hormones, and deficient secretion of counter-regulatory hormones (reviewed by Cryer 1993).

With the ready availability of home glucose monitoring, hypoglycemia can be documented in most patients who experience suggestive symptoms. Hypoglycemia that occurs during sleep may be difficult to detect but should be suspected from a history of morning headaches, night sweats, or symptoms of hypothermia. Nocturnal hypoglycemia has been proposed as a cause of morning hyperglycemia in type 1 DM patients. This syndrome, known as the *Somogyi phenomenon*, was reputedly due to an elevation of counter-regulatory hormones in response to nocturnal hypoglycemia, but several groups of investigators have been unable to reproduce it. Moreover, neuroendocrine counter-regulatory responses are severely diminished with disease duration and intensive control. Therefore, it is unlikely that in patients

with reduced neuroendocrine responses to hypoglycemia, nocturnal counter-regulatory responses to hypoglycemia could be responsible for morning hyperglycemia. The practice of reducing nighttime insulin doses in type 1 DM subjects with morning hyperglycemia thus cannot now be recommended. Rather, the current recommended therapeutic approach to treating morning hyperglycemia is to administer more long- or intermediate-acting insulin the night before, perhaps at bedtime, or to increase the basal rate of a CSII pump between the hours of 3 and 7 A.M.

All diabetic patients who receive insulin should be aware of the symptoms of hypoglycemia, carry some form of easily ingested glucose, and carry an identification card or bracelet containing pertinent medical information. When possible, patients who suspect that they are experiencing hypoglycemia should document the glucose concentration with a measurement. Mild-to-moderate hypoglycemia may be treated simply by ingestion of glucose. When hypoglycemia is severe, it should be treated with intravenous glucose or an injection of glucagon (*see below*).

Insulin Allergy and Resistance. Although there has been a dramatic decrease in the incidence of resistance and allergic reactions to insulin with the use of recombinant human insulin or highly purified preparations of the hormone, these reactions still occur as a result of reactions to the small amounts of aggregated or denatured insulin in all preparations, to minor contaminants, or because of sensitivity to one of the components added to insulin in its formulation (protamine, Zn^{2+} , phenol, *etc.*). The most frequent allergic manifestations are IgE-mediated local cutaneous reactions, although on rare occasions patients may develop life-threatening systemic responses or insulin resistance owing to IgG antibodies. Attempts should be made to identify the underlying cause of the hypersensitivity response by measuring insulin-specific IgG and IgE antibodies. Skin testing also is useful; however, many patients exhibit positive reactions to intradermal insulin without experiencing any adverse effects from subcutaneous insulin. If patients have allergic reactions to porcine insulin, human insulin should be used. If allergy persists, desensitization may be attempted; it is successful in about 50% of cases. Antihistamines may provide relief in patients with cutaneous reactions, whereas glucocorticoids have been used in patients with resistance to insulin or more severe systemic reactions.

Lipoatrophy and Lipohypertrophy. Atrophy of subcutaneous fat at the site of insulin injection (lipoatrophy) is probably a variant of an immune response to insulin, whereas lipohypertrophy (enlargement of subcutaneous fat depots) has been ascribed to the lipogenic action of high local concentrations of insulin (LeRoith *et al.*, 2000). Both problems may be related to some contaminant in insulin and are rare with more purified preparations. However, hypertrophy occurs frequently with human insulins if patients inject themselves repeatedly in the same site. When these problems occur, they may cause irregular absorption of insulin, as well as a cosmetic problem. The recommended treatment is to avoid the hypertrophic areas by using other injection sites and to inject insulin into the periphery of the atrophic sites in an attempt to restore the subcutaneous adipose tissue.

Insulin Edema. Some degree of edema, abdominal bloating, and blurred vision develops in many diabetic patients with severe hyperglycemia or ketoacidosis that is brought under control with insulin. This is associated with a weight gain of 0.5 to 2.5 kg. The edema usually disappears spontaneously within several days to a week unless there is underlying cardiac or renal disease. Edema is attributed primarily to retention of Na^+ , although increased capil-

lary permeability associated with inadequate metabolic control also may contribute.

Insulin Treatment of Ketoacidosis and Other Special Situations. Acutely ill diabetic patients may have metabolic disturbances that are sufficiently severe or labile to justify intravenous administration of insulin. Such treatment is most appropriate in patients with ketoacidosis. Although there has been some controversy over appropriate dosage, infusion of a relatively low dose of insulin (0.1 units/kg per hour) will produce plasma concentrations of insulin of about 100 μ units/ml—a level sufficient to inhibit lipolysis and gluconeogenesis completely and to produce near-maximal stimulation of glucose uptake in normal individuals. In most patients with diabetic ketoacidosis, blood glucose concentrations will fall by about 10% per hour; the acidosis is corrected more slowly. As treatment proceeds, it often is necessary to administer glucose along with the insulin to prevent hypoglycemia but to allow clearance of all ketones. Some physicians prefer to initiate therapy with a loading dose of insulin, but this tactic appears unnecessary because steady-state concentrations of the hormone are achieved within 30 minutes with a constant infusion. Patients with nonketotic hyperglycemic coma typically are more sensitive to insulin than are those with ketoacidosis. Appropriate replacement of fluid and electrolytes is an integral part of the therapy in both situations because there is always a major deficit. Regardless of the exact insulin regimen, the key to effective therapy is careful and frequent monitoring of the patient's clinical status, glucose, and electrolytes. A frequent error in the management of such patients is the failure to administer insulin subcutaneously at least 30 minutes before intravenous therapy is discontinued. This is necessary because of the very short half-life of insulin.

Intravenous administration of insulin also is well suited to the treatment of diabetic patients during the perioperative period and during childbirth (Jacobson and Sower, 1999). There is debate, however, about the optimal route of insulin administration during surgery. Although some clinicians advocate subcutaneous insulin administration, most recommend intravenous insulin infusion. The two most widely used protocols for intravenous insulin administration are the variable-rate regimen and the glucose–insulin–potassium (GIK) infusion method (see LeRoith *et al.*, 2000). Both protocols provide stable plasma glucose, fluid, and electrolyte levels during the operative and postoperative period. Despite this, many physicians give patients half their normal daily dose of insulin as intermediate-acting insulin subcutaneously on the morning of an operation and then administer 5% dextrose infusions during surgery to maintain glucose concentrations. This approach provides less minute-to-minute control than is possible with intravenous regimens and also may increase the likelihood of hypogly-

cemia. Newer subcutaneously administered basal and rapid-acting analogs may provide smoother glycemic control without the drawback of hypoglycemia. Recent multicenter trials have demonstrated dramatic improvement in patient outcome, including significant reductions in mortality, when intensive insulin regimens (predominantly intravenous) have been used to reduce glycemia after myocardial infarction or surgery (Malmberg *et al.*, 1995; Davies and Lawrence, 2002; van den Berghe *et al.*, 2001; van den Berghe 2004).

Drug Interactions and Glucose Metabolism. A large number of drugs can cause hypoglycemia or hyperglycemia or may alter the response of diabetic patients to their existing therapeutic regimens. Some drugs with hypoglycemic or hyperglycemic effects and their presumed sites of action are listed in Table 60–5.

Aside from insulin and oral hypoglycemic drugs, the most common drug-induced hypoglycemic states are those caused by *ethanol*, *β adrenergic receptor antagonists*, and *salicylates*. The primary action of ethanol is to inhibit gluconeogenesis. This is not an idiosyncratic reaction but is observed in all individuals. In diabetic patients, *β adrenergic receptor antagonists* pose a risk of hypoglycemia because of their capacity to inhibit the effects of catecholamines on gluconeogenesis and glycogenolysis. These agents also may mask the sympathetically mediated symptoms associated with the fall in blood glucose (*e.g.*, tremor and palpitations). Salicylates, on the other hand, exert their hypoglycemic effect by enhancing pancreatic *β -cell* sensitivity to glucose and potentiating insulin secretion. These agents also have a weak insulinlike action in the periphery. *Pentamidine*, an antiprotozoal agent used for the treatment of infections caused by *Pneumocystis carinii*, apparently can cause both hypoglycemia and hyperglycemia. The hypoglycemic effect results from destruction of *β cells* and release of insulin; continued use may cause secondary hypoinsulinemia and hyperglycemia. A number of drugs have no direct hypoglycemic action but may potentiate the actions of sulfonylureas (see below).

An equally large number of drugs may cause hyperglycemia in normal individuals or impair metabolic control in diabetic patients. Many of these agents have direct effects on peripheral tissues that counter the actions of insulin; examples include epinephrine, glucocorticoids, atypical antipsychotic drugs such as *clozapine* and *olanzapine*, and drugs used in highly active antiretroviral therapy (HAART) of HIV-1 infection (especially the protease inhibitors). Other drugs cause hyperglycemia by inhibiting insulin secretion directly (*e.g.*, *phenytoin*, *clonidine*, and Ca^{2+} -channel blockers) or indirectly *via* depletion of K^{+} (diuretics). It is important to be aware of such interactions and to modify treatment regimens for diabetic patients accordingly.

New Forms of Insulin Therapy. There are a number of experimental approaches to insulin delivery, including the use of new insulins, new routes of administration, intraperitoneal delivery devices, implantable pellets, the closed-loop artificial pancreas, islet cell and pancreatic transplantation, and gene therapy.

New Routes of Delivery. Attempts have been made to administer insulin orally, nasally, rectally, by inhalation, and by subcutaneous implantation of pellets. The most promising of these alternatives is by inhalation, which can be achieved by addition of various adjuvants such as *mannitol*, *glycine*, and *sodium citrate* to insulin to increase its absorption through the pulmonary mucosa (Skyler *et al.*, 2001; Cefalu *et al.*, 2001). Absorption is rapid and approaches the

rate achieved with subcutaneous administration of regular insulin. Further work is under way with the aim of reducing the size and increasing the convenience of the inhaled delivery systems. Implantable pellets have been designed to release insulin slowly over days or weeks. Although oral delivery of insulin would be preferred by patients and would provide higher relative concentrations of insulin in the portal circulation, attempts to increase intestinal absorption of the hormone have met with only limited success. Efforts have focused on protection of insulin by encapsulation or incorporation into liposomes. Intraperitoneal infusion of insulin into the portal circulation has been used experimentally in human subjects for periods of several months.

Transplantation and Gene Therapy. Transplantation and gene therapy are provocative approaches to insulin replacement. Segmental pancreatic transplantation has been employed successfully in hundreds of patients (Sutherland *et al.*, 2004). However, the surgery is technically complex and usually is considered only in patients with advanced disease and complications. The best-documented benefits have been in patients who also require a kidney transplant for diabetic nephropathy. Islet cell transplants theoretically are less complicated. Successful protocols for islet cell transplants were based on advances in islet preparation and a novel glucocorticoid-free immunosuppressive regimen (Robertson, 2004). The precise role of islet cell transplantation is debated, and the supply of available islet preparations remains very limited. In rodents, gene therapy using transcription factors that regulate β -cell function has been used to transdifferentiate hepatocytes into a functional endocrine pancreas, eliminating the need for insulin therapy for months in experimental models of diabetes mellitus (Meivar-Levy and Ferber, 2004).

ORAL HYPOGLYCEMIC AGENTS

History. In contrast to the systematic studies that led to the isolation of insulin, the *sulfonylureas* were discovered accidentally. In 1942, Janbon and colleagues noted that some sulfonamides caused hypoglycemia in experimental animals. Soon thereafter, *1-butyl-3-sulfonylurea* (*carbutamide*) became the first clinically useful sulfonylurea for the treatment of diabetes. Although later withdrawn because of adverse effects on the bone marrow, this compound led to the development of the entire class of sulfonylureas. Clinical trials of *tolbutamide*, the first widely used member of this group, were instituted in patients with type 2 DM in the early 1950s. Since that time, approximately 20 different agents of this class have been in use worldwide.

In 1997, *repaglinide*, the first member of a new class of oral insulin secretagogues called *meglitinides* (benzoic acid derivatives), was approved for clinical use; this agent has gained acceptance as a fast-acting premeal therapy to limit postprandial hyperglycemia.

The goat's rue plant (*Galega officinalis*), used to treat diabetes in Europe in medieval times, was found in the early twentieth century to contain *guanadine*. Guanadine has hypoglycemic properties but was too toxic for clinical use. During the 1920s, *biguanides* were investigated for use in diabetes, but they were overshadowed by the discovery of insulin. Later, the antimalarial agent *chloroguanide* was found to have weak hypoglycemic action. Shortly after the introduction of the sulfonylureas, the first

biguanides became available for clinical use. However, *phenformin*, the primary drug in this group, was withdrawn from the market in the United States and Europe because of an increased frequency of lactic acidosis associated with its use. Another biguanide, *metformin*, has been used extensively in Europe without significant adverse effects and was approved for use in the United States in 1995.

Thiazolidinediones were introduced in 1997 as the second major class of "insulin sensitizers." These agents bind to peroxisome proliferator-activated receptors (principally PPAR γ), resulting in increased glucose uptake in muscle and reduced endogenous glucose production. The first of these agents, *troglitazone*, was withdrawn from use in the United States in 2000 because of an association with hepatic toxicity. Two other agents of this class, *rosiglitazone* and *pioglitazone*, have not been associated with widespread liver toxicity and are used worldwide.

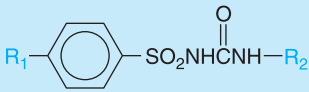

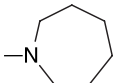

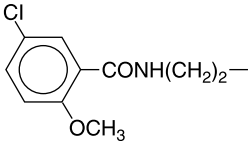

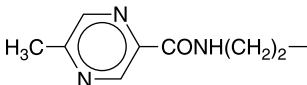

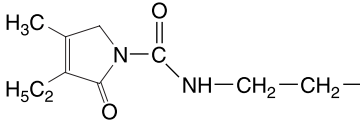

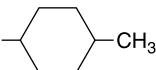

Sulfonylureas

Chemistry. The sulfonylureas are divided into two groups or generations of agents. Their structural relationships are shown in Table 60-6. All members of this class of drugs are substituted arylsulfonylureas. They differ by substitutions at the *para* position on the benzene ring and at one nitrogen residue of the urea moiety. The first group of sulfonylureas includes *tolbutamide*, *acetohexamide*, *tolazamide*, and *chlorpropamide*. A second, more potent generation of hypoglycemic sulfonylureas has emerged, including *glyburide* (*glibenclamide*), *glipizide*, *gliclazide*, and *glimepiride*.

Mechanism of Action. Sulfonylureas cause hypoglycemia by stimulating insulin release from pancreatic β cells. Their effects in the treatment of diabetes, however, are more complex. The acute administration of sulfonylureas to type 2 DM patients increases insulin release from the pancreas. Sulfonylureas also may further increase insulin levels by reducing hepatic clearance of the hormone. In the initial months of sulfonylurea treatment, fasting plasma insulin levels and insulin responses to oral glucose challenges are increased. With chronic administration, circulating insulin levels decline to those that existed before treatment, but despite this reduction in insulin levels, reduced plasma glucose levels are maintained. The explanation for this is not clear, but it may relate to reduced plasma glucose allowing circulating insulin to have more pronounced effects on its target tissues and to the fact that chronic hyperglycemia *per se* impairs insulin secretion (glucose toxicity).

The absence of acute stimulatory effects of sulfonylureas on insulin secretion during chronic treatment is attributed to down-regulation of cell surface receptors for sulfonylureas on the pancreatic β cell. If chronic sulfonylurea therapy is discontinued, pancreatic β -cell response to acute administration of the drug is restored. Sulfonylureas also stimulate release of somatostatin, and they may suppress the secretion of glucagon slightly.

Table 60–6
Structural Formulas of the Sulfonylureas

GENERAL FORMULA: 		
First-Generation Agents	R ₁	R ₂
Tolbutamide (ORINASE, others)	H ₃ C—	—C ₄ H ₉
Chlorpropamide (DIABINESE, others)	Cl—	—C ₃ H ₇

Glimepiride (AMARYL)		

Sulfonylureas bind to the SUR1 subunits and block the ATP-sensitive K⁺ channel (Aguilar-Bryan *et al.*, 1995; Philipson and Steiner, 1995). The drugs thus resemble physiological secretagogues (*e.g.*, glucose, leu-

cine), which also lower the conductance of this channel. Reduced K⁺ conductance causes membrane depolarization and influx of Ca²⁺ through voltage-sensitive Ca²⁺ channels.

There has been controversy about whether or not sulfonylureas have clinically significant extrapancreatic effects. In general, attempts to ascribe the long-term blood glucose-lowering effects of sulfonylureas to specific changes in insulin action on target tissues are confounded by the effects of a lower prevailing blood glucose level. Although extrapancreatic effects of sulfonylureas can be demonstrated, they are of minor clinical significance in the treatment of type 2 DM patients.

Absorption, Fate, and Excretion. The sulfonylureas have similar spectra of activities; thus their pharmacokinetic properties are their most distinctive characteristics (*see* Appendix II). Although the rates of absorption of the different sulfonylureas vary, all are effectively absorbed from the gastrointestinal tract. However, food and hyperglycemia can reduce the absorption of sulfonylureas. Hyperglycemia *per se* inhibits gastric and intestinal motility and thus can retard the absorption of many drugs. In view of the time required to reach an optimal concentration in plasma, sulfonylureas with short half-lives may be more effective when given 30 minutes before eating. Sulfonylureas in plasma are largely (90% to 99%) bound to protein, especially albumin; plasma protein binding is least for chlorpropamide and greatest for glyburide. The volumes of distribution of most of the sulfonylureas are about 0.2 L/kg.

The first-generation sulfonylureas vary considerably in their half-lives and extents of metabolism. The half-life of acetohexamide is short, but the drug is reduced to an active compound whose half-life is similar to those of tolbutamide and tolazamide (4 to 7 hours). It may be necessary to take these drugs in divided daily doses. Chlorpropamide has a long half-life (24 to 48 hours). The second-generation agents are approximately 100 times more potent than are those in the first group. Although their half-lives are short (3 to 5 hours), their hypoglycemic effects are evident for 12 to 24 hours, and they often can be administered once daily. The reason for the discrepancies between their half-lives and duration of action is not clear.

All the sulfonylureas are metabolized by the liver, and the metabolites are excreted in the urine. Metabolism of chlorpropamide is incomplete, and about 20% of the drug is excreted unchanged. Thus sulfonylureas should be administered with caution to patients with either renal or hepatic insufficiency.

Adverse Reactions. Adverse effects of the sulfonylureas are infrequent, occurring in about 4% of patients taking first-generation drugs and perhaps slightly less often in patients receiving second-generation agents. Not unexpectedly, sulfonylureas may cause hypoglycemic

reactions, including coma. This is a particular problem in elderly patients with impaired hepatic or renal function who are taking longer-acting sulfonylureas. Sulfonylureas can be ranked in order of decreasing risk of causing hypoglycemia. It used to be thought that longer-acting sulfonylureas resulted in a greater prevalence of hypoglycemia. That is certainly the case when comparing the older preparations such as chlorpropamide (long acting) against tolbutamide (short acting). However, more recent second-generation sulfonylureas have very differing incidences of causing hypoglycemia despite similar half-lives. Thus glyburide (glibenclamide) has been reported to result in hypoglycemia in up to 20% to 30% of users, whereas another long-acting sulfonylurea, glimepiride, results in hypoglycemia in only 2% to 4% of users. A modified long-acting version of glipizide also results in a lower hypoglycemia frequency relative to glyburide.

Recent studies have provided an insight into the physiological basis for the differing rates of hypoglycemia occurring with these long-acting sulfonylureas. As described earlier for insulin, the ability of the body to inhibit endogenous insulin secretion is central to the homeostatic defense against hypoglycemia. This glucose-dependent inhibition of insulin secretion during hypoglycemia occurs with glimepiride but not with glyburide. Additionally, the major anti-insulin counter-regulatory hormone glucagon appears to be reduced by glyburide during hypoglycemia but is preserved during glimepiride therapy.

Severe hypoglycemia in the elderly can present as an acute neurological emergency that may mimic a cerebrovascular accident. Thus, it is important to check the plasma glucose level of any elderly patient presenting with acute neurological symptoms. Because of the long half-life of some sulfonylureas, it may be necessary to treat elderly hypoglycemic patients for 24 to 48 hours with an intravenous glucose infusion.

Many other drugs may potentiate the effects of the sulfonylureas, particularly the first-generation agents, by inhibiting their metabolism or excretion. Some drugs also displace the sulfonylureas from binding proteins, thereby transiently increasing the free concentration. These include other sulfonamides, *clofibrate*, and salicylates. Other drugs, especially ethanol, may enhance the action of sulfonylureas by causing hypoglycemia.

Other side effects of sulfonylureas include nausea and vomiting, cholestatic jaundice, agranulocytosis, aplastic and hemolytic anemias, generalized hypersensitivity reactions, and dermatological reactions. About 10% to 15% of patients who receive these drugs, particularly chlorpropa-

mide, develop an alcohol-induced flush similar to that caused by *disulfiram* (see Chapter 23). Sulfonylureas, especially chlorpropamide, also may induce hyponatremia by potentiating the effects of antidiuretic hormone on the renal collecting duct (see Chapter 29). This undesirable side effect occurs in up to 5% of all patients; it is less frequent with glyburide, glipizide, and glimepiride. This effect on water retention has been used to therapeutic advantage in patients with mild forms of central diabetes insipidus.

A long-running debate centered on whether treatment with sulfonylureas is associated with increased cardiovascular mortality; this possibility was suggested by a large multicenter trial [the University Group Diabetes Program (UGDP)]. The UGDP was designed to compare the effect of diet, oral agents (tolbutamide or phenformin), and fixed-dose insulin therapy on the development of vascular complications in type 2 DM. During an 8-year period of observation, patients who received tolbutamide had a twofold higher rate of cardiovascular death than patients treated with placebo or insulin (Meinert *et al.*, 1970). A 10-year debate followed on the validity of this conclusion because the observation was unexpected, the study had not been designed to test this question, and all the excess mortality occurred in only three centers. The recent UKPDS (U.K. Prospective Diabetes Study Group, 1998a) clearly demonstrated no excess cardiovascular mortality over a 14-year period in patients receiving first- or second-generation sulfonylureas. It is worth noting that some of the newer sulfonylurea agents may confer even greater cardiovascular benefits compared with earlier second-generation compounds. Glimepiride, the most recent sulfonylurea, exerts beneficial effects with regard to ischemic preconditioning as compared with glyburide. The physiological response to an ischemic event in the coronary vasculature is a reflex vasodilation to a subsequent ischemic episode. This reflex appears to be preserved with glimepiride but reduced with glyburide.

Therapeutic Uses. Sulfonylureas are used to control hyperglycemia in type 2 DM patients who cannot achieve appropriate control with changes in diet alone. In all patients, continued dietary restrictions are essential to maximize the efficacy of the sulfonylureas. Contraindications to the use of these drugs include type 1 DM, pregnancy, lactation, and for the older preparations, significant hepatic or renal insufficiency.

Between 50% and 80% of properly selected patients will respond initially to an oral hypoglycemic agent. All the drugs appear to be equally efficacious. Concentrations of glucose often are lowered sufficiently to relieve symptoms of hyperglycemia but may not reach normal levels. To the extent that complications of diabetes are related to hyperglycemia, the goal of treatment should be normalization of both fasting and postprandial glucose concentrations. About 5% to 10% of patients per year who respond initially to a sulfonylurea become secondary failures, as defined by unacceptable levels of hyperglycemia. This may occur as a result

of a change in drug metabolism, progression of β -cell failure, change in dietary compliance, or misdiagnosis of a patient with slow-onset type 1 DM. Additional oral agent(s) can produce a satisfactory response, but most of these patients eventually will require insulin.

The usual initial daily dose of tolbutamide is 500 mg, and 3000 mg is the maximally effective total dose. Tolazamide and chlorpropamide usually are initiated in a daily dose of 100 to 250 mg, with maximal doses of 1000 (tolazamide) or 750 mg (chlorpropamide). Tolbutamide and tolazamide often are taken twice daily 30 minutes before breakfast and dinner. The initial daily dose of glyburide is 2.5 to 5 mg, and daily doses of more than 20 mg are not recommended. Therapy with glipizide usually is initiated with 5 mg given once daily. The maximal recommended daily dose is 40 mg; daily doses of more than 15 mg should be divided. The starting dose of gliclazide is 40 to 80 mg/day, and the maximal daily dose is 320 mg. Glimepiride therapy can begin with doses as low as 0.5 mg once per day. The maximal effective daily dose of the agent is 8 mg. Treatment with the sulfonylureas must be guided by the patient's response, which must be monitored frequently.

Combinations of insulin and sulfonylureas have been used in some patients with type 1 and type 2 DM. Studies in type 1 DM patients have provided no evidence that glucose control is improved by combination therapy. The results in type 2 DM patients have shown significant improvements in metabolic control. A prerequisite for a beneficial effect of combination therapy is residual β -cell activity; a short duration of diabetes also may predict a good response.

Repaglinide

Repaglinide (PRANDIN) is an oral insulin secretagogue of the meglitinide class. This agent is a derivative of benzoic acid, and its structure (shown below) is unrelated to that of the sulfonylureas.

Like sulfonylureas, repaglinide stimulates insulin release by closing ATP-dependent potassium channels in pancreatic β cells. The drug is absorbed rapidly from the gastrointestinal tract, and peak blood levels are obtained within 1 hour. The half-life of the drug is about 1 hour. These features of the drug allow for multiple preprandial use as compared with the classical once- or twice-daily

dosing of sulfonylureas. Repaglinide is metabolized primarily by the liver to inactive derivatives. Repaglinide should be used cautiously in patients with hepatic insufficiency. Because a small proportion (about 10%) of repaglinide is metabolized by the kidney, increased dosing of the drug in patients with renal insufficiency also should be performed cautiously. As with sulfonylureas, the major side effect of repaglinide is hypoglycemia.

Nateglinide

Nateglinide (STARLIX) is an orally effective insulin secretagogue derived from D-phenylalanine. Like sulfonylureas and repaglinide, nateglinide stimulates insulin secretion by blocking ATP-sensitive potassium channels in pancreatic β cells. Nateglinide promotes a more rapid but less sustained secretion of insulin than do other available oral antidiabetic agents (Kalbag *et al.*, 2001). The drug's major therapeutic effect is reducing postprandial glycemic elevations in type 2 DM patients. Nateglinide is approved by the FDA for use in type 2 DM and is most effective if administered in a dose of 120 mg 1 to 10 minutes before a meal. Nateglinide is metabolized primarily by the liver and thus should be used cautiously in patients with hepatic insufficiency. About 16% of an administered dose is excreted by the kidney as unchanged drug. Dosage adjustment is unnecessary in renal failure. Nateglinide therapy may produce fewer episodes of hypoglycemia than most other currently available oral insulin secretagogues including repaglinide (Horton *et al.*, 2001).

Biguanides

Metformin (GLUCOPHAGE, others) and phenformin were introduced in 1957, and *buformin* was introduced in 1958. The latter was of limited use, but metformin and phenformin were used widely. Phenformin was withdrawn in many countries during the 1970s because of an association with lactic acidosis. Metformin has been associated only rarely with that complication and has been used widely in Europe and Canada; it became available in the United States in 1995. Metformin given alone or in combination with a sulfonylurea improves glycemic control and lipid concentrations in patients who respond poorly to diet or to a sulfonylurea alone (DeFronzo *et al.*, 1995).

Mechanism of Action. Metformin is antihyperglycemic, not hypoglycemic (*see* Bailey, 1992). It does not cause insulin release from the pancreas and generally does not cause hypoglycemia,

even in large doses. Metformin has no significant effects on the secretion of glucagon, cortisol, growth hormone, or somatostatin. Metformin reduces glucose levels primarily by decreasing hepatic glucose production and by increasing insulin action in muscle and fat. At a molecular level, these actions are mediated at least in part by activation of the cellular kinase AMP-activated protein kinase (AMP kinase) (*see* below and Zhou *et al.*, 2001). The mechanism by which metformin reduces hepatic glucose production is controversial, but most data indicate an effect on reducing gluconeogenesis (Stumvoll *et al.*, 1995). Metformin also may decrease plasma glucose by reducing the absorption of glucose from the intestine, but this action has not been shown to have clinical relevance.

Absorption, Excretion, and Dosing. Metformin is absorbed mainly from the small intestine. The drug is stable, does not bind to plasma proteins, and is excreted unchanged in the urine. It has a half-life of about 2 hours. The maximum recommended daily dose of metformin in the United States is 2.5 g given in three doses with meals.

Precautions and Adverse Effects. Patients with renal impairment should not receive metformin. Other contraindications include hepatic disease, a past history of lactic acidosis (of any cause), cardiac failure requiring pharmacological therapy, or chronic hypoxic lung disease. The drug also should be discontinued temporarily prior to the administration of intravenous *contrast media* and prior to any surgical procedure. The drug should not be readministered any sooner than 48 hours after such procedures and should be withheld until renal function is determined to be normal. These conditions all predispose to increased lactate production and hence to the potentially fatal complication of lactic acidosis. The reported incidence of lactic acidosis during metformin treatment is less than 0.1 cases per 1000 patient-years, and the mortality risk is even lower.

Acute side effects of metformin, which occur in up to 20% of patients, include diarrhea, abdominal discomfort, nausea, metallic taste, and anorexia. These usually can be minimized by increasing the dosage of the drug slowly and taking it with meals. Intestinal absorption of *vitamin B₁₂* and *folate* often is decreased during chronic metformin therapy, and calcium supplements reverse the effect of metformin on *vitamin B₁₂* absorption.

Consideration should be given to stopping treatment with metformin if the plasma lactate level exceeds 3 mM or in the setting of decreased renal or hepatic function. It also is prudent to stop metformin if a patient is undergoing a prolonged fast or is treated with a very low calorie diet. Myocardial infarction or septicemia mandates immediate drug discontinuation. Metformin usually is administered in divided doses two or three times daily. The maximum effective dose is 2.5 g/day. Metformin lowers hemoglobin A_{1c} values by about 2%, an effect comparable with that of the sulfonylureas. Metformin does not promote weight gain and can reduce plasma triglycerides by 15% to 20%. There is a strong consensus that reduction in hemoglobin A_{1c} by any therapy (insulin or

oral agents) diminishes microvascular complications. Metformin, however, is the only therapeutic agent that has been demonstrated to reduce macrovascular events in type 2 DM (U.K. Prospective Diabetes Study Group, 1998b). Metformin can be administered in combination with sulfonylureas, thiazolidinediones, and/or insulin. Fixed-dose combinations containing metformin and glyburide (GLUCOVANCE, others), glipizide (METAGLIP), and rosiglitazone (AVANDAMET) are available.

Thiazolidinediones

Three thiazolidinediones have been used in clinical practice (troglitazone, rosiglitazone, and pioglitazone); however, troglitazone was withdrawn from use because it was associated with severe hepatic toxicity. Rosiglitazone and pioglitazone can lower hemoglobin A_{1c} levels by 1% to 1.5% in patients with type 2 DM. These drugs can be combined with insulin or other classes of oral glucose-lowering agents. The thiazolidinediones tend to increase high-density lipoprotein (HDL) cholesterol but have variable effects on triglycerides and low-density lipoprotein (LDL) cholesterol. The structures of rosiglitazone and pioglitazone are:

Mechanism of Action. Thiazolidinediones are selective agonists for nuclear peroxisome proliferator-activated receptor- γ (PPAR γ). These drugs bind to PPAR γ , which activates insulin-responsive genes that regulate carbohydrate and lipid metabolism. Thiazolidinediones require insulin to be present for their action. Thiazolidinediones exert their principal effects by increasing insulin sensitivity in peripheral tissue but also may lower glucose production by the liver. Thiazolidinediones increase glucose transport into muscle and adipose tissue by enhancing the synthesis and translocation of specific forms of the glucose transporters. The thiazolidinediones also can activate genes that regulate fatty acid metabolism in peripheral tissue. Although muscle is a major insulin-sensitive tissue, PPAR γ is virtually absent in skeletal muscle. This has provoked questions as to how thiazolo-

lidinediones can reduce peripheral insulin resistance. One suggestion is that activation of PPAR γ in adipose tissue reduces the flux of fatty acids into muscle, thereby lowering insulin resistance. Other suggestions include the activation of adipocyte hormones and/or adipokines, the most promising of which is adiponectin. Adiponectin is associated with increased insulin sensitivity and reportedly increases insulin sensitivity by elevating AMP kinase, which stimulates glucose transport into muscle and increases fatty acid oxidation (Havel, 2003). Because the actions of both metformin and the thiazolidinediones apparently converge on AMP kinase, it has emerged as an attractive target for drug development (Ruderman and Prentki, 2004).

Absorption, Excretion, and Dosing. Rosiglitazone (AVANDIA) and pioglitazone (ACTOS) are taken once a day. Both agents are absorbed within about 2 hours, but the maximum clinical effect is not observed for 6 to 12 weeks. The thiazolidinediones are metabolized by the liver and may be administered to patients with renal insufficiency but should not be used if there is active hepatic disease or significant elevations of serum liver transaminases.

Rosiglitazone is metabolized by hepatic cytochrome P450 (CYP) 2C8, whereas pioglitazone is metabolized by CYP3A4 and CYP2C8. As discussed in Chapter 3, other drugs that induce or inhibit these enzymes can cause drug interactions. Clinically significant interactions between the available thiazolidinediones and other drug classes have not yet been described, but further studies are in progress.

Precautions and Adverse Effects. Liver function should be monitored in patients receiving thiazolidinediones, even though pioglitazone and rosiglitazone rarely have been associated with hepatotoxicity (12 cases up to July 2004). This lower hepatotoxicity has been attributed to the lack of the tocopherol side chain that was included in the troglitazone molecule. Additionally, the rare cases of hepatotoxicity occurring with second-generation thiazolidinediones appear to be less severe than those occurring with troglitazone. Hepatotoxicity can occur several months after initiation of the drugs. Any patient who has suffered any hepatotoxicity (even abnormal liver function tests) while on a thiazolidinediones should not receive any drugs in this class. Thiazolidinediones also have been reported to cause anemia, weight gain, edema, and plasma volume expansion. Edema is more likely to occur when these agents are combined with insulin; these drugs should not be used in patients with New

York Heart Association class 3 or 4 heart failure. Fluid retention and even overt heart failure usually occur within 6 months of thiazolidinedione therapy. In most cases, the subjects had no past history of heart failure, but all had underlying abnormal cardiac function. Obese hypertensive individuals and those with cardiac diastolic dysfunction are at greatest risk for fluid retention with thiazolidinediones. Thiazolidinediones also can induce peripheral edema independent of heart failure; proposed mechanisms include an increase in weight, an expansion of plasma volume following a reduction in renal sodium excretion, or a direct effect to increase vascular permeability. Exacerbations of fluid retention and/or heart failure should be treated, and the thiazolidinedione should be discontinued.

The availability of thiazolidinediones as powerful PPAR γ ligands has sparked a number of novel avenues of clinical research. Studies have investigated whether thiazolidinediones can improve insulin sensitivity in HIV-associated lipodystrophy (see Chapter 50). Studies also are underway to explore the effects of thiazolidinediones on nonalcoholic hepatic steatosis. Finally, small single-site studies have investigated whether rosiglitazone can slow the progression of atheromatous lesions in carotid and coronary arteries in both nondiabetic and type 2 DM patients. Results to date have been mixed, and further multicenter studies are ongoing.

α -Glucosidase Inhibitors

α -Glucosidase inhibitors reduce intestinal absorption of starch, dextrin, and disaccharides by inhibiting the action of α -glucosidase in the intestinal brush border. Inhibition of this enzyme slows the absorption of carbohydrates; the postprandial rise in plasma glucose is blunted in both normal and diabetic subjects.

α -Glucosidase inhibitors do not stimulate insulin release and therefore do not result in hypoglycemia. These agents may be considered as monotherapy in elderly patients or in patients with predominantly postprandial hyperglycemia. α -Glucosidase inhibitors typically are used in combination with other oral antidiabetic agents and/or insulin. The drugs should be administered at the start of a meal. They are poorly absorbed.

Acarbose (PRECOSE), an oligosaccharide of microbial origin, and *miglitol* (GLYSET), a desoxynojirimycin derivative, also competitively inhibit glucoamylase and sucrase but have weak effects on pancreatic α -amylase. They reduce postprandial plasma glucose levels in type 1 and type 2 DM subjects. α -Glucosidase inhibitors can significantly improve hemoglobin A_{1c} levels in severely hyper-

glycemic type 2 DM patients. However, in patients with mild-to-moderate hyperglycemia, the glucose-lowering potential of α -glucosidase inhibitors (assessed by hemoglobin A_{1c} levels) is about 30% to 50% of that of other oral antidiabetic agents.

α -Glucosidase inhibitors cause dose-related malabsorption, flatulence, diarrhea, and abdominal bloating. Titrating the dose of drug slowly (25 mg at the start of a meal for 4 to 8 weeks, followed by increases at 4- to 8-week intervals to a maximum of 75 mg before each meal) reduces gastrointestinal side effects. Smaller doses are given with snacks. Acarbose is most effective when given with a starchy, high-fiber diet with restricted amounts of glucose and sucrose. If hypoglycemia occurs when α -glucosidase inhibitors are used with insulin or an insulin secretagogue, glucose rather than sucrose, starch, or maltose should be administered.

Reduction in the Incidence of Type 2 DM

Type 2 DM is a rapidly expanding worldwide health problem. In addition, the number of individuals who have impaired glucose tolerance (often termed *prediabetes*) may be equal to or even higher than the number of people with diabetes. In the United States, nearly 20 million individuals are diagnosed with diabetes, but perhaps twice that number have *impaired glucose tolerance* (IGT), which is defined as a fasting plasma glucose concentration of between 100 and 126 mg/dl (5.6 to 7 mM) or 2-hour values in the oral glucose tolerance test of between 140 and 199 mg/dl (7.8 to 11 mM) (Expert Committee on the Diagnosis and Classification of Diabetes, 2003). The rate of progression of IGT to overt diabetes ranges from 9% to 15% worldwide. A major factor in this increased incidence of diabetes is obesity. In the United States, approximately 60% of the population is overweight or obese. Particularly troubling is the rapid increase of obesity in children. Owing to the deleterious effects of obesity and decreased physical activity on insulin sensitivity, the incidence of type 2 DM in U.S. children has increased by tenfold over the last generation. Several large multicenter studies have investigated the effects of lifestyle and/or differing pharmacologic agents on reducing the incidence of type 2 DM. In the Diabetes Prevention Program study (Diabetes Prevention Program Research Group, 2002), a lifestyle intervention consisting of 150 minutes of exercise per week and a 7% weight loss over 2.8 years reduced the incidence of type 2 DM by 58% compared with placebo. Metformin (1700 mg/day) reduced the progression by 31%. Interestingly, when metformin was stopped, its protective effect in preventing diabetes dissi-

pated rapidly. In the Tripod study, troglitazone (400 mg/day) for 30 months reduced the progression of type 2 DM by 55% in insulin-resistant high-risk Hispanic women (Buchanan *et al.*, 2002). This protective effect of troglitazone was maintained for at least 8 months after the drug was stopped. In the Stop-NIDDM study, acarbose (100 mg/three times a day) was given over a period of 3 years and produced a 25% reduction in the progression to type 2 DM (Chiasson *et al.*, 2002). *Orlistat*, a gastrointestinal lipase inhibitor used for weight loss, was administered over a 4-year period and resulted in a 37% reduction in the progression of type 2 DM in a group of insulin-resistant obese patients (Torgerson *et al.*, 2004). Finally, although the mechanisms are poorly understood, there are reports that angiotensin-converting enzyme inhibitors are associated with a decreased incidence of diabetes mellitus in high-risk patients (Scheen, 2004).

Based on the evidence that a variety of pharmacological agents can delay—and perhaps prevent—the onset of type 2 DM, multiple studies are underway investigating the effects of a range of pharmacologic agents in the prevention of type 2 DM.

Glucagon-like Peptide 1

Over four decades ago, McIntyre and colleagues reported that oral as compared with intravenous delivery of glucose produced a greater release of insulin. Subsequent work identified two hormones—*glucose-dependent insulinotropic polypeptide* (GIP) and *glucagon-like peptide* (GLP-1)—that are released from the upper and lower bowel that augment glucose-dependent insulin secretion. These hormones are termed *incretins*. The two incretins differentially stimulate insulin secretion. GIP has little effect on augmenting insulin secretion in type 2 DM, whereas GLP-1 significantly augments glucose-dependent insulin secretion. Consequently, GLP-1 has become an attractive target for therapeutic development in type 2 DM. GLP-1 also reduces glucagon secretion, slows gastric emptying, and decreases appetite. Thus, the compound may have unique properties to reduce postprandial glucose excursions (*i.e.*, increase in insulin, reduction of glucagon, slowing of gastric emptying) and also to induce weight loss. Offsetting these advantages, circulating GLP-1 is rapidly (1 to 2 minutes) inactivated by the dipeptidyl peptidase IV enzyme (DPP-IV). Thus, GLP-1 must be infused continuously to have therapeutic benefits. Consequently, considerable work has been performed to produce GLP-1 receptor agonists that maintain the physiologic effects of the native incretin but are resistant to the actions of DPP-IV. To date, two synthe-

tic GLP-1 analogs have entered clinical trials. Exendin-4 is derived from the salivary gland of the Gila monster and has 53% homology with human GLP-1. Exendin-4 is resistant to DPP-IV and has full agonist activity at GLP-1 receptors. Several clinical studies have demonstrated that *exendin-4* (*exenatide*, BYETTA) is effective in lowering hemoglobin A_{1c} (approximately 1% to 1.3%) and also promotes weight loss in type 2 DM. The compound is administered as twice-daily injections, although studies are planned to test a weekly or perhaps even a longer-acting formulation. Based on results of clinical trials, the FDA recently approved exenatide for twice-daily injection in combination therapy with other agents in subjects with type 2 DM. Reported exendin-4 side effects include a self-limiting nausea in 15% to 30% of patients; hypoglycemia can occur when GLP-1 agonists are used in conjunction with oral insulin secretagogues. A second long-acting analog of GLP-1, known as *NN2211*, is also in clinical trials. NN2211 contains a fatty acid moiety (hexadeconyl residue) covalently linked to GLP-1. NN2211 is resistant to the action of DPP-IV but also must be injected. Early clinical studies show that NN2211 is effective in lowering hemoglobin A_{1c} but may not induce as much weight loss as exendin-4. Nausea and hypoglycemia also occur with NN2211 when used with oral hypoglycemic agents.

An alternative approach to GLP-1 therapy is to inactivate the DPP-IV protease, thereby increasing endogenous circulating GLP-1 levels. A number of orally effective DPP-IV inhibitors have entered clinical trials. One study in type 2 DM reported similar reductions in hemoglobin A_{1c} as compared with the GLP-1 receptor analogs. These agents are well tolerated and appear to result in less nausea than the GLP-1 analogs. However, since DPP-IV can metabolize a wide range of peptides, there is a theoretical concern about the long-term safety of these compounds. Furthermore, the potency of the DPP-IV inhibitors may be limited by the amount of endogenous production of GLP-1. In contrast, pharmacological amounts of the injectable GLP-1 analogs can be administered with possibly increased therapeutic effect. Ongoing studies are currently being performed to further delineate the therapeutic effects of these agents, which offer promise for a novel pharmacotherapy in type 2 DM.

GLUCAGON

History. Distinct populations of cells were identified in the islets of Langerhans before the discovery of insulin. Glucagon was dis-

enzyme in glycolysis, increasing its activity. Thus, when glucagon concentrations are high, glycolysis is inhibited, and gluconeogenesis is stimulated. This also leads to a decrease in the concentration of malonyl CoA, stimulation of fatty acid oxidation, and production of ketone bodies. Conversely, when insulin concentrations are high, glycolysis is stimulated, and gluconeogenesis and ketogenesis are inhibited (see Foster, 1984).

Glucagon exerts effects on tissues other than liver, especially at higher concentrations. In adipose tissue, it stimulates adenylyl cyclase and increases lipolysis. In the heart, glucagon increases the force of contraction. Glucagon has relaxant effects on the gastrointestinal tract; this has been observed with analogs that apparently do not stimulate adenylyl cyclase. Some tissues (including liver) possess a second type of glucagon receptor that is linked to generation of IP_3 , diacylglycerol, and Ca^{2+} . The role of this receptor in metabolic regulation remains uncertain.

Therapeutic Use. Glucagon is used to treat severe hypoglycemia, particularly in diabetic patients when intravenous glucose is not available; it also is used by radiologists for its inhibitory effects on the gastrointestinal tract.

All glucagon used clinically is extracted from bovine and porcine pancreas; its sequence is identical to that of the human hormone. For hypoglycemic reactions, 1 mg is administered intravenously, intramuscularly, or subcutaneously. The first two routes are preferred in an emergency. Clinical improvement is sought within 10 minutes to minimize the risk of neurological damage from hypoglycemia. The hyperglycemic action of glucagon is transient and may be inadequate if hepatic stores of glycogen are depleted. After the initial response to glucagon, patients should be given glucose or urged to eat to prevent recurrent hypoglycemia. Nausea and vomiting are the most frequent adverse effects.

Glucagon also is used to relax the intestinal tract to facilitate radiographic examination of the upper and lower gastrointestinal tract with barium and retrograde ileography and in magnetic resonance imaging of the gastrointestinal tract. Glucagon has been used to treat the spasm associated with acute diverticulitis and disorders of the biliary tract and sphincter of Oddi, as an adjunct in basket retrieval of biliary calculi, and for impaction of the esophagus and intussusception. Finally, it has been used diagnostically to distinguish obstructive from hepatocellular jaundice.

Glucagon releases catecholamines from pheochromocytomas and has been used experimentally as a diagnostic test for this disorder. Based on this effect, glucagon therapy is contraindicated in known pheochromocytoma. The hormone also has been used as a cardiac inotropic agent for the treatment of shock, particularly when prior administration of a β adrenergic receptor antagonist has rendered β adrenergic receptor agonists ineffective.

SOMATOSTATIN

Somatostatin was first isolated in 1973, following a search for hypothalamic factors that might regulate secretion of growth hormone from the pituitary gland (see Chapter 5). A potential physiological role for somatostatin in the islet was suggested by the observation that somatostatin inhibits secretion of insulin and glucagon. The peptide subsequently was identified in the δ cells of the pancreatic islet, in similar cells of the gastrointestinal tract, and in the central nervous system.

Somatostatin, the name originally given to a cyclic peptide containing 14 amino acids, is now known to be one of a group of relat-

ed peptides. These include the original somatostatin (S-14), an extended 28-amino-acid peptide molecule (S-28), and a fragment containing the initial 12 amino acids of somatostatin-28 [S-28(1–12)]. S-14 is the predominant form in the brain, whereas S-28 is the main form in the gut. Acting via a family of GPCRs (see Chapter 55), somatostatin inhibits the release of thyroid-stimulating hormone and growth hormone from the pituitary gland; of gastrin, motilin, VIP, glicentin, and gastrointestinal polypeptide from the gut; and of insulin, glucagon, and pancreatic polypeptide from the pancreas.

Somatostatin secreted from the pancreas can regulate pituitary function, thereby acting as a true endocrine hormone. In the gut, however, somatostatin acts as a paracrine agent that influences the functions of adjacent cells. It also can act as an autocrine agent by inhibiting its own release in the pancreas. As the last cell to receive blood flow in the islets, the δ cell is downstream of the β and α cells. Thus, somatostatin may regulate the secretion of insulin and glucagon only via the systemic circulation.

Somatostatin is released in response to many of the nutrients and hormones that stimulate insulin secretion, including glucose, arginine, leucine, glucagon, VIP, and cholecystokinin. The physiological role of somatostatin has not been defined precisely. When administered in pharmacological doses, somatostatin inhibits virtually all endocrine and exocrine secretions of the pancreas, gut, and gallbladder. Somatostatin also can inhibit secretion of the salivary glands and, under some conditions, can block parathyroid, calcitonin, prolactin, and adrenocorticotrophic hormone (ACTH) secretion. The α cell is about 50 times more sensitive to somatostatin than is the β cell, but inhibition of glucagon secretion is more transient. Somatostatin also inhibits nutrient absorption from the intestine, decreases intestinal motility, and reduces splanchnic blood flow.

Therapeutic uses of somatostatin are confined mainly to blocking hormone release in endocrine-secreting tumors, including insulinomas, glucagonomas, VIPomas, carcinoid tumors, and growth hormone-secreting adenomas (causing acromegaly). Because of its short half-life (3 to 6 minutes), substantial effort has been directed toward the production of longer-acting analogs. One such agent, *octreotide* (SANDOSTATIN), is available in the United States for treatment of carcinoid tumors, glucagonomas, VIPomas, and acromegaly. Another agent, *lanreotide*, is available in Europe. A depot form of octreotide administered intramuscularly every 4 weeks (SANDOSTATIN LAR) may be particularly suitable for chronic administration (see Chapter 55). Octreotide or lanreotide successfully controls excess secretion of growth hormone in most patients, and both have been reported to reduce the size of pituitary tumors in about one-third of cases. Octreotide also has been used to reduce the disabling form of diarrhea that occasionally occurs in diabetic autonomic neuropathy. Since octreotide also can decrease blood flow to the gastrointestinal tract, it has been used to treat bleeding esophageal varices, peptic ulcers, and postprandial orthostatic hypotension.

Gallbladder abnormalities (stones and biliary sludge) occur frequently with chronic use of the somatostatin analogs, as do gastrointestinal symptoms. Hypoglycemia, hyperglycemia, hypothyroidism, and goiter have been reported in patients being treated with octreotide for acromegaly.

DIAZOXIDE

Diazoxide is an antihypertensive, antidiuretic benzothiadiazine derivative with potent hyperglycemic actions when given orally (see

Chapter 32). Hyperglycemia results primarily from inhibition of insulin secretion. Diazoxide interacts with the ATP-sensitive K⁺ channel on the β -cell membrane and either prevents its closing or prolongs the open time; this effect is opposite to that of the sulfonylureas. The drug does not inhibit insulin synthesis, and thus there is an accumulation of insulin within the β cell. Diazoxide also has a modest capacity to inhibit peripheral glucose utilization by muscle and to stimulate hepatic gluconeogenesis.

Diazoxide (PROGLYCEM) has been used to treat patients with various forms of hypoglycemia. The usual oral dose is 3 to 8 mg/kg per day in adults and 8 to 15 mg/kg per day in infants and neonates. The drug can cause nausea and vomiting and thus usually is given in divided doses with meals. Diazoxide circulates largely bound to plasma proteins and has a half-life of about 48 hours. Thus, the patient should be maintained at any dosage for several days before evaluating the therapeutic result.

Diazoxide has a number of adverse effects, including retention of Na⁺ and fluid, hyperuricemia, hypertrichosis (especially in children), thrombocytopenia, and leucopenia, which sometimes limit its use. Despite these side effects, the drug may be quite useful in patients with inoperable insulinomas and in children with hyperinsulinism owing to nesidioblastosis.

AGENTS AFFECTING MINERAL ION HOMEOSTASIS AND BONE TURNOVER

Peter A. Friedman

PHYSIOLOGY OF MINERAL HOMEOSTASIS AND BONE METABOLISM

Calcium

Ca^{2+} , the ionized form of elemental calcium, is essential for the Ca^{2+} component of current flow across excitable membranes, fusion and release of storage vesicles, and muscle contraction. Intracellular Ca^{2+} also acts in the submicromolar range as a critical second messenger (see Chapter 1). In extracellular fluid, millimolar concentrations of calcium promote blood coagulation (Figure 61–3) (see below) and support the formation and continuous remodeling of the skeleton.

Ca^{2+} has an adaptable coordination sphere that facilitates binding to the irregular geometry of proteins. The capacity of an ion to cross-link two proteins requires a high coordination number, which dictates the number of electron pairs that can be formed and generally is six to eight for Ca^{2+} . Unlike disulfide or sugar–peptide cross-links, Ca^{2+} linking is readily reversible. Cross-linking of structural proteins in bone matrix is enhanced by the relatively high extracellular concentration of calcium.

In the face of millimolar extracellular Ca^{2+} , intracellular free Ca^{2+} is maintained at a low level, approximately 100 nM in cells in their basal state, by active extrusion by Ca^{2+} -ATPases and by $\text{Na}^+/\text{Ca}^{2+}$ exchange. As a consequence, changes in cytosolic Ca^{2+} (whether released from intracellular stores or entering *via* membrane Ca^{2+} channels) can modulate effector targets, often by interacting with the Ca^{2+} -binding protein calmodulin. The rapid association–dissociation kinetics of Ca^{2+} and the relatively high affinity and selectivity of

Ca^{2+} -binding domains permit effective regulation of Ca^{2+} over the 100 nM to 1 μM range.

Healthy adult men and women possess about 1300 and 1000 g of calcium, respectively, of which more than 99% is in bone and teeth. Ca^{2+} is the major extracellular divalent cation. Although the absolute amount of calcium in extracellular fluids is small, this fraction is stringently regulated within narrow limits. In adult humans, the normal serum calcium concentration ranges from 8.5 to 10.4 mg/dl (4.25 to 5.2 mEq/L, 2.1 to 2.6 mM) and includes three distinct chemical forms of Ca^{2+} : ionized (50%), protein-bound (40%), and complexed (10%). Thus, whereas total plasma calcium concentration is approximately 2.54 mM, the concentration of ionized Ca^{2+} in human plasma is approximately 1.2 mM.

The various pools of calcium are illustrated schematically in Figure 61–1. Only diffusible calcium, *i.e.*, ionized plus complexed, can cross cell membranes. Of the serum calcium bound to plasma proteins, albumin accounts for some 90%. Smaller percentages are bound, albeit with greater affinity, to β -globulin, α_2 -globulin, α_1 -globulin, and γ -globulin. The remaining 10% of the serum calcium is complexed in ion pairs with small polyvalent anions, primarily phosphate and citrate. The degree of complex formation depends on the ambient pH and the concentrations of ionized calcium and complexing anions. As the physiologically relevant component, it is ionized Ca^{2+} that exerts biological effects and, when perturbed, produces the characteristic signs and symptoms of hypo- or hypercalcemia.

The total plasma calcium concentration can be interpreted only by correcting for the concentration of plasma proteins. A change in plasma albumin concentration of 1.0 g/dl from the normal value of 4.0 g/dl can be expected to alter total calcium concentration by approximately 0.8 mg/dl.

Figure 61-1. Pools of calcium in serum. Concentrations are expressed as mg/dl on the left-hand axis and as mM on the right. The total serum calcium concentration is 10 mg/dl or 2.5 mM, divided into three pools: protein-bound (40%), complexed with small anions (10%), and ionized calcium (50%). The complexed and ionized pools represent the diffusible forms of calcium.

The extracellular Ca^{2+} concentration is tightly controlled by hormones that affect its entry at the intestine and its exit at the kidney; when needed, these same hormones regulate withdrawal from the large skeletal reservoir.

Calcium Stores. The skeleton contains 99% of total body calcium in a crystalline form resembling the mineral hydroxyapatite [$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$]; other ions, including Na^+ , K^+ , Mg^{2+} , and F^- , also are present in the crystal lattice. The steady-state content of calcium in bone reflects the net effect of bone resorption and bone formation, coupled with aspects of bone remodeling (see below). In addition, a labile pool of bone Ca^{2+} exchanges readily with interstitial fluid. This exchange is modulated by hormones, vitamins, drugs, and other factors that directly alter bone turnover or that influence the Ca^{2+} level in interstitial fluid.

Calcium Absorption and Excretion. In the United States, about 75% of dietary calcium is obtained from milk and dairy products. The adequate intake value for calcium is 1300 mg/day in adolescents and 1000 mg/day in adults. After age 50, the adequate intake is 1200 mg/day. This contrasts with median intakes of calcium for boys and girls aged 9 years and older of 865 and 625 mg, respec-

Figure 61-2. Schematic representation of the whole body daily turnover of calcium. (Adapted with permission from Yanagawa and Lee, 1992.)

tively, and a median daily calcium intake of 517 mg for women after age 50.

Figure 61-2 illustrates the components of whole-body daily calcium turnover. Ca^{2+} enters the body only through the intestine. *Active vitamin D-dependent transport* (see below) occurs in the proximal duodenum, whereas *facilitated diffusion* throughout the small intestine accounts for the majority of total Ca^{2+} uptake. This uptake is counterbalanced by an obligatory daily intestinal calcium loss of about 150 mg/day that reflects the mineral contained in mucosal and biliary secretions and in sloughed intestinal cells.

The efficiency of intestinal Ca^{2+} absorption is inversely related to calcium intake. Thus, a diet low in calcium leads to a compensatory increase in fractional absorption owing partly to activation of vitamin D. In older persons, this response is considerably less robust. Disease states associated with steatorrhea, diarrhea, or chronic malabsorption promote fecal loss of calcium, whereas drugs such as *glucocorticoids* and *phenytoin* depress intestinal Ca^{2+} transport.

Urinary Ca^{2+} excretion is the net difference between the quantity filtered at the glomerulus and the amount reabsorbed. About 9 g of Ca^{2+} is filtered each day. Tubular reabsorption is very efficient, with more than 98% of filtered Ca^{2+} returned to the circulation. The efficiency of reabsorption is highly regulated by parathyroid hormone (PTH) but also is influenced by filtered Na^+ , the presence of nonreabsorbed anions, and diuretic agents (see Chapter 28). Sodium intake, and therefore sodium excretion, is directly related to urinary calcium excretion. Diuretics that act on the

ascending limb of the loop of Henle (*e.g.*, *furosemide*) increase calcium excretion. By contrast, *thiazide diuretics* uncouple the relationship between Na^+ and Ca^{2+} excretion, increasing sodium excretion but diminishing calcium excretion (Friedman and Bushinsky, 1999). Dietary protein is directly related to urine Ca^{2+} excretion, presumably owing to the effect of sulfur-containing amino acids on renal tubular function.

Phosphate

In addition to its roles as a dynamic constituent of intermediary and energy metabolism and as a key regulator of enzyme activity when transferred by protein kinases from ATP to phosphorylatable serine, threonine, and tyrosine residues, phosphate is an essential component of all body tissues, being present in plasma, extracellular fluid, cell membrane phospholipids, intracellular fluid, collagen, and bone tissue. More than 80% of total body phosphorus is found in bone, and about 15% is in soft tissue.

Biologically, phosphorus (P) exists in both organic and inorganic forms. Organic forms include phospholipids and various organic esters. In extracellular fluid, the bulk of phosphorus exists as inorganic phosphate in the form of NaH_2PO_4 and Na_2HPO_4 ; the ratio of disodium to monosodium phosphate at pH 7.40 is 4:1, so plasma phosphate has an intermediate valence of 1.8. Owing to its relatively low concentration in extracellular fluid, phosphate contributes little to buffering capacity. The aggregate level of inorganic phosphate (P_i) modifies tissue concentrations of Ca^{2+} and plays a major role in renal H^+ excretion. Within bone, phosphate is complexed with calcium as hydroxyapatites having the general formula $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ and as calcium phosphate.

Absorption, Distribution, and Excretion. Phosphate is absorbed from and to a limited extent secreted into the gastrointestinal tract. Phosphate is a ubiquitous component of ordinary foods; thus, an inadequate diet rarely causes phosphate depletion. Transport of phosphate from the intestinal lumen is an active, energy-dependent process that is regulated by several factors, including vitamin D, which stimulates absorption. In adults, about two-thirds of ingested phosphate is absorbed and is excreted almost entirely into the urine. In growing children, phosphate balance is positive, and plasma concentrations of phosphate are higher than in adults.

Phosphate excretion in the urine represents the difference between the amount filtered and that reabsorbed. More than 90% of plasma phosphate is freely filtered at the glomerulus, and 80% is actively reabsorbed, predominantly in the initial segment of the

proximal convoluted tubule but also in the proximal straight tubule (*pars recta*). Renal phosphate absorption is regulated by a variety of hormones and other factors; the most important are PTH and dietary phosphate, with extracellular volume and acid–base status playing lesser roles. Dietary phosphate deficiency up-regulates renal phosphate transporters and decreases excretion, whereas a high-phosphate diet increases phosphate excretion; these changes are independent of any effect on plasma P_i , Ca^{2+} , or PTH. PTH increases urinary phosphate excretion by blocking phosphate absorption. Expansion of plasma volume increases urinary phosphate excretion. Effects of vitamin D and its metabolites on proximal tubular phosphate are modest at best.

Role of Phosphate in Urine Acidification. Despite the fact that the concentration and buffering capacity of phosphate in extracellular fluid are low, phosphate is concentrated progressively in the renal tubule and becomes the most abundant buffer system in the distal tubule and terminal nephron. The exchange of H^+ and Na^+ in the tubular urine converts disodium hydrogen phosphate (Na_2HPO_4) to sodium dihydrogen phosphate (NaH_2PO_4), permitting the excretion of large amounts of acid without lowering the urine pH to a degree that would block H^+ transport.

Actions of Phosphate Ion. If large amounts of phosphate are introduced into the gastrointestinal tract by oral administration or enema, a cathartic action will result. Thus phosphate salts are employed as mild laxatives (*see* Chapter 37). If excessive phosphate salts are introduced either intravenously or orally, they may reduce the concentration of Ca^{2+} in the circulation and induce precipitation of calcium phosphate in soft tissues.

PHYSIOLOGY OF CALCIUM AND PHOSPHATE REGULATION

A number of hormones interact to regulate the calcium and phosphate ions. The most important are parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D (*calcitriol*), which regulate mineral homeostasis by effects on the kidney, intestine, and bone (Figure 61–3).

Parathyroid Hormone (PTH)

PTH is a polypeptide hormone that helps to regulate plasma Ca^{2+} by affecting bone resorption/formation, renal Ca^{2+} excretion/reabsorption, and calcitriol synthesis (thus gastrointestinal Ca^{2+} absorption).

History. Sir Richard Owen, the curator of the British Museum of Natural History, discovered the parathyroid glands in 1852 while dissecting a rhinoceros that had died in the London Zoo. Credit for discovery of the human parathyroid glands usually is given to Sandstrom, a Swedish medical student who published an anatomical report in 1890. In 1891, von Recklinghausen reported a new bone disease, which he termed “osteitis fibrosa cystica,” which Askanazy subsequently described in a patient with a parathyroid tumor in

Figure 61–3. Calcium homeostasis and its regulation by parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D.

PTH has stimulatory effects on bone and kidney, including the stimulation of 1α -hydroxylase activity in kidney mitochondria leading to the increased production of 1,25-dihydroxyvitamin D (calcitriol) from 25-hydroxycholecalciferol, the monohydroxylated vitamin D metabolite (see Figure 61–6). Calcitriol is the biologically active metabolite of vitamin D. Solid lines indicate a positive effect; dashed lines refer to negative feedback.

1904. The glands were rediscovered a decade later by Gley, who determined the effects of their extirpation with the thyroid. Vassale and Generali then successfully removed only the parathyroids and noted that tetany, convulsions, and death quickly followed unless calcium was given postoperatively.

MacCallum and Voegtlin first noted the effect of parathyroidectomy on plasma Ca^{2+} . The relation of low plasma Ca^{2+} concentration to symptoms was quickly appreciated, and a comprehensive picture of parathyroid function began to form. Active glandular extracts alleviated hypocalcemic tetany in parathyroidectomized animals and raised the level of plasma Ca^{2+} in normal animals. For the first time, the relation of clinical abnormalities to parathyroid hyperfunction was appreciated.

While American and British investigators used physiological approaches to explore the function of the parathyroid glands, German and Austrian pathologists related the skeletal changes of osteitis fibrosa cystica to the presence of parathyroid tumors; these two diverse types of investigations finally arrived at the same con-

clusions. Much of the history of the parathyroid has been recounted by Carney (1996).

Chemistry. Human, bovine, and porcine PTH molecules are all single polypeptide chains of 84 amino acids with molecular masses of approximately 9500 daltons. Biological activity is associated with the N-terminal portion of the peptide; residues 1 to 27 are required for optimal binding to the PTH receptor and hormone activity. Derivatives lacking the first or second residue bind to PTH receptors but do not activate the cyclic AMP or IP_3 - Ca^{2+} signaling pathways. The PTH fragment lacking the first six amino acids inhibits PTH action.

Synthesis, Secretion, and Immunoassay. PTH is synthesized as a 115-amino-acid translation product called *preproparathyroid hormone*. This single-chain peptide is converted to parathyroid hormone by cleavage of 25 amino-terminal residues as the peptide is transferred to the intracisternal space of the endoplasmic reticulum. Parathyroid hormone then moves to the Golgi complex, where it is converted to PTH by cleavage of six amino acids. PTH(1–84) resides within secretory granules until it is discharged into the circulation. Neither preproparathyroid hormone nor parathyroid hormone appears in plasma. The synthesis and processing of PTH have been reviewed (Jüppner *et al.*, 2001).

A major proteolytic product of PTH is PTH(7–84). PTH(7–84) and other amino-truncated PTH fragments accumulate significantly during renal failure in part because they are cleared from the circulation predominantly by the kidneys, whereas intact PTH is also removed by extrarenal mechanisms. Rather than competitively displacing PTH(1–84), PTH(7–84) may inhibit the PTH receptor by causing it to internalize from the plasma membrane in a cell-specific manner (Sneddon *et al.*, 2003).

During periods of hypocalcemia, more PTH is secreted and less is hydrolyzed. In this setting, PTH(7–84) release is augmented. In prolonged hypocalcemia, PTH synthesis also increases, and the gland hypertrophies.

PTH(1–84) has a half-life in plasma of 2 to 5 minutes; removal by the liver and kidney accounts for about 90% of its clearance. As noted earlier, metabolism of PTH generates smaller fragments [*e.g.*, PTH(7–84)] that also circulate in blood and are measured by standard immunoradiometric assays (IRMAs) using two monoclonal antibodies, one directed toward but not at the amino terminus and the other directed toward the carboxyl-terminal portion of the hormone. Large amino-terminal PTH fragments such as PTH(7–84) also react with antibodies prepared against the intact hormone and are measured by standard IRMAs. Therefore, second-generation PTH assays have been developed that differentiate between PTH(1–84), or whole PTH, and “intact” PTH [PTH(1–84) and PTH(7–84)]. The ability to measure whole PTH separately from large amino-terminally truncated PTH fragments has increased the accuracy of laboratory testing of parathyroid and bone status in patients with renal failure (Monier-Faugere *et al.*, 2001).

Physiological Functions. The primary function of PTH is to maintain a constant concentration of Ca^{2+} in the extracellular fluid. The principal processes regulated are renal Ca^{2+} absorption and mobilization of bone Ca^{2+} (Figure 61–3). PTH also affects a variety of nonclassical

target tissues that include cartilage, vascular smooth muscle, placenta, liver, pancreatic islets, brain, dermal fibroblasts, and lymphocytes (Tian *et al.*, 1993; Urena *et al.*, 1993). The actions of PTH on its target tissues are mediated by at least two receptors. The PTH-1 receptor (PTH1R or PTH/PTHrP receptor) also binds PTH-related protein (PTHrP), and the PTH-2 receptor, found in vascular tissues, brain, pancreas, and placenta, binds only PTH. Both of these are G protein-coupled receptors that can couple with G_s and G_q in cell-type specific manners; thus, cells may show one, the other, or both types of responses. There is also evidence that PTH can activate phospholipase D through a $G_{12/13}$ -RhoA pathway (Singh *et al.*, 2005). A third receptor, designated the CPTH receptor, interacts with forms of PTH that are truncated in the amino-terminal region but that contain most of the carboxy terminus.

Regulation of Secretion. Plasma Ca^{2+} is the major factor regulating PTH secretion. As the concentration of Ca^{2+} diminishes, PTH secretion increases. Sustained hypocalcemia induces parathyroid hypertrophy and hyperplasia. Conversely, if the concentration of Ca^{2+} is high, PTH secretion decreases. Studies of parathyroid cells in culture show that amino acid transport, nucleic acid and protein synthesis, cytoplasmic growth, and PTH secretion are all stimulated by low concentrations of Ca^{2+} and suppressed by high concentrations. Thus, Ca^{2+} itself appears to regulate parathyroid gland growth as well as hormone synthesis and secretion.

Changes in plasma Ca^{2+} regulate PTH secretion by the plasma membrane-associated calcium-sensing receptor (CaSR) on parathyroid cells (Brown and MacLeod, 2001). The CaSR is a GPCR that couples with G_q -PLC and G_i . Occupancy of the CaSR by Ca^{2+} inhibits PTH secretion, whereas reduced CaSR occupancy promotes hormone secretion. Thus, the extracellular concentration of Ca^{2+} is controlled by a classical negative-feedback system, the afferent limb of which is sensitive to the ambient activity of Ca^{2+} and the efferent limb of which releases PTH. Acting *via* the CaSR, hypercalcemia reduces intracellular cyclic AMP content and protein kinase C (PKC) activity, whereas hypocalcemia leads to activation of PKC. However, the precise links between these changes and alterations in PTH secretion remain to be defined. Other agents that increase parathyroid cell cyclic AMP levels, such as β adrenergic receptor agonists and *dopamine*, also increase PTH secretion, but the magnitude of response is far less than that seen with hypocalcemia. The active vitamin D metabolite, 1,25-dihydroxyvitamin D (calcitriol), directly suppresses PTH gene expression. There appears to be no relation between physiological concentrations of extracellular phosphate and PTH secretion, except insofar as changes in phosphate concentration alter circulating Ca^{2+} . Severe hypermagnesemia or hypomagnesemia can inhibit PTH secretion.

Effects on Bone. PTH increases bone resorption and thereby increases Ca^{2+} delivery to the extracellular fluid.

This process involves the release of organic and mineral matrix components (*see* below). The apparent skeletal target cell for PTH is the osteoblast, although evidence for the presence of PTH receptors on mammalian osteoblasts is limited (Manen *et al.*, 1998). PTH also recruits osteoclast precursor cells to form new bone remodeling units (*see* below). Sustained increases in circulating PTH cause characteristic histological changes in bone that include an increase in the prevalence of osteoclastic resorption sites and in the proportion of bone surface that is covered with unmineralized matrix (Martin and Ng, 1994).

Direct effects of PTH on osteoblasts *in vitro* generally are inhibitory and include reduced formation of type I collagen, alkaline phosphatase, and osteocalcin. However, the response to PTH *in vivo* reflects not only hormone action on individual cells but also the increased total number of active osteoblasts owing to initiation of new remodeling units. Thus plasma levels of osteocalcin and alkaline phosphatase activity actually may be increased. No simple model can fully explain the molecular basis of PTH effects on bone. PTH stimulates cyclic AMP production in osteoblasts, but there also is evidence that intracellular Ca^{2+} mediates some PTH actions.

Effects on Kidney. In the kidney, PTH enhances the efficiency of Ca^{2+} reabsorption, inhibits tubular reabsorption of phosphate, and stimulates conversion of vitamin D to its biologically active form, calcitriol (Figure 61-3; *see* below). As a result, filtered Ca^{2+} is avidly retained, and its concentration increases in plasma, whereas phosphate is excreted, and its plasma concentration falls. Newly synthesized calcitriol interacts with specific high-affinity receptors in the intestine to increase the efficiency of intestinal Ca^{2+} absorption, thereby also increasing the plasma Ca^{2+} concentration.

Calcium. PTH increases tubular reabsorption of Ca^{2+} with concomitant decreases in urinary Ca^{2+} excretion. The effect occurs at distal nephron sites (Friedman, 1999). This action, along with mobilization of calcium from bone and increased absorption from the gut, increases the concentration of Ca^{2+} in plasma. Eventually, the increased glomerular filtration of Ca^{2+} overwhelms the stimulatory effect of PTH on tubular reabsorption, and hypercalciuria ensues. Conversely, reduction of serum PTH depresses tubular reabsorption of Ca^{2+} and thereby increases urinary Ca^{2+} excretion. When the plasma Ca^{2+} concentration falls below 7 mg/dl (1.75 mM), Ca^{2+} excretion decreases as the filtered load of Ca^{2+} reaches the point where the cation is almost completely reabsorbed despite reduced tubular capacity.

Phosphate. PTH increases renal excretion of inorganic phosphate by decreasing its reabsorption. This action is mediated by retrieval of the luminal membrane $Na-P_i$ cotransport protein rather than an effect on its activity. Patients with primary hyperparathyroidism therefore typically have low tubular phosphate reabsorption.

Cyclic AMP apparently mediates the renal effects of PTH on proximal tubular phosphate reabsorption. PTH-sensitive adenylyl cyclase is located in the renal cortex, and cyclic AMP synthesized in response to the hormone affects tubular transport mechanisms. A portion of the cyclic AMP synthesized at this site, so-called nephrogenous cyclic AMP, escapes into the urine; measurement of urinary cyclic AMP is used as a surrogate for parathyroid activity and renal responsiveness.

Other Ions. PTH reduces renal excretion of Mg^{2+} . This effect reflects the net result of increased renal Mg^{2+} reabsorption and increased mobilization of the ion from bone (Quamme, 1997). PTH increases excretion of water, amino acids, citrate, K^+ , bicarbonate, Na^+ , Cl^- , and SO_4^{2-} , whereas it decreases the excretion of H^+ .

Calcitriol Synthesis. The final step in the activation of vitamin D to calcitriol occurs in kidney proximal tubule cells. Three primary regulators govern the activity of the 25-hydroxyvitamin D_3 -1 α -hydroxylase that catalyzes this step: P_i , PTH, and Ca^{2+} (see below for further discussion). Reduced circulating or tissue phosphate content rapidly increases calcitriol production, whereas hyperphosphatemia or hypercalcemia suppresses it. PTH powerfully stimulates calcitriol synthesis. Thus, when hypocalcemia causes a rise in PTH concentration, both the PTH-dependent lowering of circulating P_i and a more direct effect of the hormone on the 1 α -hydroxylase lead to increased circulating concentrations of calcitriol.

Integrated Regulation of Extracellular Ca^{2+} Concentration by PTH. Even modest reductions of serum Ca^{2+} stimulate PTH secretion. For minute-to-minute regulation of Ca^{2+} , adjustments in renal Ca^{2+} handling more than suffice to maintain plasma calcium homeostasis. With more prolonged hypocalcemia, the renal 1 α -hydroxylase is induced, enhancing the synthesis and release of calcitriol that directly stimulates intestinal calcium absorption (Figure 61–3). In addition, delivery of calcium from bone into the extracellular fluid is stimulated. In the face of prolonged and severe hypocalcemia, new bone remodeling units are activated to restore circulating Ca^{2+} concentrations, albeit at the expense of skeletal integrity.

When plasma Ca^{2+} activity rises, PTH secretion is suppressed, and tubular Ca^{2+} reabsorption decreases. The reduction in circulating PTH promotes renal phosphate conservation, and both the decreased PTH and the increased phosphate reduce calcitriol production and thereby decrease intestinal Ca^{2+} absorption. Finally, bone remodeling is suppressed. These integrated physiological events ensure a coherent response to positive or negative excursions of plasma Ca^{2+} concentration. In human beings, the importance of other hormones, such as calcitonin, to this scheme remains unsettled, but it is likely that these modulate the Ca^{2+} –parathyroid–vitamin D axis rather than serving as primary regulators.

Vitamin D

Vitamin D traditionally was viewed as a permissive factor in calcium metabolism because it was thought to permit efficient absorption of dietary calcium and to allow full expression of the actions of PTH. We now know that vitamin D exerts a more active role in calcium homeostasis. Vitamin D is actually a hormone rather than a vitamin; it is synthesized in mammals and, under ideal conditions, probably is not required in the diet. Receptors for the activated form of vitamin D are expressed in many cells that are not involved in calcium homeostasis, including hematopoietic cells, lymphocytes, epidermal cells, pancreatic islets, muscle, and neurons.

History. Vitamin D is the name applied to two related fat-soluble substances, *cholecalciferol* and *ergocalciferol* (Figure 61–4), that share the capacity to prevent or cure rickets. Prior to the discovery of vitamin D, a high percentage of urban children living in temperate zones developed rickets. Some researchers believed that the disease was due to lack of fresh air and sunshine; others claimed a dietary factor was responsible. Mellanby and Huldschinsky showed both notions to be correct; addition of cod liver oil to the diet or exposure to sunlight prevented or cured the disease. In 1924, it was found that ultraviolet irradiation of animal rations was as efficacious at curing rickets as was irradiation of the animal itself. These observations led to the elucidation of the structures of chole- and ergocalciferol and eventually to the discovery that these compounds require further processing in the body to become active. The discovery of metabolic activation is attributable primarily to studies conducted in the laboratories of DeLuca (DeLuca and Schnoes, 1976) and Kodicek (Mason *et al.*, 1974).

Chemistry and Occurrence. Ultraviolet irradiation of several animal and plant sterols results in their conversion to compounds possessing vitamin D activity. The principal provitamin found in animal tissues is 7-dehydrocholesterol, which is synthesized in the skin. Exposure of the skin to sunlight converts 7-dehydrocholesterol to cholecalciferol (vitamin D_3) (Figure 61–4). Ergosterol, which is present only in plants, is the provitamin for vitamin D_2 (ergocalciferol). Ergosterol and vitamin D_2 differ from 7-dehydrocholesterol and vitamin D_3 , respectively, by the presence of a double bond between C22 and C23 and a methyl group at C24. Vitamin D_2 is the active constituent of a number of commercial vitamin preparations, and is in irradiated bread and irradiated milk. In humans there is no practical difference between the antirachitic potencies of vitamin D_2 and vitamin D_3 . Therefore, “vitamin D” will be used here as a collective term for vitamins D_2 and D_3 .

Human Requirements and Units. Although sunlight provides adequate vitamin D supplies in the equatorial belt, in temperate climates insufficient cutaneous solar radiation in winter may necessitate dietary vitamin D supplementation. It was assumed that vitamin D deficiency had been eliminated as a significant problem in the United States. However, recent evidence points to low circulating levels of vitamin D with a reemergence of vitamin D–

Figure 61-4. Photobiology and metabolic pathways of vitamin D production and metabolism. Numbering for select positions discussed in the text is shown.

dependent rickets. Potential factors contributing to the rise in vitamin D deficiency include diminished intake of vitamin D–fortified foods owing to concerns about fat intake; reduced intake of calcium-rich foods, including milk, in adolescents and young women of reproductive age; increased use of sunscreens and decreased exposure to sunlight to reduce the risk of skin cancer and prevent premature aging owing to exposure to ultraviolet radiation; and an increased prevalence and duration of exclusive breast-feeding (the combination of human milk, a poor source of vitamin D, and the high prevalence of low circulating vitamin D levels in U.S. women, particularly African-American mothers) (Nesby-O'Dell *et al.*, 2002; Stokstad, 2003; Holick *et al.*, 2005).

There is no consensus regarding optimal vitamin D intake, and determination of vitamin D requirements is remarkably unsupported by clinical measurements. The recommended dietary allowance of vitamin D for infants and children is 400 IU, or 10 μg . The basis for this dose was that it approximates that in a teaspoon (5 ml) of cod liver oil, which had long been considered safe and effective in preventing rickets (Vieth, 1999). On the basis that adults require less vitamin D than infants, the adult dose was set arbitrarily at 200 IU.

There are no recommended dietary allowances for vitamin D. However, the Food and Nutrition Board of the Institute of Medicine has developed Dietary Reference Intakes (DRI) for vitamins (Institute of Medicine, 2003). In both premature and normal infants, intake of 200 units per day of vitamin D from any source is considered adequate for optimal growth. During adolescence and beyond, this amount probably is also sufficient. There is some evidence that vitamin D requirements increase during pregnancy and lactation (Hollis and Wagner, 2004), where vitamin D doses of less than 1000 IU/day may be inadequate to maintain normal circulating 25-hydroxyvitamin D concentrations. Doses of 10,000 IU/day or less of vitamin D for up to 5 months do not elevate circulating 25-hydroxyvitamin D to concentrations greater than 90 ng/ml.

Absorption, Fate, and Excretion. Both vitamins D₂ and D₃ are absorbed from the small intestine, although vitamin D₃ may be absorbed more efficiently. Most of the vitamin appears first within chylomicrons in lymph. Bile is essential for adequate absorption of vitamin D; deoxycholic acid is the major constituent of bile in this regard (*see* Chapter 37). The primary route of vitamin D excretion is the bile; only a small percentage is found in the urine. Patients who have intestinal bypass surgery or otherwise have severe shortening or inflammation of the small intestine may fail to absorb vitamin D sufficiently to maintain normal levels; hepatic or biliary dysfunction also may seriously impair vitamin D absorption.

Absorbed vitamin D circulates in the blood in association with vitamin D–binding protein, a specific α -globu-

lin. The vitamin disappears from plasma with a half-life of 19 to 25 hours but is stored in fat depots for prolonged periods.

Metabolic Activation. Whether derived from diet or endogenously synthesized, vitamin D requires modification to become biologically active. The primary active metabolite of the vitamin is calcitriol [$1\alpha,25$ -dihydroxyvitamin D, $1,25(\text{OH})_2\text{D}$], the product of two successive hydroxylations of vitamin D (Figure 61–4).

25-Hydroxylation of Vitamin D. The initial step in vitamin D activation occurs in the liver, where cholecalciferol and ergocalciferol are hydroxylated in the 25-position to generate 25-OH-cholecalciferol (25-OHD, or calcifediol) and 25-OH-ergocalciferol, respectively. 25-OHD is the major circulating form of vitamin D₃; it has a biological half-life of 19 days, and normal steady-state concentrations are 15 to 50 ng/ml. Reduced extracellular Ca²⁺ levels stimulate 1α -hydroxylation of 25-OHD, increasing the formation of biologically active $1,25(\text{OH})_2\text{D}_3$. In contrast, when Ca²⁺ concentrations are elevated, 25-OHD is inactivated by 24-hydroxylation. Similar reactions occur with 25-OH-ergocalciferol. Normal steady-state concentrations of 25-OHD in human beings are 15 to 50 ng/ml, although concentrations below 25 ng/ml may be associated with increased circulating PTH and greater bone turnover.

1α -Hydroxylation of 25-OHD. After production in the liver, 25-OHD enters the circulation and is carried by vitamin D–binding globulin. Final activation to calcitriol occurs primarily in the kidney but also takes place in other sites, including keratinocytes and macrophages (Hewison *et al.*, 2004). The enzyme system responsible for 1α -hydroxylation of 25-OHD (CYP1 α , 25-hydroxyvitamin D₃- 1α -hydroxylase, 1α -hydroxylase) is associated with mitochondria in proximal tubules.

Vitamin D 1α -hydroxylase is subject to tight regulatory controls that result in changes in calcitriol formation appropriate for optimal calcium homeostasis. Dietary deficiency of vitamin D, calcium, or phosphate enhances enzyme activity. 1α -Hydroxylase is potently stimulated by PTH and probably also by prolactin and estrogen. Conversely, high calcium, phosphate, and vitamin D intakes suppress 1α -hydroxylase activity. Regulation (Figure 61–5) is both acute and chronic, the latter owing to changes in protein synthesis. PTH increases calcitriol production rapidly *via* a cyclic AMP–dependent pathway. Hypocalcemia can activate the hydroxylase directly in addition to affecting it indirectly by eliciting PTH secretion (Bland *et al.*, 1999). Hypophosphatemia greatly increases 1α -hydroxylase activity (Haussler and McCain, 1977; Yoshida *et al.*, 2001). Calcitriol controls 1α -hydroxylase activity by a negative-feedback mechanism that involves a direct action on the kidney, as well as inhibition of PTH secretion. The plasma half-life of calcitriol is estimated to be between 3 and 5 days in humans.

24-Hydroxylase. Calcitriol and 25-OHD are hydroxylated to $1,24,25(\text{OH})_2\text{D}$ and $24,25(\text{OH})_2\text{D}$, respectively, by another renal enzyme, 24-hydroxylase, whose expression is induced by calcitriol and suppressed by factors that stimulate the 25-OHD- 1α -hydroxylase. Both 24-hydroxylated compounds are less active than calcitriol and presumably represent metabolites destined for excretion.

Figure 61–5. Regulation of 1α -hydroxylase activity. Changes in the plasma levels of PTH, Ca²⁺, and phosphate modulate the hydroxylation of 25-OH vitamin D to the active form, 1,25-dihydroxyvitamin D. 25-OHD, 25-hydroxycholecalciferol; 1,25-(OH)₂-D, calcitriol; PTH, parathyroid hormone.

Physiological Functions and Mechanism of Action.

Calcitriol augments absorption and retention of Ca²⁺ and phosphate. Although regulation of Ca²⁺ homeostasis is considered to be its primary function, accumulating evidence underscores the importance of calcitriol in a number of other processes (*see below*).

Calcitriol acts to maintain normal concentrations of Ca²⁺ and phosphate in plasma by facilitating their absorption in the small intestine, by interacting with PTH to enhance their mobilization from bone, and by decreasing their renal excretion. It also exerts direct physiological and pharmacological effects on bone mineralization (Suda *et al.*, 2003).

The mechanism of action of calcitriol is mediated by the interaction of calcitriol with the vitamin D receptor (VDR). Calcitriol binds to cytosolic VDRs within target cells, and the receptor–hormone complex translocates to

the nucleus and interacts with DNA to modify gene transcription. The VDR belongs to the steroid and thyroid hormone receptor supergene family (Christakos *et al.*, 2003). Calcitriol also exerts nongenomic effects (Farach-Carson and Nemere, 2003) that may require the presence of a functional VDR (Zanello and Norman, 2004).

Intestinal Absorption of Calcium. Calcium is absorbed predominantly in the duodenum, with progressively smaller amounts in the jejunum and ileum. Studies of Ca²⁺ uptake by isolated cells reflect these differences and suggest that elevated amounts of transport are likely due to greater transport by each duodenal cell. The colon also contributes to calcium absorption because ileostomy reduces absorption.

In the absence of calcitriol, calcium absorption is inefficient and proceeds in a thermodynamically passive manner through the lateral intercellular spaces (paracellular pathway). Calcitriol increases the transcellular movement of Ca²⁺ from the mucosal to the serosal surface of the duodenum. Transcellular Ca²⁺ movement involves three processes: Ca²⁺ entry across the mucosal surface, diffusion through the cell, and energy-dependent extrusion across the serosal cell membrane. Calcium is also secreted from serosal to mucosal compartments. Thus net calcium absorption is the difference between the two oppositely oriented vectorial processes. The complex mechanisms and the proteins mediating calcium absorption are still incompletely understood (Bronner, 2003). Evidence implicates TRPV6 Ca²⁺ channels in mediating mucosal calcium entry in the intestine (Nijenhuis *et al.*, 2003). In humans, TRPV6 is expressed in the duodenum and proximal jejunum (Barley *et al.*, 2001). A calcium-poor diet up-regulates intestinal TRPV6 expression in mice (Van Cromphaut *et al.*, 2001). This effect is greatly reduced in VDR knockout mice, suggesting that TRPV6 mediates calcium entry and is vitamin D–dependent. Calcitriol also up-regulates the calcium-binding protein calbindin-D_{9K}.

Ca²⁺ absorption is potentially augmented by calcitriol. It is likely that calcitriol enhances all three steps involved in intestinal Ca²⁺ absorption: entry across mucosal brush border membranes, diffusion through the enterocytes, and active extrusion across serosal plasma membranes (Bronner, 2003). Calcitriol up-regulates the synthesis of calbindin-D_{9K} and calbindin-D_{28K} and the serosal plasma membrane Ca–ATPase. Calbindin-D_{9K} enhances the extrusion of Ca²⁺ by the Ca–ATPase, whereas the precise function of calbindin-D_{28K} is unsettled.

Mobilization of Bone Mineral. Although vitamin D–deficient animals show obvious deficits in bone mineral, there is little evidence that calcitriol directly promotes mineralization. Thus, although VDR knockout mice exhibit severely impaired bone formation and mineralization, these deficiencies can be entirely corrected by a high-calcium diet. These results support the view that the primary role of calcitriol is to stimulate intestinal absorption of calcium, which, in turn, indirectly promotes bone mineralization. Indeed, children with rickets caused by mutations of the VDR have been treated successfully with intravenous infusions of Ca²⁺ and phosphate (*see below*). In contrast, physiological doses of vitamin D promote mobilization of Ca²⁺ from bone, and large doses cause excessive bone turnover. Although calcitriol-induced bone resorption may be reduced in parathyroidectomized animals, the response is restored when hyperphosphatemia is corrected. Thus, PTH and calcitriol act independently to enhance bone resorption.

Calcitriol increases bone turnover by multiple mechanisms (*see Suda et al., 2003*). Mature osteoclasts apparently lack the VDR. Acting by a non-VDR mechanism, calcitriol promotes the recruitment of osteoclast precursor cells to resorption sites, as well as the development of differentiated functions that characterize mature osteoclasts.

Osteoblasts, the cells responsible for bone formation, express the VDR, and calcitriol induces their production of several proteins, including osteocalcin, a vitamin K–dependent protein that contains γ -carboxyglutamic acid residues, and interleukin-1 (IL-1), a lymphokine that promotes bone resorption (Spear *et al.*, 1988). Thus, the current view is that calcitriol is a bone-mobilizing hormone but not a bone-forming hormone. Osteoporosis is a disease in which osteoclast responsiveness to calcitriol or other bone-resorbing agents is profoundly impaired, leading to deficient bone resorption.

Renal Retention of Calcium and Phosphate. The effects of calcitriol on the renal handling of Ca^{2+} and phosphate are of uncertain importance. Calcitriol increases retention of Ca^{2+} independently of phosphate. The effect on Ca^{2+} is thought to proceed in distal tubules, whereas enhanced phosphate absorption occurs in proximal tubules.

Other Effects of Calcitriol. It now is evident that the effects of calcitriol extend beyond calcium homeostasis. Receptors for calcitriol are distributed widely throughout the body (*see Pike, 1997*). Calcitriol affects maturation and differentiation of mononuclear cells and influences cytokine production and immune function (Hayes *et al.*, 2003). One focus of research is the potential use of calcitriol to inhibit proliferation and to induce differentiation of malignant cells (*see van den Bemd et al., 2000*). The possibility of dissociating the hypercalcemic effect of calcitriol from its actions on cell differentiation has encouraged the search for analogs that might be useful in cancer therapy. Calcitriol inhibits epidermal proliferation and promotes epidermal differentiation and therefore is a potential treatment for psoriasis vulgaris (Kragballe and Iversen, 1993) (*see Chapter 62*). Calcitriol also affects the function of skeletal muscle and brain (Carswell, 1997).

Calcitonin

Calcitonin is a hypocalcemic hormone whose actions generally oppose those of PTH.

History and Source. Copp observed in 1962 that perfusion of canine parathyroid and thyroid glands with hypercalcemic blood caused a transient hypocalcemia that occurred significantly earlier than that caused by total parathyroidectomy. He concluded that the parathyroid glands secreted a calcium-lowering hormone (calcitonin) in response to hypercalcemia and in this way normalized plasma Ca^{2+} concentrations. The physiological relevance of calcitonin has been challenged vigorously: Calcitonin normally circulates at remarkably low levels; surgical removal of the thyroids has no appreciable effect on calcium metabolism; and conditions associated with profound elevations of serum calcitonin concentration are not accompanied by hypocalcemia (Hirsch and Baruch, 2003). The primary interest in calcitonin arises from its pharmacologic use in treating Paget's disease and hypercalcemia and in its diagnostic use as a tumor marker for medullary carcinoma of the thyroid (*see below*).

The thyroid parafollicular C cells are the site of production and secretion of calcitonin. Human C cells, which are derived from

neural crest ectoderm, are distributed widely in the thyroid, parathyroid, and thymus. In nonmammalian vertebrates, calcitonin is found in ultimobranchial bodies, which are separate organs from the thyroid gland.

The calcitonin gene is localized on human chromosome 11p and contains six exons (Figure 61–6). The primary transcript is alternatively spliced in a tissue-specific manner. In *thyroid C cells*, the calcitonin/calcitonin gene-related peptide (CGRP) pre-mRNA is processed primarily with common exons 2 and 3 to include exon 4. This leads to production of the 32-amino-acid peptide calcitonin, along with a flanking 21-amino-acid peptide called *katacalcin*, whose physiological significance is unknown. In *neuronal cells*, on the other hand, most of the calcitonin/CGRP pre-mRNA, is processed to exclude exon 4, resulting in inclusion of exons 5 and 6 with common exons 2 and 3, which ultimately gives rise to CGRP. This results in the production of the 37-amino-acid CGRP. Calcitonin is the most potent peptide inhibitor of osteoclast-mediated bone resorption and helps to protect the skeleton during periods of “calcium stress,” such as growth, pregnancy, and lactation. CGRP and the closely related peptide adrenomedullin, are potent endogenous vasodilators.

Chemistry and Immunoreactivity. Calcitonin is a single-chain peptide of 32 amino acids with a disulfide bridge linking the cysteine residues in positions 1 and 7 (Figure 61–7). In all species, 8 of the 32 residues are invariant, including the disulfide bridge and a carboxyl-terminal proline amide; both structural features are essential for biological activity. The residues in the middle portion of the molecule (positions 10 to 27) are more variable and apparently influence potency and/or duration of action. Calcitonins derived from salmon and eel differ from the human hormone by 13 and 16 amino acid residues, respectively, and are more potent than mammalian calcitonin. Salmon calcitonin is used therapeutically in part because it is cleared more slowly from the circulation (*see below*).

Regulation of Secretion. The biosynthesis and secretion of calcitonin are regulated by the plasma Ca^{2+} concentration. Calcitonin secretion increases when plasma Ca^{2+} is high and decreases when plasma Ca^{2+} is low. Multiple forms of calcitonin are found in plasma, including high-molecular-weight aggregates or cross-linked products. Assays for the intact monomeric peptide are now available. The circulating concentrations of calcitonin are low, normally less than 15 and 10 pg/ml for males and females, respectively. The circulating half-life of calcitonin is about 10 minutes. Abnormally elevated levels of calcitonin are characteristic of thyroid C-cell hyperplasia and medullary thyroid carcinoma.

Calcitonin secretion is stimulated by a number of agents, including catecholamines, glucagon, gastrin, and cholecystokinin, but there is little evidence for a physiological role for secretion in response to these stimuli.

Mechanism of Action. Calcitonin actions are mediated by the calcitonin receptor (CTR), which is a member of

Figure 61–6. Alternative splicing of calcitonin/calcitonin gene-related peptide (CGRP).

the PTH/secretin subfamily of GPCRs (Lin *et al.*, 1991). Six human CTR subtypes occur through alternative splicing of coding and noncoding exons (Galson and Goldring, 2002). These isoforms exhibit distinct ligand-binding specificity and/or signal-transduction pathways and are distributed in a tissue-specific pattern. Of the most abundant isoforms, hCTR1⁻ preferentially couples with the G_s-adenylyl cyclase pathway (Gorn *et al.*, 1995). The hCTR1⁺ isoform does not couple with phospholipase C (Naro *et al.*, 1998) and therefore does not activate protein kinase C or trigger an increase in Ca²⁺. Calcitonin receptors can dimerize with modulatory proteins to create receptors with high affinity for amylin (Hay *et al.*, 2005).

The hypocalcemic and hypophosphatemic effects of calcitonin are caused predominantly by direct inhibition of osteoclastic bone resorption. Although calcitonin inhibits the effects of PTH on osteolysis, it inhibits neither PTH activation of bone cell adenylyl cyclase nor PTH-induced uptake of Ca²⁺ into bone. Calcitonin interacts directly with receptors on osteoclasts to produce a rapid

and profound decrease in ruffled border surface area, thereby diminishing resorptive activity.

Depressed bone resorption reduces urinary excretion of Ca²⁺, Mg²⁺, and hydroxyproline. Plasma phosphate concentrations are lowered owing also to increased urinary phosphate excretion. Direct renal effects of calcitonin vary with species. Acute administration of pharmacological doses of calcitonin increases urinary calcium excretion, whereas calcitonin inhibits renal calcium excretion at physiological concentrations. In humans, calcitonin increases fractional urinary calcium excretion in a dose-dependent manner in subjects given a modest calcium load (Carney, 1997).

BONE PHYSIOLOGY

The skeleton is the primary structural support for the body and also provides a protected environment for hematopoiesis. It contains both a large mineralized matrix and a highly active cellular compartment.

Figure 61–7. Comparison of calcitonins from several species. Calcitonin is a 32-amino-acid polypeptide with a disulfide bond between residues 1 and 7 and a proline-amide at the C-terminus. The figure highlights the differences in amino acid sequence between human calcitonin and calcitonins of other species; lack of an entry indicates identity with human calcitonin. Salmon calcitonin is ~20 times more potent in humans than is human calcitonin.

Figure 61–8. The bone remodeling cycle. Osteoclast precursors fuse and are activated to resorb a lacuna in a previously quiescent surface. These cells are replaced by osteoblasts that deposit new bone to restore the integrity of the tissue. (Adapted from Skerry and Gowen, 1995.)

Skeletal Organization. Because their bone turnover rates differ, it is useful to consider the *appendicular*, or *peripheral*, skeleton as separate from the *axial*, or *central*, skeleton. Appendicular bones make up 80% of bone mass and are composed predominantly of compact cortical bone. Axial bones, such as the spine and pelvis, contain substantial amounts of trabecular bone within a thin cortex. Trabecular bone consists of highly connected bony plates that resemble a honeycomb. The intertrabecular interstices contain bone marrow and fat. *Alterations in bone turnover are observed first and foremost in axial bone* both because bone surfaces, where bone remodeling occurs, are more densely distributed in trabecular bone and because marrow precursor cells that ultimately participate in bone turnover lie in close proximity to trabecular surfaces.

Bone Mass. Bone mineral density (BMD) and fracture risk in later years reflect the maximal bone mineral content at skeletal maturity (peak bone mass) and the subsequent rate of bone loss. Major increases in bone mass, accounting for about 60% of final adult levels, occur during adolescence, mainly during years of highest growth velocity. Bone acquisition is largely complete by age 17 in girls and by age 20 in boys. Inheritance accounts for much of the variance in bone acquisition; other factors include circulating estrogen and androgens, physical activity, and dietary calcium.

Bone mass peaks during the third decade, remains stable until age 50, and then declines progressively. Similar trajectories occur for men and women of all ethnic groups. The fundamental accuracy of this model has been amply confirmed for cortical bone, although trabecular bone loss at some sites probably begins prior to age 50. In women, loss of estrogen at menopause accelerates the rate of bone loss. *Primary regulators of adult bone mass include physical activity, reproductive endocrine status, and calcium intake. Optimal maintenance of BMD requires sufficiency in all three areas, and deficiency in one area is not compensated by excessive attention to another.*

Bone Remodeling. Growth and development of endochondral bone are driven by a process called *modeling*. Once new bone is laid down,

it is subject to a continuous process of breakdown and renewal called *remodeling*, by which bone mass is adjusted throughout adult life (Ballock and O’Keefe, 2003). Remodeling is carried out by myriad independent “bone remodeling units” throughout the skeleton (Figure 61–8). Remodeling proceeds on bone surfaces, about 90% of which are normally inactive, covered by a thin layer of lining cells. In response to physical or biochemical signals, recruitment of marrow precursor cells to the bone surface results in their fusion into the characteristic multinucleated osteoclasts that resorb, or excavate, a cavity into the bone.

Osteoclast production is regulated by osteoblast-derived cytokines such as IL-1 and IL-6. Studies have begun to clarify the mechanisms through which osteoclast production is regulated (see Suda *et al.*, 1999). The receptor for activating NF κ B (RANK) is an osteoclast protein whose expression is required for osteoclastic bone resorption. Its natural ligand, RANK ligand (RANKL; previously called *osteoclast differentiation factor*), is a membrane-spanning osteoblast protein. On binding to RANK, RANKL induces osteoclast formation (Khosla, 2001) (Figure 61–9). RANKL initiates the activation of mature osteoclasts, as well as the differentiation of osteoclast precursors. Osteoblasts produce osteoprotegerin (OPG), which acts as a decoy ligand for RANKL. Under conditions favoring increased bone resorption, such as estrogen deprivation, OPG is suppressed, RANKL binds to RANK, and osteoclast production increases. When estrogen sufficiency is reestablished, OPG increases and competes effectively with RANKL for binding to RANK. In certain model systems, OPG is superior to bisphosphonates in suppressing bone resorption and hypercalcemia (Morony, *et al.*, 2005).

Completion of the resorption phase is followed by ingress of preosteoblasts derived from marrow stroma into the base of the resorption cavity. These cells develop the characteristic osteoblastic phenotype and begin to replace the resorbed bone by elaborating new bone matrix constituents, such as collagen and osteocalcin. Once the newly formed osteoid reaches a thickness of about 20 μ m, mineralization begins. A complete remodeling cycle normally requires about 6 months.

Figure 61–9. RANK ligand and osteoclast formation. RANKL, acting on RANK, promotes osteoclast formation and subsequent resorption of bone matrix. OPG binds to RANKL, inhibiting its binding to RANK and thereby inhibiting osteoclast differentiation.

If the replacement of resorbed bone matched the amount that was removed, remodeling would not change net bone mass. However, small bone deficits persist on completion of each cycle, reflecting inefficient remodeling dynamics. Consequently, lifelong accumulation of remodeling deficits underlies the well-documented phenomenon of age-related bone loss, a process that begins shortly after growth stops. *Alterations in remodeling activity represent the final pathway through which diverse stimuli, such as dietary insufficiency, hormones, and drugs, affect bone balance.* Changes in hormonal milieu often lead to an increase in the activation, or birth rate, of remodeling units. Examples include hyperthyroidism, hyperparathyroidism, and hypervitaminosis D. Other factors may impair osteoblast function, such as high doses of *corticosteroids* or *ethanol*. Finally, estrogen deficiency augments osteoclastic resorptive capacity by a proapoptotic action (Manolagas *et al.*, 2002).

At any given time, a transient deficit in bone, the remodeling space, represents sites of bone resorption that have not yet filled in. Stimuli that alter the rate of emergence of new remodeling units will either increase or decrease the remodeling space until a new steady-state is established at an increased or decreased bone mass.

DISORDERS OF MINERAL HOMEOSTASIS AND BONE

Abnormal Calcium Metabolism

Hypercalcemia. Moderate elevations of the concentration of Ca^{2+} in the extracellular fluid may have no clinically detectable effects. The degree of hypercalcemia and the rate of onset of the elevation in the serum calcium concentration

largely dictate the extent of symptoms. Chronic elevation of serum Ca^{2+} to 12 to 14 mg/dl (3 to 3.5 mmol/L) generally causes few manifestations, whereas an acute rise to the same levels may cause marked neuromuscular manifestations owing to an increased threshold for excitation of nerve and muscle. Symptoms include fatigue, muscle weakness, anorexia, depression, diffuse abdominal pain, and constipation.

Hypercalcemia can result from a number of conditions. Ingestion of large quantities of calcium by itself generally does not cause hypercalcemia; exceptions are hyperthyroid subjects, who absorb Ca^{2+} with increased efficiency (Benker *et al.*, 1988), and subjects with the uncommon *milk-alkali syndrome*, a condition caused by concurrent ingestion of large quantities of milk and absorbable alkali, resulting in impaired renal Ca^{2+} excretion and attendant hypercalcemia.

In an outpatient setting, the most common cause of hypercalcemia is primary hyperparathyroidism, which results from hypersecretion of PTH by one or more parathyroid glands. Secondary hyperparathyroidism, in contrast, arises as a compensation for reductions of circulating Ca^{2+} and is not associated with hypercalcemia.

Symptoms and signs of primary hyperparathyroidism include fatigue, exhaustion, weakness, polydipsia, polyuria, joint pain, bone pain, constipation, depression, anorexia, nausea, heartburn, nephrolithiasis, and hematuria. This condition frequently is accompanied by significant hypophosphatemia owing to the effects of PTH in diminishing renal tubular phosphate reabsorption. Some patients have renal calculi and peptic ulceration, and a few display classical parathyroid skeletal disease. However, most patients show few, if any, symptoms, and those that are present are often vague and nonspecific. Contemporary IRMAs that distinguish between full-length PTH(1–84) and “intact” PTH [PTH(1–84) + PTH(7–84)] obviate many of the difficulties with previous assays and, in conjunction with an elevated serum calcium, possess a diagnostic accuracy of greater than 90% (Gao *et al.*, 2001; Jüppner and Potts, 2002; Silverberg *et al.*, 2003).

Familial benign hypercalcemia (or *familial hypocalciuric hypercalcemia*) is a genetic disorder generally accompanied by extremely low urinary calcium excretion. Familial benign hypercalcemia results from heterozygous mutations in the Ca^{2+} -sensing receptor (Pollak *et al.*, 1996). Hypercalcemia usually is mild, and circulating PTH often is normal to slightly elevated. The importance of making this diagnosis lies in the fact that patients mistakenly diagnosed as having primary hyperparathyroidism may undergo surgical exploration without discovery of an adenoma and without therapeutic benefit. Patients do not experience long-term clinical consequences, except for homozygous infants, who may have severe, even lethal, hypercalcemia. Diagnosis is established by demonstrating hypercalcemia in first-degree family members and a decreased fractional excretion of calcium.

Newly diagnosed hypercalcemia in hospitalized patients is caused most often by a systemic malignancy, either with or without bony metastasis. PTH-related protein (PTHrP) is a primitive, highly conserved protein that may be abnormally expressed in malignant tissue, particularly by squamous cell and other epithelial cancers. The substantial sequence homology of the amino-terminal portion of PTHrP with that of native PTH permits it to interact with the PTH-1 receptor in target tissues, thereby causing the hypercalcemia and hypophos-

phatemia seen in humoral hypercalcemia of malignancy (Grill *et al.*, 1998). Other tumors release cytokines or prostaglandins that stimulate bone resorption. In some patients with lymphomas, hypercalcemia results from overproduction of 1,25-dihydroxyvitamin D by the tumor cells owing to expression of 1α -hydroxylase. A similar mechanism underlies the hypercalcemia that is seen occasionally in sarcoidosis and other granulomatous disorders.

Hypercalcemia associated with malignancy generally is more severe than in primary hyperparathyroidism (frequently with calcium levels that exceed 13 mg/dl) and may be associated with lethargy, weakness, nausea, vomiting, polydipsia, and polyuria. Assays for PTHrP may aid diagnosis.

Vitamin D excess may cause hypercalcemia if sufficient 25-hydroxyvitamin D is present to stimulate intestinal Ca^{2+} hyperabsorption, leading to hypercalcemia and suppressing PTH and 1,25-dihydroxyvitamin D levels. Measurement of 25-hydroxyvitamin D is diagnostic. Occasional patients with *hyperthyroidism* show mild hypercalcemia, presumably owing to increased bone turnover. *Immobilization* may lead to hypercalcemia in growing children and young adults but rarely causes hypercalcemia in older individuals unless bone turnover is already increased, as in Paget's disease or hyperthyroidism. Hypercalcemia sometimes is noted in adrenocortical deficiency, as in Addison's disease, or following removal of a hyperfunctional adrenocortical tumor. Hypercalcemia occurs following renal transplantation owing to persistent hyperfunctioning parathyroid tissue that resulted from the previous renal failure.

The differential diagnosis of hypercalcemia may pose difficulties, but advances in serum assays for PTH, PTHrP, and 25-hydroxy- and 1,25-dihydroxyvitamin D permit accurate diagnosis in the great majority of cases.

Hypocalcemia. Mild hypocalcemia [*i.e.*, reduction in ionized serum Ca^{2+} concentrations from normal to concentrations above 3.2 mg/dl (0.8 mM), approximately equal to a total serum Ca^{2+} concentration of 8 to 8.5 mg/dl (2 to 2.1 mM)] is usually asymptomatic. Again, the rapidity of change affects the clinical picture because patients exhibit greater signs and symptoms if the hypocalcemia develops acutely. The signs and symptoms of hypocalcemia include tetany and related phenomena such as paresthesias, increased neuromuscular excitability, laryngospasm, muscle cramps, and tonic-clonic convulsions. In chronic hypoparathyroidism, ectodermal changes—consisting of loss of hair, grooved and brittle fingernails, defects of dental enamel, and cataracts—are encountered; calcification in the basal ganglia may be seen on routine skull radiographs. Psychiatric symptoms such as emotional lability, anxiety, depression, and delusions often are present.

Combined deprivation of Ca^{2+} and vitamin D, as observed with malabsorption states or dietary deficiency, readily promotes hypocalcemia. When caused by malabsorption, hypocalcemia is accompanied by low concentrations of phosphate, total plasma proteins, and magnesium. Mg^{2+} deficiency may accentuate the hypocalcemia by diminishing the secretion and action of PTH. In infants with malabsorption or inadequate calcium intake, Ca^{2+} concentrations usually are depressed, with attendant hypophosphatemia resulting in rickets.

Hypoparathyroidism is most often a consequence of thyroid or neck surgery but also may be due to genetic or autoimmune disorders. In hypoparathyroidism, hypocalcemia is accompanied by hyperphosphatemia, reflecting decreased PTH action on renal phosphate transport.

Pseudohypoparathyroidism is a diverse family of hypocalcemic and/or hyperphosphatemic disorders. Pseudohypoparathyroidism results from resistance to PTH rather than PTH deficiency; this resistance is not due to mutations of the PTH receptor but rather to mutations in $G_s\alpha$ (*GNAS1*), which normally mediates hormone-induced adenylyl cyclase activation (Yu *et al.*, 1999). The variable phenotypes arising from *GNAS1* defects apparently are due to differential genomic imprinting of the maternal and paternal alleles (Levine *et al.*, 2003). Multiple hormonal abnormalities have been associated with the *GNAS1* mutation, but none is as severe as the deficient response to PTH.

Hypocalcemia is not unusual in the first several days following removal of a parathyroid adenoma. If hyperphosphatemia is also present, the condition is one of functional hypothyroidism owing to temporary failure of the remaining parathyroid glands to compensate for the missing adenomatous tissue. In patients with parathyroid bone disease, postoperative hypocalcemia associated with hypophosphatemia may reflect rapid uptake of calcium into bone, the "hungry bone" syndrome. In this setting, persistent, severe hypocalcemia may require administration of vitamin D and supplemental calcium for several months.

Neonatal tetany resulting from hypocalcemia sometimes occurs in infants of mothers with *hyperparathyroidism*; indeed, the tetany may call attention to the mother's disorder. This problem disappears when the infant's own parathyroid glands develop sufficiently to respond appropriately.

Hypocalcemia is associated with advanced renal insufficiency accompanied by hyperphosphatemia. Many patients with this condition do not develop tetany unless the accompanying acidosis is treated, which decreases the ionized calcium. High concentrations of phosphate in plasma inhibit the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol. Hypocalcemia also can occur following massive transfusions with citrated blood, which chelates calcium.

Disturbed Phosphate Metabolism

Dietary inadequacy very rarely causes phosphate depletion. Sustained use of antacids, however, can severely limit phosphate absorption and result in clinical phosphate depletion, manifest as malaise, muscle weakness, and osteomalacia (*see* Chapter 36). *Osteomalacia*, as described further below, is characterized by undermineralized bone matrix and may occur when sustained phosphate depletion is caused by inhibiting its absorption in the gastrointestinal tract (as with aluminum-containing antacids) or by excess renal excretion owing to PTH action.

Hyperphosphatemia is an important component of the bone disease seen in chronic renal failure. In this condition, phosphate retention is primary and reflects the degree of renal compromise. The increased phosphate level reduces the serum Ca^{2+} concentration, which, in turn, activates the parathyroid gland calcium-sensing receptor, stimulates

PTH secretion, and exacerbates the hyperphosphatemia. The continuing hyperphosphatemia may be modified by vigorous administration of aluminum hydroxide gel or calcium carbonate supplements. As discussed below, the Food and Drug Administration (FDA) recently approved therapeutic use of the calcium-sensing receptor agonist *cinacalcet* to suppress PTH secretion.

Disorders of Vitamin D

Hypervitaminosis D. The acute or long-term administration of excessive amounts of vitamin D or enhanced responsiveness to normal amounts of the vitamin leads to derangements in calcium metabolism. The responses to vitamin D reflect endogenous vitamin D production, tissue reactivity, and vitamin D intake. Some infants may be hyperreactive to small doses of vitamin D. In adults, hypervitaminosis D results from overtreatment of hypoparathyroidism or secondary hyperparathyroidism of renal osteodystrophy and from faddist use of excessive doses. Toxicity in children also may occur following accidental ingestion of adult doses.

The amount of vitamin D necessary to cause hypervitaminosis varies widely. As a rough approximation, continued daily ingestion of 50,000 units or more by a person with normal parathyroid function and sensitivity to vitamin D may result in poisoning. Hypervitaminosis D is particularly dangerous in patients who are receiving digoxin because the toxic effects of the cardiac glycosides are enhanced by hypercalcemia (*see* Chapters 33 and 34).

The initial signs and symptoms of vitamin D toxicity are those associated with hypercalcemia (*see* above). Since hypercalcemia in vitamin D intoxication generally is due to very high circulating levels of 25-OHD, the plasma concentrations of PTH and calcitriol typically (but not uniformly) are suppressed. In children, a single episode of moderately severe hypercalcemia may arrest growth completely for 6 months or more, and the deficit in height may never be fully corrected. Vitamin D toxicity in the fetus is associated with excess maternal vitamin D intake or extreme sensitivity and may result in congenital supravalvular aortic stenosis. In infants, this anomaly frequently is associated with other stigmata of hypercalcemia.

Vitamin D Deficiency. Vitamin D deficiency results in inadequate absorption of Ca^{2+} and phosphate. The consequent decrease of plasma Ca^{2+} concentration stimulates PTH secretion, which acts to restore plasma Ca^{2+} at the expense of bone. Plasma concentrations of phosphate remain subnormal because of the phosphaturic effect of increased circulating PTH. In children, the result is a failure to mineralize newly formed bone and cartilage matrix, causing the defect in growth known as *rickets*. As a con-

sequence of inadequate calcification, bones of individuals with rickets are soft, and the stress of weight bearing gives rise to bowing of the long bones.

In adults, vitamin D deficiency results in osteomalacia, a disease characterized by generalized accumulation of undermineralized bone matrix. Severe osteomalacia may be associated with extreme bone pain and tenderness. Muscle weakness, particularly of large proximal muscles, is typical and may reflect both hypophosphatemia and inadequate vitamin D action on muscle. Gross deformity of bone occurs only in advanced stages of the disease. Circulating 25-OHD concentrations below 8 ng/ml are highly predictive of osteomalacia.

Metabolic Rickets and Osteomalacia. These disorders are characterized by abnormalities in calcitriol synthesis or response.

Hypophosphatemic vitamin D-resistant rickets, in its most common form, is an X-linked disorder (XLH) of calcium and phosphate metabolism. Calcitriol levels are inappropriately normal for the observed degree of hypophosphatemia. Patients experience clinical improvement when treated with large doses of vitamin D, usually in combination with inorganic phosphate. Even with vitamin D treatment, calcitriol concentrations may remain lower than expected. The genetic basis for XLH has been defined (HYP Consortium, 1995). The affected protein, a phosphate-regulating gene with homologies to endopeptidases on the X chromosome (PHEX), is a neutral endoprotease. The substrate for this enzyme likely is involved in renal phosphate transport. Syndromes closely related to XLH, in which phosphate levels are altered without significant net changes in serum concentrations of calcium, PTH, or $1,25(\text{OH})_2\text{D}_3$, include *hereditary hypophosphatemic rickets with hypercalciuria* (HHRH) and *autosomal dominant hypophosphatemic rickets*. The latter disorder maps to chromosome 12p13.3 (Econs *et al.*, 1997) and is associated with mutations in the gene encoding fibroblast growth factor 23 (White *et al.*, 2001).

Vitamin D-dependent rickets (also called *vitamin D-dependent rickets type I*) is an autosomal recessive disease caused by an inborn error of vitamin D metabolism involving defective conversion of 25-OHD to calcitriol owing to mutations in *CYP1 α* (1 α -hydroxylase). The condition responds to physiological doses of calcitriol.

Hereditary 1,25-dihydroxyvitamin D resistance (also called *vitamin D-dependent rickets type II*) is an autosomal recessive disorder that is characterized by hypocalcemia, osteomalacia, rickets, and total alopecia. Mutations of the vitamin D receptor cause vitamin D-dependent rickets type II (Malloy *et al.*, 1999). Absolute hormone resistance results from premature stop mutations or missense mutations in the zinc finger DNA-binding domain. Several missense mutations in the ligand-binding domain also have been described that result in partial or complete hormone resistance. These mutations alter ligand binding or heterodimerization with the retinoid X receptor (RXR).

Serum abnormalities include low serum concentrations of calcium and phosphate and elevated serum alkaline phosphatase activity. The hypocalcemia leads to secondary hyperparathyroidism with elevated PTH levels and hypophosphatemia. The 25(OH)-vitamin D values are normal, whereas $1,25(\text{OH})_2$ -vitamin D levels are elevated in type II vitamin D-dependent rickets. This clinical feature distinguishes hereditary vitamin D-dependent rickets type II from *CYP1 α* deficiency (vitamin D-dependent rickets type I), where serum $1,25(\text{OH})_2$ -vitamin D values are depressed. Children affected by vitamin D-

dependent rickets type II are refractory even to massive doses of vitamin D and calcitriol, and they may require prolonged treatment with parenteral Ca^{2+} . Some remission of symptoms has been observed during adolescence, but the basis of remission is unknown.

Renal osteodystrophy (renal rickets) is associated with chronic renal failure and is characterized by decreased conversion of 25-OHD to calcitriol. Phosphate retention decreases plasma Ca^{2+} concentrations, leading to secondary hyperparathyroidism. In addition, calcitriol deficiency impairs intestinal Ca^{2+} absorption and mobilization from bone. Hypocalcemia commonly results (although in some patients, prolonged and severe hyperparathyroidism eventually may lead to hypercalcemia). Aluminum deposition in bone also may play a role in the genesis of the skeletal disease.

SPECIFIC DISORDERS OF BONE

Osteoporosis

Osteoporosis is a condition of low bone mass and microarchitectural disruption that results in fractures with minimal trauma. Osteoporosis is a major and growing public health problem in developed nations. Between 30% and 50% of women and between 15% and 30% of men suffer a fracture related to osteoporosis. Characteristic sites of fracture include vertebral bodies, the distal radius, and the proximal femur, but osteoporotic individuals have generalized skeletal fragility, and fractures at sites such as ribs and long bones also are common. Fracture risk increases exponentially with age and is associated with reduced survival after any type of fracture (Center *et al.*, 1999).

Osteoporosis can be categorized as *primary* or *secondary*. In 1948, Albright and Reifenstein concluded that primary osteoporosis included two separate entities: one related to menopausal estrogen loss and the other to aging. This concept was extended by the proposal that primary osteoporosis represents two fundamentally different conditions: *type I osteoporosis*, characterized by loss of trabecular bone owing to estrogen lack at menopause, and *type II osteoporosis*, characterized by loss of cortical and trabecular bone in men and women owing to long-term remodeling inefficiency, dietary inadequacy, and activation of the parathyroid axis with age. It is not clear, however, that these two entities are truly distinct. Although many osteoporotic women undoubtedly have experienced excessive menopausal bone loss, it may be more appropriate to consider osteoporosis as the result of multiple physical, hormonal, and nutritional factors acting alone or in concert.

Secondary osteoporosis is due to systemic illness or medications such as glucocorticoids or phenytoin. The most successful approach to secondary osteoporosis is prompt resolution of the underlying cause or drug discontinuation. Whether primary or secondary, osteoporosis is associated with characteristic disordered bone remodeling, so the same therapies can be used.

Paget's Disease. Paget's disease is characterized by single or multiple foci of disordered bone remodeling. The etiology of the disease is

uncertain but is thought to be the result of infection with the measles virus of the paramyxovirus family (Kurihara *et al.*, 2000). It affects up to 2% to 3% of the population over age 60. The primary pathologic abnormality is increased bone resorption followed by exuberant new bone formation. However, the newly formed bone is disorganized and of poor quality, resulting in characteristic bowing, stress fractures, and arthritis of joints adjoining the involved bone. Pagetic lesions contain many abnormal multinucleated osteoclasts associated with a disordered mosaic pattern of bone formation. Pagetic bone is thickened and has abnormal microarchitecture. The altered bone structure can produce secondary problems, such as deafness, spinal cord compression, high-output cardiac failure, and pain. Malignant degeneration to osteogenic sarcoma is a rare but lethal complication of Paget's disease.

Renal Osteodystrophy. Bone disease is a frequent consequence of chronic renal failure and dialysis. Pathologically, lesions are typical of hyperparathyroidism (osteitis fibrosa), deficiency of vitamin D (osteomalacia), or a mixture of both. The underlying pathophysiology reflects increased phosphate and decreased calcium, leading to secondary events that strive to preserve circulating levels of mineral ions at the expense of bone.

PHARMACOLOGICAL TREATMENT OF DISORDERS OF MINERAL ION HOMEOSTASIS AND BONE METABOLISM

Hypercalcemia. Hypercalcemia can be life-threatening. Such patients frequently are severely dehydrated because hypercalcemia compromises renal concentrating mechanisms. Thus, fluid resuscitation with large volumes of isotonic saline must be early and aggressive (6 to 8 L/day). Agents that augment Ca^{2+} excretion, such as loop diuretics (*see* Chapter 28), may help to counteract the effect of plasma volume expansion by saline but are contraindicated until volume is repleted because they otherwise will aggravate volume depletion and hypercalcemia.

Corticosteroids administered at high doses (*e.g.*, 40 to 80 mg/day of *prednisone*) may be useful when hypercalcemia results from sarcoidosis, lymphoma, or hypervitaminosis D (*see* Chapter 59). The response to steroid therapy is slow; from 1 to 2 weeks may be required before plasma Ca^{2+} concentration falls.

Calcitonin (CALCIMAR, MIACALCIN) may be useful in managing hypercalcemia. Reduction in Ca^{2+} can be rapid, although "escape" from the hormone commonly occurs within several days. The recommended starting dose is 4 units/kg of body weight administered subcutaneously every 12 hours; if there is no response within 1 or 2 days, the dose may be increased to a maximum of 8 units/kg every 12 hours. If the response after 2 more days still is unsatisfactory, the dose may be increased to a maximum of 8 units/kg every 6 hours.

Plicamycin (*mithramycin*, MITHRACIN) is a cytotoxic antibiotic that also decreases plasma Ca^{2+} concentrations by inhibiting bone resorption. Reduction in plasma Ca^{2+} concentrations occurs within 24 to 48 hours when a relatively low dose of this agent is given (15 to 25 $\mu\text{g}/\text{kg}$ of body weight) to minimize the high systemic toxicity of the drug.

Intravenous *bisphosphonates* (*pamidronate*, *zoledronate*) have proven very effective in the management of hypercalcemia (*see* below for further discussion of bisphosphonates). These agents potently inhibit osteoclastic bone resorption. Oral bisphosphonates are less effective for treating hypercalcemia. Therefore, pamidronate (AREDIA) is given as an intravenous infusion of 60 to 90 mg over 4 to 24 hours. With pamidronate, resolution of hypercalcemia occurs over several days, and the effect usually persists for several weeks.

Oral *sodium phosphate* lowers plasma Ca^{2+} concentrations and may offer short-term calcemic control of some patients with primary hyperparathyroidism who are awaiting surgery. However, the risk of precipitating calcium phosphate salts in soft tissues throughout the body is of concern. In light of satisfactory responses to other agents, administration of intravenous sodium phosphate is not recommended as a treatment for hypercalcemia.

Once the hypercalcemic crisis has resolved or in patients with milder calcium elevations, therapy turns to more durable resolution of the hypercalcemic state. Parathyroidectomy remains the only definitive treatment for primary hyperparathyroidism. Specific indications for surgery have been proposed (Bilezikian *et al.*, 2002). In the hands of a skilled parathyroid surgeon, resection of a single adenoma (about 80% of cases) or of the hyperplastic glands (about 15% of cases) cures hyperparathyroidism. Complications include transient postoperative hypocalcemia, which may reflect temporary disruption of blood supply to the remaining parathyroid tissue or skeletal avidity for calcium, and permanent hypoparathyroidism. As described below, a calcium mimetic that stimulates the calcium-sensing receptor is a promising new therapy for hyperparathyroidism that may be used increasingly in the future.

Therapy of hypercalcemia of malignancy ideally is directed at the underlying cancer. When this is not possible, parenteral bisphosphonates often will maintain calcium levels within an acceptable range.

Hypocalcemia and Other Therapeutic Uses of Calcium. Hypoparathyroidism is treated primarily with vitamin D (*see* below). Dietary supplementation with Ca^{2+} also may be necessary.

Calcium is used in the treatment of calcium deficiency states and as a dietary supplement. Ca^{2+} salts are specific in the immediate treatment of hypocalcemic tetany regardless of etiology. In severe tetany, symptoms are best brought under control by intravenous medication. *Calcium chloride* ($\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$) contains 27% Ca^{2+} ; it is valuable in the treatment of hypocalcemic tetany and laryngospasm. The salt is given intravenously and *must never be injected into tissues*. Injections of calcium chloride are accompa-

nied by peripheral vasodilation and a cutaneous burning sensation. The salt usually is given intravenously in a concentration of 10% (equivalent to 1.36 mEq Ca^{2+}/ml). The rate of injection should be slow (not over 1 ml/min) to prevent cardiac arrhythmias from a high concentration of Ca^{2+} . The injection may induce a moderate fall in blood pressure owing to vasodilation. Since calcium chloride is an acidifying salt, it is usually undesirable in the treatment of the hypocalcemia caused by renal insufficiency. *Calcium gluceptate* injection (a 22% solution; 18 mg or 0.9 mEq of Ca^{2+}/ml) is administered intravenously at a dose of 5 to 20 ml for the treatment of severe hypocalcemic tetany; the injection produces a transient tingling sensation when given too rapidly. When the intravenous route is not possible, injections may be given intramuscularly in the gluteal region at a dose of up to 5 ml. A mild local reaction may result. *Calcium gluconate* injection (a 10% solution; 9.3 mg of Ca^{2+}/ml) given intravenously is the treatment of choice for severe hypocalcemic tetany. Patients with moderate-to-severe hypocalcemia may be treated by intravenous infusion of calcium gluconate at a dose of 10 to 15 mg of Ca^{2+}/kg of body weight over 4 to 6 hours. Since the usual 10-ml vial of a 10% solution contains only 93 mg Ca^{2+} , many vials are needed. The intramuscular route should not be employed because abscess formation at the injection site may result.

For control of milder hypocalcemic symptoms, oral medication suffices, frequently in combination with vitamin D or one of its active metabolites. Calcium salts are acidifying, and different forms can be interchanged to avoid gastric irritation. Available Ca^{2+} salts include calcium carbonate, lactate, gluconate, phosphate, citrate, and hydroxyapatite. Calcium carbonate is prescribed most frequently, whereas calcium citrate may be absorbed more efficiently than other salts. However, absorption efficiency for most commonly prescribed calcium products is reasonable, and for many patients, cost and palatability outweigh modest differences in efficacy. Average doses for hypocalcemic patients are calcium gluconate, 15 g/day in divided doses; calcium lactate, 7.7 g plus 8 g lactose with each meal; and calcium carbonate or calcium phosphate, 1 to 2 g with meals.

Calcium carbonate and calcium acetate are used to restrict phosphate absorption in patients with chronic renal failure and oxalate absorption in patients with inflammatory bowel disease. Acute administration of calcium may be life-saving in patients with extreme hyperkalemia (serum $\text{K}^+ > 7$ mEq/L). Calcium gluconate (10 to 30 ml of a 10% solution) can reverse some of the cardiotoxic effects of hyperkalemia, providing time while other efforts are taken to lower the plasma K^+ concentration.

Additional FDA-approved uses of calcium include intravenous treatment for black widow spider envenomation and management of magnesium toxicity. Use of supplemental calcium in the prevention and treatment of osteoporosis is discussed below.

THERAPEUTIC USES OF VITAMIN D

Specific Forms of Vitamin D. Calcitriol (1,25-dihydroxycholecalciferol; CALCIJEX, ROCALTRON) is available for oral administration or injection. Several derivatives of vitamin D (Figure 61–10) are of considerable experimental and therapeutic interest.

Figure 61–10. Vitamin D analogs.

Doxercalciferol (1 α -hydroxyvitamin D_2 , HECTOROL) is a pro-drug that first must be activated by hepatic 25-hydroxylation to generate the biologically active compound, 1 α ,25-(OH) $_2\text{D}_2$ (Figure 61–10). The FDA has approved oral and intravenous preparations of 1 α -hydroxyvitamin D_2 for use in treating secondary hyperparathyroidism, starting at 10 mg three times per week.

Dihydroxycholecalciferol (DHT, ROXANE) is a reduced form of vitamin D_2 . DHT is converted in the liver to its active form, 25-hydroxydihydroxycholecalciferol. DHT is less than 1% as active as calcitriol in antirachitic assays but is much more effective in mobilizing bone mineral at high doses; it therefore can be used to maintain plasma Ca^{2+} in hypoparathyroidism. DHT is well absorbed from the gastrointestinal tract and maximally increases serum calcium concentration after 2 weeks of daily administration. The hypercalcemic effects typically persist for 2 weeks but can last for up to 1 month. DHT is available for oral administration in doses ranging from 0.2 to 1 mg/day (average 0.6 mg/day).

1 α -Hydroxycholecalciferol (1-OHD $_3$, *alphacalcidol*; ONE-ALPHA) was introduced as a substitute for 1,25(OH) $_2\text{D}_3$; *alphacalcidol* is a synthetic vitamin D_3 derivative that is already hydroxylated in the 1 α position and is rapidly hydroxylated by 25-hydroxylase to form 1,25-(OH) $_2\text{D}_3$. It is equal to calcitriol in assays for stimulation of intestinal absorption of Ca^{2+} and bone mineralization and does not require renal activation. It therefore has been used to treat renal osteodystrophy and is available in the United States for experimental purposes.

Ergocalciferol (*calciferol*, DRISDOL) is pure vitamin D_2 . It is available for oral, intramuscular, or intravenous administration. Ergocalciferol is indicated for the prevention of vitamin D deficiency and the treatment of familial hypophosphatemia, hypopar-

athyroidism, and vitamin D-resistant rickets type II, typically in doses of 50,000 to 200,000 units/day in conjunction with calcium supplements.

Analogs of Calcitriol. Several vitamin D analogs (Figure 61–10) suppress PTH secretion by the parathyroid glands but have less or negligible hypercalcemic activity. They therefore offer a safer and more effective means of controlling secondary hyperparathyroidism.

Calcipotriol (*calcipotriene*) is a synthetic derivative of calcitriol with a modified side chain that contains a 22–23 double bond, a 24(*S*)-hydroxy functional group, and carbons 25 to 27 incorporated into a cyclopropane ring. Calcipotriol has comparable affinity with calcitriol for the vitamin D receptor, but it is less than 1% as active as calcitriol in regulating calcium metabolism. This reduced calcemic activity largely reflects the pharmacokinetics of calcipotriol (Kissmeyer and Binderup, 1991). Calcipotriol has been studied extensively as a treatment for psoriasis (*see* Chapter 62), although its mode of action is not known; a topical preparation (DOVONEX) is available for that purpose. In clinical trials, topical calcipotriol has been found to be slightly more effective than glucocorticoids with a good safety profile.

Paricalcitol (1,25-dihydroxy-19-norvitamin D_2 , ZEMPLAR) is a synthetic calcitriol derivative that lacks the exocyclic C19 and has a vitamin D_2 rather than vitamin D_3 side chain (Figure 61–10). It reduces serum PTH levels without producing hypercalcemia or altering serum phosphorus (Martin *et al.*, 1998). In an animal model, paricalcitol prevented or reversed PTH-induced high-turnover

bone disease (Slatopolsky *et al.*, 2003). Paricalcitol administered intravenously is FDA approved for treating secondary hyperparathyroidism in patients with chronic renal failure.

22-Oxacalcitriol (1,25-dihydroxy-22-oxavitamin D₃, OCT, *maxicalcitol*, OXAROL) differs from calcitriol only in the substitution of C-22 with an oxygen atom. Oxacalcitriol has a low affinity for vitamin D-binding protein; as a result, more of the drug circulates in the free (unbound) form, allowing it to be metabolized more rapidly than calcitriol with a consequent shorter half-life. Oxacalcitriol is a potent suppressor of PTH gene expression and shows very limited activity on intestine and bone. It is a useful compound in patients with overproduction of PTH in chronic renal failure or even with primary hyperparathyroidism (Cunningham, 2004).

Indications for Therapy with Vitamin D

The major therapeutic uses of vitamin D may be divided into four categories: (1) prophylaxis and cure of nutritional rickets; (2) treatment of metabolic rickets and osteomalacia, particularly in the setting of chronic renal failure; (3) treatment of hypoparathyroidism; and (4) prevention and treatment of osteoporosis (discussed in the section on osteoporosis).

Nutritional Rickets. Nutritional rickets results from inadequate exposure to sunlight or deficiency of dietary vitamin D. The condition, once extremely rare in the United States and other countries where food fortification with the vitamin is practiced, is now increasing. Infants and children receiving adequate amounts of vitamin D-fortified food do not require additional vitamin D; however, breast-fed infants or those fed unfortified formula should receive 400 units of vitamin D daily as a supplement. The usual practice is to administer vitamin A in combination with vitamin D. A number of balanced vitamin A and D preparations are available for this purpose. *Since the fetus acquires more than 85% of its calcium stores during the third trimester, premature infants are especially susceptible to rickets and may require supplemental vitamin D.*

Treatment of fully developed rickets requires a larger dose of vitamin D than that used prophylactically. One thousand units daily will normalize plasma Ca²⁺ and phosphate concentrations in approximately 10 days, with radiographic evidence of healing within about 3 weeks. However, a larger dose of 3000 to 4000 units daily often is prescribed for more rapid healing, particularly when respiration is compromised by severe thoracic rickets.

Vitamin D may be given prophylactically in conditions that impair its absorption (*e.g.*, diarrhea, steatorrhea, and biliary obstruction). Parenteral administration also may be used in such cases.

Treatment of Osteomalacia and Renal Osteodystrophy. Osteomalacia, distinguished by undermineralization of bone matrix, occurs commonly during sustained phosphate depletion. Patients with chronic renal disease are at risk for developing osteomalacia but also may develop a complex bone disease called *renal osteodystrophy*. In this setting, bone metabolism is stimulated by an increase in PTH and by a delay in bone mineralization that is due to decreased renal synthesis of calcitriol. In renal osteodystrophy, low bone mineral density may be accompanied by high-turnover

bone lesions typically seen in patients with uncontrolled hyperparathyroidism or by low bone remodeling activity seen in patients with adynamic bone disease. The therapeutic approach to the patient with renal osteodystrophy depends on its specific type. In high-turnover (hyperparathyroid) or mixed high-turnover disease with deficient mineralization, dietary phosphate restriction, generally in combination with a phosphate binder, is recommended because phosphate restriction is limited by the need to provide adequate protein intake to maintain nitrogen balance. Although highly effective, *aluminum* is no longer used as a phosphate binder because it promotes adynamic bone disease, anemia, myopathy, and occasionally dementia. Calcium-containing phosphate binders along with calcitriol administration may contribute to oversuppression of PTH secretion and likewise result in adynamic bone disease and an increased incidence of vascular calcification. Highly effective non-calcium-containing phosphate binders have been developed. *Sevelamer hydrochloride* (RENAGEL), a nonabsorbable phosphate-binding polymer, effectively lowers serum phosphate concentration in hemodialysis patients, with a corresponding reduction in the calcium × phosphate product. Sevelamer hydrochloride consists of cross-linked poly[allylamine hydrochloride] that is resistant to digestive degradation. Partially protonated amines spaced one carbon from the polymer backbone chelate phosphate ions by ionic and hydrogen bonding. Side effects of sevelamer include vomiting, nausea, diarrhea, and dyspepsia. Sevelamer does not affect the bioavailability of *digoxin*, *warfarin*, *enalapril*, or *metoprolol*.

Renal osteodystrophy associated with low bone turnover (adynamic bone disease) is increasingly common and may be due to oversuppression of PTH with aggressive use of either calcitriol or other vitamin D analogs. While PTH levels generally are low (<100 pg/ml), a high PTH level does not exclude the presence of adynamic bone disease, especially with PTH assays that do not distinguish between biologically active and inactive PTH fragments (Monier-Faugere *et al.*, 2001). Current guidelines suggest that treatment with an active vitamin D preparation is indicated if serum 25-OHD levels are less than 30 ng/ml and serum calcium is less than 9.5 mg/dl (2.37 mM). However, if 25-OHD and serum calcium levels are elevated, vitamin D supplementation should be discontinued. If the serum calcium level is less than 9.5 mg/dl, treatment with a vitamin D analog is warranted irrespective of the 25-OHD level (Eknoyan *et al.*, 2003).

Hypoparathyroidism. Vitamin D and its analogs are a mainstay of the therapy of hypoparathyroidism. Dihydroxycholesterol (DHT) has a faster onset, shorter duration of action, and a greater effect on bone mobilization than does vitamin D and traditionally has been a preferred agent. Calcitriol also is effective in the management of hypoparathyroidism and certain forms of pseudohypoparathyroidism in which endogenous levels of calcitriol are abnormally low. However, most hypoparathyroid patients respond to any form of vitamin D. Calcitriol may be preferred for temporary treatment of hypocalcemia while awaiting effects of a slower-acting form of vitamin D.

Miscellaneous Uses of Vitamin D. Vitamin D is used to treat hypophosphatemia associated with Fanconi syndrome. Large doses of vitamin D (over 10,000 units/day) are not useful in patients with osteoporosis and even can be dangerous. However, administration of 400 to 800 units/day of vitamin D to frail, elderly men and women has been shown to suppress bone remodeling, protect bone

mass, and reduce fracture incidence (*see* later section on osteoporosis). Clinical trials suggest that calcitriol may become an important agent for the treatment of psoriasis (Kowalick, 2001). As such non-traditional uses of vitamin D are discovered, it will become important to develop noncalcemic analogs of calcitriol that achieve effects on cellular differentiation without the risk of hypercalcemia.

Adverse Effects of Vitamin D Therapy

The primary toxicity associated with calcitriol reflects its potent effect to increase intestinal calcium and phosphate absorption, along with the potential to mobilize osseous calcium and phosphate. Hypercalcemia, with or without hyperphosphatemia, commonly complicates calcitriol therapy and may limit its use at doses that effectively suppress PTH secretion. As described earlier, noncalcemic vitamin D analogs provide alternative interventions, although they do not obviate the need to monitor serum calcium and phosphorus concentrations.

Hypervitaminosis D is treated by immediate withdrawal of the vitamin, a low-calcium diet, administration of glucocorticoids, and vigorous fluid support. As noted earlier under hypercalcemia, forced saline diuresis with loop diuretics is also useful. With this regimen, the plasma Ca^{2+} concentration falls to normal, and Ca^{2+} in soft tissue tends to be mobilized. Conspicuous improvement in renal function occurs unless renal damage has been severe.

CALCITONIN

Diagnostic Uses of Calcitonin

Calcitonin is a sensitive and specific marker for the presence of medullary thyroid carcinoma (MTC), a neuroendocrine malignancy originating in thyroid parafollicular C cells. MTC can be hereditary (25%) or sporadic (75%) and is present in all patients with the multiple endocrine neoplasia type 2 (MEN2) syndromes. Because one form of MEN2 is inherited as a dominant trait, relatives of patients should be examined repeatedly by calcitonin measurements from early childhood. Because calcitonin levels may be low in early tumor stages or in premalignant C-cell hyperplasia, pentagastrin-induced calcitonin provides greater sensitivity and increased MTC detection (Karanikas *et al.*, 2004). The identification of discrete mutations in the *RET* protooncogene in subjects with MEN2 offers hope that genetic screening will supplant reliance on testing serum calcitonin, which can give spurious results.

Therapeutic Uses. Calcitonin lowers plasma Ca^{2+} and phosphate concentrations in patients with hypercalcemia; this effect results from decreased bone resorption and is greater in patients in whom bone turnover rates are high. Although calcitonin is effective for up to 6 hours in the initial treatment of hypercalcemia, patients become refractory after a few days. This is likely due to receptor down-regulation (Takahashi *et al.*, 1995). Use of calcitonin does not substitute for aggressive fluid resuscitation, and the bisphosphonates are the preferred agents (*see* above on hypercalcemia).

Calcitonin is effective in disorders of increased skeletal remodeling, such as Paget's disease, and in some patients with osteoporosis. In Paget's disease, chronic use of calcitonin produces long-term reductions of serum alkaline phosphatase activity and symptoms. Development of antibodies to calcitonin occurs with prolonged therapy, but this is not necessarily associated with clinical resistance. Side effects of calcitonin include nausea, hand swelling, urticaria, and rarely, intestinal cramping. Side effects appear to occur with equal frequency with human and salmon calcitonin. *Salmon calcitonin* is approved for clinical use. The latter product also is available as a nasal spray, introduced for once-daily treatment of postmenopausal osteoporosis (*see* below). For Paget's disease, calcitonin generally is administered by subcutaneous injection because intranasal delivery is relatively ineffective owing to limited bioavailability. After initial therapy at 100 units/day, the dose typically is reduced to 50 units three times a week.

BISPHOSPHONATES

Bisphosphonates are analogs of pyrophosphate (Figure 61–11) that contain two phosphate groups attached to a geminal (central) carbon that replaces the oxygen in pyrophosphate. Because they form a three-dimensional structure capable of chelating divalent cations such as Ca^{2+} , the bisphosphonates have a strong affinity for bone, targeting especially bone surfaces undergoing remodeling. Accordingly, they are used extensively in conditions characterized by osteoclast-mediated bone resorption, including osteoporosis, steroid-induced osteoporosis, Paget's disease, tumor-associated osteolysis, breast and prostate cancer, and hypercalcemia. Recent evidence suggests that second- and third-generation bisphosphonates also may be effective anticancer drugs (*see* below). For a review of the basic and clinical pharmacology of bisphosphonates, *see* Licata (2005).

The clinical utility of bisphosphonates resides in their direct inhibition of bone resorption. First-generation bisphosphonates contain minimally modified side chains

Figure 61–11. Structures of pyrophosphate and bisphosphonates. The substituents (R_1 and R_2) on the central carbon of the bisphosphonate parent structure are shown in blue.

(R_1 , R_2) (*medronate*, *clodronate*, and *etidronate*) or contain a chlorophenyl group (*tiludronate*) (Figure 61–11). They are the least potent and in some instances cause bone demineralization. Second-generation aminobisphosphonates (*e.g.*, *alendronate* and *pamidronate*) contain a nitrogen group in the side chain. They are 10 to 100 times more potent than first-generation compounds. Third-generation bisphosphonates (*e.g.*, *risedronate* and *zoledronate*) contain a nitrogen atom within a heterocyclic ring and are up to 10,000 times more potent than first-generation agents.

Bisphosphonates concentrate at sites of active remodeling. Because they are highly negatively charged, bisphosphonates are membrane impermeable but are incorporated into the bone matrix by fluid-phase endocytosis (Stenbeck and Horton, 2000). Bisphosphonates remain

in the matrix until the bone is remodeled and then are released in the acid environment of the resorption lacunae beneath the osteoclast as the overlying mineral matrix is dissolved. The importance of this process for the antiresorptive effect of bisphosphonates is evidenced by the fact that calcitonin blocks the antiresorptive action.

Although bisphosphonates prevent hydroxyapatite dissolution, their antiresorptive action is due to direct inhibitory effects on osteoclasts rather than strictly physiochemical effects. The antiresorptive activity apparently involves two primary mechanisms: osteoclast apoptosis and inhibition of components of the cholesterol biosynthetic pathway.

The current model is that apoptosis accounts for the antiresorptive effect of first-generation bisphospho-

nates, whereas the inhibitory action of aminobisphosphonates proceeds through the latter mechanism. Consistent with this view, the antiresorptive effect of aminobisphosphonates such as alendronate and risedronate, but not of clodronate or etidronate, persists when apoptosis is suppressed (Halasy-Nagy *et al.*, 2001). First-generation bisphosphonates are metabolized into a nonhydrolyzable ATP analog (AppCCl₂p) that accumulates within osteoclasts and induces apoptosis (Rogers, 2003). In contrast, the aminobisphosphonates such as alendronate and *ibandronate* directly inhibit multiple steps in the pathway from mevalonate to cholesterol and isoprenoid lipids, such as geranylgeranyl diphosphate, that are required for the prenylation of proteins that are important for osteoclast function. The potency of aminobisphosphonates for inhibiting farnesyl synthase correlates directly with their antiresorptive activity (Dunford *et al.*, 2001).

Available Bisphosphonates

Several bisphosphonates are available in the United States (Figure 61–11). Etidronate sodium (DIDRONEL) is used for treatment of Paget's disease and may be used parenterally to treat hypercalcemia. Since etidronate is the only bisphosphonate that inhibits mineralization, it has been supplanted largely by pamidronate and zoledronate for treating hypercalcemia. Pamidronate (AREDIA) is approved for management of hypercalcemia but also is effective in other skeletal disorders. Pamidronate is available in the United States only for parenteral administration. For treatment of hypercalcemia, pamidronate may be given as an intravenous infusion of 60 to 90 mg over 4 to 24 hours.

Several newer bisphosphonates have been approved for treatment of Paget's disease. These include tiludronate (SKELID), alendronate (FOSAMAX), and risedronate (ACTONEL). Although the drug is approved only for treating hypercalcemia of malignancy, a single injection of zoledronate (ZOMETA) decreased bone turnover markers for 90 days in patients with Paget's disease (Buckler *et al.*, 1999). Tiludronate and the potent bisphosphonate ibandronate currently are under development for treatment of women with osteoporosis, with encouraging preliminary results.

Absorption, Fate, and Excretion. All oral bisphosphonates are very poorly absorbed from the intestine and have remarkably limited bioavailability [$<1\%$ (alendronate, risedronate) to 6% (etidronate tiludronate)]. Thus these drugs should be administered with a full glass of water following an overnight fast and at least 30 minutes before breakfast. Oral bisphosphonates have not been used widely in chil-

dren or adolescents because of uncertainty of long-term effects of bisphosphonates on the growing skeleton.

Bisphosphonates are excreted primarily by the kidneys. Adjusted doses for patients with diminished renal function have not been determined; bisphosphonates currently are not recommended for patients with a creatinine clearance of less than 30 ml/min.

Adverse Effects. As noted earlier, the first-generation bisphosphonate etidronate was associated with osteomalacia. This adverse effect, coupled with its relatively low efficacy, has limited its current use. Although alendronate and risedronate were well tolerated in clinical trials, some patients experience symptoms of esophagitis. Symptoms often abate when patients fastidiously take the medication with water and remain upright. Esophageal complications are infrequent when the drug is taken as described. If symptoms persist despite these precautions, use of a proton pump inhibitor at bedtime may be helpful (*see* Chapter 36). Both drugs may be better tolerated on a once-weekly regimen with no reduction of efficacy. Patients with active upper gastrointestinal disease should not be given oral bisphosphonates.

Mild fever and aches may attend the first parenteral infusion of pamidronate, likely owing to cytokine release. These symptoms are short-lived and generally do not recur with subsequent administration.

Zoledronate has been associated with renal toxicity, deterioration of renal function, and potential renal failure. Thus, the infusion should be given over at least 15 minutes, and the dose should be 4 mg. Patients who receive zoledronate should have standard laboratory and clinical parameters of renal function assessed prior to treatment and periodically after treatment to monitor for deterioration in renal function.

Therapeutic Uses

Hypercalcemia. The use of pamidronate in the management of malignancy-associated hypercalcemia was described earlier. Zoledronate appears to be more effective than pamidronate and at least as safe and can be infused over 15 minutes rather than 2 to 4 hours. It therefore has received FDA approval for this indication.

Postmenopausal Osteoporosis. Much interest is focused on the role of bisphosphonates in the treatment of osteoporosis (*see* "Osteoporosis," below). Clinical trials show that treatment is associated with increased bone mineral density and protection against fracture.

Cancer. Bisphosphonates also may act as anticancer drugs by inhibiting the activation of cancer-associated proteins, such as Ras, through suppression of geranylgeranylation and farnesylation. Second- and third-generation bisphosphonates inhibit the proliferation of some cancer cells by preventing post-translational prenylation of Ras-related proteins. Zoledronate has been used successfully as an adjunct in treating Philadelphia chromosome–positive chronic myelogenous leukemia.

PARATHYROID HORMONE (PTH)

Continuous administration of PTH or high circulating PTH levels achieved in primary hyperparathyroidism causes bone demineralization and osteopenia. However, *intermittent* PTH administration promotes bone growth. Selye first described the anabolic action of PTH some 80 years ago, but this observation was largely ignored and generally forgotten. Beginning in the 1970s, studies focused on the anabolic action of PTH, culminating with FDA approval of synthetic human 34-amino-acid amino-terminal PTH fragment [hPTH(1–34), *teriparatide*] for use in treating severe osteoporosis (Hodsman *et al.*, 2005). Full-length PTH(1–84) is likely to be approved in the near future; its benefits over PTH(1–34) are unclear.

Absorption, Fate, and Excretion. Pharmacokinetics and systemic actions of teriparatide on mineral metabolism are the same as for PTH. Teriparatide is administered by once-daily subcutaneous injection of 20 μg into the thigh or abdomen. With this regimen, serum PTH concentrations peak at 30 minutes after the injection and decline to undetectable concentrations within 3 hours, whereas the serum calcium concentration peaks at 4 to 6 hours after administration. Based on aggregate data from different dosing regimens, teriparatide bioavailability averages 95%. Teriparatide clearance averages 62 L/hour in women and 94 L/hour in men, which exceeds normal liver plasma flow, consistent with both hepatic and extrahepatic PTH removal. The serum half-life of teriparatide is approximately 1 hour when administered subcutaneously *versus* 5 minutes when administered intravenously. The longer half-life following subcutaneous administration reflects the time required for absorption from the injection site. The elimination of PTH(1–34) and full-length PTH proceeds by nonspecific enzymatic mechanisms in the liver, followed by renal excretion.

Clinical Effects. In postmenopausal women with osteoporosis, teriparatide increases BMD and reduces the risk of vertebral and nonvertebral fractures. Several laboratories have examined the effects of intermittent PTH on BMD in patients with osteoporosis. In these studies, teriparatide increased axial bone mineral, although initial reports of effects on cortical bone were disappointing. Coadministration of hPTH(1–34) with estrogen or synthetic androgen led to impressive gains in vertebral bone mass or trabecular bone. However, in some early studies there was only maintenance or even loss of cortical bone. Vitamin D insufficiency in patients at baseline or pharmacokinetic differences involving bioavailability or circulating half-life may have contributed to observed differences on cortical bone. The most comprehensive studies to date established the value of daily hPTH(1–34) administration on total BMD, with significant elevations of BMD in lumbar spine and femoral neck and with significant reductions of vertebral and nonvertebral fracture risk in osteoporotic women (Neer *et al.*, 2001) and men (Finkelstein *et al.*, 2003).

Candidates for teriparatide treatment include women who have a history of osteoporotic fracture, who have multiple risk

factors for fracture, or who failed or are intolerant of previous osteoporosis therapy.

Adverse Effects. In rats, teriparatide increased the incidence of bone tumors, including osteosarcoma (Vahle *et al.*, 2004). The clinical relevance of this finding is unclear, especially since patients with primary hyperparathyroidism have considerably higher elevations of serum PTH without a greater incidence of osteosarcoma. Nonetheless, teriparatide should not be used in patients who are at increased baseline risk for osteosarcoma (including those with Paget's disease of bone, unexplained elevations of alkaline phosphatase, open epiphyses, or prior radiation therapy involving the skeleton). Full-length PTH(1–84), which is in clinical trials, has not been associated with osteosarcomas. Other adverse effects have included exacerbation of nephrolithiasis and elevation of serum uric acid levels.

CALCIUM SENSOR MIMETICS: CINACALCET

Calcimimetics are drugs that mimic the stimulatory effect of calcium to inhibit PTH secretion by the parathyroid glands. By enhancing the sensitivity of the CaSR to extracellular Ca^{2+} , calcimimetics lower the concentration of Ca^{2+} at which PTH secretion is suppressed. The type II calcimimetics are phenylalkylamine derivatives that allosterically modulate the CaSR. *Cinacalcet* (SENSIPAR) (Figure 61–12) is FDA approved for the treatment of secondary hyperparathyroidism owing to chronic renal disease and for patients with hypercalcemia associated with parathyroid carcinoma. Cinacalcet lowers serum PTH levels in patients with normal or reduced renal function (Block *et al.*, 2004; Barman Balfour and Scott, 2005). In clinical trials, cinacalcet at 20- to 100-mg doses lowered PTH levels in a concentration-dependent manner by 15% to 50% and serum calcium \times phosphate product by 7% compared with placebo (Franceschini *et al.*, 2003). Cinacalcet also effectively reduced PTH in patients with primary hyperparathyroidism and provided sustained normalization of serum calcium without altering bone mineral density (Shoback *et al.*, 2003). Long-term control

Figure 61–12. Structure of cinacalcet. Cinacalcet exists as optical isomers. The *R*-enantiomer, which is more active, is shown.

of PTH levels was achieved during a 2-year study of cinacalcet, suggesting that resistance does not develop. There currently is insufficient information to know whether reducing serum PTH levels with cinacalcet improves outcomes such as risk of cardiovascular events, bone disease, or mortality.

Absorption, Fate, and Excretion. Cinacalcet (αR)-(-)- α -methyl-N-[3-[3-(trifluoromethylphenyl)propyl]-1-naphthalenemethanamine hydrochloride) exhibits first-order absorption, with maximal serum concentrations achieved 2 to 6 hours after oral administration. Maximal effects, as defined by the nadir of serum PTH, occur 2 to 4 hours after administration. After absorption, plasma concentrations of cinacalcet decrease with a half-life of 30 to 40 hours. Cinacalcet is eliminated primarily by renal excretion, with some 85% recovered in the urine after oral administration; the drug is also metabolized by multiple hepatic cytochromes, including CYP3A4, CYP2D6, and CYP1A2.

Cinacalcet is available in 30-, 60-, and 90-mg tablets. Optimal doses have not been defined. The recommended starting dose for treatment of secondary hyperparathyroidism in patients with chronic kidney disease on dialysis is 30 mg once daily, with a maximum of 180 mg/day. For treatment of parathyroid carcinoma, a starting dose of 30 mg twice daily is recommended, with a maximum of 90 mg four times daily. The starting dose is titrated upward every 2 to 4 weeks to maintain the PTH level between 150 and 300 pg/ml (secondary hyperparathyroidism) or to normalize serum calcium (parathyroid carcinoma).

Adverse Reactions. The principal adverse event with cinacalcet is hypocalcemia. Thus, the drug should not be used if the initial serum calcium concentration is less than 8.4 mg/dl; serum calcium and phosphorus concentrations should be measured within 1 week, and PTH should be measured within 4 weeks after initiating therapy or after changing dosage.

Hypocalcemia can be diminished by initiating therapy with a low dose and gradually titrating it as necessary or adjusting the dose when vitamin D and/or phosphate binders are administered concomitantly. Patients on hemodialysis with low-calcium dialysate need to be monitored closely for hypocalcemia. Seizure threshold is lowered by significant reductions in serum Ca^{2+} , so patients with a history of seizure disorders should be monitored especially closely. Finally, adynamic bone disease may develop if the PTH level is less than 100 pg/ml, and the drug should be discontinued or the dose decreased if the PTH level falls below 150 pg/ml.

Drug Interactions. Potential drug interactions can be anticipated with drugs that interfere with calcium homeostasis or that hinder cinacalcet absorption. Based on these considerations, potentially interfering drugs may include vitamin D analogs, phosphate binders, bisphosphonates, calcitonin, glucocorticoids, *gallium*, and *cisplatin*. The other category of drug interactions is for compounds metabolized by CYPs. Caution is recommended when cinacalcet is coadministered with inhibitors of CYP3A4 (e.g., *ketoconazole*, *erythromycin*, or *itraconazole*), CYP2D6 (many β adrenergic receptor blockers, *flecainide*, *vinblastine*, and most *tricyclic antidepressants*), and many other drugs.

INTEGRATED APPROACH TO OSTEOPOROSIS PREVENTION AND TREATMENT

Osteoporosis is a major and growing public health problem in developed nations, causing fractures in 30% to 50% of women and 15% to 30% of men. Important reductions in fracture risk can be achieved with appropriate lifelong attention to prevention. Regular physical activity of reasonable intensity is endorsed at all ages. For children and adolescents, adequate dietary calcium is important if peak bone mass is to reach the level appropriate for genetic endowment. Attention to nutritional status (*i.e.*, increased dietary calcium or calcium and/or vitamin D supplements) also may be required in the seventh decade and beyond. Although the administration of estrogen to women at menopause is a powerful intervention to preserve bone and protect against fracture, the detrimental effects of hormone-replacement therapy (HRT) have mandated a major reexamination on treatment options (*see* below and Chapter 57).

Pharmacological agents used to manage osteoporosis act by decreasing the rate of bone resorption and thereby slowing the rate of bone loss (antiresorptive therapy) or by promoting bone formation (anabolic therapy). Since bone remodeling is a coupled process, antiresorptive drugs ultimately decrease the rate of bone formation and therefore do not promote substantial gains in BMD. They nonetheless reduce fracture risk, particularly in the spine but also in the hip (for alendronate and risedronate). Increases in BMD during the first years of antiresorptive therapy represent a constriction of the remodeling space to a new steady-state level, after which BMD reaches a plateau (Figure 61–13). One consequence of this phenomenon is that therapeutic trials in osteoporosis must be of sufficient duration (*i.e.*, at least 2 years) to determine whether an increase in BMD represents anything more than a simple reduction in remodeling space.

Pharmacologic treatment of osteoporosis is aimed at restoring bone strength and preventing fractures. The long-standing centerpiece of this approach has been antiresorptive drugs such as the bisphosphonates, *estrogen*, or the selective estrogen receptor modulator (SERM) *raloxifene* and, to some extent, calcitonin. These drugs inhibit osteoclast-mediated bone loss, thereby reducing bone turnover.

Until recently, antiresorptives were the only drugs approved in the United States for treating osteoporosis. The increase in bone density that they produce is variable

Figure 61-13. Relative efficacy of different therapeutic interventions on bone mineral density of the lumbar spine.

Teriparatide (40 μg) (Neer *et al.*, 2001), PTH (25 μg) + estradiol (Lindsay *et al.*, 1997), alendronate (10 mg) (Lieberman *et al.*, 1995), estradiol (0.625 mg/day) (Writing Group for the PEPI Trial, 1996), raloxifene (120 mg) (Ettinger *et al.*, 1999), calcitonin (200 IU) (Reginster *et al.*, 1995). Typical results with placebo treatment underscore the inexorable bone loss without intervention. Some of the indicated treatment interventions involved combination therapy, and absolute comparisons should not be made.

and depends on the site and the particular drug; generally, the increase is less than 10% after 3 years (Figure 61-12). This situation changed in 2002 when the FDA approved the biologically active PTH fragment PTH(1-34) (*teriparatide*, FORTEO) for use in treating postmenopausal women with osteoporosis and to increase bone mass in men with primary or hypogonadal osteoporosis. For a review and proposed guidelines for teriparatide/PTH use, see Hodsmann *et al.* (2005). Therapeutic approaches likely will evolve considerably as newer treatment paradigms are developed and combinations of antiresorptive agents and PTH are introduced, and as the molecular physiology of osteoblast and osteoclast function is elucidated (Grey and Reid, 2005).

Antiresorptive Agents. Bisphosphonates. Bisphosphonates have emerged as the most effective drugs currently approved for prevention and treatment of osteoporosis. Second- and third-generation oral bisphosphonates alendronate and risedronate have sufficient potency to suppress bone resorption at doses that do not inhibit mineralization.

Alendronate is approved for prevention (5 mg daily, 35 mg once weekly) and treatment (10 mg daily, 70 mg once weekly) of

osteoporosis and for the treatment of glucocorticoid-associated osteoporosis. In fact, 3-, 7-, and 10-year studies of daily treatment with alendronate established its efficacy to increase bone mineral density, decrease bone turnover, and reduce the risk of vertebral fracture among women with osteoporosis (Bone *et al.*, 2004; Liberman *et al.*, 1995; Tonino *et al.*, 2000; Tucci *et al.*, 1996). The results of 10-year daily treatment with 10 mg of alendronate (with 500 mg of supplemental calcium) reported a 14% increase of lumbar spine BMD, with smaller increments at the trochanter, total hip, and femoral neck (Bone *et al.*, 2004). On reduction and discontinuation of treatment, BMD at the lumbar spine was maintained. Although significant decreases of BMD occurred at the total hip, femoral neck, and forearm, BMD at the lumbar spine, trochanter, total hip, and total body remained significantly above baseline values at year 10.

Alendronate conserves BMD in recently menopausal women (Hosking *et al.*, 1998), as well as in men, and also improves BMD in patients receiving glucocorticoids (Saag *et al.*, 1998).

For patients in whom oral bisphosphonates cause severe esophageal distress despite countermeasures, intravenous pamidronate (ARELIA) offers skeletal protection without causing adverse GI effects. For treatment of osteoporosis, pamidronate is given as a 3-hour infusion, 30 mg every 3 months. Oral pamidronate (150 or 300 mg daily) has been evaluated for treatment of postmenopausal osteoporosis. Both doses are effective; however, gastrointestinal side effects are frequent with the 300-mg dose. Oral risedronate has been approved for treatment of postmenopausal osteoporosis (5 mg daily or 35 mg once weekly) and glucocorticoid-induced osteoporosis. Risedronate improves BMD and reduces vertebral fracture incidence in postmenopausal women. Combined analysis of four placebo-controlled, randomized trials with risedronate in women with low bone density but no previous vertebral fracture displayed increases of lumbosacral and femoral neck BMD with a significant reduced risk of first vertebral compression fracture (Heaney *et al.*, 2002).

Thiazide Diuretics. Although not strictly antiresorptive, *thiazides* reduce urinary Ca^{2+} excretion and constrain bone loss in patients with hypercalciuria. Whether they will prove to be useful in patients who are not hypercalciuric is not clear, but data suggest that they reduce hip fracture risk. No sustained effect is observed (Schoofs *et al.*, 2003). *Hydrochlorothiazide*, 25 mg once or twice daily, may reduce urinary Ca^{2+} excretion substantially. Effective doses of thiazides for reducing urinary Ca^{2+} excretion generally are lower than those necessary for blood pressure control. For a more detailed discussion of thiazide diuretics, see Chapter 28.

Calcium. The physiological roles of Ca^{2+} and its use in the treatment of hypocalcemic disorders were discussed earlier. The rationale for using supplemental calcium to protect bone varies with time of life.

For preteens and adolescents, adequate substrate calcium is required for bone accretion. Controlled trials indicate that supplemental calcium promotes adolescent bone acquisition (Johnston *et al.*, 1992), but its impact on peak bone mass is not known. Higher calcium intake during the third decade of life is positively related to

the final phase of bone acquisition (Recker *et al.*, 1992). There is controversy about the role of calcium during the early years after menopause, when the primary basis for bone loss is estrogen withdrawal. Although little effect of calcium on trabecular bone has been reported, reduction in cortical bone loss with calcium supplementation has been observed, even in populations with high dietary calcium intake. In elderly subjects, supplemental calcium suppresses bone turnover, improves BMD, and decreases the incidence of fracture (Dawson-Hughes *et al.*, 1997).

Patients who are unable or unwilling to increase calcium by dietary means alone may choose from many palatable, low-cost calcium preparations. As noted previously, numerous oral calcium preparations are available, the most frequently prescribed being carbonate. Traditional dosing of calcium is about 1000 mg/day, nearly the amount present in a quart of milk. Added to the 500 to 600 mg of dietary calcium that typifies the diet of elderly men and women, this provides a total daily intake of about 1500 mg. More may be necessary to overcome endogenous intestinal calcium losses, but daily intakes of 2000 mg or more frequently are reported to be constipating. Calcium supplements are taken most often with meals to improve absorption.

Vitamin D and Its Analogs. Modest supplementation with vitamin D (400 to 800 IU/day) may improve intestinal Ca^{2+} absorption, suppress bone remodeling, and improve BMD in individuals with marginal or deficient vitamin D status. Although supplemental vitamin D appeared to reduce fracture incidence in several trials, a prospective study found that neither dietary calcium nor vitamin D intake was of major importance for the primary prevention of osteoporotic fractures in women (Michaelsson *et al.*, 2003). Nonetheless, because women commonly consume less than the recommended intake of vitamin D, use of supplemental vitamin D or increased consumption of such vitamin D-rich foods as dark fish may be prudent.

The use of calcitriol to treat osteoporosis is distinct from ensuring vitamin D nutritional adequacy. Here, the rationale is to suppress parathyroid function directly and reduce bone turnover. Calcitriol and the polar vitamin D metabolite 1α -hydroxycholecalciferol are used frequently in Japan and other countries, but experience in the United States has been mixed. Higher doses of calcitriol appear to be more likely to improve BMD, but at the risk of hypercalciuria and hypercalcemia; therefore, close scrutiny of patients and dose modification are required. Restriction of dietary calcium may reduce toxicity during calcitriol therapy (Gallagher and Goldgar, 1990). A low incidence of hypercalciuric and hypercalcemic complications of therapy in Japan may reflect relatively poor calcium intakes in that country.

Estrogen. There is an unambiguous relationship between estrogen deficiency and osteoporosis. Postmenopausal status or estrogen deficiency at any age significantly increases a patient's risk for osteoporosis and

fractures. Likewise, overwhelming evidence supports the positive impact of estrogen replacement on the conservation of bone and protection against osteoporotic fracture after menopause (Rosen and Kessenich, 1997) (*see* Chapter 57). The outcome of the Women's Health Initiative (WHI) studies, however, has strikingly altered the view of the therapeutic use of HRT for long-term prevention or treatment of osteoporosis. Significantly increased risks of heart disease and breast cancer were found (Anderson *et al.*, 2004; Cauley *et al.*, 2003). The consensus among experts now is to reserve HRT only for the short-term relief of vasomotor symptoms associated with menopause. HRT should be limited to osteoporosis prevention in women with significant ongoing vasomotor symptoms who are not at an increased risk for cardiovascular disease. An annual individualized risk-benefit reassessment should be performed on these patients.

Selective Estradiol Receptor Modulators (SERMs). Considerable work has been undertaken to develop estrogenic compounds with tissue-selective activities. One of these, raloxifene (EVISTA), acts as an estrogen agonist on bone and liver, is inactive on the uterus, and acts as an antiestrogen on the breast (*see* Chapter 57). In postmenopausal women, raloxifene stabilizes and modestly increases BMD and has been shown to reduce the risk of vertebral compression fracture (Ettinger *et al.*, 1999). Raloxifene is approved for both the prevention and treatment of osteoporosis. With the decreased use of estrogen for treating osteoporosis, the SERM raloxifene would seem to be an ideal alternative to HRT because raloxifene reduces the risk of vertebral fractures (albeit without a positive effect on nonvertebral fractures), breast cancer, and coronary events (coronary death, nonfatal myocardial infarction, and hospitalized acute coronary syndromes other than myocardial infarction) (Clemett and Spencer, 2000). The major drawback of raloxifene is that it can worsen vasomotor symptoms.

Calcitonin. Calcitonin inhibits osteoclastic bone resorption and modestly increases bone mass in patients with osteoporosis (Civitelli *et al.*, 1988); the largest increases occurred in patients with high intrinsic rates of bone turnover. One study showed that calcitonin nasal spray (200 units/day) reduced the incidence of vertebral compression fractures by about 40% in osteoporotic women (Chesnut *et al.*, 2000).

Combination Therapies

Because teriparatide stimulates bone formation, whereas bisphosphonates reduce bone resorption, it was predicted

that therapy combining the two would enhance the effect on BMD more than treatment with either one alone. However, addition of alendronate to PTH treatment provided no additional benefit for BMD and reduced the anabolic effect of PTH in both women and men (Black *et al.*, 2003; Body *et al.*, 2002; Finkelstein *et al.*, 2003). Sequential treatment with PTH(1–84) followed by alendronate increased vertebral BMD to a greater degree than alendronate or estrogen alone (Rittmaster *et al.*, 2000). Recent work underscores the beneficial action of alendronate in consolidating the gains in lumbar spine BMD achieved by antecedent teriparatide treatment in men.

Paget's Disease. Although most patients with Paget's disease require no treatment, factors such as severe pain, neural compression, progressive deformity, hypercalcemia, high-output congestive heart failure, and repeated fracture risk are considered indications for treatment. Bisphosphonates and calcitonin decrease the elevated biochemical markers of bone turnover, such as plasma alkaline phosphatase activity and urinary excretion of hydroxyproline. An initial course of bisphosphonate typically is given once daily or once weekly for 6 months. With treatment, most patients experience a decrease in bone pain over several weeks. Such treatment may induce long-lasting remission. If symptoms recur, additional courses of therapy can be effective. When etidronate is given at higher doses (10 to 20 mg/kg per day) or continuously for longer than 6 months, there is a substantial risk for osteomalacia. At lower doses (5 to 7.5 mg/kg per day), focal osteomalacia has been observed occasionally. Defective mineralization has not been observed with other bisphosphonates or with calcitonin.

Choice of optimal therapy for Paget's disease varies among patients. Bisphosphonates are the standard therapy. Intravenous pamidronate induces long-term remission following a single infusion. Zoledronate seems to exhibit greater response rates and a longer median duration of complete response (Major *et al.*, 2001). Compared with calcitonin, bisphosphonates have the advantage of oral administration, lower cost, lack of antigenicity, and generally fewer side effects. Resistance to calcitonin develops in most patients. However, calcitonin is highly reliable and may have a distinct skeletal analgesic property. Mithramycin (plicamycin) has been used in difficult cases of Paget's disease that do not respond to bisphosphonates or calcitonin. Therapeutic utility of this agent is limited by a high potential for hemorrhagic and other toxicities, and it is not generally recommended.

FLUORIDE

Fluoride is discussed because of its toxic properties and its effect on dentition and bone.

Absorption, Distribution, and Excretion. Human beings obtain fluoride predominantly from the ingestion of plants and water, with most absorption taking place in the intestine. The degree of fluoride absorption correlates with its water solubility. Relatively soluble compounds, such as sodium fluoride, are absorbed almost completely, whereas relatively insoluble compounds, such as cryolite

(Na_3AlF_6) and the fluoride found in bone meal (*fluoroapatite*) are absorbed poorly. A second route of absorption is through the lungs, and inhalation of fluoride present in dusts and gases constitutes the major route of industrial exposure.

Fluoride is distributed widely in organs and tissues but is concentrated in bone and teeth, and the skeletal burden is related to intake and age. Bone deposition reflects skeletal turnover; growing bone shows greater deposition than mature bone.

The kidneys are the major site of fluoride excretion. Small amounts of fluoride also appear in sweat, milk, and intestinal secretions; in a very hot environment, sweat can account for nearly 50% of total fluoride excretion.

Pharmacological Actions and Uses. Because it is concentrated in the bone, the radionuclide ^{18}F has been used in skeletal imaging. Sodium fluoride enhances osteoblast activity and increases bone volume. These effects may be bimodal, with low doses stimulating and higher doses suppressing osteoblasts; if true, this may account for the poorly mineralized and mechanically defective bone seen in some studies. In doses of 30 to 60 mg/day, fluoride increases trabecular bone mineral density in many, but not all, patients. In one controlled trial, fluoride increased lumbar spine density (cancellous bone) but decreased cortical bone mineral density; these changes were associated with a significant increase in peripheral fractures and stress fractures (Riggs *et al.*, 1990). In one study, sustained-release fluoride, which provided lower blood fluoride levels, increased bone mineral density and decreased fractures (Pak *et al.*, 1994). Intermittent courses of slow-release fluoride also have been evaluated. When the total fluoride dose was kept constant (Balena *et al.*, 1998), there was no difference in outcome between continuous and intermittent fluoride treatment; notably, both regimens increased cancellous and trabecular thickness to the same extent. *Unfortunately, increased bone mass is not synonymous with increased bone strength* (Riggs *et al.*, 1990). Thus, the apparent effects of fluoride in osteoporosis are slight compared with those achieved with PTH or other agents.

Other pharmacological actions of fluoride can be classified as toxic, as described below. Fluoride inhibits several enzyme systems and diminishes tissue respiration and anaerobic glycolysis.

Acute Poisoning. Acute fluoride poisoning usually results from accidental ingestion of fluoride-containing insecticides or rodenticides. Initial symptoms (salivation, nausea, abdominal pain, vomiting, and diarrhea) are secondary to the local action of fluoride on the intestinal mucosa. Systemic symptoms are varied and severe: increased irritability of the central nervous system consistent with the Ca^{2+} -binding effect of fluoride and the resulting hypocalcemia; hypotension, presumably owing to central vasomotor depression as well as direct cardiotoxicity; and stimulation and then depression of respiration. Death can result from respiratory paralysis or cardiac failure. The lethal dose of sodium fluoride for human beings is about 5 g, although there is considerable variation. Treatment includes the intravenous administration of glucose in saline and gastric lavage with lime water (0.15% calcium hydroxide solution) or other Ca^{2+} salts to precipitate the fluoride. Calcium gluconate is given intravenously for tetany; urine volume is kept high with vigorous fluid resuscitation.

Chronic Poisoning. In human beings, the major manifestations of chronic ingestion of excessive fluoride are osteosclerosis and mottled enamel. Osteosclerosis is characterized by increased bone density secondary both to elevated osteoblastic activity and to the

replacement of hydroxyapatite by the denser fluoroapatite. The degree of skeletal involvement varies from changes that are barely detectable radiologically to marked cortical thickening of long bones, numerous exostoses scattered throughout the skeleton, and calcification of ligaments, tendons, and muscle attachments. In its severest form, it is a disabling and crippling disease.

Mottled enamel, or dental fluorosis, was first described more than 60 years ago. In very mild mottling, small, opaque, paper-white areas are scattered irregularly over the tooth surface. In severe cases, discrete or confluent, deep brown- to black-stained pits give the tooth a corroded appearance. Mottled enamel results from a partial failure of the enamel-forming ameloblasts to elaborate and lay down enamel. Since mottled enamel is a developmental injury, fluoride ingestion following the eruption of teeth has no effect. Mottling is one of the first visible signs of excess fluoride intake during childhood. Continuous use of water containing about 1 ppm of fluoride may result in very mild mottling in 10% of children; at 4 to 6 ppm the incidence approaches 100%, with a marked increase in severity.

Severe dental fluorosis formerly occurred in regions where local water supplies had a very high fluoride content (*e.g.*, Pompeii, Italy, and Pike's Peak, Colorado). Current regulations in the United States require lowering the fluoride content of the water supply or providing an alternative source of acceptable drinking water for affected communities. Sustained consumption of water with a fluoride content of 4 mg/L (4 ppm) is associated with deficits in cortical bone mass and increased rates of bone loss over time (Sowers *et al.*, 1991).

Fluoride and Dental Caries. After a new water supply was established, children in Bauxite, Arkansas, had a much higher incidence of caries than those who had been exposed to the former fluoride-containing water. Subsequent studies established definitely that supplementation of water fluoride content to 1.0 ppm is a safe and practical intervention that substantially reduces the incidence of caries in permanent teeth.

There are partial benefits for children who begin drinking fluoridated water at any age; however, optimal benefits are obtained at ages before permanent teeth erupt. Topical application of fluoride solutions by dental personnel appears to be particularly effective on newly erupted teeth and can reduce the incidence of caries by 30% to 40%. Dietary fluoride supplements should be considered for children younger than age 12 years whose drinking water contains less than 0.7 ppm fluoride. Conflicting results have been reported from studies of fluoride-containing toothpastes.

Adequate incorporation of fluoride into teeth hardens the outer layers of enamel and increases resistance to demineralization. Fluoride deposition apparently involves exchange with hydroxyl or citrate anions in the enamel apatite crystal surface. The mechanism by which fluoride prevents caries is not completely understood. There is no convincing evidence that fluoride from any source reduces the development of caries after the permanent teeth are completely formed (usually about age 14).

The fluoride salts usually employed in dentifrices are *sodium fluoride* and *stannous fluoride*. Sodium fluoride also is available in a variety of preparations for oral and topical use, including tablets, drops, rinses, and gels.

Since its inception, regulation of the fluoride concentration of community water supplies periodically has encountered vocal opposition, including allegations of putative adverse health consequences of fluoridated water. Careful examination of these issues indicates that cancer and all-cause mortalities do not differ significantly between communities with fluoridated and nonfluoridated water (Richmond, 1985).

CLINICAL SUMMARY

Increasing evidence supports the concept that regular physical activity, adequate calcium intake, and lifestyle changes have a positive impact on bone remodeling, constrain bone loss, and reduce fracture risk. Antiresorptive agents such as bisphosphonates, estrogen, selective estrogen response modulators (SERMs), and calcium, will slow bone resorption. Recombinant human PTH has been approved for the treatment of osteoporosis and provides significant intervention for restoring normal bone mass.

Cinacalcet, a drug that acts directly on the parathyroid calcium-sensing receptor, also has been approved, providing a novel approach to decreasing PTH secretion in secondary hyperparathyroidism and parathyroid carcinoma. Improved assays for measuring biologically active and inactive forms of PTH likely will facilitate the diagnosis and treatment of diseases associated with PTH resistance.

Estrogen-replacement therapy, once a mainstay treatment for osteoporosis in women, has been curtailed by the findings of the Women's Health Initiative: Despite estrogen's beneficial effects on bone and fracture risk, alone or in combination with *progestin*, estrogen promotes an array of serious adverse cardiovascular consequences. The FDA now recommends that estrogen be reserved for women at significant risk of osteoporosis who cannot take other medications.

SECTION XIII

Dermatology

CHAPTER

62

DERMATOLOGICAL PHARMACOLOGY

Lindy P. Fox, Hans F. Merk, and David R. Bickers

The skin has many essential functions, including protection, thermoregulation, immune responsiveness, biochemical synthesis, sensory detection, and social and sexual communication. Therapy to correct dysfunction in any of these activities may employ chemical agents that can be delivered systemically, intralesionally, or topically and physical agents to which the skin can be exposed, including ultraviolet and ionizing radiation.

A unique aspect of dermatological pharmacology is the direct accessibility of the skin as a target organ for diagnosis and treatment (Figure 62–1). Topical agents are employed alone or in conjunction with phototherapy and/or systemic medications in the management of most dermatological conditions. Therapeutic agents can reach epidermal keratinocytes and immunocompetent cells in the epidermis and the underlying dermis that are involved in the pathogenesis of numerous cutaneous diseases. Topical agents can be applied directly to the skin but must penetrate into the tissue to achieve efficacy. Appropriate use of topical agents requires an appreciation of the factors that influence percutaneous absorption.

Antibacterial, antiviral, and antifungal agents are employed widely both topically and systemically. Oral antimalarial, cytotoxic, and immunosuppressive agents and antihistamines frequently are used for treatment of dermatological diseases. *Calcipotriene*, a vitamin D analog, is used topically for psoriasis. Ultraviolet radiation

therapy is a frequent mode of treatment that can be administered independently or in combination with photosensitizers. The pathogenetic role of ultraviolet radiation in cutaneous cancers has led to the development of sunscreens to reduce or prevent premalignant and malignant skin lesions. An improved understanding of the pathogenesis of immunologic disorders has led to a number of novel biological agents that hold considerable promise to match the efficacy of *glucocorticoids* and other immunosuppressive agents in dermatologic diseases, possibly with fewer serious adverse effects.

THE STRUCTURE AND FUNCTION OF SKIN

The skin acts as a two-way barrier to prevent absorption or loss of water and electrolytes. The barrier resides in the outermost layer of the epidermis, the stratum corneum, as evidenced by approximately equal rates of penetration of chemicals through isolated stratum corneum or whole skin. Having lost their nuclei and cytoplasmic organelles, the corneocytes of the stratum corneum are nonviable. The cells are flattened, and the fibrous keratins are aligned into disulfide cross-linked macrofibers in association with filaggrin, the major protein component of the keratohyalin granule. Each cell develops a cornified enve-

Figure 62–1. Skin as a pharmacological target. The skin is a multicellular organ containing numerous indigenous cells and structures as well as circulating cells that are potential targets for pharmacological intervention (black arrows). UVB, ultraviolet radiation (290–320 nm); PUVA, psoralen activated by UVA radiation (320–400 nm).

lope resulting from cross-linking of involucrin and keratohyalin, forming an insoluble exoskeleton that acts as a rigid scaffold for the internal keratin filaments. The intercellular spaces are filled with hydrophobic lamellar lipids derived from membrane-coating granules. The combination of hydrophilic cornified cells in hydrophobic intercellular material provides a barrier to both hydrophilic and hydrophobic substances (Ebling, 1993). In dermatological diseases, the thickened epidermis may further diminish the penetration of pharmacological agents into the dermis.

DRUG DELIVERY IN DERMATOLOGICAL DISEASES

Topical Preparations

Molecules can penetrate the skin by three routes: through intact stratum corneum, through sweat ducts, or through the sebaceous follicle. The surface of the stratum corneum presents more than 99% of the total skin surface available for percutaneous drug absorption. Passage through this outermost layer is the rate-limiting step for percutaneous absorption. The major steps involved in percutaneous absorption include the establishment of a concentration gradient, which provides the driving force for drug movement across the skin; release of drug from the vehicle (partition coefficient); and drug diffusion across the layers of the skin (diffusion coefficient). Preferable characteristics of topical drugs include low molecular mass (600 Da), adequate solubility in oil and water, and a high partition coefficient (Barry, 2004). Except for very small particles, water-soluble

ions and polar molecules do not penetrate intact stratum corneum. The relationship of these factors to one another is summarized in the following equation:

$$J = C_{\text{veh}} \cdot K_m \cdot D/x$$

where J is the rate of absorption, C_{veh} is the concentration of drug in vehicle, K_m is the partition coefficient, D is the diffusion coefficient, and x is the thickness of stratum corneum (Piacquadio and Kligman, 1998).

Metabolism

The viable epidermis contains a variety of enzyme systems capable of metabolizing drugs that reach this compartment, including CYPs, epoxide hydrolase, transferases such as *N*-acetyl-transferases, and diverse enzymes including glucuronyl transferases and sulfatases (Baron *et al.*, 2001; Du *et al.*, 2004). A specific CYP isoform, CYP26A1, metabolizes retinoic acid and may control its level in the skin (White *et al.*, 1997; Baron *et al.*, 2001). In addition, transporter proteins that influence influx (OATP) or efflux (MRD and LRD) of certain xenobiotics are present in human keratinocytes (Baron *et al.*, 2001). While substrate turnover is considerably less than that for hepatic CYPs, these enzymes influence concentrations of xenobiotics in the skin.

General Guidelines for Topical Therapy

Dosage. An amount of topical medication sufficient to cover affected body surfaces in repeated applications must be dispensed to the patient. A general rule is that approximately 30 g is required to cover the body surface.

Regional Anatomic Variation. Permeability generally is inversely proportional to the thickness of the stratum corneum. Drug penetration is higher on the face, in intertriginous areas, and especially in the perineum. Consequently, the skin in these regions may be more susceptible to irritant and allergic contact reactions. Skin sites that are naturally occluded by apposing surfaces, such as the axillae, groin, and inframammary areas, also may be vulnerable to drug-related toxicity such as atrophy from potent topical glucocorticoids.

Altered Barrier Function. In many dermatological diseases, such as psoriasis, the stratum corneum is abnormal, and barrier function is compromised. In these settings, percutaneous absorption may be increased to the point that standard drug doses can result in systemic toxicity (e.g., hypothalamic–pituitary–adrenal axis suppression can result from systemic absorption of potent topical glucocorticoids).

Hydration. Drug absorption is increased with *hydration*, defined as an increase in the water content of the stratum corneum that is produced by inhibiting transepidermal loss of water. Methods of hydration include occlusion with an impermeable film, application of lipophilic occlusive vehicles such as ointments, and soaking dry skin before occlusion.

Vehicle. Many factors influence the rate and extent to which topical medications are absorbed. Most topical medications are incorporated into bases or vehicles that are applied directly to the skin. The chosen vehicle can influence drug absorption and provide therapeutic efficacy; for example, an ointment is more occlusive and has superior emollient properties than a cream or a lotion base.

Newer vehicles include liposomes and microgel formulations. Liposomes are concentric spherical shells of phospholipids in an aqueous medium that may enhance percutaneous absorption. Variations in size, charge, and lipid content can influence liposome function substantially. Liposomes penetrate compromised epidermal barriers more efficiently (Korting *et al.*, 1991). Microgels are polymers that may enhance solubilization of certain drugs, thereby enhancing penetration and diminishing irritancy.

Transfersomes are a drug-delivery technology based on highly deformable, ultraflexible lipid vesicles that penetrate the skin when applied nonocclusively (Barry, 2004). Finally, pressure waves generated by intense laser radiation can permeabilize the stratum corneum and may provide a novel system for transdermal drug delivery.

Age. Children have a greater ratio of surface area to mass than adults, so a given amount of topical drug results in a greater systemic dose. Based on transepidermal water loss and percutaneous absorption studies, term infants seem to possess a stratum corneum with barrier properties comparable with adults.

Application Frequency. Topical agents often are applied twice daily. For certain drugs, once-daily application of a larger dose may be equally effective as more frequent applications of smaller doses. The stratum corneum may act as a drug reservoir that allows gradual penetration into the viable skin layers over a prolonged period. Intermittent pulse therapy—treatment for several days or weeks alternating with treatment-free periods—may prevent development of tachyphylaxis associated with drugs such as topical glucocorticoids.

Intralesional Administration. Intralesional drug administration is used mainly for inflammatory lesions but also can be used for treatment of warts and selected neoplasms. Medications injected intralesionally have the advantages of direct contact with the underlying pathologic process, no first-pass metabolism, and the formation of a slowly absorbed depot of drug. In considering the use of intralesional medications, it is important to be cognizant of the possibility of systemic absorption of the medication.

Systemic Administration. Systemic administration of medication in dermatology usually involves oral ingestion but also can involve intramuscular (e.g., *methotrexate* and glucocorticoids), intravenous (e.g., *immunoglobulin* and *alefacept*), or subcutaneous administration (e.g., *efalizumab* and *etanercept*).

GLUCOCORTICOIDS

Glucocorticoids are prescribed frequently for their immunosuppressive and antiinflammatory properties. They are administered locally, through topical and intralesional routes, and systemically, through intramuscular, intravenous, and oral routes. Mechanisms of glucocorticoid action are numerous, as discussed in Chapter 59. These include apoptosis of lymphocytes, inhibitory effects on the arachidonic acid cascade, depression of production of many cytokines, and myriad effects on inflammatory cells.

Shortly after the synthesis of *hydrocortisone* in 1951, topical glucocorticoids were recognized as effective agents for the treatment of skin disease. With the development of appropriate vehicles, these agents rapidly became the mainstay of therapy for many inflammatory skin diseases.

Topical glucocorticoids have been grouped into seven classes in order of decreasing potency (Table 62–1); many of the more potent drugs have a fluorinated hydrocortisone backbone. Potency traditionally is measured using a vasoconstrictor assay in which an agent is applied to skin under occlusion, and the area of skin blanching is assessed. Vasoconstriction-induced blanching can be readily quantified by this methodology, which has been verified using laser–Doppler perfusion imaging (Sommer *et*

Table 62-1

Potency of Selected Topical Glucocorticoids

CLASS OF DRUG*	GENERIC NAME, FORMULATION	TRADE NAME
1	Betamethasone dipropionate cream, ointment 0.05% (in optimized vehicle)	DIPROLENE
	Clobetasol propionate cream, ointment 0.05%	TEMOVATE
	Diflorasone diacetate ointment 0.05%	PSORCON
	Halobetasol propionate ointment 0.05%	ULTRAVATE
2	Amcinonide ointment 0.1%	CYCLOCORT
	Betamethasone dipropionate ointment 0.05%	DIPROSONE, others
	Desoximetasone cream, ointment 0.25%, gel 0.05%	TOPICORT
	Diflorasone diacetate ointment 0.05%	FLORONE, MAXIFLOR
	Fluocinonide cream, ointment, gel 0.05%	LIDEX, LIDEX-E, FLUONEX
	Halcinonide cream, ointment 0.1%	HALOG, HALOG-E
3	Betamethasone dipropionate cream 0.05%	DIPROSONE, others
	Betamethasone valerate ointment 0.1%	BETATREX, others
	Diflorasone diacetate cream 0.05%	FLORONE, MAXIFLOR
	Triamcinolone acetonide ointment 0.1%, cream 0.5%	ARISTOCORT A, others
4	Amcinonide cream 0.1%	CYCLOCORT
	Desoximetasone cream 0.05%	TOPICORT LP
	Fluocinolone acetonide cream 0.2%	SYNALAR-HP
	Fluocinolone acetonide ointment 0.025%	SYNALAR
	Flurandrenolide ointment 0.05%, tape 4 $\mu\text{g}/\text{cm}^2$	CORDRAN
	Hydrocortisone valerate ointment 0.2%	WESTCORT
	Triamcinolone acetonide ointment 0.1%	KENALOG, ARISTOCORT
	Mometasone furoate cream, ointment 0.1%	ELOCON
5	Betamethasone dipropionate lotion 0.05%	DIPROSONE, others
	Betamethasone valerate cream, lotion 0.1%	BETATREX, others
	Fluocinolone acetonide cream 0.025%	SYNALAR
	Flurandrenolide cream 0.05%	CORDRAN SP
	Hydrocortisone butyrate cream 0.1%	LOCOID
	Hydrocortisone valerate cream 0.2%	WESTCORT
	Triamcinolone acetonide cream, lotion 0.1%	KENALOG
	Triamcinolone acetonide cream 0.025%	ARISTOCORT
6	Aclometasone dipropionate cream, ointment 0.05%	ACLOVATE
	Desonide cream 0.05%	TRIDESILON, DESOWEN
	Fluocinolone acetonide cream, solution 0.01%	SYNALAR
7	Dexamethasonesodium phosphate cream 0.1%	DECADRON
	Hydrocortisone cream, ointment, lotion 0.5%, 1.0%, 2.5%	HYTONE, NUTRICORT, PENECORT

*Class 1 is most potent; class 7 is least potent. Adapted from Arndt, K.A. *Manual of Dermatologic Therapeutics*, 4th ed. Little, Brown, and Company, Boston, 1989, p. 234, with permission.

al., 1998). Other assays of glucocorticoid potency involve suppression of erythema and edema after experimentally induced inflammation and the psoriasis bioassay, in which the effect of steroid on psoriatic lesions is quantified.

Therapeutic Uses. Many inflammatory skin diseases respond to topical or intralesional administration of glucocorticoids. Absorption varies among body areas; the steroid is selected on the basis of its potency, the site of involvement, and the severity of the skin disease. Often, a

more potent steroid is used initially, followed by a less potent agent. Most practitioners become familiar with one glucocorticoid in each class so as to select the appropriate strength of drug. Twice-daily application is sufficient, and more frequent application does not improve response (Yohn and Weston, 1990). In general, only nonfluorinated glucocorticoids should be used on the face or in occluded areas such as the axillae or groin.

Intralesional preparations of glucocorticoids include insoluble preparations of *triamcinolone acetonide* (KENALOG-10 and others) and *triamcinolone hexacetonide* (KENOLOG-40 AND ARISTOSPAN), which solubilize gradually and therefore have a prolonged duration of action.

Toxicity and Monitoring. Chronic use of class I topical glucocorticoids can cause skin atrophy, striae, telangiectasias, purpura, and acneiform eruptions. Because perioral dermatitis and rosacea can develop after the use of fluorinated compounds on the face, they should not be used in this site.

Systemic Glucocorticoids

Therapeutic Uses. Systemic glucocorticoid therapy is used for severe dermatological illnesses. In general, it is best to reserve this method for allergic contact dermatitis to plants (*e.g.*, poison ivy) and for life-threatening vesiculobullous dermatoses such as pemphigus vulgaris and bullous pemphigoid. Chronic administration of oral glucocorticoids is problematic, given the side effects associated with their long-term use (*see* Chapter 59).

Daily morning dosing with *prednisone* generally is preferred, although divided doses are used occasionally to enhance efficacy. Fewer side effects are seen with alternate-day dosing, and if required for chronic therapy, prednisone is tapered to every other day as soon as it is practical. Pulse therapy using large intravenous doses of *methylprednisolone sodium succinate* (SOLU-MEDROL) is an option for severe resistant pyoderma gangrenosum, pemphigus vulgaris, systemic lupus erythematosus with multisystem disease, and dermatomyositis (Werth, 1993). The dose usually is 0.5 g to 1 g given over 2 to 3 hours. More rapid infusion has been associated with increased rates of hypotension, electrolyte shifts, and cardiac arrhythmias.

Toxicity and Monitoring. Oral glucocorticoids have numerous systemic effects, as discussed in Chapter 59. Most side effects are dose-dependent. Long-term use is associated with a number of complications, including psy-

chiatric problems, cataracts, myopathy, osteoporosis, avascular bone necrosis, glucose intolerance or overt diabetes mellitus, and hypertension. In addition, psoriatic patients treated with parenteral or topical glucocorticoids may have a pustular flare, particularly if the steroid is tapered rapidly.

RETINOIDS

Retinoids include natural compounds and synthetic derivatives of retinol that exhibit vitamin A activity. Retinoids have many important functions throughout the body, including roles in vision, regulation of cell proliferation and differentiation and bone growth, immune defense, and tumor suppression (Chandraratna, 1998). Because vitamin A affects normal epithelial differentiation, it was investigated as a treatment for cutaneous disorders but was abandoned initially because of unfavorable side effects. Molecular modifications yielded compounds with vastly improved margins of safety. First-generation retinoids include *retinol*, *tretinoin* (all-*trans*-retinoic acid), *isotretinoin* (13-*cis*-retinoic acid), and *alitretinoin* (9-*cis*-retinoic acid). Second-generation retinoids, also known as *aromatic retinoids*, were created by alteration of the cyclic end group and include *acitretin*. Third-generation retinoids contain further modifications and are called *arotinoids*. Members of this generation include *tazarotene* and *bexarotene*. *Adapalene*, a derivative of naphthoic acid with retinoid-like properties, does not fit precisely into any of the three generations.

Retinoic acid (RA) exerts its effects on gene expression by activating two families of receptors—*retinoic acid receptors* (RARs) and the *retinoid X receptors* (RXRs)—that are members of the thyroid/steroid hormone receptor superfamily (Winterfield *et al.*, 2003). Retinoids (ligands) bind transcription factors (nuclear receptors), and the ligand–receptor complex then binds to the promoter regions of target genes to regulate their expression (Saurat, 1999). The gene products formed contribute to the desirable pharmacological effects of these drugs and their unwanted side effects (Shroot, 1998). Additional complexity arises because each receptor has three isoforms (α , β , and γ) that form homo- and heterodimers. Retinoid-responsive tissues express one or more RAR and RXR subtypes in various combinations that determine activity locally (Petkovich, 2001). Human skin contains mainly RAR α and RAR β .

First- and second-generation retinoids can bind to several retinoid receptors because of the flexibility imparted by

their alternating single and double bonds. This relative lack of receptor specificity may lead to greater side effects. The structures of third-generation retinoids are much less flexible than those of earlier-generation retinoids and therefore interact with fewer retinoid receptors (Chandraratna, 1998).

Acute retinoid toxicity is similar to vitamin A intoxication. Side effects of retinoids include dry skin, nosebleeds from dry mucous membranes, conjunctivitis, and hair loss. Less frequently, musculoskeletal pain, pseudotumor cerebri, and mood alterations occur. Oral retinoids are potent teratogens and cause severe fetal malformations. Because of this, *systemic retinoids should be used with great caution in females of childbearing potential.*

Retinoids are used in the treatment of diverse diseases and are effective in the treatment of inflammatory skin disorders, skin malignancies, hyperproliferative disorders, photoaging, and many other disorders. Topical retinoids can normalize disordered keratinization in sebaceous follicles and reduce inflammation, and they may enhance the penetration of other topical medications. Specific retinoids and their uses in the treatment of dermatologic disorders are discussed below.

Tretinoin

Tretinoin (RETIN-A, others) has been used in the treatment of acne vulgaris for almost four decades. A primary use for tretinoin is to reduce the hyperkeratinization that leads to microcomedone formation, the initial lesion in acne. Follicular corneocytes become less cohesive as a result of shedding of desmosomes, decreasing tonofilaments and increasing keratinocyte autolysis and intracellular deposition of glycogen (Wolff *et al.*, 1975).

In addition to treating acne, tretinoin improves photo-damaged human skin (Kligman *et al.*, 1986). Epidermal effects include increased epidermal and granular layer thickness, decreased melanocytic activity, and increased secretion of a glycosaminoglycan-like substance into the intercellular space. In the dermis, blood vessel vasodilation and angiogenesis and increased papillary dermal collagen synthesis have been documented. Clinically, this translates to modest attenuation of fine and coarse wrinkling, smoother texture, increased pinkness, and diminished hyperpigmentation (Green *et al.*, 1993). In clinical trials, wrinkling, mottled hyperpigmentation, and roughness improved in most patients treated with retinoids, a response rate roughly twice that of control subjects who used sunscreens and emollients (Stern, 2004). Ultraviolet radiation also activates growth factor and cytokine receptors on epidermal keratinocytes and dermal cells. These receptors stimulate mitogen-activated protein kinases (MAP kinases), which, in turn, induce c-Jun

expression. This transcription factor heterodimerizes with c-Fos to form activated AP-1 complexes that induce the transcription of metalloproteinases that degrade dermal collagens and other proteins (Fisher and Voorhees, 1998).

Tretinoin is approved for the treatment of acne vulgaris and as an adjunctive agent for treating photoaging. Topical preparations contain from 0.01% to 0.1% tretinoin in cream, gel, and solution formulations. Initiation of therapy with lower-strength preparations and progression to higher strengths may be useful because individual sensitivity is unpredictable. Tretinoin formulations with a cream base are indicated for dry skin, whereas gel-based formulations are indicated for oily skin. The medication is applied once daily before bedtime to minimize photodegradation. Maximum clinical response in acne may require several months, and maintenance therapy is necessary. A formulation of tretinoin with active drug incorporated into microsponges (RETIN-A MICRO) has been developed (Gollnick and Krautheim, 2003). The microsponges not only decrease irritation by slowing the release of the medication but also may enhance efficacy by targeting delivery to the sebaceous follicle (Webster, 1998).

A 0.5% emollient cream formulation of tretinoin (RENOVA) is one formulation approved for treatment of photoaged skin. Nightly application produces maximum response within 1 year, and application one to three times weekly is said to maintain improvement (Green *et al.*, 1993). Treatment must be combined with a rigorous program of photoprotection, including sunscreens, sun avoidance, and photoprotective clothing.

Adapalene

Adapalene (DIFFERIN), a derivative of naphthoic acid, is a synthetic retinoid-like compound that is available in solution, cream, and gel formulations for topical use. In addition to displaying typical retinoid effects, it also has anti-inflammatory properties. Adapalene has similar efficacy to tretinoin, but unlike tretinoin, it is stable in sunlight (Weiss and Shavin, 1998) and tends to be less irritating. The structure for adapalene is shown below.

ADAPALENE

Tazarotene

Tazarotene (TAZORAC) is a third-generation retinoid approved for the treatment of psoriasis and acne vulgaris (Duvic and Marks, 1998). This retinoid binds to all three RARs. In mice, tazarotene blocks ornithine decarboxylase activity, which is associated with cell proliferation and hyperplasia. In cell culture, it suppresses markers of epidermal inflammation and inhibits cornification of the keratinocyte.

Tazarotene gel, applied once daily to dry skin, may be used as monotherapy or in combination with other medications, such as topical corticosteroids, for the treatment of localized plaque psoriasis. This is the first topical retinoid approved by the Food and Drug Administration (FDA) for the treatment of psoriasis. Side effects of burning, itching, and skin irritation are relatively common, and patients should avoid sun exposure.

Alitretinoin

Alitretinoin (PANRETIN) is a retinoid that binds all types of retinoid receptors and is approved only for treatment of the skin manifestations of Kaposi's sarcoma. Approximately 50% of patients in an open-label trial responded positively to topical application of this drug (Walmsley *et al.*, 1999).

Toxicity and Monitoring. Adverse effects of all topical retinoids include erythema, desquamation, burning, and stinging. These effects often decrease spontaneously with time and are lessened by concomitant use of emollients. Photosensitivity can occur as a result of epidermal thinning, with a resulting greater potential for phototoxic reactions such as sunburn. Although there is little systemic absorption of tretinoin and no alteration in plasma vitamin A levels with its use as a topical agent, most physicians do not prescribe tretinoin during pregnancy, and the FDA lists it as category X for pregnant women.

Isotretinoin

Oral isotretinoin (ACUTANE) is approved for the treatment of severe nodulocystic acne vulgaris. The drug has remarkable efficacy in severe acne and may induce prolonged remissions after a single course of therapy. It normalizes keratinization in the sebaceous follicle, reduces sebocyte number with decreased sebum synthesis, and reduces *Propionibacterium acnes*, the organism that produces inflammation in acne (Layton and Cunliffe, 1992; Harper and Thiboutot, 2003).

Therapeutic Uses. Isotretinoin is administered orally. The recommended dose is 0.5 to 2 mg/kg per day for 15 to

20 weeks. Lower doses are effective but are associated with shorter remissions. The cumulative dose also is important, so smaller doses for longer periods can be used to achieve a total dose in the range of 120 mg/kg (Smith, 1999). Approximately 40% of patients will relapse, usually within 3 years of therapy, and may require retreatment (Layton *et al.*, 1993). Preteens and patients with acne conglobata or androgen excess are at increased risk of relapse. However, mild relapses may respond to conventional management with topical and systemic antiacne agents.

Isotretinoin is prescribed for severe, recalcitrant nodular acne, moderate acne unresponsive to oral antibiotics, and acne that produces scarring. It also is used commonly for other related disorders, such as gram-negative folliculitis, acne rosacea, and hidradenitis suppurativa (Leyden, 1988).

Toxicity and Monitoring. A consensus statement regarding the safe and optimal use of isotretinoin has been published (Goldsmith *et al.*, 2004). Dose-dependent adverse effects on the skin and mucous membranes are observed most commonly, including cheilitis, mucous membrane dryness, epistaxis, dry eyes, blepharoconjunctivitis, erythematous eruptions, and xerosis. Alteration of epidermal surfaces may facilitate *Staphylococcus aureus* colonization and, rarely, subsequent infection. Hair loss, exuberant granulation tissue formation, photosensitivity, and dark adaptation dysfunction are rarer occurrences.

Systemic side effects generally are less significant with short-term therapy. Transitory elevations in serum transaminases occur rarely. Hyperlipidemia is frequent, with 25% of patients developing increased triglyceride levels and, less frequently, increased cholesterol and low-density lipoproteins and decreased high-density lipoproteins (Ber-shad *et al.*, 1985). Myalgia and arthralgia are common complaints. Headaches occur and rarely are a symptom of pseudotumor cerebri. Use of isotretinoin concomitantly with *tetracycline* antibiotics may increase the risk of pseudotumor cerebri. Controversy exists regarding the potential linking of isotretinoin to depression, suicidal thoughts, and suicide. Epidemiological studies to date have not shown an association between isotretinoin and depression or suicide, perhaps because acne itself may be a risk factor for depression. Some physicians have proposed a causal relationship with mood changes and depression in a limited number of patients. These uncontrolled clinical observations have not been examined in a rigorous, prospective manner. In addition, there is a paucity of data on the effect of retinoids on adult brain function (Goldsmith *et al.*, 2004). Long-term therapy may produce skeletal side effects, including diffuse idiopathic skeletal hyperostoses, extraskelatal ossification (particularly at tendinous

insertions), and premature epiphyseal closure in children (DiGiovanna, 2001).

Teratogenicity is a major problem; it occurs if the drug is given within the first 3 weeks of gestation and is not dose-related. Teratogenic effects include CNS, cardiac, thymus, and craniofacial abnormalities. Spontaneous abortion occurs in one-third of patients (Lammer *et al.*, 1985). *Pregnancy is an absolute contraindication to the use of isotretinoin*. Females of childbearing potential should initiate therapy at the beginning of a normal menstrual period after giving informed consent and obtaining two negative pregnancy tests. Two forms of birth control (one of which must be surgical or hormonal) must be practiced during therapy and for 1 month both before beginning therapy and after completion of therapy; pregnancy tests should be repeated monthly. Patients should not donate blood for transfusion during treatment and for 1 month after treatment.

Other laboratory evaluations should include a complete blood count, liver function tests, and fasting lipid determination before initiating therapy. Testing should be repeated after 1 month of therapy and thereafter only as abnormalities indicate.

Acitretin

Acitretin (SORIATANE) is the major metabolite of *etretinate*, an aromatic retinoid that formerly was approved for psoriasis but withdrawn from the market because of its undesirable pharmacokinetics. Acitretin has an elimination half-life of 2 to 3 days.

Acitretin is readily esterified *in vivo* to produce *etretinate*, especially in the presence of *ethanol* (Katz *et al.*, 1999). The optimal dosing range for acitretin in adults is 25 to 50 mg/day, providing efficacy with an acceptable level of side effects. Improvement of plaque psoriasis requires up to 3 to 6 months for optimal results. As monotherapy, acitretin has an overall rate of complete remission of less than 50% (Ling, 1999); response rates are higher when the drug is combined with other modalities (Lebwohl, 1999; Lebwohl *et al.*, 2004). At doses of 10 to 25 mg/day, both pustular and erythrodermic psoriasis usually respond more rapidly than common plaque psoriasis. Excellent control of these conditions usually can be achieved with acitretin (Goldfork and Ellis, 1998). Common side effects include dry skin and mucous membranes, xerophthalmia, and hair thinning. Less frequently, arthralgias and decreased night vision have been noted. Serious side effects (*e.g.*, hepatotoxicity or pseudotumor cerebri) are rare (Katz *et al.*, 1999). *Acitretin is a potent teratogen and should not be used by females who intend to become pregnant during therapy or at any time for at least 3 years following discontinuation of therapy.*

The same precautions regarding blood donation described earlier for isotretinoin should be followed. Laboratory monitoring should include a baseline pregnancy test in all female patients and a complete blood count, lipid profile, and hepatic profile in all patients. Serial follow-up of laboratory tests should be conducted every 1 to 2 weeks until stable and thereafter as clinically indicated.

Bexarotene

Bexarotene (TARGRETIN) is a retinoid that selectively binds RXRs. Bexarotene has been used in patients with cutaneous T-cell lymphoma with a suggested dose of 300 mg/m² per day. Because it is metabolized by CYP3A4, inhibitors of CYP3A4 (*e.g.*, *imidazole antifungals* and *macrolide antibiotics*) will increase and inducers of the CYP3A4 system will decrease plasma levels of bexarotene. Side effects include lipid abnormalities, hypothyroidism secondary to a reversible RXR-mediated suppression of *TSH* gene expression (Sherman, 2003), pancreatitis, leukopenia, and gastrointestinal symptoms. Blood lipids and thyroid function should be measured before initiating therapy and periodically thereafter.

Cancer Chemoprevention with Retinoids. The association of vitamin A deficiency with squamous metaplasia, increased cell proliferation, hyperkeratosis, and carcinoma suggested that retinoids might be valuable in the treatment and prevention of cutaneous premalignant and malignant disorders. Clinical trials indicate that retinoids have significant activity in the reversal of oral, skin, and cervical premalignancies and in the prevention of head and neck, lung, and skin primary tumors. As with the treatment of other dermatological diseases, individual retinoids show selectivity in tumor prevention and treatment.

Systemic and topical retinoids have been used successfully to treat premalignant skin conditions and may have a role in chemoprevention of skin malignancies. High-dose isotretinoin (2 mg/kg per day) has suppressed skin cancers in patients with increased risk of skin malignancy from congenital disorders such as xeroderma pigmentosa and nevoid basal cell carcinoma syndrome. To achieve an anti-cancer effect, toxic doses of retinoids generally are required. Acitretin at a dose of 25 mg/day or more appears to reduce the risk of skin cancer by about 25% among patients with psoriasis who are at high risk for squamous cell carcinoma because of prior use of 8-methoxypsoralen and ultraviolet radiation or other carcinogenic modalities for psoriasis (Nijsten and Stern, 2003). Tretinoin cream applied once or twice daily decreased the size and number of actinic keratoses by 50% in one multicenter study.

High doses of isotretinoin produce partial regression of multiple basal cell carcinomas (Peck *et al.*, 1988) but are more effective in suppressing the formation of new tumors, as demonstrated in patients with xeroderma pigmentosum (Kraemer *et al.*, 1988). Isotretinoin also prevents second primary tumors in patients who have had a previous squamous cell carcinoma of the head and neck (Hong *et al.*, 1990). Isotretinoin also is effective for oral leukoplakia (Hong *et al.*, 1986). Topical tazarotene has shown efficacy in some basal cell carcinomas (Peris *et al.*, 1999). Cutaneous T-cell lymphoma has been shown to respond to several types of topical and systemic retinoids, including bexarotene (Zhang and Duvic, 2003). The benefits of long-term retinoid use in malignant lymphomas such as cutaneous T-cell lymphoma must be balanced by appreciation of retinoid toxicity and the chronicity of the disease.

β -Carotene. β -Carotene (SOLATENE, others) is a precursor of vitamin A that is present in green and yellow vegetables. The drug is used in dermatology to reduce skin photosensitivity in patients with erythropoietic protoporphyria. The mechanism of action is controversial but may involve an antioxidant effect that decreases the production of free radicals or singlet oxygen (Harber and Bickers, 1989). While this concept has led to the use of β -carotene as a chemopreventative agent, current evidence indicates that this compound has no discernible cancer chemoprevention effects in human skin cancer (Darlington *et al.*, 2003).

PHOTOCHEMOTHERAPY

Electromagnetic radiation is defined by its wavelength and frequency; for convenience, it can be classified into different regions based on its photon energy. For therapeutic purposes, dermatologists are most concerned with the ultraviolet (UV) B (290 to 320 nm), A-I (320 to 340 nm), and A-II (340 to 400 nm) and visible (400 to 800 nm) portions of the solar spectrum. UVC (100 to 290 nm) is absorbed by stratospheric ozone, does not reach earth's surface, and is no longer used therapeutically. UVB is the most erythrogenic and melanogenic type of radiation. It is the major action spectrum for sunburn, tanning, skin cancer, and photoaging. The longer wavelengths of UVA are a thousand times less erythrogenic than UVB; however, they penetrate more deeply into the skin and contribute substantially to photoaging and photosensitivity diseases. They also enhance UVB-induced erythema and increase the risk of skin carcinogenesis. Visible radiation may augment the severity of some photosensitive eruptions. Electromagnetic radiation has proven to be highly efficacious in the treatment of numerous dermatologic diseases (Scheinfield and Deleo, 2003; Lebwohl *et al.*, 2004). Phototherapy and photochemotherapy are treatment methods in which ultraviolet or visible radiation is used to induce a therapeutic response either alone or in the presence of a photosensitizing drug. Phototherapy using broad-band (290 to 320 nm) or narrow-band (311 to 313 nm) UVB or high-dose UVA-I is efficacious in selected dermatological diseases. To be effective, the incident radiation must be absorbed by a target or chromophore in the skin—which in phototherapy is endogenous and in photochemotherapy must be admin-

istered exogenously. Patients treated with these modalities should be monitored for concomitant use of other potential photosensitizing medications before initiation of therapy. Such drugs include *phenothiazines, thiazides, sulfonamides, nonsteroidal antiinflammatory agents, sulfonylureas, tetracyclines, and benzodiazepines.*

PUVA: Psoralens and UVA

Photochemotherapy with *psoralen*-containing plant extracts was employed for the treatment of vitiligo in Egypt and India as early as 1500 B.C. Orally administered *8-methoxy-psoralen* followed by UVA (PUVA) is FDA approved for the treatment of vitiligo, psoriasis, and cutaneous T-cell lymphoma.

Chemistry. Psoralens belong to the furocoumarin class of compounds, which are derived from the fusion of a furan with a coumarin. They occur naturally in many plants, including limes, lemons, figs, and parsnips. Two psoralens, 8-methoxy-psoralen (*methoxsalen*) and 4, 5, 8-trimethylpsoralen (*trioxsalen*, TRISORALEN) are available in the United States. Methoxsalen is used primarily because of its superior gastrointestinal absorption. Structures of the two psoralens are:

Pharmacokinetics. The psoralens are absorbed rapidly after oral administration. Photosensitivity typically is maximal 1 to 2 hours after ingestion of methoxsalen. There is significant but saturable first-pass elimination in the liver, which may account for variations in plasma levels among individuals after a standard dose. Methoxsalen has a serum half-life of approximately 1 hour, but the skin remains sensitive to light for 8 to 12 hours. Despite widespread drug distribution throughout the body, it is photoactivated only in the skin where the UVA penetrates.

Mechanism of Action. The mechanism by which PUVA induces photosensitivity is not known. The action spectrum for oral PUVA is between 320 and 400 nm. Two distinct photoreactions take place. Type I reactions involve the oxygen-independent formation of mono- and bifunctional adducts in DNA. Type II reactions are oxygen-dependent and involve sensitized transfer of energy to molecular oxygen. The therapeutic effects of PUVA in psoriasis may result from a decrease in DNA-dependent proliferation after adduct formation. Perhaps more important, PUVA can alter cytokine profiles and cause immunocyte apoptosis, thereby interrupting immunopathologic processes (Godar, 1999).

PUVA promotes melanogenesis in normal skin. Increased pigmentation results from augmented transfer

of melanosomes from melanocytes to keratinocytes; however, there is no change in the size of melanosomes or in their distribution pattern.

Therapeutic Uses. Methoxsalen is supplied in soft gelatin capsules (OXSORALEN-ULTRA) and hard gelatin capsules (8-MOP). The dose is 0.4 mg/kg for the soft capsule and 0.6 mg/kg for the hard capsule taken 1.5 to 2 hours before UVA exposure. A lotion containing 1% methoxsalen (OXSORALEN) also is available for topical application. It can be diluted for use in bath water to minimize systemic absorption. The risk of phototoxicity is increased with topical PUVA therapy. In U.S. and European multicenter cooperative studies of PUVA for the treatment of psoriasis, initial clearance rates approaching 90% were achieved (Melski *et al.*, 1977; Henseler *et al.*, 1981). Relapse occurs within 6 months of cessation of treatment in many patients, which has prompted efforts to design maintenance protocols.

PUVA also is used to repigment the leukoderma of vitiligo. Success rates are highest in young individuals with recent onset of disease involving nonacral areas. Localized vitiligo can be treated with topical PUVA and more extensive disease with systemic administration. PUVA also is employed in the treatment of cutaneous T-cell lymphoma, atopic dermatitis, alopecia areata, lichen planus, urticaria pigmentosa, and as a preventive modality in some forms of photosensitivity.

Toxicity and Monitoring. The major acute side effects of PUVA include nausea, blistering, and painful erythema. PUVA-induced redness and blistering generally peak within 48 to 72 hours.

Chronic PUVA therapy accelerates photoaging and the development of actinic keratoses, nonmelanoma skin cancer, and melanoma. Squamous cell carcinomas occur at 10 times the expected frequency. In patients receiving 250 or more treatments, there is an increased risk of melanoma. Careful monitoring of patients for cutaneous carcinoma therefore is essential.

Photopheresis. Extracorporeal photopheresis (ECP) is a form of pheresis therapy that has proven effective in the treatment of cutaneous T-cell lymphoma (Edelson *et al.*, 1987). After oral administration of methoxsalen, leukocytes are separated from whole blood using an extracorporeal pheresis device and then exposed to UVA radiation. The irradiated cells then are returned to the patient. Multiple mechanisms probably contribute to the effectiveness of this procedure. ECP simultaneously and efficiently induces apoptosis of disease-causing T cells and con-

version of monocytes to functional dendritic cells. By processing and presenting the unique antigenic determinants of pathogenic T-cell clones, the dendritic cells can either initiate a clinically relevant anti-cutaneous T-cell lymphoma cytotoxic response or suppress the activity of autoreactive T-cell clones (Bisaccia *et al.*, 2000; Knobler and Girardi, 2001).

Initially, patients receive therapy monthly on two consecutive days. Treatment intervals are increased as the patient improves. Patients with Sézary syndrome or those with the plaque stage of cutaneous T-cell lymphoma who have atypical peripheral blood cells are most responsive to the therapy. For patients with disease parameters suggesting a low probability of response to photopheresis alone, adjuvant therapy with interferon- α or superficial electron-beam irradiation is employed. Prolonged clinical remissions can occur in patients with Sézary syndrome. Favorable results also have been obtained in pemphigus vulgaris, scleroderma (Sapadin and Fleischmajer, 2002), and graft-versus-host disease (Coyle *et al.*, 2004). Clinical trials are being conducted in patients undergoing allogeneic organ transplantation.

Photodynamic Therapy (PDT). This modality combines the use of photosensitizing drugs and visible light for the treatment of various dermatological disorders, particularly nonmelanoma skin cancer and precancerous actinic keratoses (Kalka *et al.*, 2000; Lopez *et al.*, 2004; Taub 2004). The concept is predicated on the insight that tumor tissue selectively absorbs greater amounts of porphyrins than surrounding nontumor tissue. The agents most widely employed in PDT are *porphyrins*, their precursors, or derivatives thereof. The photosensitized chemical reaction is oxygen-dependent. Light delivered to the skin is absorbed by porphyrin molecules. These molecules transfer their energy to oxygen, forming reactive oxygen species that result in injury or destruction of lipid-rich membranes and subsequent tissue damage.

Early studies with PDT employed complex mixtures of poorly defined porphyrins known as *hematoporphyrin derivative* (PHOTOFRIN I) or a partially purified mixture known as *porfimer sodium* (PHOTOFRIN II) that was administered parenterally with subsequent irradiation using polychromatic light sources. The major problem with this approach was the prolonged period (4 to 6 weeks) of photosensitivity caused by skin retention of the porphyrin formulations. This led to a search for compounds that could be administered topically and that were eliminated more readily from the skin. The porphyrin precursor δ -aminolevulinic acid (ALA) is converted to various porphyrins, particularly *protoporphyrin* (PROTO), in tissues including the skin (*see below*). Protoporphyrin subsequently is eliminated rapidly from the body, thereby minimizing the period of skin photosensitivity to a few hours. Topically applied ALA HCl (20% w/v) and, more recently, the methyl ester of ALA have been used successfully for the PDT of various types of nonmelanoma skin cancers and premalignant lesions (Lopez *et al.*, 2004; Taub, 2004).

Incoherent (nonlaser) and laser light sources have been used for PDT. The wavelengths chosen must include those within the action spectrum of protoporphyrin and ideally those that permit maximum skin penetration. Light sources in use emit energy predominantly in the blue portion (maximum porphyrin absorption) or the red portion (better tissue penetration) of the visible spectrum. Nonhypertrophic actinic keratoses (Piacquadro *et al.*, 2004) and superficial basal cell carcinomas and Bowen's disease seem to respond best to PDT. Topical ALA products for PDT approved by the FDA include LEVULAN KERASTICK, BLU-U blue light, and METVIX.

ANTIHISTAMINES

Histamine is a potent vasodilator, bronchial smooth muscle constrictor, and stimulant of nociceptive itch nerves (Repka-Ramirez and Baraniuk, 2002). In addition to histamine, multiple chemical itch mediators can act as pruritogens on C-fibers, including *neuropeptides*, *prostaglandins*, *serotonin*, *acetylcholine*, and *bradykinin* (Stander *et al.*, 2003). Furthermore, new receptor systems such as vanilloid, opioid, and cannabinoid receptors on cutaneous sensory nerve fibers that may modulate itch offer novel targets for antipruritic therapy.

Histamine is in mast cells, basophils, and platelets. Human skin mast cells express H_1 , H_2 , and H_4 receptors but not H_3 receptors (Lippert *et al.*, 2004). H_1 and H_2 receptors are involved in wheal formation and erythema, whereas only H_1 receptor agonists cause pruritus. Complete blockade of H_1 receptors does not totally relieve itching, and combinations of H_1 and H_2 blockers may be superior to H_1 blockers alone.

Oral *antihistamines*, particularly H_1 -receptor antagonists, have some anticholinergic activity and are sedating (*see* Chapter 24), making them useful for the control of pruritus. First-generation sedating H_1 -receptor antagonists include *hydroxyzine hydrochloride* (ATARAX), which is given in a dose of 0.5 mg/kg every 6 hours; *diphenhydra-*

mine (BENADRYL; others); *promethazine* (PHENERGAN); and *cyproheptadine* (PERIACTIN). *Doxepin* (ADAPIN, SINEQUAN), which has tricyclic antidepressant and sedative antihistamine effects (*see* Chapter 17), is a good alternative for severe pruritus. A topical formulation of doxepin also is available as a 5% cream (ZONALON), which can be used in conjunction with low- to moderate-potency topical glucocorticoids. The systemic effect from topical doxepin is comparable with that of low-dose oral therapy.

Second-generation H_1 -receptor antagonists lack anticholinergic side effects and are described as nonsedating largely because they do not cross the blood-brain barrier. They include *cetirizine* (ZYRTEC), *loratadine* (CLARITIN), *desloratadine* (CLARINEX), and *fexofenadine hydrochloride* (ALLEGRA). While second-generation nonsedating H_1 -receptor blockers are as effective as the first-generation H_1 blockers (Monroe, 1993), they are metabolized by CYP3A4 and, to a lesser extent, by CYP2D6 and should not be coadministered with medications that inhibit these enzymes (*e.g.*, imidazole antifungals and macrolide antibiotics).

H_2 -receptor blockers include *cimetidine* (TAGAMET), *ranitidine* (ZANTAC), *famotidine* (PEPCID), and *nizatidine* (AXID). Besides their use in combination with H_1 -receptor blockers for pruritus, the H_2 -receptor blockers have immunomodulating effects, and this property has been exploited in children to treat warts (Orlow and Paller, 1993).

ANTIMICROBIAL AGENTS

Antibiotics

These drugs are used commonly to treat superficial cutaneous infections (pyoderma) and noninfectious diseases. Topical agents are very effective for the treatment of superficial bacterial infections and acne vulgaris. Systemic antibiotics also are prescribed commonly for acne and for deeper bacterial infections. The pharmacology of individual antibacterial agents is discussed in Section VIII, Chemotherapy of Microbial Diseases. Only the topical and systemic antibacterial agents principally used in dermatology are discussed here.

Acne vulgaris is the most common dermatologic disorder treated with either topical or systemic antibiotics. The anaerobe *Propionibacterium acnes* is a component of normal skin flora that proliferates in the obstructed, lipid-rich lumen of the pilosebaceous unit, where O_2 tension is low. *P. acnes* generates free fatty acids that are irritants and may lead to microcomedo formation and result in the inflammatory lesions of acne. Suppression of cutaneous

P. acnes with antibiotic therapy is correlated with clinical improvement (Tan, 2003).

Resistant strains of *P. acnes* are emerging that may respond to judicious use of retinoids in combination with antibiotics (Leyden, 2001). Commonly used topical antimicrobials in acne include erythromycin, clindamycin (CLEOCIN-T), and benzoyl peroxide and antibiotic–benzoyl peroxide combinations (BENZAMYCIN, BENZACLIN, others). Other antimicrobials used in treating acne include sulfacetamide (KLARON), sulfacetamide/sulfur combinations (SULFACET-R), metronidazole (METROCREAM, METROGEL, NORITATE), and azelaic acid (AZELEX). Systemic therapy is prescribed for patients with more extensive disease and acne that is resistant to topical therapy. Effective agents include tetracycline (SUMYCIN, others), minocycline (MINOCIN, others), erythromycin (ERYC, others), clindamycin (CLEOCIN), and trimethoprim–sulfamethoxazole (BACTRIM, others). Antibiotics usually are administered twice daily, and doses are tapered after control is achieved. Tetracycline is the most commonly employed antibiotic because it is inexpensive, safe, and effective. The initial daily dose is usually 1 g in divided doses. Although tetracycline is an antimicrobial agent, its efficacy in acne may be more dependent on its antiinflammatory activity.

Minocycline has better gastrointestinal absorption than tetracycline and may be less photosensitizing than either tetracycline or doxycycline. Side effects of minocycline include dizziness and hyperpigmentation of the skin and mucosa, serum-sickness-like reactions, and drug-induced lupus erythematosus. With all the tetracyclines, vaginal candidiasis is a common complication that is readily treated with local administration of antifungal drugs.

In healthy individuals taking oral antibiotics for acne, laboratory monitoring is not necessary. Orally administered antibiotics also may be indicated in other noninfectious conditions, including acne rosacea, perioral dermatitis, hidradenitis suppurativa, autoimmune blistering diseases, sarcoidosis, and pyoderma gangrenosum (Carter, 2003).

Cutaneous Infections. Gram-positive organisms, including *Staphylococcus aureus* and *Streptococcus pyogenes*, are the most common cause of pyoderma. Skin infections with gram-negative bacilli are rare, although they can occur in diabetics and patients who are immunosuppressed; appropriate parenteral antibiotic therapy is required for their treatment.

Topical therapy frequently is adequate for impetigo, the most superficial bacterial infection of the skin caused by *S. aureus* and *S. pyogenes*. Pseudomonic acid (MUPIROCIN, BACTROBAN), produced by *Pseudomonas fluorescens*, is effective for such localized infections. It inhibits protein synthesis by binding to bacterial isoleucyl-tRNA synthetase. Mupirocin is highly active against staphylococci and all streptococci except those of group D. It is less active against

gram-negative organisms, but it has *in vitro* activity against *Haemophilus influenzae*, *Neisseria gonorrhoeae*, *Pasteurella multocida*, *Moraxella catarrhalis*, and *Bordetella pertussis*. Mupirocin is inactive against normal skin flora (Leyden, 1992). Its antibacterial activity is enhanced by the acid pH of the skin surface. Mupirocin is available as a 2% ointment or cream (BACTODERM, BACTROBAN, BACTROBAN NASAL, EISMYCIN) and is applied three times daily.

Topical therapy often is employed for prophylaxis of superficial infections caused by wounds and injuries. Neomycin is active against staphylococci and most gram-negative bacilli. It may cause allergic contact dermatitis, especially on disrupted skin. Bacitracin inhibits staphylococci, streptococci, and gram-positive bacilli. Polymyxin B is active against aerobic gram-negative bacilli. Bacitracin and polymyxin B are combined in a number of over-the-counter preparations.

Deeper bacterial infections of the skin include folliculitis, erysipelas, cellulitis, and necrotizing fasciitis. Since streptococcal and staphylococcal species also are the most common causes of deep cutaneous infections, penicillins (especially β -lactamase-resistant β -lactams) and cephalosporins are the systemic antibiotics used most frequently in their treatment (Carter, 2003) (see Chapter 44). A growing concern is the increased incidence of skin and soft tissue infections with hospital- and community-acquired methicillin-resistant *S. aureus* (MRSA) and drug-resistant pneumococci. Infection with community-acquired MRSA often is susceptible to trimethoprim–sulfamethoxazole (Cohen and Grossman, 2004).

Novel antibacterial agents such as linezolid, quinupristin–dalbapristin, and daptomycin (see Chapter 46) have been approved for the treatment of complicated skin and skin-structure infections (Schweiger and Weinberg, 2004).

Antifungal Agents

Fungal infections are among the most common causes of skin disease in the United States, and numerous effective topical and oral antifungal agents have been developed. Griseofulvin, topical and oral imidazoles, triazoles, and allylamines are the most effective agents available. The pharmacology, uses, and toxicities of antifungal drugs are discussed in Chapter 48. This section will address the management of common cutaneous fungal diseases. Recommendations for cutaneous antifungal therapy are summarized in Table 62–2.

The azoles miconazole (MICATIN, others) and econazole (SPECTRAZOLE, others) and the allylamines naftifine (NAFTIN) and terbinafine (LAMISIL, others) are effective topical agents for the treatment of localized tinea corporis and uncomplicated tinea pedis. Topical therapy with the azoles is preferred for localized cutaneous candidiasis and tinea versicolor.

Systemic therapy is necessary for the treatment of tinea capitis. Oral griseofulvin (FULVICIN V/F, P/G, others) has been the traditional medication for treatment of tinea capitis. Oral terbinafine is a safe and effective alternative to griseofulvin in treating tinea capitis in children (Moosavi *et al.*, 2001).

Table 62–2

Recommended Cutaneous Antifungal Therapy

CONDITION	TOPICAL THERAPY	ORAL THERAPY
Tinea corporis, localized	Azoles, allylamines	—
Tinea corporis, widespread	—	Griseofulvin, terbinafine, itraconazole, fluconazole
Tinea pedis	Azoles, allylamines	Griseofulvin, terbinafine, itraconazole, fluconazole
Onychomycosis	—	Griseofulvin, terbinafine, itraconazole, fluconazole
Candidiasis, localized	Azoles	—
Candidiasis, widespread and mucocutaneous	—	Ketaconazole, itraconazole, fluconazole
Tinea versicolor, localized	Azoles, allylamines	—
Tinea versicolor, widespread	—	Ketaconazole, itraconazole, fluconazole

Tinea Pedis. Topical therapy with the azoles and allylamines is effective for tinea pedis. Macerated toe web disease may require the addition of antibacterial therapy. *Econazole nitrate*, which has a limited antibacterial spectrum, can be useful in this situation. Systemic therapy with griseofulvin, terbinafine, or *itraconazole* (SPORANOX, others) is used for more extensive tinea pedis. It should be recognized that long-term topical therapy may be necessary in some patients after courses of systemic antifungal therapy.

Onychomycosis. Fungal infection of the nails is caused most frequently by dermatophytes and *Candida*. Mixed infections are common. The nail must be cultured or clipped for histological examination before initiating therapy because up to a third of dystrophic nails that appear clinically to be onychomycosis are actually due to psoriasis or other conditions.

Systemic therapy is necessary for effective management of onychomycosis. Treatment of onychomycosis of toenails with griseofulvin for 12 to 18 months produces a cure rate of 50% and a relapse rate of 50% after 1 year. Terbinafine and itraconazole offer significant potential advantages. They quickly produce high drug levels in the nail, which persist after therapy is discontinued. Additional advantages include a broader spectrum of coverage with itraconazole and few drug interactions with terbinafine. Treatment of toenail onychomycosis requires 3 months with terbinafine (250 mg/day) or itraconazole (pulsed dosing 1 week per month for 3 months). Cure rates of 75% or greater have been achieved with both drugs (Gupta *et al.*, 1994a, 1994b; Darkes *et al.*, 2003).

Ciclopirox topical (PENLAC) solution is a nail lacquer that is FDA approved for the treatment of onychomycosis but demonstrates low complete cure rates (5.5% to 8.5%).

Antiviral Agents

Viral infections of the skin are very common and include verrucae [human papillomavirus (HPV)], herpes simplex (HSV), condyloma acuminatum (HPV), molluscum contagiosum (poxvirus), and chicken pox [varicella-zoster virus (VZV)]. *Acyclovir* (ZOVIRAX), *famciclovir* (FAMVIR), and *valacyclovir* (VALTREX) frequently are used systemically to treat herpes simplex and varicella infections (*see* Chapter 49). *Cidofovir* (VISTIDE) may be useful in treating acyclovir-resistant HSV or VZV and other cutaneous viral infections (Anonymous, 2002a). Topically, acyclovir, *docosanol* (ABREVA), and *penciclovir* (DENA VIR) are available for treating mucocutaneous HSV. *Podophyllin* (25% solution) and *podofilox* (CONDYLOX; 0.5% solution) are used to treat condylomata. The immune response modifier *imiquimod* (ALDARA) is discussed below. Interferons α -2b (INTRON-A), α -n1 (not commercially available in the United States), and α -n3 (ALFERON N) may be useful for treating refractory or recurrent warts (Carter *et al.*, 2004).

Agents Used to Treat Infestations

Infestations with ectoparasites such as body lice and scabies are common throughout the world. These conditions have a significant impact on public health in the form of disabling pruritus, secondary infection, and in the case of the body louse, transmission of life-threatening illnesses such as typhus. Topical and oral medications are available to treat these infestations.

Perhaps the best known anti-ectoparasitic medication is 1% γ -benzene hexachloride lotion, also known as *lindane*. Its chemical structure is:

Lindane has been used as a commercial insecticide as well as a topical medication. It is highly effective in the treatment of ectoparasites. Neurotoxicity, although a concern with the use of lindane, is a rare side effect when the medication is used correctly. However, the FDA has defined lindane as a second-line drug in treating pediculosis and scabies and has highlighted the potential for neurotoxicity in children and adults weighing less than 110 pounds (FDA, 2003). The lotion is applied in a thin layer from the neck down, left in place for 8 to 12 hours or overnight, and removed by thorough washing at the end of the 8- to 12-hour period. The treatment may be repeated in 1 week. To avoid problems with neurotoxicity, the lotion should be applied only in a thin coat to dry skin, should not be applied immediately after bathing, and should be kept away from the eyes, mouth, and open cuts or sores. A 1% lindane shampoo also is available for head and body lice.

A second topical agent that is very useful in the treatment of ectoparasites is *permethrin*. Its structure is:

Permethrin is a synthetic derivative of the insecticide pyrethrum, which was obtained originally from *Chrysanthemum cinerariaefolium*. Neurotoxicity associated with this compound is extremely rare. A 5% cream (ACTICIN, ELIMITE, others) is available for the treatment of scabies. This is used as an 8- to 12-hour or overnight application. A 1% permethrin cream rinse (NIX) also is available for the treatment of lice.

Ivermectin (STROMEKTOL), an anthelmintic drug (see Chapter 41) used traditionally to treat onchocerciasis, also is effective in the off-label treatment of scabies. Its structure is:

Because ivermectin does not cross the blood–brain barrier, there is no major CNS toxicity. Ivermectin, available as a 6-mg tablet, is given at a dose of 250 to 400 $\mu\text{g}/\text{kg}$, which is repeated in a week. Cure rates of 70% after one dose and 95% after two doses given 2 weeks apart have been achieved (Usha *et al.*, 2000). For treatment of scabies outbreaks in large groups, this drug has obvious advantages as compared with topical therapy.

Other, less effective topical treatments for scabies include 10% *crotamiton* cream and lotion (EURAX) and 5% precipitated *sulfur* in petrolatum. Crotamiton and sulfur typically are considered for use in patients in whom lindane or permethrin may be contraindicated.

ANTIMALARIAL AGENTS

The major antimalarials used commonly in dermatology include *chloroquine* (ARALEN), *hydroxychloroquine* (PLAQUE-NIL), and to a lesser extent, *quinacrine* (no longer available in the United States); all three drugs are useful because of their antiinflammatory effects, especially in connective tissue disorders and photosensitivity diseases (see Chapter 39).

The mechanism of action of antimalarials is controversial, but there are immunological and antiinflammatory effects. Likely mechanisms of action include inhibition of phospholipase A_2 , inhibition of platelet aggregation, a range of lysosomal effects (*e.g.*, an increase in pH, membrane stabilization, and inhibition of release and activity of lysosomal enzymes), inhibition of phagocytosis, an increase in intracellular pH in cytoplasmic vacuoles leading to decreased stimulation of autoimmune CD4^+ T cells, decreased cytokine release from lymphocytes and stimulated monocytes, inhibition of immune complex formation, and antioxidant activity (Van Beek and Piette, 2001; Callen and Camisa, 2001). In patients with porphyria cutanea tarda, chloroquine and hydroxychloroquine bind to porphyrins and/or iron to facilitate their hepatic clearance. The ability to bind to melanin and other pigments may contribute to the retinal toxicity seen occasionally when antimalarial agents are used.

Therapeutic Uses. FDA-approved dermatological uses of hydroxychloroquine include treatment of discoid and systemic lupus erythematosus. Unapproved but first-line uses include treatment of dermatomyositis, porphyria cutanea tarda, polymorphous light eruption, sarcoidosis, eosinophilic fasciitis, lymphocytic infiltrate of Jessner, lymphocytoma cutis, solar urticaria, granuloma annulare, and some forms of panniculitis.

The usual doses of antimalarials are hydroxychloroquine, 200 mg twice a day; chloroquine, 250 to 500 mg/day; and quinacrine, 100 to 200 mg/day. Usually, hydroxychloroquine is started first, and if no improvement is noted in 3 months, quinacrine is added. Alternatively, chloroquine is used as a single agent. Dosing should be adjusted for low-weight individuals so that chloroquine dosing is 2.5 mg/kg per day and hydroxychloroquine is 6.5 mg/kg per day. Antimalarial agents are the treatment of choice for widespread forms of cutaneous lupus that do not respond to topical glucocorticoids and sunscreens. Clinical improvement may be delayed for several months.

Porphyria cutanea tarda, characterized by fluid-filled vesicles and bullae on sun-exposed areas, can be either genetic or associated with alcohol abuse or hepatitis C. Although the associated iron overload is treated with phlebotomy, the dermatologic manifestations sometimes are treated with antimalarial agents. These patients require reduced doses because of the potential for hepatotoxicity, as manifested by elevated transaminase levels, and the rapid excretion of large amounts of uroporphyrins in the urine that can occur with usual doses. Low-dose twice-weekly administration is effective and avoids these side effects.

Toxicity and Monitoring. The toxic effects of antimalarial agents are described in Chapter 39. The incidence of retinopathy from chloroquine and hydroxychloroquine is low, as long as the doses are within the above-mentioned guidelines and the medication is used for less than 10 years in patients with normal renal function (Callen and Camisa, 2001).

Quinacrine does not cause retinopathy. Current recommendations for ophthalmological supervision may be overly cautious, and eye examinations every 6 months or even yearly after a baseline examination probably are sufficient, provided dosing guidelines are followed. Although caution is required, there is evidence that antimalarial agents probably are safe in pregnancy and in children (Parke, 1993; Callen and Camisa, 2001).

Rare hematological side effects include agranulocytosis, aplastic anemia, and hemolysis in patients with glucose-6-phosphatase deficiency. Liver function tests and

complete blood counts should be performed monthly at the start of therapy and at least every 4 to 6 months throughout treatment.

CYTOTOXIC AND IMMUNOSUPPRESSANT DRUGS

Cytotoxic and immunosuppressive drugs are used in dermatology for immunologically mediated diseases such as psoriasis, the autoimmune blistering diseases, and leukocytoclastic vasculitis. These agents are discussed in detail in Chapters 51 and 52.

Antimetabolites

Methotrexate. The antimetabolite methotrexate is a folic acid analog that competitively inhibits dihydrofolate reductase. Methotrexate has been used for moderate-to-severe psoriasis since 1951. It suppresses immunocompetent cells in the skin, and it also decreases the expression of cutaneous lymphocyte-associated antigen (CLA)-positive T cells and endothelial cell E-selectin, which may account for its efficacy in psoriasis (Sigmundsdottir *et al.*, 2004). It is useful in treating a number of other dermatological conditions, including pityriasis lichenoides et varioliformis, lymphomatoid papulosis, sarcoidosis, pemphigus vulgaris, pityriasis rubra pilaris, lupus erythematosus, dermatomyositis, and cutaneous T-cell lymphoma.

Despite its widespread acceptance for decades as a first-line systemic monotherapy for the treatment of psoriasis, methotrexate (RHEUMATREX, others) was subjected only recently to a randomized, controlled clinical trial comparing its efficacy with that of orally administered *cyclosporine* for the treatment of moderate to severe chronic plaque psoriasis (Heydendael *et al.*, 2003). Both medications were equally effective in achieving partial or complete clearing of psoriasis. Methotrexate is used often in combination with phototherapy and photochemotherapy or other systemic agents, and it also may be useful in combination with the biologics (Saporito and Menter, 2004) (*see Biological Agents*, below).

A usual starting dose for methotrexate therapy is 5 to 7.5 mg/week (maximum of 15 mg/week). This dose may be increased gradually to 20 to 30 mg/week if needed. Widely used regimens include three oral doses given at 12-hour intervals once weekly or weekly intramuscular injections. Doses must be decreased for patients with impaired renal clearance. *Methotrexate should never be*

coadministered with trimethoprim–sulfamethoxazole, probenecid, salicylates, or other drugs that can compete with it for protein binding and thereby raise plasma concentrations to levels that may result in bone marrow suppression. Fatalities have occurred because of concurrent treatment with methotrexate and nonsteroidal antiinflammatory agents. Methotrexate exerts significant antiproliferative effects on the bone marrow; therefore, complete blood counts should be monitored serially. Physicians administering methotrexate should be familiar with the use of *folinic acid (leucovorin)* to rescue patients with hematologic crises caused by methotrexate-induced bone marrow suppression. Careful monitoring of liver function tests is necessary but may not be adequate to identify early hepatic fibrosis in patients receiving chronic methotrexate therapy. Some believe that methotrexate-induced hepatic fibrosis occurs more commonly in patients with psoriasis than in those with rheumatoid arthritis. Consequently, liver biopsy is recommended when the cumulative dose reaches 1 to 1.5 g. A baseline liver biopsy also is recommended for patients with increased potential risk for hepatic fibrosis, such as a history of alcohol abuse or infection with hepatitis B or C. Patients with significantly abnormal liver function tests, symptomatic liver disease, or evidence of hepatic fibrosis should not use this drug. Pregnancy and lactation are absolute contraindications to methotrexate use (Roeningk *et al.*, 1998).

Azathioprine (IMURAN) is discussed in detail in Chapters 38 and 52. In dermatologic practice, the drug is used as a steroid-sparing agent for autoimmune and inflammatory dermatoses, including pemphigus vulgaris, bullous pemphigoid, dermatomyositis, atopic dermatitis, chronic actinic dermatitis, lupus erythematosus, psoriasis, pyoderma gangrenosum, and Behçet's disease (Silvis, 2001). The usual starting dose is 1 to 2 mg/kg per day. Since it often takes 6 to 8 weeks to achieve therapeutic effect, azathioprine often is started early in the course of disease management. Careful laboratory monitoring is important (Silvis, 2001). The enzyme thiopurine *S*-methyltransferase is critical for the metabolism of azathioprine to nontoxic metabolites. Homozygous deficiency of this enzyme may raise plasma levels of the drug and cause myelosuppression, and some experts advocate measuring this enzyme before initiating azathioprine therapy (*see* Chapter 38).

Fluorouracil (5-FU) interferes with DNA synthesis by blocking the methylation of deoxyuridylic acid to thymidylic acid (Dinehart, 2000). Topical formulations (CARAC, EFUDEX, FLUOROPLEX) are used in multiple actinic keratoses, actinic cheilitis, Bowen's disease, and superficial basal cell carcinomas not amenable to other treatments.

Fluorouracil is applied twice daily for 2 to 4 weeks. The treated areas may become severely inflamed during treatment, but the inflammation subsides after the drug is stopped. Intralesional injection of 5-FU has been used for keratoacanthomas, warts, and porokeratoses.

Alkylating Agents. *Cyclophosphamide (CYTOXAN, NEOSAR)* is an effective cytotoxic and immunosuppressive agent.

Both oral and intravenous preparations of cyclophosphamide are used in dermatology (Fox and Pandya, 2000). Cyclophosphamide is FDA approved for treatment of advanced cutaneous T-cell lymphoma. Other uses include treatment of pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, paraneoplastic pemphigus, pyoderma gangrenosum, toxic epidermal necrolysis, Wegener's granulomatosis, polyarteritis nodosa, Churg-Strauss angitis, Behçet's disease, scleromyxedema, and cytophagic histiocytic panniculitis (Ho and Zloty, 1993; Silvis, 2001). The usual oral dose is 2 to 3 mg/kg per day in divided doses, and there is often a 4- to 6-week delay in onset of action. Alternatively, intravenous pulse administration of cyclophosphamide may offer advantages, including lower cumulative dose and a decreased risk of bladder cancer (Fox and Pandya, 2000; Silvis, 2001).

Cyclophosphamide has many adverse effects, including the risk of secondary malignancy and myelosuppression, and thus is used only in the most severe, recalcitrant dermatological diseases. The secondary malignancies have included bladder, myeloproliferative, and lymphoproliferative malignancies and have been seen with the use of cyclophosphamide alone or in combination with other antineoplastic drugs.

Mechlorethamine hydrochloride (MUSTARGEN) and *carmustine (bischloronitrosourea, BCNU, BICNU)* are used topically to treat cutaneous T-cell lymphoma. Both can be applied as a solution or in ointment form. It is important to monitor complete blood counts and liver function tests because systemic absorption can cause bone marrow suppression and hepatitis. Other side effects include allergic contact dermatitis, irritant dermatitis, secondary cutaneous malignancies, and pigmentary changes. Carmustine also can cause erythema and posttreatment telangiectasias (Zackheim *et al.*, 1990).

Calcineurin Inhibitors. Cyclosporine (SANDIMMUNE, NEORAL, SANGCYA) is a potent immunosuppressant isolated from the fungus *Tolypocladium inflatum*. It inhibits calcineurin, a phosphatase that normally dephosphorylates the cytoplasmic subunit of nuclear factor of activated T cells (NFAT), thus permitting NFAT to translocate to the nucleus and augment transcription of numerous cytokines.

In T-lymphocytes, calcineurin inhibition blocks interleukin 2 (IL-2) gene transcription and release and ultimately results in inhibition of T-cell activation (Cather *et al.*, 2001). The presence of calcineurin in Langerhans' cells, mast cells, and keratinocytes may further explain the therapeutic efficacy of cyclosporine and the other calcineurin inhibitors (*e.g.*, *tacrolimus* and *pimecrolimus*; see below) (Reynolds and Al-Daraji, 2002). Cyclosporine has FDA approval for the treatment of psoriasis. Other cutaneous disorders that typically respond well to cyclosporine are atopic dermatitis (Czech *et al.*, 2000), alopecia areata, epidermolysis bullosa acquisita, pemphigus vulgaris, bullous pemphigoid, lichen planus, and pyoderma gangrenosum. The usual initial oral dose is 3 to 5 mg/kg per day given in divided doses.

Hypertension and renal dysfunction are the major adverse effects associated with the use of cyclosporine. These risks can be minimized by monitoring serum creatinine (which should not rise more than 30% above baseline), calculating creatinine clearance or glomerular filtration rate in patients on long-term therapy or with a rising creatinine, maintaining a daily dose of less than 5 mg/kg, and regular monitoring of blood pressure (Cather *et al.*, 2001). Alternation with other therapeutic modalities may diminish cyclosporine toxicity (Shupack *et al.*, 1997). *Laboratory monitoring during therapy is essential.* Cyclosporine is not mutagenic. However, as with other immunosuppressive agents, patients with psoriasis treated with cyclosporine are at increased risk of cutaneous, solid organ, and lymphoproliferative malignancies (Flores and Kerdel, 2000). The risk of cutaneous malignancies is compounded if patients have received phototherapy with PUVA.

Tacrolimus (FK506, PROGRAF), a metabolite of *Streptomyces tsukubaensis*, was discovered in 1984. The structure of tacrolimus is:

TACROLIMUS

It is a potent macrolide immunosuppressant traditionally used to prevent kidney, liver, and heart allograft rejection. Like cyclosporine, tacrolimus works mainly by inhibiting early activation of T-lymphocytes, thereby inhibiting the release of IL-2, suppressing humoral and cell-mediated immune responses, and suppressing mediator release from mast cells and basophils (Anonymous, 2001; Assmann and Ruzicka, 2002). In contrast to cyclosporine, this effect is mediated by binding to the intracellular protein FK506-binding protein 12, generating a complex that inhibits the phosphatase activity of calcineurin.

Tacrolimus is available in oral and topical forms for the treatment of skin disease. Systemic tacrolimus has shown some efficacy in the treatment of inflammatory skin diseases such as psoriasis, pyoderma gangrenosum, and Behçet's disease (Dé Tran *et al.*, 2001; Assmann and Ruzicka, 2002). When administered systemically, the most common side effects are hypertension, nephrotoxicity, neurotoxicity, gastrointestinal symptoms, hyperglycemia, and hyperlipidemia. Topical formulations of tacrolimus penetrate into the epidermis.

In commercially available topical formulations (0.03% and 0.1%), tacrolimus ointment (PROTOPTIC) is effective in and approved for the treatment of atopic dermatitis in adults (0.03% and 0.1%) and children (0.03%). Other uses in dermatology include intertriginous psoriasis, vitiligo, mucosal lichen planus, graft-versus-host disease, allergic contact dermatitis, and rosacea (Ngheim *et al.*, 2002). It is applied to the affected area twice a day and generally is well tolerated.

A major benefit of topical tacrolimus compared with topical glucocorticoids is that tacrolimus does not cause skin atrophy and therefore can be used safely in locations such as the face and intertriginous areas. Common side effects at the site of application are transient erythema, burning, and pruritus, which tend to improve with continued treatment. Other reported adverse effects include skin tingling, flu-like symptoms, headache, alcohol intolerance, folliculitis, acne, and hyperesthesia (Ngheim *et al.*, 2002). Skin infections have been reported, although whether an increased risk truly exists relative to age-matched controls is uncertain (Anonymous, 2001). Systemic absorption generally is very low and decreases with resolution of the dermatitis. However, topical tacrolimus should be used with extreme caution in patients with Netherton's syndrome because these patients have been shown to develop elevated blood levels of the drug after topical application (Assmann and Ruzicka, 2002). Mice treated with 0.1% topical tacrolimus had a higher incidence of lymphoma and, after exposure to UV radiation, showed decreased time to skin tumor formation. It therefore is recommended that patients using tacrolimus use

sunscreen and avoid excessive UV exposure. The risk of lymphoma development in humans is uncertain (Anonymous, 2001).

Pimecrolimus 1% cream (ELIDEL), a macrolide derived from ascomycin, is FDA approved for the treatment of atopic dermatitis in patients older than 2 years of age. The structure of pimecrolimus is:

PIMECROLIMUS

Its mechanism of action and side-effect profile are similar to those of tacrolimus. Burning, while occurring in some patients, appears to be less common with pimecrolimus than with tacrolimus (Ngheim *et al.*, 2002). In addition, pimecrolimus has less systemic absorption. Similar precautions with regard to UV exposure should be taken during treatment with pimecrolimus (Anonymous, 2002b).

MISCELLANEOUS IMMUNOSUPPRESSANT AND ANTIINFLAMMATORY AGENTS

Mycophenolate mofetil (CELLCEPT) is an immunosuppressant approved for prophylaxis of organ rejection in patients with renal, cardiac, and hepatic transplants (*see* Chapter 52). Mycophenolic acid, the active derivative of mycophenolate mofetil, inhibits the enzyme inosine monophosphatase dehydrogenase (IMPDH), thereby depleting guanosine nucleotides essential for DNA and RNA synthesis (Frieling and Luger, 2002). Moreover, mycophenolic acid is a fivefold more potent inhibitor of the type II isoform of IMPDH found in activated B- and T-lymphocytes and thus functions as a specific inhibitor of T- and B-lymphocyte activation and proliferation. The drug also may enhance apoptosis.

Mycophenolate mofetil is used increasingly to treat inflammatory and autoimmune diseases in dermatology (Carter *et al.*, 2004) in doses ranging from 1 to 2 g/day

orally. Mycophenolate mofetil is particularly useful as a corticosteroid-sparing agent in the treatment of autoimmune blistering disorders, including pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, and pemphigus foliaceus. It also has been used effectively in the treatment of inflammatory diseases such as psoriasis, atopic dermatitis, and pyoderma gangrenosum.

Imiquimod (ALDARA) is a synthetic imidazoquinoline amine believed to exert immunomodulatory effects by acting as a ligand at toll-like receptors in the innate immune system and inducing the cytokines interferon- α (IFN- α), tumor necrosis factor- α (TNF- α), and IL-1, IL-6, IL-8, IL-10, and IL-12. The structure of imiquimod is:

IMIQUIMOD

Approved for the treatment of genital warts since 1997, imiquimod is applied to genital or perianal lesions three times a week usually for a 16-week period that may be repeated as necessary. Imiquimod also has been approved recently for the treatment of actinic keratoses. In this capacity, imiquimod is applied three times a week for 16 weeks to the face, scalp, and arms (Anonymous, 2004). Phase II trials evaluating imiquimod for the treatment of nodular and superficial basal cell carcinomas (BCC) suggest that imiquimod may prove useful when applied daily over a 6- to 12-week period (Salasche and Shumack, 2003), and the drug is approved for this indication by the FDA. Off-label applications include the treatment of non-genital warts, molluscum contagiosum, extramammary Paget's disease, and Bowen's disease. Irritant reactions occur in virtually all patients, and some develop edema, vesicles, erosions, or ulcers. It appears that the degree of inflammation parallels therapeutic efficacy. No systemic effects have been reported.

Systemic *vinblastine* (VELBAN, others) is approved for use in Kaposi's sarcoma and advanced cutaneous T-cell lymphoma. Intralesional vinblastine also is used to treat Kaposi's sarcoma (Hengge *et al.*, 2002). Intralesional *bleomycin* (BLENOXANE, others) is used for recalcitrant warts and has cytotoxic and proinflammatory effects (Templeton *et al.*, 1994). Intralesional injection of bleomycin into the digits has been associated with a vasospastic response

that mimics Raynaud's phenomenon, local skin necrosis, and flagellate hyperpigmentation (Abess *et al.*, 2003). Intraleisional bleomycin has been used for palliative treatment of squamous cell carcinoma. Systemic bleomycin has been used for Kaposi's sarcoma (*see* Chapter 51 for a more complete discussion of these agents). Liposomal anthracyclines [specifically *doxorubicin* (DOXIL, CAELYX)] may provide first-line monotherapy for advanced Kaposi's sarcoma (Hengge *et al.*, 2002).

Dapsone (4,4'-diaminodiphenylsulfone) has been in clinical use for almost 50 years. Its structure is:

Dapsone is used in dermatology for its antiinflammatory properties, particularly in sterile (noninfectious) pustular diseases of the skin. Dapsone prevents the respiratory burst from myeloperoxidase, suppresses neutrophil migration by blocking integrin-mediated adherence, inhibits adherence of antibodies to neutrophils, and decreases the release of eicosanoids and blocks their inflammatory effects; all these actions are likely to be important in autoimmune skin diseases (Booth *et al.*, 1992; Thuong-Nguyen *et al.*, 1993; Zhu and Stiller, 2001).

Dapsone is approved for use in dermatitis herpetiformis and leprosy. It is particularly useful in the treatment of linear immunoglobulin A (IgA) dermatosis, bullous systemic lupus erythematosus, erythema elevatum diutinum, and subcorneal pustular dermatosis. In addition, reports indicate efficacy in patients with acne fulminans, pustular psoriasis, lichen planus, Hailey-Hailey disease, pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, leukocytoclastic vasculitis, Sweet's syndrome, granuloma faciale, relapsing polychondritis, Behçet's disease, urticarial vasculitis, pyoderma gangrenosum, and granuloma annulare (Paniker and Levine, 2001).

An initial dose of 50 mg/day is prescribed, followed by increases of 25 mg/day at weekly intervals, always with appropriate laboratory testing. Potential side effects of dapsone include methemoglobinemia and hemolysis. The glucose-6-phosphate dehydrogenase (G6PD) level should be checked in all patients before initiating dapsone therapy because dapsone hydroxylamine, the toxic metabolite of dapsone formed by hydroxylation, depletes glutathione within G6PD-deficient cells. The nitroso derivative then causes peroxidation reactions, leading to rapid hemolysis. A maximum dose of 150 to 300 mg/day should be given

in divided doses to minimize the risks of methemoglobinemia. The H₂ blocker cimetidine, at a dose of 400 mg three times daily, alters the degree of methemoglobinemia by competing with dapsone for CYPs. Toxicities include agranulocytosis, peripheral neuropathy, and psychosis.

Thalidomide (THALOMID) is an antiinflammatory, immunomodulating, antiangiogenic agent experiencing resurgence in the treatment of dermatologic diseases (*see* Chapter 52). Its structure is:

The mechanisms that underlie the pharmacologic properties of thalidomide are not clear, although modulation of inflammatory cytokines such as TNF- α , IFN- α , IL-10, IL-12, cyclooxygenase 2, and possibly nuclear factor κ B (NF- κ B) may be involved (Franks *et al.*, 2004). It also can modulate T cells by altering their patterns of cytokine release and can increase keratinocyte migration and proliferation (Wines *et al.*, 2002).

Thalidomide is FDA approved for the treatment of erythema nodosum leprosum. There are reports suggesting its efficacy in actinic prurigo, aphthous stomatitis, Behçet's disease, Kaposi's sarcoma, and the cutaneous manifestations of lupus erythematosus, as well as prurigo nodularis and uremic prurigo. Thalidomide has been associated with increased mortality when used to treat toxic epidermal necrolysis. The drug always will be infamous for its association with limb abnormalities (phocomelia), as well as other congenital anomalies. It also may cause an irreversible neuropathy. *Because of its teratogenic effects, thalidomide use is restricted to specially licensed physicians who fully understand the risks. Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug.*

BIOLOGICAL AGENTS

Biological agents (*see* Chapters 38 and 52) are highly specialized systemic therapies that target specific mediators of the immunologic/inflammatory reactions that are, at least in part, responsible for the clinical manifestations of a disease. The rapidly advancing knowledge of cutaneous immunolo-

Figure 62–2. Immunopathogenesis of psoriasis. Psoriasis is a prototypical inflammatory skin disorder in which specific T-cell populations are stimulated by as yet undefined antigen(s) presented by antigen-presenting cells. The T cells release proinflammatory cytokines such as TNF- α and IFN- γ that induce keratinocyte and endothelial cell proliferation.

gy has brought with it equally impressive innovations in the therapy of malignant disorders such as cutaneous T-cell lymphoma and of immunologic diseases such as psoriasis and psoriatic arthritis. Investigational studies are evaluating a variety of biological agents for the treatment of malignancy and autoimmune diseases. This section will focus on agents that have been well studied or applied widely to the treatment of dermatological disease.

Once thought to be primarily a disorder of keratinocyte hyperproliferation, psoriasis now is known to be an autoimmune process mediated by T-lymphocytes that can react with epidermal keratinocytes (Figure 62–2). The mechanism of biological therapies in psoriasis can be illustrated by a conceptual model that outlines four strategies in the treatment of psoriasis: (1) reduction of pathogenic T cells; (2) inhibition of T-cell activation; (3) immune deviation (from a T_H1 to a T_H2 immune response); and (4) blockade of the activity of inflammatory cytokines (Weinberg, 2003).

Although there are limited long-term data regarding the efficacy and safety of biological agents solely for the treatment of psoriasis, similar, if not identical, therapies have been used extensively in the treatment of rheumatoid arthritis and Crohn's disease. The major advantage of biological agents in the treatment of psoriasis appears to be that they specifically target the activity of T-lymphocytes and cytokines that mediate inflammation with fewer side effects than traditional systemic immunosuppressive/cytotoxic agents.

When evaluating the efficacy of biological agents, it is important to understand the standard measurement of efficacy in psoriasis treatment, the Psoriasis Area Severity Index (PASI). The PASI

quantitates the extent and severity of skin involvement in different body regions as a score from 0 (no lesions) to 72 (severe disease). To gain FDA approval for the treatment of psoriasis, a biological agent must decrease the PASI by 75%. While such quantitation is an essential element in controlled clinical trials, many patients in practice may gain clinically significant benefit from biological treatment without achieving this degree of PASI improvement.

Alefacept (AMEVIVE) was the first immunobiological agent approved for the treatment of moderate-to-severe psoriasis in patients who are candidates for systemic therapy. Alefacept consists of a recombinant fully human fusion protein composed of the binding site of the leukocyte function-associated antigen 3 (LFA-3) protein and a human IgG1 Fc domain. The LFA-3 portion of the alefacept molecule binds to CD2 on the surface of T cells, thus blocking a necessary costimulation step in T-cell activation (Figure 62–3). Importantly, since CD2 is expressed preferentially on memory-effector T cells, naive T cells largely are unaffected by alefacept. A second important action of alefacept is its ability to induce apoptosis of memory-effector T cells through simultaneous binding of its IgG1 portion to immunoglobulin receptors on cytotoxic cells and its LFA-3 portion to CD2 on T cells, thus inducing granzyme-mediated apoptosis of memory-effector T cells.

Alefacept is administered by in-office intramuscular injection at a dose of 15 mg/week for 12 weeks. An additional 12-week course can be initiated if required, and a continuous 24-week regimen is under investigation. In an international randomized, double-blind, placebo-controlled phase III trial of intramuscular alefacept (15 mg once weekly for 12 weeks, 10 mg once weekly for 12 weeks, or placebo), 21% of patients receiving the 15-mg dose showed a 75%

Figure 62–3. Mechanisms of action of selected biological agents in psoriasis. Newer biological agents can interfere with one or more steps in the pathogenesis of psoriasis, resulting in clinical improvement. See text for details.

reduction in PASI, and 42% of patients showed a 50% decrease in PASI at week 14. Of those patients who achieved a 75% PASI reduction at week 14, 71% maintained a minimum PASI improvement of 50% throughout the 12-week follow-up period (Lebwohl *et al.*, 2004), suggesting that alefacept may induce longer remissions than do other biological agents. Adverse effects include a reduction in CD4⁺ lymphocyte counts, requiring a baseline T-lymphocyte count before initiating alefacept and weekly monitoring of T cells during therapy.

Efalizumab (RAPTIVA) is a humanized monoclonal antibody against the CD11a molecule of LFA-1. By binding to CD11a on T cells, efalizumab prevents binding of LFA-1 to intercellular adhesion molecule 1 (ICAM-1) on the surface of antigen-presenting cells, vascular endothelial cells, and cells in the dermis and epidermis (see Figure 62–3), thereby interfering with T-cell activation and migration and cytotoxic T-cell function (Weinberg, 2003). Efalizumab is FDA approved for the treatment of moderate-to-severe psoriasis in patients who are candidates for systemic therapy.

The drug is administered by subcutaneous injection once a week at a dose of 1 mg/kg, usually for 12 or 24 weeks. In a phase III, multicenter, randomized, placebo-controlled, double-blind trial, at a dose of 1 mg/kg per week, 52% and 22% of patients achieved reductions in their PASI scores of 50 and 75, respectively. At a dose of 2 mg/kg, 57% and 28% of patients achieved PASI reductions of 50 and 75, respectively. In patients who achieved PASI reductions

of 75 or greater at week 12 and were treated through week 24 with 2 mg/kg every other week, 78% and 95% of patients achieved PASI reductions of 50 and 75, respectively (Lebwohl *et al.*, 2004). After discontinuation of therapy, patients may experience rebound of disease. It is recommended that periodic evaluation of platelet levels be performed during therapy. Side effects generally are mild, and there is no evidence to date of increased risk of malignancy, infection, or end-organ toxicity (Weinberg, 2003).

Etanercept (ENBREL) is FDA approved for the treatment of psoriasis, psoriatic arthritis, rheumatoid arthritis, juvenile rheumatoid arthritis, and ankylosing spondylitis. Etanercept is a soluble, recombinant, fully human TNF receptor fusion protein consisting of two molecules of the ligand-binding portion of the TNF receptor fused to the Fc portion of IgG1. As a dimeric molecule, it can bind two molecules of TNF. Etanercept binds soluble and membrane-bound TNF, thereby inhibiting the action of TNF (Krueger and Callis, 2004).

Etanercept is administered by subcutaneous injection at doses of either 25 or 50 mg twice a week. In a phase III, placebo-controlled, double-blind, parallel-group study, 34% and 44% of patients receiving the 25-mg dose reached PASI reductions of 75% at 12 and 24 weeks, respectively, and 58% and 70% of patients achieved PASI reductions of 50% at 12 and 24 weeks, respectively. At the 50-mg dose, 49% and 59% reached PASI reduction of 75% at 12 and 24 weeks, respectively, and 74% and 77% reached PASI reductions of 50% at 12 and 24 weeks, respectively. Except for injection-site reactions, the drug is well tolerated. Monthly complete blood counts with a differential should be monitored for the first 3 months of treatment. Potential side effects include aplastic anemia, increased risk of infection, and exacerbation of congestive heart failure and demyelinating disorders. The risk of malignancy is unknown but may be increased with the use of etanercept.

Infliximab (REMICADE) is a mouse–human chimeric monoclonal antibody that binds to soluble and membrane-bound TNF- α and inhibits binding with its receptors (Krueger and Callis, 2004). Infliximab is a complement-fixing antibody that induces complement-dependent and cell-mediated lysis when bound to cell-surface-bound TNF- α . It also induces proinflammatory cytokines, such as IL-1 and IL-6, and enhances leukocyte migration. Infliximab is FDA approved for the treatment of Crohn’s disease and rheumatoid arthritis, but it is also in phase III trials for the treatment of psoriasis.

Infliximab is administered by intravenous infusion over 2 hours at doses of 3 or 5 mg/kg, usually at weeks 0, 2, and 6. In a phase II trial, 82% and 72% of patients given the 3 mg/kg dose for 10 weeks achieved PASI reductions of 50% and 75%, respectively, whereas 97% and 75% of those receiving the 5 mg/kg dose achieved PASI reductions of 50% and 75%, respectively (Weinberg, 2003). Complications of therapy include infusion reactions, reactivation of latent tuberculosis infection, exacerbation of congestive heart failure, and multiple sclerosis–like syndromes. Purified protein derivative (PPD) testing is required before initiating therapy. Neutralizing antibodies to

infliximab may develop, and concomitant administration of methotrexate or glucocorticoids may suppress antibody formation.

Denileukin diftitox or DAB₃₈₉-IL-2, (ONTAK) is a fusion protein composed of diphtheria toxin fragments A and B and the receptor-binding portion of IL-2. DAB₃₈₉-IL-2 is indicated for advanced cutaneous T-cell lymphoma in patients with more than 20% of T cells expressing the surface marker CD25. The IL-2 portion of the fusion protein binds the CD25 marker on the T cell and promotes destruction of the T cell by the cytotoxic action of diphtheria toxin.

In a phase III trial consisting of 9 or 18 $\mu\text{g}/\text{kg}$ per day of DAB₃₈₉-IL-2 given as an intravenous infusion for 5 consecutive days every 3 weeks for up to 6 months or eight courses, the overall response rate was 36% with 18 $\mu\text{g}/\text{kg}$ per day and 23% with 9 $\mu\text{g}/\text{kg}$ per day. Adverse effects included pain, fevers, chills, nausea, vomiting, and diarrhea. Immediate hypersensitivity manifested by hypotension, back pain, dyspnea, and chest pain occurred in 60% of patients within 24 hours of drug administration; other serious side effects of DAB₃₈₉-IL-2 are the capillary leak syndrome (*i.e.*, edema, hypoalbuminemia, and/or hypotension), occurring in 20% to 30% of patients, and elevated blood levels of hepatic transaminases (Olsen *et al.*, 2001; Apisarnthanarax *et al.*, 2002).

INTRAVENOUS IMMUNOGLOBULIN IN DERMATOLOGY

Intravenous immunoglobulin (IVIG) is prepared from fractionated pooled human sera derived from thousands of donors with various antigenic exposures (*see* Chapter 52). Commercial preparations of IVIG are composed mainly of IgG with minimal amounts of IgA. There is a risk of anaphylaxis if IgA-deficient patients receive IVIG that is not IgA-poor. Although the mechanism of action of IVIG is not understood fully, proposed mechanisms include anti-idiotypic interactions, Fc receptor modulation, cytokine inhibition, neutralization of causative microbes or toxins, superantigen neutralization, and acceleration of IgG catabolism (Colsky, 2000). While mostly anecdotal, reports of successful use of IVIG in the treatment of autoimmune and inflammatory dermatoses are accumulating. IVIG has been used to treat dermatomyositis, chronic recalcitrant urticaria/angioedema, atopic dermatitis, systemic lupus erythematosus, and autoimmune blistering disorders.

A multicenter retrospective analysis of 48 cases of toxic epidermal necrolysis (TEN) treated with IVIG at a dose of 1 g/kg per day for 3 days demonstrated remarkably rapid cessation of cutaneous and mucosal blistering and improved survival (Prins *et al.*, 2003). A subsequent retrospective chart review that compared the outcome of 24 TEN patients treated with IVIG with 21 patients who did not receive IVIG found no improvement in mortality

but rather a possible detrimental trend in treated patients (Brown *et al.*, 2004). Clearly, a multicenter, prospective, double-blind, randomized trial is needed to determine the usefulness of IVIG in the treatment of TEN.

SUNSCREENS

Photoprotection from the acute and chronic effects of sun exposure is readily available with sunscreens. The major active ingredients of available sunscreens include chemical agents that absorb incident solar radiation in the UVB and/or UVA ranges and physical agents that contain particulate materials that can block or reflect incident energy and reduce its transmission to the skin. Many of the sunscreens available are mixtures of organic chemical absorbers and particulate physical substances. Ideal sunscreens provide a broad spectrum of protection and are formulations that are photostable and remain intact for sustained periods on the skin. They also should be nonirritating, invisible, and nonstaining to clothing. No single sunscreen ingredient possesses all these desirable properties, but many are quite effective nonetheless.

UVA Sunscreen Agents

Currently available UVA filters in the United States include (1) *avobenzene*, also known as *Parsol 1789*; (2) *oxybenzone* (2-hydroxy-4-methoxy-benzophenone); (3) *titanium dioxide*; and (4) *zinc oxide*. Additional UVA sunscreens, including *ecamsule* (MEXORYL SX and XL), *bisethylhexyloxyphenol methoxyphenyl triazine* (TINOSORB S), and *methylene bisbenzotriazolyl tetramethylbutylphenol* (TINSORB M), are available in Europe and elsewhere but not in the United States.

UVB Sunscreen Agents

There are numerous UVB filters, including (1) PABA esters (*e.g.*, *padimate O*); (2) cinnamates (*octinoxate*); (3) *octocrylene* (2-ethylhexyl-2-cyano-3,3 diphenylacrylate); and (4) salicylates (*octisalate*).

The major measurement of sunscreen photoprotection is the *sun protection factor* (SPF), which defines a ratio of the minimal dose of incident sunlight that will produce erythema or redness (sunburn) on skin with the sunscreen in place (protected) and the dose that evokes the same reaction on skin without the sunscreen (unprotected). The SPF provides valuable information regarding UVB protection but is useless in documenting UVA efficacy because no standard systems have been developed to measure UVA protection. Such protocols are needed because more than 85% of solar ultraviolet radiation reaching earth's surface is UVA, which penetrates more deeply into human skin than does UVB and appears to play an important role in photoaging and photocarcinogenesis. Despite their universal availability, a major problem with sunscreens is the fact that people do not use them on a regular basis. In a population study evaluating the use of sunscreens in northern England, it was reported that only 35% of females and 8% of males regularly used sunscreens (Ling *et al.*, 2003). Furthermore, 22% of those surveyed used no sunscreen at all, and 34% recalled at least one sunburn reaction in the previous 2 years.

There is evidence that the regular use of sunscreens can reduce the risk of actinic keratoses (Thompson *et al.*, 1993) and squamous cell carcinomas (SCCs) of the skin. One study noted a 46% decrease in the incidence of SCCs in people who used sunscreen regularly for 4.5 years (Green *et al.*, 1999).

Except for total sun avoidance, sunscreens are the best single method of protection from UV-induced damage to the skin. There is a need for more definitive answers to questions related to the efficacy of sunscreens in reducing skin cancer risk. Prospects for more effective photoprotection are excellent as better sunscreen components are developed and as more careful evaluations are performed (Rigel, 2002).

THE TREATMENT OF PRURITUS

The term *pruritus* is derived from the Latin *prurire*, which means “to itch.” Pruritus is a symptom unique to skin that occurs in a multitude of dermatologic disorders, including dry skin or xerosis, atopic eczema, urticaria, and infestations. Itching also may be a sign of internal disorders, including malignant neoplasms, chronic renal failure, and hepatobiliary disease. The treatment of pruritus varies greatly depending on the underlying disorder.

General measures employing copious application of emollients usually are sufficient for xerosis. Inflammatory disorders such as atopic dermatitis, contact dermatitis, and lichen simplex chronicus may respond better to potent topical glucocorticoids and oral doses of sedating antihistamines. Antihistamines are useful in histamine-induced pruritus and in other pruritic disorders in which the sedating effects of these drugs facilitate sleep and reduce scratching at night, when most pruritic disorders are more symptomatic.

Cholestasis-associated pruritus may respond to *cholestyramine* (QUESTRAN, others; *see* Chapter 35), *ursodeoxycholic acid* (ACTIGALL, others; *see* Chapter 37), *ondansetron* (ZOFRAN; *see* Chapter 37), or *rifampin* (*see* Chapter 47). Recently, *nalmefene* (REVEX) (20 mg twice per day; *see* Chapter 21) has been shown to be effective in cholestatic pruritus (Bergasa *et al.*, 1999).

The pruritus of uremia is treated most effectively with UVB radiation. Prurigo, a ubiquitous disorder associated with itchy nodules of the skin, is notoriously difficult to treat. In addition to topical and intralesional steroids, prurigo may respond to the opioid antagonist *naltrexone* (*see* Chapter 21) at a dose of 50 mg/day (Metze *et al.*, 1999) or to the proton pump inhibitor *omeprazole* (*see* Chapter 36).

MISCELLANEOUS DRUGS

Azelaic acid (AZELEX, FINACEA) is a naturally occurring dicarboxylic acid used for the treatment of acne and pig-

mentary disorders such as melasma and postinflammatory hyperpigmentation. Its structure is:

In the United States, azelaic acid is available as a 20% cream. Azelaic acid has been used for the treatment of pigmentary disorders because of its inhibition of tyrosinase, the rate-limiting enzyme in the synthesis of melanin (Hsu and Quan, 2001). Azelaic acid also possesses comedolytic and antimicrobial activity and may have additional antiinflammatory properties. Applied topically twice a day, azelaic acid is effective for the treatment of acne. In patients with papulopustular rosacea, 15% azelaic acid gel was superior to metronidazole gel (0.75%) in the treatment of inflammatory lesions and erythema; neither medication improved the telangiectatic blood vessels that frequently accompany rosacea (Elewski *et al.*, 2003).

Calcipotriene (DOVONEX) is a vitamin D analog that is used in the treatment of psoriasis. Its structure is:

It was developed after the fortuitous observation of improved psoriasis in a patient with osteoporosis receiving an oral derivative of 1,25-dihydroxyvitamin D₃ [1,25-(OH)₂D₃], the active form of vitamin D (Morimoto and Kumahara, 1985) (*see* Chapter 61). 1,25-(OH)₂D₃ plays a major role in calcium homeostasis by activating the vitamin D receptor, which belongs to the steroid/thyroid hormone receptor superfamily. The receptor–vitamin D complex binds to DNA and modulates the transcription of genes related to cell proliferation and differentiation.

Calcipotriene is applied twice daily to plaque psoriasis on the body. Improvement is detectable within 1 to 2 weeks, and maximum clinical response occurs within 6 to 8 weeks. Most patients show some improvement, but

complete resolution occurs in no more than 15%. Maintenance therapy usually is necessary, and tachyphylaxis does not occur (Kragballe, 1992). Reports of hypercalcemia with calcipotriene are rare (Hardman *et al.*, 1993).

DRUGS FOR HYPERKERATOTIC DISORDERS

Keratolytic agents—including *lactic acid*, *glycolic acid*, *salicylic acid*, *urea*, and *sulfur*—are employed to treat various forms of hyperkeratosis ranging from calluses and verrucae to severe xerosis. Lactic and glycolic acid are α -hydroxy acids that are thought to disrupt ionic bonds and thus diminish corneocyte cohesion (Van Scott and Yu, 1984).

Salicylic acid is a β -hydroxy acid that is thought to function through solubilization of intercellular cement, again reducing corneocyte adhesion. It appears to eliminate the stratum corneum layer by layer from the outermost level downward. This contrasts with the α -hydroxy acids, which preferentially diminish cellular cohesion between the corneocytes at the lowest levels of the stratum corneum.

Urea is an antimicrobial agent that denatures and dissolves proteins and increases skin absorption and retention of water (Hessel *et al.*, 2001). Sulfur is antiseptic, antiparasitic, antiseborrheic, and keratolytic, accounting for its myriad uses in dermatology.

Keratolytics are available in a multitude of formulations for treating skin diseases. Prolonged use of salicylic acid preparations over large areas, especially in children and patients with renal and hepatic impairment, can result in salicylism. Irritation is a common side effect with higher concentrations. Lactic acid (LAC-HYDRIN, others) is an emollient that contains 12% lactic acid that is an effective moisturizer indicated for the treatment of xerosis and ichthyosis vulgaris.

Glycolic acid is marketed in multiple cosmetic preparations (4% to 10%) and is used for the treatment of xerosis, ichthyosis, and photoaging.

Destructive Agents

Podophyllin (podophyllum resin) is a mixture of chemicals from the plant *Podophyllum peltatum* (mandrake or May apple). The major constituent of the resin is podophyllotoxin (podofilox). It binds to microtubules and causes mitotic arrest in metaphase. Podophyllum resin (10% to 40%) is applied by a physician and left in place for 2 to 6 hours weekly for the treatment of anogenital warts. Irritation and ulcerative local reactions are the major side effects. It should not be used in the mouth or during pregnancy. Podofilox (CONDYLOX, others) is available as a 0.5% solution for application twice daily for 3 consecutive days. Weekly cycles may be repeated.

DRUGS FOR ANDROGENETIC ALOPECIA

Androgenetic alopecia, commonly known as male and female pattern baldness, is the most common cause of hair loss in adults older than age 40. Up to 50% of men and women are affected. Androgenetic alopecia is a genetically inherited trait with variable expression. In susceptible hair follicles, dihydrotestosterone binds to the androgen receptor, and the hormone–receptor complex activates the genes responsible for the gradual transformation of large terminal follicles into miniaturized vellus follicles. Treatment of androgenetic areata is aimed at reducing hair loss and maintaining existing hair. The capacity to stimulate substantial regrowth of human hair remains a formidable pharmacological challenge.

Minoxidil (ROGAINE) was first developed as an antihypertensive agent (*see* Chapter 32) and was noted to be associated with hypertrichosis in some patients. A topical formulation of minoxidil then was developed to exploit this side effect. The structure of minoxidil is:

Topical minoxidil is available as a 2% solution (ROGAINE) and a 5% solution (ROGAINE EXTRA STRENGTH FOR MEN). Minoxidil enhances follicular size, resulting in thicker hair shafts, and stimulates and prolongs the anagen phase of the hair cycle, resulting in longer and increased numbers of hairs (Fiedler, 1999). Treatment must be continued, or any drug-induced hair growth will be lost. Allergic and irritant contact dermatitis can occur, and care should be taken in applying the drug because hair growth may emerge in undesirable locations. This is reversible on stopping the drug. Patients should be instructed to wash their hands after applying minoxidil.

Finasteride (PROPECIA) inhibits the type II isozyme of 5α -reductase, the enzyme that converts testosterone to dihydrotestosterone (*see* Chapter 58). The structure of finasteride is:

The type II 5 α -reductase is found in hair follicles. Balding areas of the scalp are associated with increased dihydrotestosterone levels and smaller hair follicles than nonbalding areas. Orally administered finasteride (1 mg/day) has been shown to variably increase hair growth in men over a 2-year period, increasing hair counts in the vertex and the frontal scalp (Leyden *et al.*, 1999). Finasteride is approved for use only in men. Pregnant women should not be exposed to the drug because of the potential for inducing genital abnormalities in male fetuses. Adverse effects of finasteride include decreased libido, erectile dysfunction, ejaculation disorder, and decreased ejaculate volume. Each of these occurs in less than 2% of patients (Kaufman *et al.*, 1998). Like minoxidil, treatment with finasteride must be continued, or any new hair growth will be lost.

TREATMENT OF HYPERPIGMENTATION

Hyperpigmentation is treated with products containing *hydroquinone* that produce reversible depigmentation of the skin by inhibiting the enzymatic oxidation of tyrosine to 3,4-dihydroxyphenylalanine and also inhibiting other melanocyte metabolic processes. It is indicated for the gradual bleaching of hyperpigmented skin in conditions such as melasma, freckles, and solar lentigines. Concomitant application of SPF 15 to 30 sunscreens and meticulous photoprotection are essential to minimize sun-induced exacerbation of hyperpigmentation. Numerous preparations are available (SOLAQUIN FORTE, others). The structure of hydroquinone is:

MISCELLANEOUS AGENTS

Capsaicin is a naturally occurring substance derived from hot chili peppers of the genus *Capsicum*. Its structure is:

Capsaicin interacts with the vanilloid receptor (VR1) on sensory afferents. VR1 is a gated cation channel of the TRP family, modulated by a variety of noxious stimuli (Caterina

and Julius, 2001). Chronic exposure to capsaicin stimulates and desensitizes this channel. Capsaicin also causes local depletion of substance P, an endogenous neuropeptide involved in sensory perception and pain transmission. Capsaicin is available as a 0.025% cream (ZOSTRIX, others) and a 0.075% cream (ZOSTRIX HP, others) to be applied three to four times daily. Capsaicin is FDA approved for the treatment of postherpetic neuralgia and painful diabetic neuropathy, although its efficacy in relieving pain is debatable.

Masoprocol, a dicatechol compound with an aliphatic spacer, is derived from the plant *Larrea divaricata*; it is a potent 5-lipoxygenase inhibitor with anti-tumor activity. It is effective for the topical therapy of actinic keratoses (Olsen *et al.*, 1991). Masoprocol is available as a cream (ACTINEX) and is applied twice daily for approximately 1 month. Common side effects include redness, scaling, and pruritus.

Ophthalmology

CHAPTER

63

OCULAR PHARMACOLOGY

Jeffrey D. Henderer and Christopher J. Rapuano

OVERVIEW OF OCULAR ANATOMY, PHYSIOLOGY, AND BIOCHEMISTRY

The eye is a specialized sensory organ that is relatively secluded from systemic access by the blood–retinal, blood–aqueous, and blood–vitreous barriers; as a consequence, the eye exhibits some unusual pharmacodynamic and pharmacokinetic properties. Because of its anatomical isolation, the eye offers a unique, organ-specific pharmacological laboratory to study the autonomic nervous system and effects of inflammation and infectious diseases. No other organ in the body is so readily accessible or as visible for observation; however, the eye also presents some unique opportunities as well as challenges for drug delivery (Robinson, 1993).

Extraocular Structures

The eye is protected by the eyelids and by the orbit, a bony cavity of the skull that has multiple fissures and foramina that conduct nerves, muscles, and vessels (Figure 63–1). In the orbit, connective (*i.e.*, Tenon’s capsule) and adipose tissues and six extraocular muscles support and align the eyes for vision. The retrobulbar region lies immediately behind the eye (or *globe*). Understanding ocular and orbital anatomy is important for safe periocular drug delivery, including subconjunctival, sub-Tenon’s, and retrobulbar injections.

The eyelids serve several functions. Foremost, their dense sensory innervation and eyelashes protect the eye from mechanical and chemical injuries. Blinking, a coordinated movement of the orbicularis oculi, levator palpebrae, and Müller’s muscles, serves to distribute tears over the cornea and conjunctiva. In humans, the average blink rate is 15 to 20 times per minute. The external surface of the eyelids is covered by a thin layer of skin; the internal surface is lined with the palpebral portion of the conjunctiva, which is a vascularized mucous membrane continuous with the bulbar conjunctiva. At the reflection of the palpebral and bulbar conjunctivae is a space called the fornix, located superiorly and inferiorly behind the upper and lower lids, respectively. Topical medications usually are placed in the inferior fornix, also known as the inferior cul-de-sac.

The lacrimal system consists of secretory glandular and excretory ductal elements (Figure 63–2). The secretory system is composed of the main lacrimal gland, which is located in the temporal outer portion of the orbit, and accessory glands, also known as the glands of Krause and Wolfring (Figure 63–1), located in the conjunctiva. The lacrimal gland is innervated by the autonomic nervous system (Table 63–1 and Chapter 6). The parasympathetic innervation is clinically relevant since a patient may complain of dry eye symptoms while taking medications with anticholinergic side effects, such as tricyclic antidepressants (*see* Chapter 17), antihistamines (*see* Chapter 25),

Figure 63–1. *Anatomy of the globe in relationship to the orbit and eyelids.* Various routes of administration of anesthesia are demonstrated by the blue needle pathways.

and drugs used in the management of Parkinson's disease (see Chapter 20). Located just posterior to the eyelashes are meibomian glands (Figure 63–1), which secrete oils that retard evaporation of the tear film. Abnormalities in gland function, as in acne rosacea and meibomitis, can greatly affect tear film stability.

Conceptually, tears constitute a trilaminar lubrication barrier covering the conjunctiva and cornea. The anterior layer is composed primarily of lipids secreted by the meibomian glands. The middle aqueous layer, produced by the main lacrimal gland and accessory lacrimal glands

(i.e., Krause and Wolfring glands), constitutes about 98% of the tear film. Adherent to the corneal epithelium, the posterior layer is a mixture of mucins produced by goblet cells in the conjunctiva. Tears also contain nutrients, enzymes, and immunoglobulins to support and protect the cornea.

The tear drainage system starts through small puncta located on the medial aspects of both the upper and lower eyelids (Figure 63–2). With blinking, tears enter the puncta and continue to drain through the canaliculi, lacrimal sac, nasolacrimal duct, and then into the nose. The nose is

Figure 63–2. *Anatomy of the lacrimal system.*

Table 63–1
Autonomic Pharmacology of the Eye and Related Structures

TISSUE	Adrenergic Receptors		Cholinergic Receptors	
	SUBTYPE	RESPONSE	SUBTYPE	RESPONSE
Corneal epithelium	β_2	Unknown	M^{\dagger}	Unknown
Corneal endothelium	β_2	Unknown	Undefined	Unknown
Iris radial muscle	α_1	Mydriasis		
Iris sphincter muscle			M_3	Miosis
Trabecular meshwork	β_2	Unknown		
Ciliary epithelium [‡]	α_2/β_2	Aqueous production		
Ciliary muscle	β_2	Relaxation [§]	M_3	Accommodation
Lacrimal gland	α_1	Secretion	M_2, M_3	Secretion
Retinal pigment epithelium	α_1/β_2	H ₂ O transport/unknown		

[†]Although acetylcholine and choline acetyltransferase are abundant in corneal epithelium of most species, the function of this neurotransmitter in this tissue is unknown. [‡]The ciliary epithelium is also the target of carbonic anhydrase inhibitors. Carbonic anhydrase isoenzyme II is localized to both the pigmented and nonpigmented ciliary epithelium. [§]Although β_2 adrenergic receptors mediate ciliary body smooth muscle relaxation, there is no clinically significant effect on accommodation.

lined by a highly vascular mucosal epithelium; consequently, topically applied medications that pass through this nasolacrimal system have direct access to the systemic circulation.

Ocular Structures

The eye is divided into anterior and posterior segments (Figure 63–3A). Anterior segment structures include the cornea, limbus, anterior and posterior chambers, trabecular meshwork, Schlemm's canal, iris, lens, zonule, and ciliary body. The posterior segment comprises the vitreous, retina, choroid, sclera, and optic nerve.

Anterior Segment. The cornea is a transparent and avascular tissue organized into five layers: epithelium, Bowman's membrane, stroma, Descemet's membrane, and endothelium (Figure 63–3B).

Representing an important barrier to foreign matter, including drugs, the hydrophobic epithelial layer comprises five to six cell layers. The basal epithelial cells lie on a basement membrane that is adjacent to Bowman's membrane, a layer of collagen fibers. Constituting approximately 90% of the corneal thickness, the stroma, a hydrophilic layer, is uniquely organized with collagen lamellae synthesized by keratocytes. Beneath the stroma lies Descemet's membrane, the basement membrane of the corneal endothelium. Lying most posteriorly, the endothelium is a monolayer of cells adhering to each other by tight junctions. These cells maintain corneal integrity by active transport processes and serve as a hydrophobic barrier. Hence, drug absorption across the cornea requires penetration of the

trilaminar hydrophobic-hydrophilic-hydrophobic domains of the various anatomical layers.

At the periphery of the cornea and adjacent to the sclera lies a transitional zone (1 to 2 mm wide) called the limbus. Limbal structures include the conjunctival epithelium, which contains the stem cells, Tenon's capsule, episclera, corneoscleral stroma, Schlemm's canal, and trabecular meshwork (Figure 63–3B). Limbal blood vessels, as well as the tears, provide important nutrients and immunological defense mechanisms for the cornea. The anterior chamber holds approximately 250 μ l of aqueous humor. The peripheral anterior chamber angle is formed by the cornea and the iris root. The trabecular meshwork and canal of Schlemm are located just above the apex of this angle. The posterior chamber, which holds approximately 50 μ l of aqueous humor, is defined by the boundaries of the ciliary body processes, posterior surface of the iris, and lens surface.

Aqueous Humor Dynamics and Regulation of Intraocular Pressure. Aqueous humor is secreted by the ciliary processes and flows from the posterior chamber, through the pupil, into the anterior chamber, and leaves the eye primarily by the trabecular meshwork and canal of Schlemm. From the canal of Schlemm, aqueous humor drains into an episcleral venous plexus and into the systemic circulation. This conventional pathway accounts for 80% to 95% of aqueous humor outflow and is the main target for cholinergic drugs used in glaucoma therapy. Another outflow pathway is the uveoscleral route (*i.e.*, fluid flows through the ciliary muscles and into the suprachoroidal space), which is the target of selective prostanooids (*see* Chapter 25 and later in this chapter).

The peripheral anterior chamber angle is an important anatomical structure for differentiating two forms of glaucoma: open-angle glaucoma, which is by far the most common form of glaucoma in the United States, and angle-closure glaucoma. Current medical therapy of *open-angle glaucoma* is aimed at decreasing aqueous humor production and/or increasing aqueous outflow. The preferred management for *angle-closure glaucoma* is surgical iridectomy, either by laser or by incision, but short-term medical management

Figure 63-3. A. Anatomy of the eye. B. Enlargement of the anterior segment revealing the cornea, angle structures, lens, and ciliary body. (B. Adapted with permission from Riordan-Eva, P., Tabbara, K.F. Anatomy and embryology of the eye. In, *General Ophthalmology*, 13th ed. (Vaughan, D., Asbury, T., Riordan-Eva, P., eds.) Appleton & Lange, Stamford, CT, 1992.)

may be necessary to reduce the acute intraocular pressure elevation and to clear the cornea prior to surgery. Long-term intraocular pressure reduction may be necessary, especially if the peripheral iris has permanently covered the trabecular meshwork. Acute angle-closure glaucoma may be induced rarely in anatomically predisposed eyes

by anticholinergic, sympathomimetic, and antihistaminic agents. Interestingly, however, individuals with susceptible angles are not aware of a risk of angle-closure glaucoma. Unfortunately, drug warning labels do not always specify the type of glaucoma for which this rare risk exists. Thus, unwarranted concern is raised

among patients who have open-angle glaucoma who need not be concerned about taking these drugs. In any event, in anatomically susceptible eyes, anticholinergic, sympathomimetic, and antihistaminic drugs can lead to partial dilation of the pupil and a change in the vectors of force between the iris and the lens. The aqueous humor then is prevented from passing through the pupil from the posterior chamber to the anterior chamber. The result is known as an acute attack of pupillary-block angle-closure glaucoma. The change in the lens-iris relationship leads to an increase in pressure in the posterior chamber, causing the iris base to be pushed against the angle wall, thereby closing the filtration angle and markedly elevating the intraocular pressure.

Iris and Pupil. The iris is the most anterior portion of the uveal tract, which also includes the ciliary body and choroid. The anterior surface of the iris is the stroma, a loosely organized structure containing melanocytes, blood vessels, smooth muscle, and parasympathetic and sympathetic nerves. Differences in iris color reflect individual variation in the number of melanocytes located in the stroma. Individual variation may be an important consideration for ocular drug distribution due to drug-melanin binding (see “Distribution,” below). The posterior surface of the iris is a densely pigmented bilayer of epithelial cells. Anterior to the pigmented epithelium, the dilator smooth muscle is oriented radially and is innervated by the sympathetic nervous system (Figure 63–4) which causes mydriasis (dilation). At the pupillary margin, the sphincter smooth muscle is organized in a circular band with parasympathetic innervation, which when stimulated causes miosis (constriction). The use of pharmacological agents to dilate normal pupils (*i.e.*, for clinical purposes such as examining the ocular fundus) and to evaluate the pharmacological response of the pupil (*e.g.*, unequal pupils, or anisocoria, seen in Horner’s syndrome or Adie’s pupil) is summarized in Table 63–2. Figure 63–5 provides a flowchart for the diagnostic evaluation of anisocoria.

Ciliary Body. The ciliary body serves two very specialized roles in the eye: secretion of aqueous humor by the epithelial bilayer and accommodation by the ciliary muscle. The anterior portion of the ciliary body, called the pars plicata, is composed of 70 to 80 ciliary processes with intricate folds. The posterior portion is the pars plana. The ciliary muscle is organized into outer longitudinal, middle radial, and inner circular layers. Coordinated contraction of this smooth muscle apparatus by the parasympathetic nervous system causes the zonule suspending the lens to relax, allowing the lens to become more convex and to shift slightly forward. This process, known as *accommodation*, permits focusing on near objects and may be pharmacologically blocked by muscarinic cholinergic antagonists, through the process called *cycloplegia*. Contraction of the ciliary muscle also puts traction on the scleral spur, and

Figure 63–4. Autonomic innervation of the eye by the sympathetic (a) and parasympathetic (b) nervous systems. (Adapted with permission from Wybar, K.C., Karr Muir, M. *Baillière’s Concise Medical Textbooks, Ophthalmology*, 3rd ed. Baillière Tindall, New York, 1984.)

hence widens the spaces within the trabecular meshwork. This latter effect accounts for at least some of the intraocular pressure-lowering effect of both directly acting and indirectly acting parasympathomimetic drugs.

Lens. The lens, a transparent biconvex structure, is suspended by *zonules*, specialized fibers emanating from the ciliary body. The lens is approximately 10 mm in diameter and is enclosed in a capsule. The bulk of the lens is composed of fibers derived from proliferating lens epithelial cells located under the anterior portion of the lens capsule. These lens fibers are continuously produced throughout life. Aging, in addition to certain medications, such as corticosteroids, and certain diseases, such as diabetes mellitus, cause the lens to become opacified, which is termed a *cataract*.

Posterior Segment. Because of the anatomical and vascular barriers to both local and systemic access, drug delivery to the eye’s posterior pole is particularly challenging.

Sclera. The outermost coat of the eye, the sclera, covers the posterior portion of the globe. The external surface of the scleral shell is covered by an episcleral vascular coat, by Tenon’s capsule, and by the conjunctiva. The ten-

Table 63–2
Effects of Pharmacological Agents on the Pupil

CLINICAL SETTING	DRUG*	PUPILLARY RESPONSE
Normal	Sympathomimetic drugs	Dilation (mydriasis)
Normal	Parasympathomimetic drugs	Constriction (miosis)
Horner's syndrome	Cocaine 4–10%	No dilation
Preganglionic Horner's	Hydroxyamphetamine 1%	Dilation
Postganglionic Horner's	Hydroxyamphetamine 1%	No dilation
Adie's pupil	Pilocarpine 0.05–0.1% [†]	Constriction
Normal	Opioids (oral or intravenous)	Pinpoint pupils

*Topically applied ophthalmic drugs unless otherwise noted. [†]This percentage of pilocarpine is not commercially available and usually is prepared by the physician administering the test or by a pharmacist. This test also requires that no prior manipulation of the cornea (*i.e.*, tonometry for measuring intraocular pressure or testing corneal sensation) be done so that the normal integrity of the corneal barrier is intact. Normal pupils will not respond to this weak dilution of pilocarpine; however, an Adie's pupil manifests a denervation supersensitivity and is, therefore, pharmacodynamically responsive to this dilute cholinergic agonist.

dons of the six extraocular muscles insert into the superficial scleral collagen fibers. Numerous blood vessels pierce the sclera through emissaria to supply as well as drain the choroid, ciliary body, optic nerve, and iris.

Inside the scleral shell, the vascular choroid nourishes the outer retina by a capillary system in the choriocapillaris. Between the outer retina and the choriocapillaris lie Bruch's membrane and the retinal pigment epithelium, whose tight junctions provide an outer barrier between the retina and the choroid. The retinal pigment epithelium serves many functions, including vitamin A metabolism, phagocytosis of the rod outer segments, and multiple transport processes.

Retina. The retina is a thin, transparent, highly organized structure of neurons, glial cells, and blood vessels. Of all structures within the eye, the neurosensory retina has been the most widely studied. The unique organization and biochemistry of the photoreceptors have provided a superb system for investigating signal transduction mechanisms. The wealth of information about rhodopsin has made it an excellent model for the G protein–coupled signal transduc-

tion. Such detailed understanding holds promise for targeted therapy for some of the hereditary retinal diseases.

Vitreous. Approximately 80% of the eye's volume is the vitreous, which is a clear medium containing collagen type II, hyaluronic acid, proteoglycans, a variety of macromolecules including glucose, ascorbic acid, amino acids, and a number of inorganic salts. Glutamate in the vitreous has been suspected to have a possible relationship to glaucoma. The ganglion cells appear to die in glaucoma *via* a process of apoptosis (Quigley *et al.*, 1995; Wax *et al.*, 1998) and glutamate has been shown to induce apoptosis *via* NMDA-receptor excitotoxicity (Sucher *et al.*, 1997). Elevated glutamate levels have been noted in experimental animal models (Dreyer *et al.*, 1996; Yoles and Schwartz, 1998) and in humans with glaucoma (Dreyer *et al.*, 1996), although this has been questioned (Levkovitch-Verbin *et al.*, 2002). *Memantine*, an uncompetitive NMDA-receptor antagonist (Vorwerk *et al.*, 1996; Chen and Lipton, 1997), is currently being investigated clinically as a possible treatment for glaucoma.

Optic Nerve. The optic nerve is a myelinated nerve conducting the retinal output to the central nervous system. It is composed of (1) an intraocular portion, which is visible as the 1.5-mm optic disk in the retina; (2) an intraorbital portion; (3) an intracanalicular portion; and (4) an intracranial portion. The nerve is ensheathed in meninges continuous with the brain. At present, pharmacological treatment of some optic neuropathies is based on management of the underlying disease. For example, optic neuritis may be treated best with intravenous glucocorticoids (Beck *et al.*, 1992; Beck *et al.*, 1993); glaucomatous optic neuropathy is medically managed by decreasing intraocular pressure.

PHARMACOKINETICS AND TOXICOLOGY OF OCULAR THERAPEUTIC AGENTS

Drug Delivery Strategies

Properties of varying ocular routes of administration are outlined in Table 63–3. A number of delivery systems have been developed for treating ocular diseases. Most ophthalmic drugs are delivered in solutions, but for compounds with limited solubility, a suspension form facilitates delivery.

Several formulations prolong the time a drug remains on the surface of the eye. These include gels, ointments, solid inserts, soft contact lenses, and collagen shields. *Prolonging the time in the cul-de-sac facilitates drug*

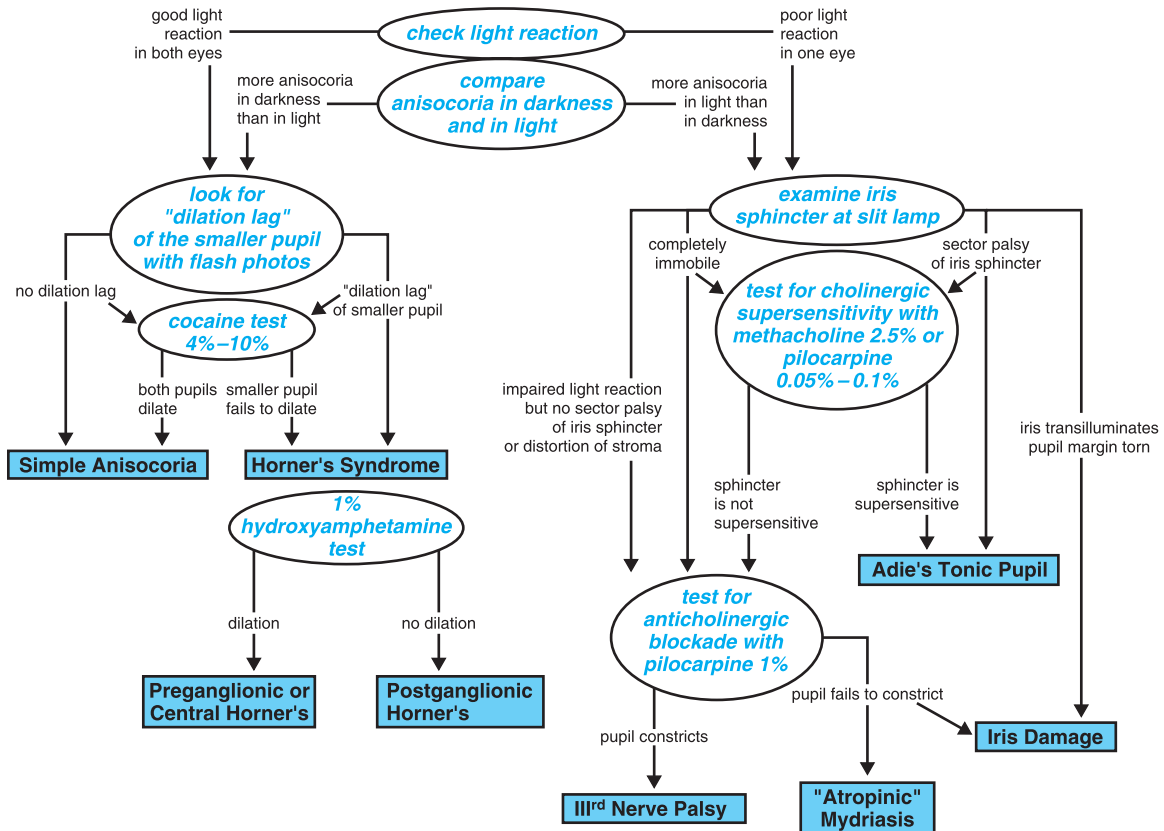

Figure 63–5. Anisocoria evaluation flowsheet. (Adapted with permission from Thompson and Pilley, 1976.)

absorption. Ophthalmic gels (e.g., pilocarpine 4% gel) release drugs by diffusion following erosion of soluble polymers. The polymers used include cellulosic ethers, polyvinyl alcohol, carbopol, polyacrylamide, polymethylvinyl ether–maleic anhydride, poloxamer 407, and puronic acid. Ointments usually contain mineral oil and a petrolatum base and are helpful in delivering antibiotics, cycloplegic drugs, or miotic agents. Solid inserts, such as the *ganciclovir* intravitreal implant, provide a *zero-order* rate of delivery by steady-state diffusion, whereby drug is released at a more constant rate over a finite period of time rather than as a bolus. This surgical implant has been used to deliver anti-cytomegalovirus medication in proximity to the retinal infection (Marx *et al.*, 1996). The intent is to deliver a sustained dose of medication over several months with reduced spikes in drug delivery (Kunou *et al.*, 2000) independent of patient compliance.

Pharmacokinetics

Classical pharmacokinetic theory based on studies of systemically administered drugs (*see* Chapter 1) does not

fully apply to all ophthalmic drugs (Kaur and Kanwar, 2002). Although similar principles of absorption, distribution, metabolism, and excretion determine the fate of drug disposition in the eye, alternative routes of drug administration, in addition to oral and intravenous routes, introduce other variables in compartmental analysis (Table 63–3 and Figure 63–6). Most ophthalmic medications are formulated to be applied topically. Drugs also may be injected by subconjunctival, sub-Tenon's, and retrobulbar routes (Figure 63–1 and Table 63–3). For example, anesthetic agents are administered commonly by injection for surgical procedures and antibiotics and glucocorticoids also may be injected to enhance their delivery to local tissues. The antimetabolite *5-fluorouracil* and the DNA alkylating agent *mitomycin C* may be administered subconjunctivally to retard the fibroblast proliferation related to scarring after glaucoma surgery. Mitomycin C also can be applied to the cornea to prevent scarring after corneal surgery. Intraocular (*i.e.*, intravitreal) injections of antibiotics are considered in instances of endophthalmitis, a severe intraocular infection. The sensitivities of the organisms to the antibiotic and the retinal

Table 63-3
Some Characteristics of Ocular Routes of Drug Administration*

ROUTE	ABSORPTION PATTERN	SPECIAL UTILITY	LIMITATIONS AND PRECAUTIONS
Topical	Prompt, depending on formulation	Convenient, economical, relatively safe	Compliance, corneal and conjunctival toxicity, nasal mucosal toxicity, systemic side effects from nasolacrimal absorption
Subconjunctival, sub-Tenon's, and retrobulbar injections	Prompt or sustained, depending on formulation	Anterior segment infections, posterior uveitis, cystoid macular edema	Local toxicity, tissue injury, globe perforation, optic nerve trauma, central retinal artery and/or vein occlusion, direct retinal drug toxicity with inadvertent globe perforation, ocular muscle trauma, prolonged drug effect
Intraocular (intracameral) injections	Prompt	Anterior segment surgery, infections	Corneal toxicity, intraocular toxicity, relatively short duration of action
Intravitreal injection or device	Absorption circumvented, immediate local effect, potential sustained effect	Endophthalmitis, retinitis	Retinal toxicity

*See text for more complete discussion of individual routes.

toxicity threshold may be nearly the same for some antibiotics; hence, the antibiotic dose injected intravitreally must be carefully titrated. Intraocular inserts are used to treat intraocular viral infections. The ganciclovir implant is indicated to treat cytomegalovirus retinitis in patients with AIDS.

Unlike clinical pharmacokinetic studies on systemic drugs, where data are collected relatively easily from blood samples, there is significant risk in obtaining tissue and fluid samples from the human eye. Consequently, animal models, frequently rabbits, are studied to provide pharmacokinetic data on ophthalmic drugs.

Absorption. After topical instillation of a drug, the rate and extent of absorption are determined by the time the drug remains in the cul-de-sac and precorneal tear film, elimination by nasolacrimal drainage, drug binding to tear proteins, drug metabolism by tear and tissue proteins, and diffusion across the cornea and conjunctiva (Lee, 1993). A drug's residence time may be prolonged by changing its formulation. Residence time also may be extended by blocking the egress of tears from the eye by closing the tear drainage ducts with plugs or cautery. Nasolacrimal drainage contributes to systemic absorption of topically administered ophthalmic medications. Absorption from the nasal mucosa avoids so-called first-pass metabolism by the liver (see Chapter 1), and consequently significant systemic side effects may be caused by topical medications, especially when used chronically. Possible absorption pathways of an ophthalmic drug following topical application to the eye are shown schematically in Figure 63-6.

Transcorneal and transconjunctival/scleral absorption are the desired routes for localized ocular drug effects. The time period

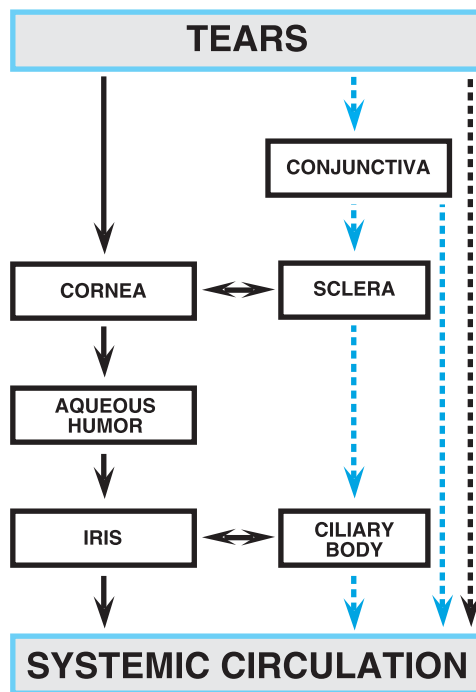

Figure 63-6. Possible absorption pathways of an ophthalmic drug following topical application to the eye. Solid black arrows represent the corneal route; dashed blue arrows represent the conjunctival/scleral route; the black dashed line represents the nasolacrimal absorption pathway. (Adapted with permission from Chien *et al.*, 1990.)

between drug instillation and its appearance in the aqueous humor is defined as the *lag time*. The drug concentration gradient between the tear film and the cornea and conjunctival epithelium provides the driving force for passive diffusion across these tissues. Other factors that affect a drug's diffusion capacity are the size of the molecule, chemical structure, and steric configuration. Transcorneal drug penetration is conceptualized as a differential solubility process; the cornea may be thought of as a trilamellar "fat-water-fat" structure corresponding to the epithelial, stromal, and endothelial layers. The epithelium and endothelium represent barriers for hydrophilic substances; the stroma is a barrier for hydrophobic compounds. Hence, a drug with both hydrophilic and lipophilic properties is best suited for transcorneal absorption.

Drug penetration into the eye is approximately linearly related to its concentration in the tear film. Certain disease states, such as corneal ulcers and other corneal epithelial defects, may alter drug penetration. Medication absorption usually is increased when an anatomic barrier is compromised or removed. Experimentally, drugs may be screened for their potential clinical utility by assessing their corneal permeability coefficients. These pharmacokinetic data combined with the drug's octanol/water partition coefficient (for lipophilic drugs) or distribution coefficient (for ionizable drugs) yield a parabolic relationship that is a useful parameter for predicting ocular absorption. Of course, such *in vitro* studies do not account for other factors that affect corneal absorption, such as epithelial integrity, blink rate, dilution by tear flow, nasolacrimal drainage, drug binding to proteins and tissue, and transconjunctival absorption; hence, these studies have limitations in predicting ocular drug absorption *in vivo*.

Distribution. Topically administered drugs may undergo systemic distribution primarily by nasal mucosal absorption and possibly by local ocular distribution by transcorneal/transconjunctival absorption. Following transcorneal absorption, the aqueous humor accumulates the drug, which then is distributed to intraocular structures as well as potentially to the systemic circulation *via* the trabecular meshwork pathway (Figure 63–3B). Melanin binding of certain drugs is an important factor in some ocular compartments. For example, the mydriatic effect of α adrenergic receptor agonists is slower in onset in human volunteers with darkly pigmented irides compared to those with lightly pigmented irides. In rabbits, radiolabeled *atropine* binds significantly to melanin granules in irides of nonalbino animals. This finding correlates with the fact that atropine's mydriatic effect lasts longer in nonalbino rabbits than in albino rabbits, and suggests that drug–melanin binding is a potential reservoir for sustained drug release. Another clinically important consideration for drug–melanin binding involves the retinal pigment epithelium. In the retinal pigment epithelium, accumulation of *chloroquine* (see Chapter 39) causes a toxic retinal lesion known as a "bull's-eye" maculopathy, which is associated with a decrease in visual acuity.

Metabolism. Enzymatic biotransformation of ocular drugs may be significant since a variety of enzymes, including esterases, oxidoreductases, lysosomal enzymes, peptidases, glucuronide and sulfate transferases, glutathione-conjugating enzymes, catechol-O-methyl-transferase, monoamine oxidase, and 11 β -hydroxysteroid dehydrogenase are found in the eye. The esterases have been of particular interest because of the development of prodrugs for enhanced corneal permeability; for example, *dipivefrin hydrochloride* is a prodrug for *epinephrine*, and *latanoprost* is a prodrug for *prostaglandin F_{2 α}* ; both drugs are used for glaucoma management. Typically

applied ocular drugs are eliminated by the liver and kidney after systemic absorption, but enzymatic transformation of systemically administered drugs also is important in ophthalmology.

Toxicology. All ophthalmic medications are potentially absorbed into the systemic circulation (Figure 63–6), so undesirable systemic side effects may occur. Most ophthalmic drugs are delivered locally to the eye, and the potential local toxic effects are due to hypersensitivity reactions or to direct toxic effects on the cornea, conjunctiva, periocular skin, and nasal mucosa. Eyedrops and contact lens solutions commonly contain preservatives such as benzalkonium chloride, chlorobutanol, chelating agents, and thimerosal for their antimicrobial effectiveness. In particular, benzalkonium chloride may cause a punctate keratopathy or toxic ulcerative keratopathy (Grant and Schuman, 1993). Thimerosal currently is used rarely due to a high incidence of hypersensitivity reactions.

THERAPEUTIC AND DIAGNOSTIC APPLICATIONS OF DRUGS IN OPHTHALMOLOGY

Chemotherapy of Microbial Diseases in the Eye

Antibacterial Agents. General Considerations. A number of antibiotics have been formulated for topical ocular use (Table 63–4). The pharmacology, structures, and kinetics of individual drugs have been presented in detail in Section VIII. Appropriate selection of antibiotic and route of administration is dependent on the patient's symptoms, the clinical examination, and the culture/sensitivity results. Specially formulated antibiotics also may be extemporaneously prepared by qualified pharmacists for serious eye infections such as corneal infiltrates or ulcers and endophthalmitis.

Therapeutic Uses. Infectious diseases of the skin, eyelids, conjunctivae, and lacrimal excretory system are encountered regularly in clinical practice. Periocular skin infections are divided into preseptal and postseptal or orbital cellulitis. Depending on the clinical setting (*i.e.*, preceding trauma, sinusitis, age of patient, relative immunocompromised state), oral or parenteral antibiotics are administered. The microbiological spectrum for orbital cellulitis is changing; for example, there has been a sharp decline in *Haemophilus influenzae* after the introduction in 1985 of the *H. influenzae* vaccine (Ambati *et al.*, 2000).

Dacryoadenitis, an infection of the lacrimal gland, is most common in children and young adults. It may be bacterial (typically *Staphylococcus aureus*, *Streptococcus* species) or viral (most commonly seen in mumps, infectious mononucleosis, influenza, and herpes zoster). When bacterial infection is suspected, systemic antibiotics usually are indicated.

Table 63-4

Topical Antibacterial Agents Commercially Available for Ophthalmic Use*

GENERIC NAME (TRADE NAME)	FORMULATION†	TOXICITY†	INDICATIONS FOR USE
Bacitracin zinc (AK-TRACIN)	500 units/g ointment	H	Conjunctivitis, blepharitis
Chloramphenicol (AK-CHLOR, CHLORO-MYCETIN, CHLOROPTIC)	0.5% solution 1% ointment	H, BD	Conjunctivitis, keratitis
Ciprofloxacin hydrochloride (CIXOXAN)	0.3% solution 0.3% ointment	H, D-RCD	Conjunctivitis, keratitis
Erythromycin (ILOTYCIN)	0.5% ointment	H	Blepharitis, conjunctivitis
Gatifloxacin (ZYMAR)	0.3% solution	H	Conjunctivitis
Gentamicin sulfate (GARAMYCIN, GENOPTIC, GENT-AK, GENTACIDIN)	0.3% solution 0.3% ointment	H	Conjunctivitis, blepharitis, keratitis
Levofloxacin (QUIXIN)	0.5% solution	H	Conjunctivitis
Levofloxacin (IQUIX)	1.5% solution	H	Conjunctivitis, keratitis
Moxifloxacin (VIGAMOX)	0.5% solution	H	Conjunctivitis
Ofloxacin (OCUFLOX)	0.3% solution	H	Conjunctivitis, keratitis
Sulfacetamide sodium (BLEPH-10, CETAMIDE, SULF-10, ISOPTO CETAMIDE, SULAMYD SODIUM, others)	10, 15, 30% solution 10% ointment	H, BD	Conjunctivitis, keratitis
Polymyxin B combinations‡	Various solutions Various ointments		Conjunctivitis, blepharitis, keratitis
Tobramycin sulfate (TOBEX, AKTOB)	0.3% solution 0.3% ointment	H	Conjunctivitis, blepharitis, keratitis

*For specific information on dosing, formulation, and trade names, refer to the *Physician's Desk Reference for Ophthalmology*, which is published annually. †Abbreviations: H, hypersensitivity; BD, blood dyscrasia; D-RCD, drug-related corneal deposits. ‡Polymyxin B is formulated for delivery in combination with bacitracin, neomycin, gramicidin, oxytetracycline, or trimethoprim. See Chapters 43 through 46 for further discussion of these antibacterial agents.

Dacryocystitis is an infection of the lacrimal sac. In infants and children, the disease usually is unilateral and secondary to an obstruction of the nasolacrimal duct. In adults, dacryocystitis and canalicular infections may be caused by *Staphylococcus aureus*, *Streptococcus* species, *Diphtheroids*, *Candida* species, and *Actinomyces israelii*. Any discharge from the lacrimal sac should be sent for smears and cultures. Systemic antibiotics typically are indicated.

Infectious processes of the lids include *hordeolum* and *blepharitis*. A hordeolum, or stye, is an infection of the meibomian, Zeis, or Moll glands at the lid margins. The typical offending bacterium is *S. aureus*, and the usual treatment consists of warm compresses and topical antibiotic ointment. Blepharitis is a common bilateral inflammatory process of the eyelids characterized by irritation and burning, and it also is usually associated with a *Staphylococcus* species. Local hygiene is the mainstay of therapy; topical antibiotics frequently are used, usually in ointment form, particularly when the disease is accompanied

by conjunctivitis and keratitis. Systemic *tetracycline*, *doxycycline*, *minocycline*, and *erythromycin* often are effective in reducing severe eyelid inflammation, but must be used for weeks to months.

Conjunctivitis is an inflammatory process of the conjunctiva that varies in severity from mild hyperemia to severe purulent discharge. The more common causes of conjunctivitis include viruses, allergies, environmental irritants, contact lenses, and chemicals. The less common causes include other infectious pathogens, immune-mediated reactions, associated systemic diseases, and tumors of the conjunctiva or eyelid. The more commonly reported infectious agents are adenovirus and herpes simplex virus, followed by other viral (*e.g.*, enterovirus, coxsackievirus, measles virus, varicella zoster virus, and vaccinia-variola virus) and bacterial sources (*e.g.*, *Neisseria* species, *Streptococcus pneumoniae*, *Haemophilus* species, *S. aureus*, *Moraxella lacunata*, and chlamydial species). *Rickettsia*, fungi, and parasites, in both cyst and trophozoite form, are rare causes of conjunctivitis. Effective man-

agement is based on selection of an appropriate antibiotic for suspected bacterial pathogens. Unless an unusual causative organism is suspected, bacterial conjunctivitis is treated empirically with a broad-spectrum topical antibiotic without obtaining a culture.

Keratitis, or corneal inflammation, can occur at any level of the cornea (*e.g.*, epithelium, subepithelium, stroma, and endothelium). It can be due to noninfectious or infectious causes. Numerous microbial agents have been identified as causes of infectious keratitis, including bacteria, viruses, fungi, spirochetes, and cysts and trophozoites. Severe infections, with tissue loss (corneal ulcers), generally are treated more aggressively than infections without tissue loss (corneal infiltrates). The mild, small, more peripheral infections usually are not cultured and the eyes are treated with broad-spectrum topical antibiotics. In more severe, central, or larger infections, corneal scrapings for smears, cultures, and sensitivities are performed and the patient is immediately started on intensive hourly, around-the-clock topical antibiotic therapy. The goal of treatment is to eradicate the infection and reduce the amount of corneal scarring and the chance of corneal perforation and severe decreased vision or blindness. The initial medication selection and dosage are adjusted according to the clinical response and culture and sensitivity results.

Table 63–5
*Antiviral Agents for Ophthalmic Use**

GENERIC NAME (TRADE NAME)	ROUTE OF ADMINISTRATION	OCULAR TOXICITY†	INDICATION FOR USE
Trifluridine (VIOPTIC)	Topical (1% solution)	PK, H	Herpes simplex keratitis Herpes simplex conjunctivitis
Vidarabine (VIRA-A)	Topical (3% ointment)	PK, H	Herpes simplex keratitis Herpes simplex conjunctivitis
Acyclovir (ZOVIRAX)	Oral, intravenous (200-mg capsules, 400- and 800-mg tablets)		Herpes zoster ophthalmicus Herpes simplex iridocyclitis
Valacyclovir (VALTREX)	Oral (500-mg, 1000-mg tablets)		Herpes simplex keratitis Herpes zoster ophthalmicus
Famciclovir (FAMVIR)	Oral (125-mg, 250-mg, 500-mg tablets)		Herpes simplex keratitis Herpes zoster ophthalmicus
Foscarnet (FOSCAVIR)	Intravenous Intravitreal		Cytomegalovirus retinitis
Ganciclovir (CYTOVENE) (VITRASERT)	Intravenous, oral Intravitreal implant		Cytomegalovirus retinitis
Formivirsen (VITRAVENE)	Intravitreal injection		Cytomegalovirus retinitis
Cidofovir (VISTIDE)	Intravenous		Cytomegalovirus retinitis

*For additional details, see Chapter 49. †Abbreviations: PK, punctate keratopathy; H, hypersensitivity.

Endophthalmitis is a potentially severe and devastating inflammatory, and usually infectious, process involving the intraocular tissues. When the inflammatory process encompasses the entire globe, it is called *panophthalmitis*. Endophthalmitis is usually caused by bacteria or fungi, or rarely by spirochetes. The typical case occurs during the early postoperative course (*e.g.*, after cataract, glaucoma, cornea, or retinal surgery), following trauma, or by endogenous seeding in the immunocompromised host or intravenous drug user. Acute postoperative endophthalmitis requires a prompt vitreous tap for smears and cultures and empirical injection of intravitreal antibiotics. Immediate vitrectomy (*i.e.*, specialized surgical removal of the vitreous) is beneficial for patients who have light perception–only vision (Endophthalmitis Vitrectomy Study Group, 1995). Vitrectomy for other causes of endophthalmitis (*e.g.*, glaucoma bleb–related, posttraumatic, or endogenous) may be beneficial. In cases of endogenous seeding, parenteral antibiotics have a role in eliminating the infectious source, but the efficacy of systemic antibiotics with trauma is not well established.

Antiviral Agents. General Considerations. The various antiviral drugs currently used in ophthalmology are summarized in Table 63–5 (*see* Chapter 49 for additional details about these agents).

Therapeutic Uses. The primary indications for the use of antiviral drugs in ophthalmology are viral keratitis, herpes zoster ophthalmicus (Liesegang, 1999; Chern and Margolis, 1998), and retinitis. There currently are no antiviral agents for the treatment of viral conjunctivitis caused by adenoviruses, which usually has a self-limited course and typically is treated by symptomatic relief of irritation.

Viral keratitis, an infection of the cornea that may involve either the epithelium or stroma, is most commonly caused by herpes simplex type I and varicella zoster viruses. Less common viral etiologies include herpes simplex type II, Epstein-Barr virus, and cytomegalovirus. Topical antiviral agents are indicated for the treatment of epithelial disease due to herpes simplex infection. *When treating viral keratitis topically, there is a very narrow margin between the therapeutic topical antiviral activity and the toxic effect on the cornea;* hence, patients must be followed very closely. The role of oral *acyclovir* and glucocorticoids in herpetic corneal and external eye disease has been examined in the Herpetic Eye Disease Study (Herpetic Eye Disease Study Group, 1997a; Herpetic Eye Disease Study Group, 1998). Topical glucocorticoids are contraindicated in herpetic epithelial keratitis due to active viral replication. In contrast, for herpetic disciform keratitis, which predominantly is presumed to involve a cell-mediated immune reaction, topical glucocorticoids accelerate recovery (Wilhelmus *et al.*, 1994). For recurrent herpetic stromal keratitis, there is clear benefit from treatment with oral acyclovir in reducing the risk of recurrence (Herpetic Eye Disease Study Group, 1998).

Herpes zoster ophthalmicus is a latent reactivation of a varicella zoster infection in the first division of the trigeminal cranial nerve. Systemic acyclovir, *valacyclovir*, and *famciclovir* are effective in reducing the severity and complications of herpes zoster ophthalmicus (Colin *et al.*, 2000). Currently, there are no ophthalmic preparations of acyclovir approved by the FDA, although an ophthalmic ointment is available for investigational use.

Viral retinitis may be caused by herpes simplex virus, cytomegalovirus (CMV), adenovirus, and varicella zoster virus. With the highly active antiretroviral therapy (HAART; see Chapter 50), CMV retinitis does not appear to progress when specific anti-CMV therapy is discontinued, but some patients develop an immune recovery uveitis (Jacobson *et al.*, 2000; Whitcup, 2000). Treatment usually involves long-term parenteral administration of antiviral drugs. Intravitreal administration of ganciclovir has been found to be an effective alternative to the systemic route (Sanborn *et al.*, 1992). Acute retinal necrosis and progressive outer retinal necrosis, most often caused by varicella zoster virus, can be treated by various combinations of oral, intravenous,

intravitreal injection, and intravitreal implantation of antiviral medications (Roig-Melo *et al.*, 2001).

Antifungal Agents. General Considerations. The only currently available topical ophthalmic antifungal preparation is a polyene, *natamycin* (NATACYN), which has the following structure:

Other antifungal agents may be extemporaneously compounded for topical, subconjunctival, or intravitreal routes of administration (Table 63–6). The pharmacology and structures of available antifungal agents are given in Chapter 48.

Therapeutic Uses. As with systemic fungal infections, the incidence of ophthalmic fungal infections has risen with the growing number of immunocompromised hosts. Ophthalmic indications for antifungal medications include fungal keratitis, scleritis, endophthalmitis, mucormycosis, and canaliculitis. Risk factors for fungal keratitis include trauma, chronic ocular surface disease, and immunosuppression (including topical steroid use). When fungal infection is suspected, samples of the affected tissues are obtained for smears, cultures, and sensitivities, and this information is used for drug selection.

Antiprotozoal Agents. General Considerations. Parasitic infections involving the eye usually manifest themselves as a form of *uveitis*, an inflammatory process of either the anterior or posterior segments, and less commonly as conjunctivitis, keratitis, and retinitis.

Therapeutic Uses. In the United States, the most commonly encountered protozoal infections include *Acanthamoeba* and *Toxoplasma gondii*. In contact-lens wearers who develop keratitis, physicians should be highly suspicious of the presence of *Acanthamoeba* (McCulley *et al.*, 2000). Additional risk factors for *Acanthamoeba* keratitis include poor contact lens hygiene, wearing contact lenses in a pool or hot tub, and ocular trauma. Treatment usually consists of a combination topical antibiotic, such as *poly-*

Table 63–6
Antifungal Agents for Ophthalmic Use*

DRUG CLASS/AGENT	METHOD OF ADMINISTRATION	INDICATIONS FOR USE
<i>Polyenes</i>		
Amphotericin B	0.1–0.5% (typically 0.15%) topical solution	Yeast and fungal keratitis and endophthalmitis
	0.8–1 mg subconjunctival	Yeast and fungal endophthalmitis
	5- μ g intravitreal injection	Yeast and fungal endophthalmitis
Natamycin	5% topical suspension	Yeast and fungal endophthalmitis
<i>Imidazoles</i>		
Fluconazole	oral, intravenous	Yeast keratitis and endophthalmitis
Itraconazole	oral	Yeast and fungal keratitis and endophthalmitis
Ketoconazole	oral	Yeast keratitis and endophthalmitis
Miconazole	1% topical solution	Yeast and fungal keratitis
	5–10 mg subconjunctival	Yeast and fungal endophthalmitis
	10 μ g intravitreal injection	Yeast and fungal endophthalmitis

*Only natamycin (NATACYN) is commercially available for ophthalmic use. The other antifungal drugs must be formulated for the given method of administration. For further dosing information, refer to the *Physicians' Desk Reference for Ophthalmology*. For additional discussion of these antifungal agents, see Chapter 48.

myxin B sulfate, *bacitracin zinc*, and *neomycin sulfate* (e.g., NEOSPORIN), and sometimes an imidazole (e.g., *clotrimazole*, *miconazole*, or *ketoconazole*). In the United Kingdom, the aromatic diamidines (i.e., *propamidine isethionate*) have been used successfully to treat this relatively resistant infectious keratitis (Hargrave *et al.*, 1999). The cationic antiseptic agent *polyhexamethylene biguanide* (PHMB) also is typically used in drop form for *acanthamoeba* keratitis, although this is not an FDA-approved antiprotozoal agent. Topical *chlorhexidine* can be used as an alternative to PHMB. Oral itraconazole or ketoconazole often are used in addition to the topical medications. Resolution of *Acanthamoeba* keratitis may require many months of treatment.

Toxoplasmosis may present as a posterior (e.g., focal retinochoroiditis, papillitis, vitritis, or retinitis) or occasionally as an anterior uveitis. Treatment is indicated when inflammatory lesions encroach upon the macula and threaten central visual acuity. Several regimens have been recommended with concurrent use of systemic steroids: (1) *pyrimethamine*, *sulfadiazine*, and *folinic acid* (*leucovorin*); (2) *pyrimethamine*, *sulfadiazine*, *clindamycin*, and *folinic acid*; (3) *sulfadiazine* and *clindamycin*; (4) *clindamycin*; and (5) *trimethoprim-sulfamethoxazole* with or without *clindamycin*.

Other protozoal infections (e.g., *giardiasis*, *leishmaniasis*, and *malaria*) and helminths are less common eye

pathogens in the United States. Systemic pharmacological management as well as vitrectomy may be indicated for selected parasitic infections.

In the eye, infections can occur in a variety of locations, such as the cornea, sclera, vitreous and retina, and can be due to bacteria, viruses, fungi, and parasites. Treatment is based on severity of infection, location, and the class of infectious agent. Within each group of microbial cause, different organisms are treated with different medications. Gram-positive bacteria respond to certain antibiotics and gram-negative bacteria to others. Some organisms are quite susceptible to many antimicrobial agents, while others are not. Still others may have been susceptible in the past but have become resistant. The task of staying ahead of the rapidly developing resistances is becoming increasingly difficult. In ophthalmology, fortunately, newer-generation topical fluoroquinolones recently were brought to market, which have at least temporarily helped stem the tide of resistant infections. Additional topical fluoroquinolones are in development.

While the selection of topical antiviral agents is rather limited, two new systemic antiviral agents have become available in the past decade. Similarly, there is only one commercially available topical antifungal medication, but there are numerous systemic agents, several of them new in the past few years. Potentially, some of these systemic medications could be modified for topical use or even formulat-

ed as intraocular implants, greatly expanding our options in the treatment of many ophthalmic infectious diseases.

Use of Autonomic Agents in the Eye

General Considerations. General autonomic pharmacology has been discussed extensively in Chapters 6 through

10. The autonomic agents used in ophthalmology as well as the responses (*i.e.*, mydriasis and cycloplegia) to muscarinic cholinergic antagonists are summarized in Table 63–7.

Therapeutic Uses. Autonomic drugs are used extensively for diagnostic and surgical purposes and for the treatment of glaucoma, uveitis, and strabismus.

Table 63–7

*Autonomic Drugs for Ophthalmic Use**

DRUG CLASS (TRADE NAME)	FORMULATION	INDICATIONS FOR USE	OCULAR SIDE EFFECTS
<i>Cholinergic agonists</i>			
Acetylcholine (MIOCHOL-E)	1% solution	Intraocular use for miosis in surgery	Corneal edema
Carbachol (MIOSTAT, ISOPTO CARBACHOL, others)	0.01 to 3% solution	Intraocular use for miosis in surgery, glaucoma	Corneal edema, miosis, induced myopia, decreased vision, brow ache, retinal detachment
Pilocarpine (AKARPINE, ISOPTO CARPINE, PILOCAR, PILAGAN, PILOPINEHS, PILOPTIC, PILOSTAT, others)	0.25–10% solution, 4% gel	Glaucoma	Same as for carbachol
<i>Anticholinesterase agents</i>			
Physostigmine (ESERINE)	0.25% ointment	Glaucoma, accommodative esotropia, louse and mite infestation of lashes	Retinal detachment, miosis, cataract, pupillary block glaucoma iris cysts, brow ache, punctal stenosis of the nasolacrimal system
Echothiophate (PHOSPHOLINE IODIDE)	0.125% solution	Glaucoma, accommodative esotropia	Same as for physostigmine
<i>Muscarinic antagonists</i>			
Atropine (ATROPISOL, ATROPINE-CARE, ISOPTO ATROPINE)	0.5–2% solution, 1% ointment	Cycloplegic retinoscopy, dilated fundoscopic exam, cycloplegia [†]	Photosensitivity, blurred vision
Scopolamine (ISOPTO HYOSCINE)	0.25% solution	Same as for atropine	Same as for atropine
Homatropine (ISOPTO HOMATROPINE)	2 & 5% solution	Same as for atropine	Same as for atropine
Cyclopentolate (AK-PENTOLATE, CYCLOGYL, PENTOLAIR)	0.5, 1, & 2% solution	Same as for atropine	Same as for atropine
Tropicamide (MYDRIACYL, TROPICACYL, OPTICYL)	0.5 & 1% solution	Same as for atropine	Same as for atropine
<i>Sympathomimetic agents</i>			
Dipivefrin (PROPINE, AKPRO)	0.1% solution	Glaucoma	Photosensitivity, conjunctival hyperemia, hypersensitivity

(Continued)

Table 63–7

Autonomic Drugs for Ophthalmic Use* (Continued)

DRUG CLASS (TRADE NAME)	FORMULATION	INDICATIONS FOR USE	OCULAR SIDE EFFECTS
Epinephrine (EPINAL, EPIFRIN, GLAUCON)	0.1, 0.5, 1, & 2% solution	Glaucoma	Same as for dipivefrin
Phenylephrine (AK-DILATE, MYDFRIN, NEO-SYNEPHRINE, others)	0.12, 2.5, & 10% solution	Mydriasis	Same as for dipivefrin
Apraclonidine (IOPIDINE)	0.5 & 1% solution	Glaucoma, pre- & postlaser prophylaxis of intraocu- lar pressure spike	Same as for dipivefrin
Brimonidine (ALPHAGAN)	0.15 and 0.2% solution	Glaucoma	Same as for dipivefrin
Cocaine	1–4% solution	Topical anesthesia, evalu- ate anisocoria (<i>see</i> Figure 63–5)	
Hydroxyamphetamine (PAREDRIE)	1% solution	Evaluate anisocoria (<i>see</i> Figure 63–5)	
Naphazoline (AK-CON, ALBALON, CLEAR EYES, NAPHCN, VASOCLEAR, VASOCON REGULAR, others)	0.012 to 0.1% solution	Decongestant	Same as for dipivefrin
Tetrahydrozoline (COLLYRIUM FRESH, MURINE PLUS, VISINE MOISTURIZING, others)	0.05% solution	Decongestant	Same as for dipivefrin
<i>α & β Adrenergic antagonists</i>			
Dapiprazole (α) (REV-EYES)	0.5% solution	Reverse mydriasis	Conjunctival hyperemia
Betaxolol (β ₁ -selective) (BETOPTIC, BETOPTIC-S)	0.25 & 0.5% sus- pension	Glaucoma	
Carteolol (β) (OCUPRESS)	1% solution	Glaucoma	
Levobunolol (β) (BETAGAN, AKBETA)	0.25 & 0.5% solu- tion	Glaucoma	
Metipranolol (β) (OPTIPRANOLOL)	0.3% solution	Glaucoma	
Timolol (β) (TIMOPTIC, TIMOPTIC XE, BETIMOL)	0.25 & 0.5% solu- tion & gel	Glaucoma	

*Refer to *Physicians' Desk Reference for Ophthalmology* for specific indications and dosing information. †Mydriasis and cycloplegia, or paralysis of accommodation, of the human eye occurs after one drop of atropine 1%, scopolamine 0.5%, homatropine 1%, cyclopentolate 0.5% or 1%, and tropicamide 0.5% or 1%. Recovery of mydriasis is defined by return to baseline pupil size to within 1 mm. Recovery of cycloplegia is defined by return to within two diopters of baseline accommodative power. The maximal mydriatic effect of homatropine is achieved with a 5% solution, but cycloplegia may be incomplete. Maximal cycloplegia with tropicamide may be achieved with a 1% solution. Times to development of maximal mydriasis and to recovery, respectively, are: for *atropine*, 30 to 40 minutes and 7 to 10 days; for *scopolamine*, 20 to 130 minutes and 3 to 7 days; for homatropine, 40 to 60 minutes and 1 to 3 days; for *cyclopentolate*, 30 to 60 minutes and 1 day; for *tropicamide*, 20 to 40 minutes and 6 hours. Times to development of maximal cycloplegia and to recovery, respectively, are: for *atropine*, 60 to 180 minutes and 6 to 12 days; for *scopolamine*, 30 to 60 minutes and 3 to 7 days; for *homatropine*, 30 to 60 minutes and 1 to 3 days; for *cyclopentolate*, 25 to 75 minutes and 6 hours to 1 day; for *tropicamide*, 30 minutes and 6 hours.

Glaucoma. In the United States, glaucoma is the second leading cause of blindness in African-Americans, the third leading cause in Caucasians, and the leading cause in Hispanic-Americans (Congdon *et al.*, 2004). African-Americans have three times the age-adjusted prevalence of glaucoma compared to Caucasians (Friedman *et al.*, 2004). Characterized by progressive optic nerve cupping and visual field loss, glaucoma is responsible for the bilateral blindness of 90,000 Americans (half of whom are African-American or Hispanic) (Congdon *et al.*, 2004), and about 2.2 million have the disease (1.86% of the population over age 40). This number is expected to increase by 50% by the year 2020 (Friedman *et al.*, 2004). Risk factors associated with glaucomatous nerve damage include increased intraocular pressure (IOP), positive family history of glaucoma, African-American heritage, and possibly myopia and hypertension. The production and regulation of aqueous humor have been discussed in an earlier section of this chapter. Previously an intraocular pressure of greater than 21 was considered abnormal. This, however, is incorrect, as intraocular pressure is not an accurate indicator of disease. Nonetheless, elevated intraocular pressure is a risk factor for glaucoma. Several randomized, controlled trials have determined that reducing intraocular pressure can delay glaucomatous nerve or field damage (Fluorouracil Filtering Surgery Study Group, 1996; AGIS Investigators, 2000; Heijl *et al.*, 2002). Although markedly elevated intraocular pressures (*e.g.*, greater than 30 mm Hg) usually will lead to optic nerve damage, the optic nerves in certain patients apparently can tolerate intraocular pressures in the mid-to-high twenties. These patients are referred to as *ocular hypertensives*. A recent prospective multicenter trial found that prophylactic medical reduction of intraocular pressure reduced the risk of progression to glaucoma from about 10% to about 5% (Kass *et al.*, 2002). Other patients have progressive glaucomatous optic nerve damage despite having intraocular pressures in the normal range, and this form of the disease sometimes is called *normal- or low-tension glaucoma*. A reduction of intraocular pressure by 30% reduces disease progression from about 35% to about 10%, even for normal-tension glaucoma patients (Collaborative Normal-Tension Glaucoma Study Group, 1998a; Collaborative Normal-Tension Glaucoma Study Group, 1998b). Despite overwhelming evidence that intraocular pressure reduction is a helpful treatment, at present the pathophysiological processes involved in glaucomatous optic nerve damage and the relationship to aqueous humor dynamics are not understood.

Current pharmacotherapies are targeted to decrease the production of aqueous humor at the ciliary body and to increase outflow

through the trabecular meshwork and uveoscleral pathways. There is no consensus on the best intraocular pressure-lowering technique for glaucoma therapy. Currently, a National Eye Institute-sponsored clinical trial, the Collaborative Initial Glaucoma Treatment Study (CIGTS), aims to determine whether it is best, in terms of preservation of visual function and quality of life, to treat patients newly diagnosed with open-angle glaucoma with filtering surgery or with medication. Initial results show no difference in disease progression rates between the two treatment groups at 5 years (Lichter *et al.*, 2001), but the study is ongoing.

The CIGTS study aside, a stepped medical approach depends on the patient's health, age, and ocular status. Some general principles prevail in patient management: (1) asthma and chronic obstructive pulmonary disease with a bronchospastic component are relative contraindications to the use of topical β adrenergic receptor antagonists because of the risk of significant side effects from systemic absorption *via* the nasolacrimal system; (2) some cardiac dysrhythmias (*i.e.*, bradycardia and heart block) also are relative contraindications to β adrenergic antagonists for similar reasons; (3) history of nephrolithiasis, or kidney stones, sometimes is a contraindication for carbonic anhydrase inhibitors; (4) young patients usually are intolerant of miotic therapy secondary to visual blurring from induced myopia; (5) direct miotic agents are preferred over cholinesterase inhibitors in "phakic" patients (*i.e.*, those patients who have their own crystalline lens), since the latter drugs can promote cataract formation; and (6) in patients who have an increased risk of retinal detachment, miotics should be used with caution, since they have been implicated in promoting retinal tears in susceptible individuals; such tears are thought to be due to altered forces at the vitreous base produced by ciliary body contraction induced by the drug.

The goal is to prevent progressive glaucomatous optic-nerve damage with minimum risk and side effects from either topical or systemic therapy. With these general principles in mind, a stepped medical approach may begin with a topical prostaglandin analog. Due to their once-daily dosing, low incidence of systemic side effects, and potent intraocular pressure lowering effect, prostaglandin analogs have largely replaced β adrenergic receptor antagonists as first-line medical therapy for glaucoma. The prostaglandin analogs consist of latanoprost (XALATAN), travoprost (TRAVATAN), bimatoprost (LUMIGAN), and unoprostone (RESCULA). The chemical structure of latanoprost is shown below.

Prostaglandin $\text{PGF}_{2\alpha}$ was found to reduce IOP but has intolerable local side effects. Modifications to the chemical structure of $\text{PGF}_{2\alpha}$ have produced a number of analogs with a more acceptable side-effect profile. In primates and humans, $\text{PGF}_{2\alpha}$ analogs appear to lower intraocular pressure by facilitating aqueous outflow through the accessory uveoscleral outflow pathway. The mechanism by which this occurs is unclear. $\text{PGF}_{2\alpha}$ and its analogs (prodrugs that are hydrolyzed to $\text{PGF}_{2\alpha}$) bind to FP receptors that link to G_{q11} and thence to the $\text{PLC-IP}_3\text{-Ca}^{2+}$ pathway. This pathway is active in isolated human ciliary muscle cells. Other cells in the eye also may express FP receptors. Theories of IOP lowering by $\text{PGF}_{2\alpha}$ range

from altered ciliary muscle tension to effects on trabecular meshwork cells to release of matrix metalloproteases and digestion of extracellular matrix materials that may impede outflow tracts. There also is less myocilin protein noted in monkey smooth muscle after $\text{PGF}_{2\alpha}$ treatment (Lindsey *et al.*, 2001).

The β -receptor antagonists now are the next most common topical medical treatment. There are two classes of topical β blockers. The nonselective ones bind to both β_1 and β_2 receptors and include *timolol maleate* and *hemihydrate*, *levobunolol*, *metipranolol*, and *carteolol*. There is one β_1 -selective antagonist, *betaxolol*, available for ophthalmic use, but it is less efficacious than the nonselective β blockers since the β receptors of the eye are largely of the β_2 subtype. However, because the β_1 receptors are found preferentially in the heart while the β_2 receptors are found in the lung, betaxolol is less likely to cause breathing difficulty. In the eye, the targeted tissues are the ciliary body epithelium and blood vessels, where β_2 receptors account for 75% to 90% of the total population. How β blockade leads to decreased aqueous production and reduced IOP is uncertain. Production of aqueous humor seems to be activated by a β -receptor-mediated cyclic AMP-PKA pathway; β blockade blunts adrenergic activation of this pathway by preventing catecholamine stimulation of the β receptor, thereby decreasing intracellular cAMP. Another hypothesis is that β blockers decrease ocular blood flow, which decreases the ultrafiltration responsible for aqueous production (Juzych and Zimmerman, 1997).

When there are medical contraindications to the use of prostaglandin analogs or β -receptor antagonists, other agents, such as an α_2 adrenergic receptor agonist or topical carbonic anhydrase inhibitor may be used as first-line therapy. The α_2 adrenergic agonists improve the pharmacologic profile of the nonselective sympathomimetic agent epinephrine and its derivative, dipivefrin (PROPINE). Epinephrine stimulates both α and β adrenergic receptors. The drug appears to decrease IOP by enhancing both conventional (*via* a β_2 -receptor mechanism) and uveoscleral outflow (perhaps *via* prostaglandin production) from the eye. Although effective, epinephrine is poorly tolerated, principally due to localized irritation and hyperemia. Dipivefrin is an epinephrine prodrug that is converted into epinephrine by esterases in the cornea. It is much better tolerated, but still is prone to cause epinephrine-like side effects (Fang and Kass, 1997). The α_2 adrenergic agonist *clonidine* is effective at reducing IOP, but also readily crosses the blood-brain barrier and causes systemic hypotension; as a result it no longer is used for glaucoma. In contrast, *apraclonidine* (IOPIDINE) is a relatively selective α_2 adrenergic agonist that is highly ionized at physiologic pH and therefore does not cross the blood-brain barrier. *Brimonidine* (ALPHAGAN, others) is also a selective α_2 adrenergic agonist, but is lipophilic, enabling easy corneal penetration. Both apraclonidine and brimonidine reduce aqueous production and may enhance some uveoscleral outflow. Both appear to bind to pre- and postsynaptic α_2 receptors. By binding to the presynaptic receptors, the drugs reduce the amount of neurotransmitter release from sympathetic nerve stimulation and thereby lower IOP. By binding to postsynaptic α_2 receptors, these drugs stimulate the G_i pathway, reducing cellular cyclic AMP production, thereby reducing aqueous humor production (Juzych *et al.*, 1997).

The development of a topical carbonic anhydrase inhibitor took many years but was an important event because of the poor side-effect profile of oral carbonic anhydrase inhibitors (CAIs). *Dorzolamide* (TRUSOPT) and *brinzolamide* (AZOPT) both work by inhibiting carbonic anhydrase (isozyme II), which is found in the ciliary body epithelium. This reduces the formation of bicarbonate ions, which reduces fluid transport and thus IOP (Sharir, 1997).

Any of these four drug classes can be used as additive second- or third-line therapy. In fact, the β -receptor antagonist timolol has been combined with the carbonic anhydrase inhibitor dorzolamide (*see* structure below) in a single medication (COSOPT).

Such combinations reduce the number of drops needed and may improve compliance. Other combination products involving prostaglandin analogs and β blockers are in development.

Topical miotic agents are historically important glaucoma medications but are less commonly used today. Miotics lower IOP by causing muscarinic-induced contraction of the ciliary muscle, which facilitates aqueous outflow. They do not affect aqueous production. Multiple miotic agents have been developed. Pilocarpine and *carbachol* are cholinomimetics that stimulate muscarinic receptors. *Echothiophate* (PHOSPHOLINE IODIDE) is an organophosphate inhibitor of acetylcholinesterase; it is relatively stable in aqueous solution, and by virtue of its quaternary ammonium structure, is positively charged and poorly absorbed. The usefulness of these medicines is lessened by their numerous side effects and the need to use them three to four times a day (Kaufman and Gabelt, 1997).

If combined topical therapy fails to achieve the target intraocular pressure or fails to halt glaucomatous optic nerve damage, then systemic therapy with carbonic anhydrase inhibitors is a final medication option before resorting to laser or incisional surgical treatment. The best-tolerated oral preparation is *acetazolamide* in sustained-release capsules (*see* Chapter 28), followed by *methazolamide*. The least well-tolerated are acetazolamide tablets.

Toxicity of Agents in Treatment of Glaucoma. Ciliary body spasm is a muscarinic cholinergic effect that can lead to induced myopia and a changing refraction due to iris and ciliary body contraction as the drug effect waxes and wanes between doses. Headaches can occur from the iris and ciliary body contraction. Epinephrine-related compounds, effective in intraocular pressure reduction, can cause a vasoconstriction-vasodilation rebound phenomenon leading to a red eye. Ocular and skin allergies from topical epinephrine, related prodrug formulations, apraclonidine, and brimonidine are common. Brimonidine is less likely to cause ocular allergy and is therefore more commonly used. These agents can cause CNS depression and apnea in neonates and are contraindicated in children under the age of 2.

Systemic absorption of epinephrine-related drugs and β adrenergic antagonists can induce all the side effects found with direct systemic administration. The use of carbonic anhydrase inhibitors systematically may give some patients significant problems with

malaise, fatigue, depression, paresthesias, and nephrolithiasis; the topical CAIs may minimize these relatively common side effects. These medical strategies for managing glaucoma do help to slow the progression of this disease, yet there are potential risks from treatment-related side effects, and treatment effects on quality of life must be recognized.

Uveitis. Inflammation of the uvea, or uveitis, has both infectious and noninfectious causes, and medical treatment of the underlying cause (if known) is essential in addition to the use of topical therapy. *Cyclopentolate*, or sometimes even longer-acting antimuscarinic agents such as atropine, *scopolamine*, and *homatropine* frequently are used to prevent posterior synechia formation between the lens and iris margin and to relieve ciliary muscle spasm that is responsible for much of the pain associated with anterior uveitis. If posterior synechiae already have formed, an α adrenergic agonist may be used to break the synechiae by enhancing pupillary dilation. A solution containing scopolamine 0.3% in combination with 10% *phenylephrine* is available for this purpose. Topical steroids usually are adequate to decrease inflammation, but sometimes they must be supplemented by systemic steroids.

Strabismus. *Strabismus*, or ocular misalignment, has numerous causes and may occur at any age. Besides causing *diplopia* (double vision), in children, strabismus may lead to *amblyopia* (reduced vision). Nonsurgical efforts to treat amblyopia include occlusion therapy, orthoptics, optical devices, and pharmacological agents. An eye with *hyperopia*, or farsightedness, must accommodate to focus distant images. In some hyperopic children, the synkinetic accommodative-convergence response leads to excessive convergence and a manifest *esotropia* (turned-in eye). The brain rejects diplopia and suppresses the image from the deviated eye. If proper vision is not restored by about the age of 7, the brain never learns to process visual information from that eye. The result is that the eye appears structurally normal but does not develop normal visual acuity and is therefore amblyopic. Unfortunately this is a fairly common cause of visual disability. In this setting, atropine (1%) instilled in the preferred seeing eye produces cycloplegia and the inability of this eye to accommodate, thus forcing the child to use the amblyopic eye (Pediatric Eye Disease Investigator Group, 2002; Pediatric Eye Disease Investigator Group, 2003). Echthiophate iodide also has been used in the setting of accommodative strabismus. Accommodation drives the near reflex, the triad of miosis, accommodation, and convergence. An irreversible cholinesterase inhibitor such as echthiophate causes miosis and an accommodative change in the shape of the lens; hence, the accommodative drive to initiate the near reflex is reduced, and less convergence will occur.

Surgery and Diagnostic Purposes. For certain surgical procedures and for clinical funduscopic examination, it is desirable to maximize the view of the retina and lens. Muscarinic cholinergic antagonists and α_2 adrenergic agonists frequently are used singly or in combination for this purpose (Table 63–7).

Intraoperatively, there are circumstances when miosis is preferred, and two cholinergic agonists are available for intraocular use, *acetylcholine* and carbachol. Patients with myasthenia gravis may first present to an ophthalmologist with complaints of double vision (diplopia) or lid droop (ptosis); the *edrophonium test* is helpful in diagnosing these patients (see Chapter 8).

Use of Immunomodulatory Drugs for Ophthalmic Therapy

Glucocorticoids. Glucocorticoids have an important role in managing ocular inflammatory diseases; their chemistry and pharmacology are described in Chapter 59.

Therapeutic Uses. Currently the glucocorticoids formulated for topical administration to the eye are *dexamethasone* (DECADRON, others), *prednisolone* (PRED FORTE, others), *fluorometholone* (FML, others), *loteprednol* (ALREX, LOTEMAX), *medrysone* (HMS), and *rimexolone* (VEXOL). Because of their antiinflammatory effects, topical corticosteroids are used in managing significant ocular allergy, anterior uveitis, external eye inflammatory diseases associated with some infections and ocular cicatricial pemphigoid, and postoperative inflammation following refractive, corneal, and intraocular surgery. After glaucoma filtering surgery, topical steroids can delay the wound-healing process by decreasing fibroblast infiltration, thereby reducing potential scarring of the surgical site (Araujo *et al.*, 1995). Steroids are commonly given systemically and by sub-Tenon's capsule injection to manage posterior uveitis. Intravitreal injection of steroids now is being used to treat a variety of retinal conditions including age-related macular degeneration, diabetic retinopathy, and cystoid macular edema. Parenteral steroids followed by tapering oral doses are the preferred treatment for optic neuritis (Kaufman *et al.*, 2000; Trobe *et al.*, 1999).

Toxicity of Steroids. Steroid drops, pills, and creams are associated with ocular problems, as are intravitreal and intravenous steroids. Ocular complications include the development of posterior subcapsular cataracts, secondary infections (see Chapter 59), and secondary open-angle glaucoma (Becker and Mills, 1963). There is a significant increase in risk for developing secondary glaucoma when there is a positive family history of glaucoma. In the absence of a family history of open-angle glauco-

ma, only about 5% of normal individuals respond to topical or long-term systemic steroids with a marked increase in intraocular pressure. With a positive family history, however, moderate to marked steroid-induced intraocular pressure elevations may occur in up to 90% of patients. The pathophysiology of steroid-induced glaucoma is not fully understood, but there is evidence that the *GLCIA* gene may be involved (Stone *et al.*, 1997). Typically, steroid-induced elevation of intraocular pressure is reversible once administration of the steroid ceases. However, intraocular or sub-Tenon's steroid-related pressure elevation may persist for months and may require treatment with glaucoma medication or even filtering surgery. Newer topical steroids, so called "soft steroids" (*e.g.*, loteprednol), have been developed that reduce, but do not eliminate, the risk of elevated intraocular pressure.

Nonsteroidal Antiinflammatory Agents. General Considerations. Nonsteroidal drug therapy for inflammation is discussed in Chapter 26. Nonsteroidal antiinflammatory drugs (NSAIDs) now are being applied to the treatment of ocular disease.

Therapeutic Uses. Currently, there are three topical NSAIDs approved for ocular use: *diclofenac* (VOLTAREN), *flurbiprofen* (OCUFEN), and *ketorolac* (ACULAR). Diclofenac and flurbiprofen are discussed in Chapter 26; the chemical structure of ketorolac, a pyrrolo-pyrrole derivative, is shown below:

Flurbiprofen is used to counter unwanted intraoperative miosis during cataract surgery. Ketorolac is given for seasonal allergic conjunctivitis. Diclofenac is used for postoperative inflammation. Both ketorolac (Weisz *et al.*, 1999) and diclofenac have been found to be effective in treating cystoid macular edema occurring after cataract surgery. In patients treated with prostaglandin analogs such as latanoprost or bimatoprost, ketorolac and diclofenac may help decrease postoperative inflammation. They also are useful in decreasing pain after corneal refractive surgery. Topical NSAIDs occasionally have been associated with sterile corneal melts and perforations, especially in older patients with ocular surface disease, such as dry eye syndrome.

Antihistamines and Mast-Cell Stabilizers. *Pheniramine* (*see* Chapter 24) and *antazoline*, both H₁-receptor antago-

nists, are formulated in combination with *naphazoline*, a vasoconstrictor, for relief of allergic conjunctivitis. The chemical structure of antazoline is:

Topical antihistamines include *emedastine difumarate* (EMADINE) and *levocabastine hydrochloride* (LIVOSTIN).

Cromolyn sodium (CROLOM), which prevents the release of histamine and other autacoids from mast cells (*see* Chapter 27), has found limited use in treating conjunctivitis that is thought to be allergen-mediated, such as vernal conjunctivitis. *Lodoxamide tromethamine* (ALOMIDE) and *pemirolast* (ALAMAST), mast-cell stabilizers, also are available for ophthalmic use. *Nedocromil* (ALOCRIL) also is primarily a mast-cell stabilizer with some antihistamine properties. *Olopatadine hydrochloride* (PATANOL), *ketotifen fumarate* (ZADITOR), and *azelastine* (OPTIVAR) are H₁ antagonists with mast cell-stabilizing properties. *Epinastine* (ELESTAT) antagonizes H₁ and H₂ receptors and exhibits mast cell-stabilizing activity.

Immunosuppressive and Antimitotic Agents. General Considerations. The principal application of immunosuppressive and antimitotic agents to ophthalmology relates to the use of 5-fluorouracil and mitomycin C in corneal and glaucoma surgeries. Interferon alpha-2b also has occasionally been used. Certain systemic diseases with serious vision-threatening ocular manifestations—such as Behçet's disease, Wegener's granulomatosis, rheumatoid arthritis, and Reiter's syndrome—require systemic immunosuppression (*see* Chapter 52).

Therapeutic Uses. In glaucoma surgery, both fluorouracil and mitomycin (MUTAMYCIN), which also are anti-neoplastic agents (*see* Chapter 51), improve the success of filtration surgery by limiting the postoperative wound-healing process. Mitomycin is used intraoperatively as a single subconjunctival application at the trabeculectomy site. Meticulous care is used to avoid intraocular penetration, since mitomycin is extremely toxic to intraocular structures. Fluorouracil may be used intraoperatively at the trabeculectomy site and/or subconjunctivally during the postoperative course (Fluorouracil Filtering Surgery Study Group, 1989). Although both agents work by limiting the healing process, sometimes this can result in thin,

ischemic, avascular tissue that is prone to breakdown. The resultant leaks can cause hypotony (low intraocular pressure) and increase the risk of infection.

In cornea surgery, mitomycin has been used topically after excision of pterygium, a fibrovascular membrane that can grow onto the cornea. Mitomycin can be used to reduce the risk of scarring after certain procedures to remove corneal opacities and also prophylactically to prevent corneal scarring after excimer laser surface ablation (photorefractive and phototherapeutic keratectomy). Mitomycin also is used to treat certain conjunctival and corneal tumors. Interferon alpha-2b has been used in the treatment of conjunctival papilloma and certain conjunctival tumors. Although the use of mitomycin for both corneal surgery and glaucoma filtration surgeries augments the success of these surgical procedures, caution is advocated in light of the potentially serious delayed ocular complications (Rubinfeld *et al.*, 1992; Hardten and Samuelson, 1999).

Immunomodulatory Agent. Topical *cyclosporine* (RESTASIS) is approved for the treatment of chronic dry eye associated with inflammation. Cyclosporine is an immunomodulatory agent that inhibits activation of T cells. Use of cyclosporine is associated with decreased inflammatory markers in the lacrimal gland, increased tear production, and improved vision and comfort (Sall *et al.*, 2000).

Drugs and Biological Agents Used in Ophthalmic Surgery

Adjuncts in Anterior Segment Surgery. *Viscoelastic* substances assist in ocular surgery by maintaining spaces, moving tissue, and protecting surfaces. These substances are prepared from hyaluronate, chondroitin sulfate, or hydroxypropylmethylcellulose and share the following important physical characteristics: viscosity, shear flow, elasticity, cohesiveness, and coatability. Various viscoelastic agents emphasize certain features that are broadly characterized as dispersive or cohesive. They are used almost exclusively in anterior segment surgery. Complications associated with viscoelastic substances are related to transient elevation of intraocular pressure after the surgical procedure.

Ophthalmic Glue. Cyanoacrylate tissue adhesive (ISODENT, DERMABOND, HISTOACRYL), while not FDA approved for the eye, is widely used in the management of corneal ulcerations and perforations. It is applied in liquid form and polymerized into a solid plug.

Fibrinogen glue (TISSEEL) is increasingly being used on the ocular surface to secure tissue such as conjunctiva, amniotic membrane, and lamellar corneal grafts. It is FDA approved for use in cardiac and gastrointestinal surgery, but not for the eye.

Corneal Band Keratopathy. *Edetate disodium* (disodium EDTA; ENDRATE) is a chelating agent that can be used to remove a band keratopathy (*i.e.*, a calcium deposit at the level of Bowman's membrane on the cornea). After the overlying corneal epithelium is removed, it is applied topically to chelate the calcium deposits from the cornea.

Anterior Segment Gases. Sulfur hexafluoride (SF₆) and perfluoropropane gases have long been used as vitreous substitutes during retinal surgery. In the anterior segment they are used in nonexpansile concentrations to treat Descemet's detachments, typically after cataract surgery. These detachments can cause mild to severe corneal edema. The gas is injected into the anterior chamber to push Descemet's membrane up against the stroma, where ideally it reattaches and clears the corneal edema.

Vitreous Substitutes. The primary use of vitreous substitutes is reattachment of the retina following vitrectomy and membrane-peeling procedures for complicated proliferative vitreoretinopathy and traction retinal detachments. Several compounds are available, including gases, perfluorocarbon liquids, and silicone oil (Table 63–8). With the exception of air, the gases expand because of interaction with systemic oxygen, carbon dioxide, and nitrogen, and this property makes them desirable to temporarily tamponade areas of the retina. However, use of these expansile gases carries the risk of complications from elevated intraocular pressure, subretinal gas, corneal edema, and cataract formation. The gases are absorbed over a time period of days (for air) to 2 months (for perfluoropropane).

The liquid perfluorocarbons, with specific gravities between 1.76 and 1.94, are denser than vitreous and are helpful in flattening the retina when vitreous is present. If a lens becomes dislocated into the vitreous, a perfluorocarbon liquid injection posteriorly will float the lens anteriorly, leading to easier surgical retrieval. This liquid can be an important tool for flattening and unrolling severely detached and contorted retinas such those found in giant retinal tears and proliferative vitreoretinopathy. This liquid is potentially toxic if it remains in chronic contact with the retina.

Silicone oil has had extensive use both in Europe and in the United States for long-term tamponade of the retina. Complications from silicone oil use include glaucoma,

Vitreous Substitutes*

VITREOUS SUBSTITUTE	CHEMICAL STRUCTURE	CHARACTERISTICS (DURATION OR VISCOSITY)
<i>Nonexpansile gases</i>		
Air		Duration of 5–7 days
Argon		
Carbon dioxide		
Helium		
Krypton		
Nitrogen		
Oxygen		
Xenon		Duration of 1 day
<i>Expansile gases</i>		
Sulfur hexafluoride (SF ₆)		Duration of 10–14 days
Octafluorocyclobutane (C ₄ F ₈)		
Perfluoromethane (CF ₄)		Duration of 10–14 days
Perfluoroethane (C ₂ F ₆)		Duration of 30–35 days
Perfluoropropane (C ₃ F ₈)		Duration of 55–65 days
Perfluoro- <i>n</i> -butane (C ₄ F ₁₀)		
Perfluoropentane (C ₅ F ₁₂)		
<i>Silicone oils</i>		
Nonfluorinated silicone oils	(CH ₃) ₃ SiO[(CH ₃) ₂ SiO] _n Si(CH ₃) ₃	Viscosity range from 1000–30,000 cs
Fluorosilicone	(CH ₃) ₃ SiO[(C ₃ H ₄ F ₃)(CH ₃)SiO] _n Si(CH ₃) ₃	Viscosity range from 1000–10,000 cs
“High-tech” silicone oils	(CH ₃) ₃ SiO[(C ₆ H ₅)(CH ₃)SiO] _n Si(CH ₃) ₃	May terminate as trimethylsiloxy (shown) or polyphenylmethylsiloxane, viscosity not reported

*See Parel and Villain, 1994, and Chang, 1994, for further details. cs, centistoke (unit of viscosity).

cataract formation, corneal edema, corneal band keratopathy, and retinal toxicity.

Surgical Hemostasis and Thrombolytic Agents.

Hemostasis has an important role in most surgical procedures and usually is achieved by temperature-mediated coagulation. In some intraocular surgeries, thrombin has a valuable role in hemostasis. Intravitreal administration of thrombin can assist in controlling intraocular hemorrhage during vitrectomy. When used intraocularly, a potentially significant inflammatory response may occur, but this reaction can be minimized by thorough irrigation after hemostasis is achieved. This coagulation factor also may be applied topically *via* soaked sponges to exposed conjunctiva and sclera, where hemostasis may be a challenge due to the rich vascular supply.

Topical *aminocaproic acid* (CAPROGEL) has been advocated to prevent rebleeding after traumatic *hyphema* (blood in the anterior chamber), but recent clinical trials report mixed success (Karkhaneh *et al.*, 2003; Pieramici *et al.*, 2003).

Depending on the intraocular location of a clot, there may be significant problems relating to intraocular pressure, retinal degeneration, and persistent poor vision. *Tissue plasminogen activator* (t-PA) (*see* Chapter 54) has been used during intraocular surgeries to assist evacuation of a *hyphema*, subretinal clot, or nonclearing vitreous hemorrhage. t-PA also has been administered subconjunctivally and intracamerally (*i.e.*, controlled intraocular administration into the anterior segment) to lyse blood clots obstructing a glaucoma filtration site. The main complication related to the use of t-PA is bleeding.

Botulinum Toxin Type A in the Treatment of Strabismus, Blepharospasm, and Related Disorders.

Botulinum toxin type A (BOTOX) has been used to treat strabismus, blepharospasm, Meige's syndrome, spasmodic torticollis hemifacial spasm, facial wrinkles, and certain migraine headaches (Tsui, 1996; Price *et al.*, 1997) (*see also* Chapter 9). By preventing acetylcholine release at the neuromuscular junction, botulinum toxin A usually causes a temporary paralysis of the locally injected muscles. The variability in duration of paralysis may be related to the rate of developing antibodies to the toxin, upregulation of nicotinic cholinergic postsynaptic receptors, and aberrant regeneration of motor nerve fibers at the neuromuscular junction. Complications related to this toxin include double vision (diplopia) and lid droop (ptosis).

Blind and Painful Eye. Retrobulbar injection of either absolute or 95% ethanol may provide relief from chronic

pain associated with a blind and painful eye. Retrobulbar chlorpromazine also has been used. This treatment is preceded by administration of local anesthesia. Local infiltration of the ciliary nerves provides symptomatic relief from pain, but other nerve fibers may be damaged, causing paralysis of the extraocular muscles, including those in the eyelids, or neuroparalytic keratitis. The sensory fibers of the ciliary nerves may regenerate, and repeated injections sometimes are needed to control pain.

Systemic Agents with Ocular Side Effects. Just as certain systemic diseases have ocular manifestations, certain systemic drugs have ocular side effects. These can range from mild and inconsequential to severe and vision threatening.

Retina. Numerous drugs have toxic side effects on the retina. The antiarthritis and antimalarial medicines *hydroxychloroquine* (PLAQUENIL) and chloroquine can cause a central retinal toxicity by an unknown mechanism. With normal dosages, toxicity does not appear until about 6 years after the drug is started. Stopping the drug will not reverse the damage, but will prevent further toxicity. *Sildenafil* (VIAGRA) inhibits PDE5 in the corpus cavernosum for the purpose of helping to achieve and maintain penile erection. The drug also mildly inhibits PDE6, which controls the levels of cyclic GMP in the retina. Visually, this can result in seeing a blueish haze or experiencing light sensitivity. Although no retinal damage has been reported, no long-term studies have been reported (Marmor and Kessler, 1999). Two new phosphodiesterase inhibitors, *ildenafil* and *tadalafil*, also are associated with similar visual disturbances.

Optic Nerve. Multiple medications can cause a toxic optic neuropathy characterized by gradually progressive bilateral central scotomas and vision loss. There can be accompanying optic nerve pallor. These medicines include *ethambutol*, *chloramphenicol*, and *rifampin*. Systemic or ocular steroids can cause elevated IOP and glaucoma. If the steroids cannot be stopped, glaucoma medications, and even filtering surgery, often are required.

Anterior Segment. Steroids also have been implicated in cataract formation. If vision is reduced, cataract surgery may be necessary. *Rifabutin*, if used in conjunction with *clarithromycin* or *fluconazole* for treatment of *Mycobacterium avium complex* (MAC) opportunistic infections in HIV-positive persons, is associated with an iridocyclitis and even hypopyon. This will resolve with steroids or by stopping the medication.

Ocular Surface. *Isotretinoin* (AC CUTANE) has a drying effect on mucous membranes and is associated with dry eye.

Corneal Side Effects of Systemic Medications. The cornea, conjunctiva, and even eyelids can be affected by systemic medications. One of the most common drug deposits found in the cornea is from the cardiac medication *amiodarone*. It deposits in the inferior and central cornea in a whorl-like pattern termed *cornea verticillata*. It appears as fine tan or brown pigment in the epithelium. Fortunately, the deposits seldom affect vision and, therefore, this is rarely a cause to discontinue the medication. The deposits disappear slowly if the medication is stopped. Other medications can cause a similar pattern, including *indomethacin*, *atovaquone*, chloroquine, and hydroxychloroquine.

The phenothiazines, including *chlorpromazine* and *thioridazine*, can cause brown pigmentary deposits in the cornea, conjunctiva, and eyelids. The deposits generally are found in Descemet's membrane and the posterior cornea. They typically do not affect vision. The ocular deposits generally persist after discontinuation of the medication and can even worsen, perhaps because the medication deposits in the skin are slowly released and accumulate in the eye.

Gold treatments for arthritis (now rarely used) can lead to gold deposition in the cornea and conjunctiva, which are termed *chrysiasis* and are gold to violet in color. With lower cumulative doses (1 to 2 g) the deposits are found primarily in the epithelium and anterior stroma. These deposits usually disappear with discontinuation of the medication. With higher doses, the gold is deposited in Descemet's membrane and posterior stroma and can involve the entire stroma. These changes can be permanent. The deposits generally do not affect vision and are not a reason to stop gold therapy.

Tetracyclines can cause a yellow discoloration of the light-exposed conjunctiva. Systemic minocycline can induce a blue-gray scleral pigmentation that is most prominent in the interpalpebral zone (Morrow and Abbott, 1998).

Agents Used to Assist in Ocular Diagnosis

A number of agents are used in an ocular examination (*e.g.*, mydriatic agents and topical anesthetics, and dyes to evaluate corneal surface integrity), to facilitate intraocular surgery (*e.g.*, mydriatic and miotic agents, topical and local anesthetics), and to help in making a diagnosis in cases of anisocoria (Figure 63–5) and retinal abnormalities (*e.g.*, intravenous contrast agents). The autonomic agents have been discussed earlier. The diagnostic and therapeutic uses of topical and intravenous dyes and of topical anesthetics are discussed below.

Anterior Segment and External Diagnostic Uses.

Epiphora (excessive tearing) and surface problems of the cornea and conjunctiva are commonly encountered external ocular disorders. The dyes *fluorescein*, *rose bengal*, and *lissamine green* are used in evaluating these problems. Available both as a 2% alkaline solution and as an impregnated paper strip, fluorescein reveals epithelial defects of the cornea and conjunctiva and aqueous humor leakage that may occur after trauma or ocular surgery. In the setting of epiphora, fluorescein is used to help determine the patency of the nasolacrimal system. In addition, this dye is used as part of the procedure of *applanation tonometry* (intraocular pressure measurement) and to assist in determining the proper fit of rigid and semirigid contact lenses. Fluorescein in combination with *proparacaine* or *benoxinate* is available for procedures in which a disclosing agent is needed in conjunction with a topical anesthetic. *Fluorexon* (FLUORESOF), a high-molecular-weight fluorescent solution, is used when fluorescein is contraindicated (as when soft contact lenses are in place).

Rose bengal and lissamine green, which also are available as a 1% solution and as saturated paper strips, stain devitalized tissue on the cornea and conjunctiva.

Posterior Segment Diagnostic and Therapeutic Uses.

The integrity of the blood–retinal and retinal pigment epithelial barriers may be examined directly by retinal angiography using intravenous administration of either *fluorescein sodium* or *indocyanine green* (structures shown below). These agents commonly cause nausea and may precipitate serious allergic reactions in susceptible individuals.

FLUORESCIN SODIUM

INDOCYANINE GREEN

Verteporfin (VISUDYNE) is approved for photodynamic therapy of the exudative form of age-related macular degeneration with predominantly classic choroidal neovas-

Table 63–9
Ophthalmic Effects of Selected Vitamin Deficiencies and Zinc Deficiency

DEFICIENCY	EFFECTS IN ANTERIOR SEGMENT	EFFECTS IN POSTERIOR SEGMENT
<i>Vitamin</i>		
A (retinol)	Conjunctiva (Bitot's spots, xerosis) Cornea (keratomalacia; punctate keratopathy)	Retina (nyctalopia; impaired rhodopsin synthesis); retinal pigment epithelium (hypopigmentation)
B ₁ (thiamine)		Optic nerve (temporal atrophy with corresponding visual field defects)
B ₆ (pyridoxine)	Cornea (neovascularization)	Retina (gyrate atrophy)
B ₁₂ (cyanocobalamin)		Optic nerve (temporal atrophy with corresponding visual field defects)
C (ascorbic acid)	Lens (?cataract formation)	
E (tocopherol)		Retina and retinal pigment epithelium (?macular degeneration)
Folic acid		Vein occlusion
K	Conjunctiva (hemorrhage) Anterior chamber (hyphema)	Retina (hemorrhage)
Zinc		Retina and retinal pigment epithelium (?macular degeneration)

See Chambers, 1994.

The purified plant pigment carotene (provitamin A) is a remarkably potent source of vitamin A. β -Carotene, the most active carotenoid found in plants, has the structural formula shown in Figure 63–7A. The structural formulas for the vitamin A family of retinoids are shown in Figure 63–7B.

Retinol, a primary alcohol, is present in esterified form in the tissues of animals and saltwater fish, mainly in the liver.

A number of *cis-trans* isomers exist because of the unsaturated carbons in the retinol side chain. Fish liver oils contain mixtures of the stereoisomers; synthetic retinol is the all-*trans* isomer. Interconversion between isomers readily takes place in the body. In the visual cycle, the reaction between retinal (vitamin A aldehyde) and opsin to form rhodopsin occurs only with the 11-*cis* isomer. Ethers and esters derived from the alcohol also show activity *in vivo*. The ring structure of retinol (β -ionone), or the more unsaturated ring in 3-dehydroretinol (dehydro- β -ionone), is essential for activity; hydrogenation destroys biological activity. Of all known derivatives, all-*trans*-retinol and its aldehyde, retinal, exhibit the greatest biological potency *in vivo*; 3-dehydroretinol has about 40% of the potency of all-*trans*-retinol.

Retinoic acid, in which the alcohol moiety has been oxidized, shares some but not all of the actions of retinol. Retinoic acid is ineffective in restoring visual or reproductive function in certain species where retinol is effective. However, retinoic acid is very potent in promoting growth and controlling differentiation and maintenance of epithelial tissue in vitamin A–deficient animals. Indeed, all-*trans*-retinoic acid (*tretinoin*) appears to be the active form of vitamin A in all tissues except the retina, and is ten- to one hundredfold more potent than retinol in various systems *in vitro*. Isomerization of this compound in the body yields 13-*cis*-retinoic

acid (*isotretinoin*), which is nearly as potent as tretinoin in many of its actions on epithelial tissues, but may be only one-fifth as potent in producing the toxic symptoms of hypervitaminosis A.

Many retinoic acid analogs have been synthesized, including the prodrug *etretinate*, which is the ethyl ester of the active compound *acitretin*. These compounds are representative of the “second-generation” retinoids, in which the β -ionone ring is aromatized; they are more active than tretinoin in some systems but are less active in others. The highly potent “third-generation” retinoids feature two aromatic rings that serve to restrict the flexibility of the polyenoic side chain. This class of aromatic retinoids has been called *arotinoids*, and includes the carboxylic acid Ro 13-7410, and the ethyl sulfone Ro 15-1570.

Physiological Functions and Pharmacological Actions. Vitamin A plays an essential role in the function of the retina, is necessary for growth and differentiation of epithelial tissue, and is required for growth of bone, reproduction, and embryonic development. Together with certain carotenoids, vitamin A enhances immune function, reduces the consequences of some infectious diseases, and may protect against the development of certain malignancies. As a result, there is considerable interest in the pharmacological use of retinoids for cancer prophylaxis and for treating various premalignant conditions. Because of the effects of vitamin A on epithelial tissues, retinoids and their analogs are used to treat a number of skin diseases, including some of the consequences of aging and prolonged exposure to the sun (see Chapter 62).

The functions of vitamin A are mediated by different forms of the molecule. In vision, the functional vitamin is retinal. Retinoic acid appears to be the active form in functions associated with growth, differentiation, and transformation.

Figure 63–7. A. Structural formula for β -Carotene. B. Structural formulas for the vitamin A family of retinoids.

Retinal and the Visual Cycle. Vitamin A deficiency interferes with vision in dim light, a condition known as *night blindness* (nyctalopia).

Photoreception is accomplished by two types of specialized retinal cells, termed *rods* and *cones*. Rods are especially sensitive to light of low intensity; cones act as receptors of high-intensity light and are responsible for color vision. The initial step is the absorption of light by a chromophore attached to the receptor protein. The chromophore of both rods and cones is 11-*cis*-retinal. The holoreceptor in rods is termed *rhodopsin*—a combination of the protein opsin and 11-*cis*-retinal attached as a prosthetic group. The three different types of cone cells (red, green, and blue) contain individual, related photoreceptor proteins and respond optimally to light of different wavelengths.

In the synthesis of rhodopsin, 11-*cis*-retinol is converted to 11-*cis*-retinal in a reversible reaction that requires pyridine nucleotides. 11-*cis*-Retinal then combines with the ϵ -amino group of a specific lysine residue in opsin to form rhodopsin. Most rhodopsin is located in the membranes of the discs situated in the outer segments of the

rods. The polypeptide chain of the protein spans the membrane seven times, a characteristic shared by all receptors whose functions are transduced *via* G proteins.

The visual cycle, depicted in Figure 63–8, is initiated by the absorption of a photon of light, followed by the photodecomposition, or bleaching, of rhodopsin through a cascade of unstable conformational states, leading ultimately to the isomerization of 11-*cis*-retinal to the all-*trans* form and dissociation of the opsin moiety. Activated rhodopsin interacts rapidly with another protein of the retinal rod outer segment, a G protein termed *transducin* or G_t . Transducin stimulates a cyclic GMP-specific phosphodiesterase (Figure 63–9). The resultant decline in cyclic GMP concentration causes a decreased conductance of cyclic GMP-gated Na^+ channels in the plasma membrane and an increased transmembrane potential (Figure 63–10). After processing within the retinal circuitry, this primary receptor potential ultimately leads to the generation of action potentials that travel to the brain *via* the optic nerve (Stryer, 1991). All-*trans*-retinal can isomerize to 11-*cis*-retinal, which then may

Figure 63-8. The visual cycle.

recombine with opsin to form rhodopsin. Alternatively, all-*trans*-retinal can cycle through all-*trans*-retinol and 11-*cis*-retinol to 11-*cis*-retinal, which combines with opsin to regenerate rhodopsin (Figure 63-8).

Humans deficient in vitamin A lose their ability for dark adaptation. Rod vision is affected more than cone vision. Upon depletion of retinol from liver and blood, usually at plasma concentrations of retinol of less than 0.2 mg/liter (0.70 μ M), the concentrations of retinol and rhodopsin in the retina fall. Unless the deficiency is overcome, opsin, lacking the stabilizing effect of retinal, decays and anatomical deterioration of the rods' outer segments takes place. In rats

maintained on a vitamin A-deficient diet, irreversible ultrastructural changes leading to blindness then supervene, a process that takes approximately 10 months.

Following short-term deprivation of vitamin A, dark adaptation can be restored to normal by the addition of retinol to the diet. However, vision does not return to normal for several weeks after adequate amounts of retinol have been supplied. The reason for this delay is unknown.

Vitamin A and Epithelial Structures. The functional and structural integrity of epithelial cells throughout the body is dependent upon an adequate supply of vitamin A. The vitamin plays a major role in the induction and control of epithelial differentiation in mucus-secreting or keratinizing tissues. In the presence of retinol or retinoic acid, basal epithelial cells are stimulated to produce mucus. Excessive concentrations of the retinoids lead to the production of a thick layer of mucin, the inhibition of keratinization, and the display of goblet cells.

In the absence of vitamin A, goblet mucous cells disappear and are replaced by basal cells that have been stimulated to proliferate. These undermine and replace the original epithelium with a stratified, keratinizing epithelium. The suppression of normal secretions leads to irritation and infection. Reversal of these changes is achieved by the administration of retinol, retinoic acid, or other retinoids. When this process happens in the cornea, severe hyperkeratinization (xerophthalmia) may lead to permanent blindness. Worldwide, xerophthalmia remains one of the most common causes of blindness.

Mechanism of Action. In isolated fibroblasts or epithelial tissue, retinoids enhance the synthesis of some proteins (*e.g.*, fibronectin) and reduce the synthesis of others (*e.g.*, collagenase, certain species of keratin), and molecular evidence suggests that these actions can be entirely accounted for by changes in nuclear transcription (Mangelsdorf *et al.*, 1994). Retinoic acid appears to

Figure 63-9. The cGMP cascade of phototransduction. The cycle on the right shows the steps by which the absorption of light by rhodopsin leads to the activation of a phosphodiesterase (PDE) hydrolyzing cGMP. T represents the GTP-binding protein transduction. (Reproduced with permission from Falk, G. Retinal physiology. In: (Heckenlively, J.R., and Arden, G.B., eds.) *Principles and Practice of Clinical Electrophysiology of Vision*. Mosby Year Book, New York, 1991.)

Figure 63–10. Ion movements across the surface membrane of a rod. In the dark there is a circulating current as cations, mainly Na ions, cross the outer segment membrane while K ions exit from the inner segment. Rhodopsin is embedded in stacks of disc membranes that are separated from each other and from the surface membrane. Light, absorbed by rhodopsin, leads to a change in the concentration of a diffusible substance and the closure of ion channels in the outer segment surface membrane, and this reduces the circulating current. (Reproduced with permission from Lamb, T.D. Transduction in vertebrate photoreceptors: the roles of cyclic GMP and calcium. *Trends Neurosci.*, 1986, 9:224–228.)

be considerably more potent than retinol in mediating these effects.

Retinoic acid influences gene expression by combining with nuclear receptors. Multiple retinoid receptors have been described. These are grouped into two families. One family, the retinoic acid receptors (RARs), designated α , β , and γ , are derived from genes localized to human chromosomes 17, 3, and 12, respectively. The second family, the retinoid X receptors (RXRs), also is composed of α , β , and γ receptor isoforms (Chambon, 1995). The retinoid receptors show extensive sequence homology to each other in both their DNA and hormone-binding domains and belong to a receptor superfamily that includes receptors for steroid and thyroid hormones and calcitriol (Mangelsdorf *et al.*, 1994). Cellular responses to thyroid hormones, calcitriol, and retinoic acid are enhanced by the presence of RXR. Gene activation involves binding of the hormone-receptor complex to promoter elements in target genes, followed by dimerization with an RXR-ligand complex. The endogenous RXR ligand is 9-*cis*-retinoic acid (Heyman *et al.*, 1992; Levin *et al.*, 1992). No comparable receptor for retinol has been identi-

fied; retinol may need to be oxidized to retinoic acid to produce its effects within target cells.

Retinoids can influence the expression of receptors for certain hormones and growth factors, and thus can influence the growth, differentiation, and function of target cells by both direct and indirect actions (Love and Gudas, 1994).

Therapeutic Uses. Nutritional vitamin A deficiency causes *xerophthalmia*, a progressive disease characterized by *nyctalopia* (night blindness), *xerosis* (dryness), and *keratomalacia* (corneal thinning) which may lead to perforation; xerophthalmia may be reversed with vitamin A therapy (WHO/UNICEF/IVAGG Task Force, 1988). However, rapid, irreversible blindness ensues once the cornea perforates. Vitamin A also is involved in epithelial differentiation and may have some role in corneal epithelial wound healing. Currently, there is no evidence to support using topical vitamin A for keratoconjunctivitis sicca in the absence of a nutritional deficiency. The current recommendation for retinitis pigmentosa is to administer 15,000 IU of vitamin A palmitate daily under the supervision of an ophthalmologist and to avoid high-dose vitamin E.

The recent Age-Related Eye Disease Study (AREDS) found a reduction in the risk of progression of some types of age-related macular degeneration for those randomized to receive high-doses of vitamins C (500 mg), E (400 IU), β -carotene (15 mg), cupric oxide (2 mg), and zinc (80 mg) (Age-Related Eye Disease Study Research Group, 2001b). Interestingly, zinc has been found to be neuroprotective in a rat model of glaucoma. The mechanism appears to be mediated by heat shock proteins and may represent a novel treatment strategy for glaucoma (Park *et al.*, 2001).

Wetting Agents and Tear Substitutes. General Considerations. The current management of dry eyes usually includes instilling artificial tears and ophthalmic lubricants. In general, tear substitutes are hypotonic or isotonic solutions composed of electrolytes, surfactants, preservatives, and some viscosity-increasing agent that prolongs the residence time in the cul-de-sac and precorneal tear film. Common viscosity agents include cellulose polymers (*e.g.*, *carboxymethylcellulose*, *hydroxyethyl cellulose*, *hydroxypropyl cellulose*, *hydroxypropyl methylcellulose*, and *methylcellulose*), *polyvinyl alcohol*, *polyethylene glycol*, *polysorbate*, *mineral oil*, *glycerin*, and *dextran*. The tear substitutes are available as preservative-containing or preservative-free preparations. The viscosity of the tear substitute depends on its exact formulation and can range from watery to gel-like. Some tear formulations also are combined with a vasoconstrictor, such as naphazoline, phenylephrine, or *tetrahydrozoline*. In other countries, *hyaluronic acid* sometimes is used as a viscous agent; *hyaluronate* has not been approved for use in the United States.

The lubricating ointments are composed of a mixture of white petrolatum, mineral oil, liquid or alcohol lanolin, and sometimes a preservative. These highly viscous formulations cause considerable blurring of vision, and consequently they are used primarily at bedtime, in critically ill patients, or in very severe dry eye conditions.

Such aqueous and ointment formulations are only fair substitutes for the precorneal tear film, which is truly a poorly understood lipid, aqueous, and mucin trilaminar barrier (*see above*).

Therapeutic Uses. Many local eye conditions and systemic diseases may affect the precorneal tear film. Local eye disease, such as blepharitis, ocular rosacea, ocular pemphigoid, chemical burns, or corneal dystrophies, may alter the ocular surface and change the tear

composition. Appropriate treatment of the symptomatic dry eye includes treating the accompanying disease and possibly the addition of tear substitutes. There also are a number of systemic conditions that may manifest themselves with symptomatic dry eyes, including Sjögren's syndrome, rheumatoid arthritis, vitamin A deficiency, Stevens-Johnson syndrome, and trachoma. Treating the systemic disease may not eliminate the symptomatic dry eye complaints; chronic therapy with tear substitutes or surgical occlusion of the lacrimal drainage system may be indicated.

Osmotic Agents and Drugs Affecting Carbonic Anhydrase. General Considerations. The main osmotic drugs for ocular use include *glycerin*, *mannitol* (see Chapter 28), and *hypertonic saline*. With the availability of these agents, the use of urea for management of acutely elevated intraocular pressure is nearly obsolete.

Therapeutic Uses. Ophthalmologists occasionally use glycerin and mannitol for short-term management of acute rises in intraocular pressure. Sporadically, these agents are used intraoperatively to dehydrate the vitreous prior to anterior segment surgical procedures. Many patients with acute glaucoma do not tolerate oral medications because of nausea; therefore, intravenous administration of mannitol and/or acetazolamide may be preferred over oral administration of glycerin. These agents should be used with caution in patients with congestive heart failure or renal failure.

Corneal edema is a clinical sign of corneal endothelial dysfunction, and topical osmotic agents may effectively dehydrate the cornea. Identifying the cause of corneal edema will guide therapy, and topical osmotic agents, such as hypertonic saline, may temporize the need for surgical intervention in the form of a corneal transplant. Sodium chloride is available in either aqueous or ointment formulations. Topical glycerin also is available; however, because it causes pain upon contact with the cornea and conjunctiva, its use is limited to urgent evaluation of filtration-angle structures. In general, when corneal edema occurs secondary to acute glaucoma, the use of an oral osmotic agent to help reduce intraocular pressure is preferred to topical glycerin, which simply clears the cornea temporarily. Reducing the intraocular pressure will help clear the cornea more permanently to allow both a view of the filtration angle by gonioscopy and a clear view of the iris as required to perform laser iridotomy.

SECTION XV

Toxicology

CHAPTER

64

PRINCIPLES OF TOXICOLOGY AND TREATMENT OF POISONING

Curtis D. Klaassen

Toxicology is the science of the adverse effects of chemicals, including drugs, on living organisms. The discipline often is divided into several major areas. The *descriptive toxicologist* performs toxicity tests (*see below*) to obtain information that can be used to evaluate the risk that exposure to a chemical poses to humans and to the environment. The *mechanistic toxicologist* attempts to determine how chemicals exert deleterious effects on living organisms. Such studies are essential for the development of tests for the prediction of risks, for facilitating the search for safer chemicals, and for rational treatment of the manifestations of toxicity. The *regulatory toxicologist* judges whether a drug or other chemical has a low enough risk to justify making it available for its intended purpose. Two specialized areas of toxicology are particularly important for medicine. *Forensic toxicology*, which combines analytical chemistry and fundamental toxicology, is concerned with the medicolegal aspects of chemicals. Forensic toxicologists assist in postmortem investigations to establish the cause or circumstances of death. *Clinical toxicology* focuses on diseases that are caused by or are uniquely associated with toxic substances. Clinical toxicologists treat patients who are poisoned by drugs and other chemicals and develop new techniques for the diagnosis and treatment of such intoxications.

The clinician must evaluate the possibility that a patient's signs and symptoms may be caused by toxic chemicals present in the environment or administered as therapeutic agents. Many of the adverse effects of drugs mimic symptoms of disease. Appreciation of the principles of toxicology is necessary for the recognition and management of such clinical problems.

DOSE–RESPONSE RELATIONSHIP

Evaluation of the dose–response or the dose–effect relationship is crucially important to toxicologists. There is a graded dose–response relationship in an *individual* and a quantal dose–response relationship in the *population* (*see Chapters 1 and 5*). Graded doses of a drug given to an individual usually result in a greater magnitude of response as the dose is increased. In a quantal dose–response relationship, the percentage of the population affected increases as the dose is raised; the relationship is quantal in that the effect is specified to be either present or absent in a given individual (*see Figure 5–4*). This quantal dose–response phenomenon is extremely important in toxicology and is used to determine the *median lethal dose* (LD_{50}) of drugs and other chemicals.

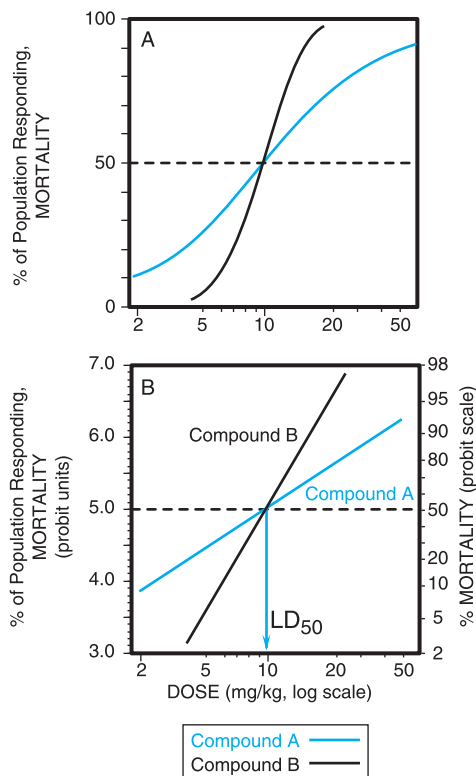

Figure 64-1. Dose-response relationships. *A.* The toxic response to a chemical is evaluated at several doses in the toxic or lethal range. The midpoint of the curve representing percent of population responding (response here is DEATH) versus dose (log scale) represents the LD₅₀, or the concentration of drug that is lethal in 50% of the population. *B.* A linear transformation of the data in *A* is provided by plotting the log of the dose administered versus the percent of the population killed in probit units.

The LD₅₀ of a compound is determined experimentally, usually by administration of the chemical to mice or rats (orally or intraperitoneally) at several doses (usually four or five) in the lethal range (Figure 64-1A). To linearize such data, the response (death) can be converted to units of *deviation from the mean*, or *probits (probability units)*. The probit designates the deviation from the median; a probit of 5 corresponds to a 50% response, and because each probit equals one standard deviation, a probit of 4 equals 16% and a probit of 6 equals 84%. A plot of the percentage of the population responding, in probit units, against log dose yields a straight line (Figure 64-1B). The LD₅₀ is determined by drawing a vertical line from the point on the line where the probit unit equals 5 (50% mortality). The slope of the dose-effect curve also is important. The LD₅₀ for both compounds depicted in Figure 64-1 is the same (10 mg/kg). However, the slopes of the dose-response curves are quite different. At a dose equal to one-half the LD₅₀ (5 mg/kg), less than 5% of the animals exposed to compound B would die, but 30% of the animals given compound A would die.

The quantal, or “all-or-none,” response is not limited to lethality. As described in Chapters 1 and 5, similar dose-effect curves can be constructed for any effect produced by chemicals.

RISK AND ITS ASSESSMENT

There are marked differences in the LD₅₀ values of various chemicals. Some result in death at doses of a fraction of a microgram (LD₅₀ for botulinum toxin equals 10 pg/kg); others may be relatively harmless in doses of several grams or more. While categories of toxicity that are of some practicality have been devised based on the amount required to produce death, often it is not easy to distinguish between toxic and nontoxic chemicals. Paracelsus (1493–1541) noted: “All substances are poisons; there is none which is not a poison. The right dose differentiates a poison and a remedy.” It is simply not possible to categorize all chemicals as either safe or toxic. The real concern is the *risk* associated with use of the chemical. In the assessment of risk, one must consider concentration or dose as well as the harmful effects of the chemical accrued directly or indirectly through adverse effects on the environment when used in the quantity and in the manner proposed. Depending on the use and disposition of a chemical, a very toxic compound ultimately may be less harmful than a relatively nontoxic one.

At present, there is much concern about the risk from exposure to chemicals that have produced cancer in laboratory animals. For most of these chemicals, it is not known if they also produce cancer in humans. Regulatory agencies take one of three approaches to potential chemical carcinogens. For food additives, the U.S. Food and Drug Administration (FDA) is very cautious because large numbers of people are likely to be exposed to the chemicals, and they are not likely to have beneficial effects to individuals. For drugs, the FDA weighs the relative risks and benefits of the drugs for patients. Thus it is unlikely that the FDA will approve the use of a drug that produces tumors in laboratory animals for a mild ailment, but it may approve its use for a serious disease. In fact, most cancer chemotherapeutic drugs also are chemical carcinogens.

In the regulation of environmental carcinogens, government agencies, such as the U.S. Environmental Protection Agency (EPA), attempt to limit lifetime exposure such that the incidence of cancer due to the chemical would be no more than one in a million people. To determine the daily allowable exposure for humans, mathematical models are used to extrapolate doses of chemicals that produce a particular incidence of tumors in laboratory animals (often in the range of 10% to 20%) to those that should produce cancer in no more than one person in a million. The models used are conservative and are thought to provide adequate protection from undue risks from exposure to potential carcinogens. As discussed in Chapter 3, variations in drug metabolism often result in substantial differences between the biological responses of humans and rodents.

Acute versus Chronic Exposure. Effects of acute exposure to a chemical often differ from those that follow chronic exposure. Acute exposure occurs when a dose is delivered as a single event. Chronic exposure is likely to be to small quantities of a substance over a long period of

time, which often results in slow accumulation of the compound in the body. Evaluation of *cumulative* toxic effects is receiving increased attention because of chronic exposure to low concentrations of various natural and synthetic chemical substances in the environment.

Chemical Forms of Drugs That Produce Toxicity. The “parent” drug administered to the patient often is the chemical form producing the desired therapeutic effect; the parent drug also may produce the toxic effects of drug. However, both therapeutic and toxic effects also can be due to metabolites of the drug produced by enzymes, light, or reactive oxygen species. In considering the toxicity of drugs and chemicals, it is important to understand their metabolism, activation, or decomposition.

Toxic Metabolites. The metabolites of many chemicals are responsible for their toxicities. Most organophosphate insecticides are biotransformed by cytochrome P450 enzymes (CYPs) to produce the active toxin. For example, parathion is biotransformed to paraoxon (Figure 64–2). Paraoxon is a stable metabolite that binds to and inactivates cholinesterase. Some drug metabolites are not chemically stable and are referred to as *reactive intermediates*. An example of a toxic reactive intermediate is the metabolite of acetaminophen (Figure 64–3), which is very reactive and binds to nucleophiles such as glutathione; when cellular glutathione is depleted, the metabolite binds to cellular macromolecules, the mechanism by which acetaminophen kills liver cells (see Chapter 26). Both parathion and acetaminophen are more toxic under conditions in which CYPs are increased, such as following *ethanol* or *phenobarbital* exposure, because CYPs produce the toxic metabolites (see Chapter 3).

Phototoxic and Photoallergic Reactions. Many chemicals are activated to toxic metabolites by hepatic enzymatic biotransformation. However, some chemicals can be activated in the skin by ultraviolet and/or visible radiation. In photoallergy, radiation absorbed by a drug, such as a *sulfonamide*, results in its conversion to a product that is a more potent allergen than the parent compound. Phototoxic reactions to drugs, in contrast to photoallergic ones, do not have an immunological component. Drugs that are either absorbed locally into the skin or have reached the skin through the systemic circulation may be the object of photochemical reactions within the skin; this can lead directly either to chemically induced photosensitivity reactions or to enhancement of the usual effects of sunlight. *Tetracyclines*, sulfonamides, *chlorpro-*

Figure 64–2. Biotransformation of parathion.

Figure 64–3. Pathways of acetaminophen metabolism.

mazine, and *nalidixic acid* are examples of phototoxic chemicals; generally, they are innocuous to skin if not exposed to light.

Reactive Oxygen Species. Paraquat is a herbicide that produces severe lung injury. Its toxicity is not due to paraquat or its metabolites but rather to reactive oxygen species formed during one-electron reduction of paraquat paired with an electron donation to oxygen (Figure 64–4).

SPECTRUM OF UNDESIRABLE EFFECTS

The spectrum of undesired effects of chemicals may be broad and ill defined (Figure 64–5). In therapeutics, a

Figure 64–4. Biotransformation of paraquat.

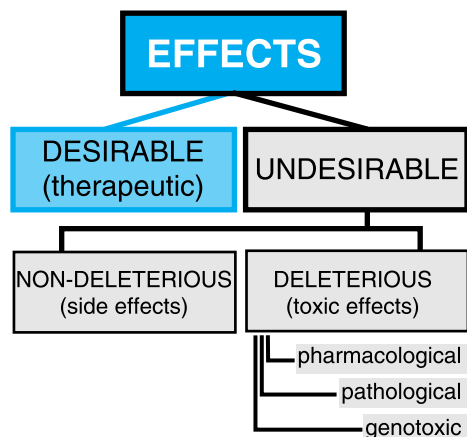

Figure 64–5. Classification of the effects of chemicals.

drug typically produces numerous effects, but usually only one is sought as the primary goal of treatment; most of the other effects are referred to as *undesirable effects* of that drug for that therapeutic indication. *Side effects* of drugs usually are nondeleterious; they include effects such as dry mouth occurring with tricyclic antidepressant therapy. Some side effects may be *adverse* or *toxic*. Mechanistic categorization of *toxic* effects is a necessary prelude to their avoidance or, if they occur, to effect their rational and successful management.

Types of Toxic Reactions. Toxic effects of drugs may be classified as pharmacological, pathological, or genotoxic (alterations of DNA), and their incidence and seriousness are related, at least over some range, to the concentration of the toxic chemical in the body. An example of a pharmacological toxicity is excessive depression of the central nervous system (CNS) by barbiturates; of a pathological effect, hepatic injury produced by acetaminophen; of a genotoxic effect, a neoplasm produced by a *nitrogen mustard*. If the concentration of chemical in the tissues does not exceed a critical level, the effects usually will be reversible. The pharmacological effects usually disappear when the concentration of drug or chemical in the tissues is decreased by biotransformation or excretion from the body. Pathological and genotoxic effects may be repaired. If these effects are severe, death may ensue within a short time; if more subtle damage to DNA is not repaired, cancer may appear in a few months or years in laboratory animals or in a decade or more in humans.

Local versus Systemic Toxicity. Local toxicity occurs at the site of first contact between the biological system and the toxicant. Local effects can be caused by ingestion of caustic substances or

inhalation of irritant materials. Systemic toxicity requires absorption and distribution of the toxicant; most substances, with the exception of highly reactive chemical species, produce systemic toxic effects. The two categories are not mutually exclusive. Tetraethyl lead, for example, injures skin at the site of contact and deleteriously affects the CNS after it is absorbed into the circulation (see Chapter 65).

Most systemic toxicants predominantly affect one or a few organs. The target organ of toxicity is not necessarily the site of accumulation of the chemical. For example, lead is concentrated in bone, but its primary toxic action is on soft tissues; DDT (chlorophenothane) is concentrated in adipose tissue but produces no known toxic effects there.

The CNS is involved in systemic toxicity most frequently because many compounds with prominent effects elsewhere also affect the brain. Next in order of frequency of involvement in systemic toxicity are the circulatory system; the blood and hematopoietic system; visceral organs such as liver, kidney, and lung; and the skin. Muscle and bone are least often affected. With substances that have a predominantly local effect, the frequency of tissue reaction depends largely on the portal of entry (skin, gastrointestinal tract, or respiratory tract).

Reversible and Irreversible Toxic Effects. The effects of drugs on humans, whenever possible, must be reversible; otherwise, the drugs would be prohibitively toxic. If a chemical produces injury to a tissue, the capacity of the tissue to regenerate or recover largely will determine the reversibility of the effect. Injuries to a tissue such as liver, which has a high capacity to regenerate, usually are reversible; injury to the CNS is largely irreversible because the highly differentiated neurons of the brain have a more limited capacity to divide and regenerate.

Delayed Toxicity. Most toxic effects of drugs occur at a predictable (usually short) time after administration. However, such is not always the case. For example, aplastic anemia caused by *chloramphenicol* may appear weeks after the drug has been discontinued. Carcinogenic effects of chemicals usually have a long latency period: 20 to 30 years may pass before tumors are observed. Because such delayed effects cannot be assessed during any reasonable period of initial evaluation of a chemical, there is an urgent need for reliably predictive short-term tests for such toxicity, as well as for systematic surveillance of the long-term effects of marketed drugs and other chemicals (see Chapter 5).

Chemical Carcinogens. Chemical carcinogens are classified into two major groups, *genotoxic* and *nongenotoxic*. Genotoxic carcinogens interact with DNA, whereas nongenotoxic carcinogens do not. Chemical carcinogenesis is a multistep process. Most genotoxic carcinogens are themselves unreactive (*procarcinogens* or *proximate carcinogens*) but are converted to *primary* or *ultimate carcinogens* in the body. The drug-metabolizing enzymes often convert the proximate carcinogens to reactive electron-deficient intermediates (electrophiles). These reactive intermediates can interact with electron-rich (nucleophilic) centers in DNA to produce a mutation. Such interaction of the ultimate carcinogen with DNA in a cell is thought to be the initial step in chemical carcinogenesis. The DNA may revert to nor-

mal if DNA repair mechanisms operate successfully; if not, the transformed cell may grow into a tumor that becomes apparent clinically.

Nongenotoxic carcinogens, also referred to as *promoters*, do not produce tumors alone but do potentiate the effects of genotoxic carcinogens. Promotion involves facilitation of the growth and development of so-called dormant or latent tumor cells. The time from initiation to the development of a tumor probably depends on the presence of such promoters; for many human tumors, the latent period is 15 to 45 years.

To determine whether a chemical is potentially carcinogenic to humans, two main types of laboratory tests are conducted. One type of study is performed to determine whether the chemical is mutagenic because many carcinogens are also mutagens. These studies often use assays such as the Ames test (*see below*), which can be completed within a few days and can detect genotoxic carcinogens but not promoters. The second type of study to detect chemical carcinogens consists of feeding laboratory animals (mice and rats) the chemical at high dosages for their entire life span, after which autopsies and histopathological examinations are performed on each animal. The incidence of tumors in control animals and animals fed the chemical are compared to determine whether the chemical produces an increased incidence of tumors. This latter study can detect both promoters and genotoxic carcinogens.

Allergic Reactions. *Chemical allergy* is an adverse reaction that results from previous sensitization to a particular chemical or to one that is structurally similar. Such reactions are mediated by the immune system. The terms *hypersensitivity* and *drug allergy* often are used to describe the allergic state.

For a low-molecular-weight chemical to cause an allergic reaction, it or its metabolic product usually acts as a hapten, combining with an endogenous protein to form an antigenic complex. Such antigens induce the synthesis of antibodies, usually after a latent period of at least 1 or 2 weeks. Subsequent exposure of the organism to the chemical results in an antigen–antibody interaction that provokes the typical manifestations of allergy. Dose–response relationships usually are not apparent for the provocation of allergic reactions.

Allergic responses have been divided into four general categories based on the mechanism of immunological involvement (Coombs and Gell, 1975). Type I, or anaphylactic, reactions, are mediated by IgE antibodies. The Fc portion of IgE can bind to receptors on mast cells and basophils (*see Chapter 27*). If the Fab portion of the antibody molecule then binds antigen, various mediators (*e.g.*, histamine, leukotrienes, and prostaglandins) are released and cause vasodilation, edema, and an inflammatory response. The main targets of this type of reaction are the gastrointestinal tract (food allergies), the skin (urticaria and atopic dermatitis), the respiratory system (rhinitis and asthma), and the vasculature (anaphylactic shock). These responses tend to occur quickly after challenge with an antigen to which the individual has been sensitized and are termed *immediate hypersensitivity reactions*.

Type II, or cytolytic, reactions are mediated by both IgG and IgM antibodies and usually are attributed to their ability to activate the complement system. The major target tissues for cytolytic reactions are the cells in the circulatory system. Examples of type II allergic responses include *penicillin*-induced hemolytic anemia, *methyl dopa*-induced autoimmune hemolytic anemia, *quinidine*-induced thrombocytopenic purpura, and sulfonamide-induced granulocytopenia. Fortunately, these autoimmune reactions to drugs usually subside within several months after removal of the offending agent.

Type III, or Arthus, reactions are mediated predominantly by IgG; the mechanism involves the generation of antigen–antibody complexes that subsequently fix complement. The complexes are deposited in the vascular endothelium, where a destructive inflammatory response called *serum sickness* occurs. This phenomenon contrasts with the type II reaction, in which the inflammatory response is induced by antibodies directed against tissue antigens. The clinical symptoms of serum sickness include urticarial skin eruptions, arthralgia or arthritis, lymphadenopathy, and fever. These reactions usually last for 6 to 12 days and then subside after the offending agent is eliminated. Several drugs (*e.g.*, sulfonamides, penicillins, certain *anticonvulsants*, and *iodides*) can induce serum sickness. Stevens-Johnson syndrome, such as that caused by sulfonamides, is a more severe form of immune vasculitis. Manifestations of this reaction include erythema multiforme, arthritis, nephritis, CNS abnormalities, and myocarditis.

Type IV, or delayed-hypersensitivity, reactions are mediated by sensitized T-lymphocytes and macrophages. When sensitized cells come in contact with antigen, an inflammatory reaction is generated by the production of lymphokines and the subsequent influx of neutrophils and macrophages. An example of type IV or delayed hypersensitivity is the contact dermatitis caused by poison ivy.

Idiosyncratic Reactions. *Idiosyncrasy* is an abnormal reactivity to a chemical that is peculiar to a given individual. The idiosyncratic response may take the form of extreme sensitivity to low doses or extreme insensitivity to high doses of chemicals. We now know that certain idiosyncratic reactions can result from genetic polymorphisms that cause individual differences in drug pharmacokinetics; for example, an increased incidence of peripheral neuropathy is seen in patients with inherited deficiencies in acetylation when *isoniazid* is used to treat tuberculosis. The polymorphisms also can be due to pharmacodynamic factors such as drug–receptor interactions (Evans and Relling, 1999). For example, many black males (about 10%) develop a serious hemolytic anemia when they receive *primaquine* as an antimalarial therapy. Such individuals have a deficiency of erythrocyte glucose-6-phosphate dehydrogenase (*see Chapter 39*). Genetically determined resistance to the anticoagulant action of *warfarin* is due to an alteration in the vitamin K epoxide reductase (*see Chapter 54*). The use of genetic information to explain interindividual differences in drug responses or to individualize dosages of drugs for patients with known genetic polymorphisms is referred to as *pharmacogenomics* (*see Chapters 3 and 4*).

Interactions between Chemicals. The existence of numerous toxicants requires consideration of their potential interactions (Figure 64–6). Concurrent exposures may alter the pharmacokinetics of drugs by changing rates of absorption, the degree of protein binding, or the rates of biotransformation or excretion of one or both interacting compounds. The pharmacodynamics of chemicals can be altered by competition at the receptor; for example, *atropine* is used

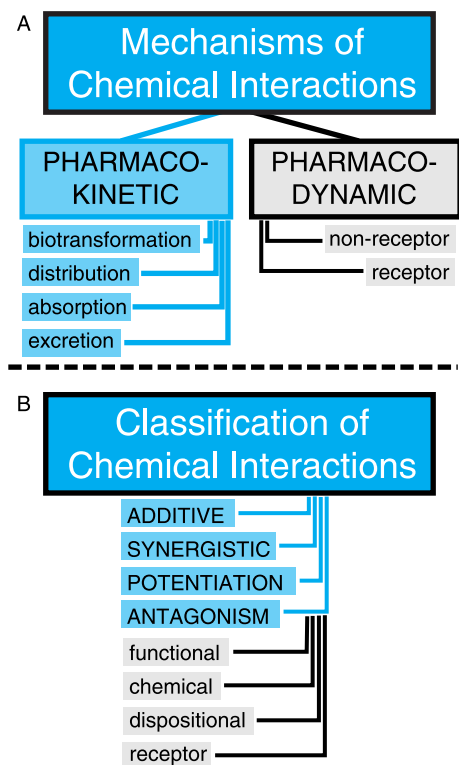

Figure 64-6. Mechanisms and classifications of chemical interactions.

to treat organophosphate insecticide toxicity because it blocks muscarinic cholinergic receptors and prevents their stimulation by the excess acetylcholine accruing from inhibition of acetylcholinesterase by the insecticide. Nonreceptor pharmacodynamic drug interactions also can occur when two drugs have different mechanisms of action: *Aspirin* and *heparin* given together can cause unexpected bleeding. The response to combined toxicants thus may be equal to, greater than, or less than the sum of the effects of the individual agents.

Numerous terms describe pharmacological and toxicological interactions (Figure 64-6B). An *additive* effect describes the combined effect of two chemicals that equals the sum of the effect of each agent given alone; the additive effect is the most common. A *synergistic* effect is one in which the combined effect of two chemicals exceeds the sum of the effects of each agent given alone. For example, both carbon tetrachloride and ethanol are hepatotoxins, but together they produce much more injury to the liver than expected from the sum of their individual effects. *Potentiation* is the increased effect of a toxic agent acting simultaneously with a nontoxic one. *Iso-propanol* alone, for example, is not hepatotoxic; however, it greatly increases the hepatotoxicity of carbon tetrachloride. *Antagonism* is the interference of one chemical with the action of another. An antagonistic agent is often desirable as an antidote. *Functional or physiological antagonism* occurs when two chemicals produce opposite effects on the same physiological function. For example, this principle is applied to the use of intravenous infusion of dopamine to maintain perfusion of vital organs during certain severe intoxications characterized by marked hypotension. *Chemical antagonism* or *inactivation* is a reaction between two chemicals to neutralize their effects. For example, *dimercaprol* chelates various metals to decrease their toxicity (see

Chapter 65). *Dispositional antagonism* is the alteration of the disposition of a substance (its absorption, biotransformation, distribution, or excretion) so that less of the agent reaches the target organ or its persistence there is reduced (see below). *Antagonism* at the *receptor* for the chemical entails the blockade of the effect of an agonist with an appropriate antagonist that competes for the same site. For example, the antagonist *naloxone* is used to treat respiratory depression produced by opioids (see Chapter 21).

DESCRIPTIVE TOXICITY TESTS IN ANIMALS

Two main principles underlie all descriptive toxicity tests performed in animals. First, effects of chemicals produced in laboratory animals, when properly qualified, apply to human toxicity. When calculated on the basis of dose per unit of body surface, toxic effects in human beings usually are encountered in the same range of concentrations as those in experimental animals. On the basis of body weight, human beings generally are more vulnerable than experimental animals. Such information is used to select dosages for clinical trials of candidate therapeutic agents and to attempt to set limits on permissible exposure to environmental toxicants.

Second, exposure of experimental animals to toxic agents in high doses is a necessary and valid method to discover possible hazards to human beings who are exposed to much lower doses. This principle is based on the quantal dose–response concept. As a matter of practicality, the number of animals used in experiments on toxic materials usually will be small compared with the size of human populations potentially at risk. For example, 0.01% incidence of a serious toxic effect (such as cancer) represents 25,000 people in a population of 250 million. Such an incidence is unacceptably high. Yet, detecting an incidence of 0.01% experimentally probably would require a minimum of 30,000 animals. To estimate risk at low dosage, large doses must be given to relatively small groups. The validity of the necessary extrapolation is clearly a crucial question.

Chemicals are first tested for toxicity by estimation of the LD₅₀ in two animal species by two routes of administration; one of these is the expected route of exposure of human beings to the chemical being tested. The number of animals that die in a 14-day period after a single dose is recorded. The animals also are examined for signs of intoxication, lethargy, behavioral modification, and morbidity.

The chemical is next tested for toxicity by repeat exposure, usually for 90 days. This study is performed most often in two species by the route of intended use or exposure with at least three doses. A number of parameters are monitored during this period, and at the end of the study, organs and tissues are examined by a pathologist.

Long-term or chronic studies are carried out in animals at the same time that clinical trials are undertaken. For drugs, the length of

exposure depends somewhat on the intended clinical use. If the drug normally would be used for short periods under medical supervision, as would an antimicrobial agent, a chronic exposure of animals for 6 months might suffice. If the drug would be used in human beings for longer periods, a study of chronic use for 2 years may be required.

Studies of chronic exposure often are used to determine the carcinogenic potential of chemicals. These studies usually are performed in rats and mice for the average lifetime of the species. Other tests are designed to evaluate teratogenicity (congenital malformations), perinatal and postnatal toxicity, and effects on fertility. Teratogenicity studies usually are performed by administering drugs to pregnant rats and rabbits during the period of organogenesis.

In addition to chronic studies for evaluation of carcinogenic potential or teratogenicity, drugs often are tested for *mutagenic* potential. The most popular such test currently available, the reverse mutation test developed by Ames and colleagues (Ames *et al.*, 1975), uses a strain of *S. typhimurium* that has a mutant gene for the enzyme phosphoribosyl adenosine triphosphate (ATP) synthetase. This enzyme is required for histidine synthesis, and the bacterial strain is unable to grow in a histidine-deficient medium unless a reverse mutation is induced. Because many chemicals are not mutagenic or carcinogenic unless activated by enzymes on the endoplasmic reticulum, rat hepatic microsomes usually are added to the medium containing the mutant bacteria and the drug. The Ames test is rapid and sensitive. Its usefulness for the prediction of genotoxic carcinogens is widely accepted, but it does not detect nongenotoxic carcinogens (promoters).

INCIDENCE OF ACUTE POISONING

The true incidence of poisoning in the United States is not known, but in 2003, nearly 2.4 million cases were voluntarily reported to the American Association of Poison Control Centers. The number of actual poisonings almost certainly exceeds by far the number reported.

Deaths in the United States owing to poisoning number more than 1100 per year. The incidence of poisoning in children younger than 5 years of age has decreased dramatically over the past four decades. For example, there were no reported childhood deaths owing to aspirin in 2003, compared with about 140 deaths per year in the early 1960s. This favorable trend probably is due to safety packaging of drugs, drain cleaners, turpentine, and other household chemicals; improved medical training and care; and increased public awareness of potential poisons.

The substances involved most frequently in human poison exposures are shown in Table 64–1. Analgesic drugs lead the list, followed by two nondrug entries, cleaning agents and cosmetics. However, the top five categories of substances that produce deaths are drugs (Table 64–2). The categories most commonly associated with fatalities are analgesics (*e.g.*, acetaminophen and salicylates), sedative-hypnotics/antipsychotics, antidepressants, stimulants and street drugs (including *opiates* and *cocaine*), and cardiovascular drugs (including *digoxin* and Ca^{2+} channel blockers). The most

Table 64–1
Substances Most Frequently Involved in Human
Poison Exposures in the United States

SUBSTANCE	NUMBER	%*
Analgesics	256,843	10.8
Cleaning substances	225,578	9.5
Cosmetics and personal care products	219,877	9.2
Foreign bodies	110,000	5.0
Sedatives/hypnotics/antipsychotics	111,001	4.7
Topicals	105,815	4.4
Cough and cold preparations	100,612	4.2
Antidepressants	99,800	4.2
Bites/envenomations	98,585	4.1
Pesticides	96,112	4.0
Plants	84,578	3.6
Food products, food poisoning	75,813	3.2
Alcohols	69,215	2.9
Antihistamines	69,107	2.9
Antimicrobials	63,372	2.7
Cardiovascular drugs	61,056	2.6
Hydrocarbons	59,132	2.5
Chemicals	54,623	2.3

NOTE: Despite a high frequency of involvement, these substances are not necessarily the most toxic, but rather may only be the most readily accessible. *Percentages are based on total number of known ingested substances in the United States rather than the total number of human exposure cases. SOURCE: From Watson *et al.*, 2004. Courtesy of the *American Journal of Emergency Medicine*.

common categories of nonpharmaceutical poisons were alcohols (particularly methanol) and fumes (principally carbon monoxide). Most of the people who die from poisoning are adults, and the deaths often result from intentional rather than accidental exposure. Children younger than 6 years of age account for 52% of the poisoning incidents reported but only 3% of the deaths. Children between 1 and 2 years of age have the highest incidence of accidental poisoning. Fortunately, most of the substances available to these young children are not highly toxic. Iron and pesticides are the leading cause of pediatric accidental poisoning fatalities.

The incidence of serious and fatal adverse drug reactions in U.S. hospitals is extremely high (Lazarou *et al.*, 1998; Institute of Medicine, 1999). It is estimated that about 2 million hospitalized patients have serious adverse drug reactions each year, and about 100,000 have fatal adverse drug reactions. If this estimate is correct, then more people die annually from medication errors than from highway

Table 64–2
Categories with Largest Numbers of Deaths*

CATEGORY	NUMBER	% OF ALL EXPOSURES
Analgesics	659	0.257
Sedative/hypnotics/ antipsychotics	364	0.328
Antidepressants	318	0.316
Stimulants and street drugs	242	0.528
Cardiovascular drugs	181	0.295

accidents, breast cancer, or the acquired immune deficiency syndrome (AIDS).

MAJOR SOURCES OF INFORMATION ON POISONING

Pharmacology textbooks are a good source of information on the treatment of poisoning by drugs, but they usually say little about other chemicals. Additional information on drugs and other chemicals can be found in books on poisoning (Ellenhorn, 1997; Goldfrank *et al.*, 2002; Haddad *et al.*, 1998; Klaassen, 2001). A popular computerized system for information on toxic substances is POISIN-DEX (Micromedex, Inc., Denver, CO).

The Web site of the American Association of Poison Control Centers (<http://www.aapcc.org/>) lists 78 members, including 11 regional centers. Valuable information can be obtained from these centers by telephone (800-222-1222). The National Library of Medicine maintains a

very informative Web site on toxicology and environmental health (<http://sis.nlm.nih.gov/Tox/ToxMain.html>), including a link to ToxNet (<http://toxnet.nlm.nih.gov/>), a cluster of databases on toxicology, hazardous chemicals, and related areas.

PREVENTION AND TREATMENT OF POISONING

Many acute poisonings from drugs could be prevented if physicians provided common-sense instructions about the storage of drugs and other chemicals and if patients or parents of patients accepted this advice. These instructions are so widely publicized that they need not be repeated here.

For clinical purposes, all toxic agents can be divided into two classes: those for which a specific treatment or antidote exists and those for which there is no specific treatment. For the vast majority of drugs and other chemicals, there is no specific treatment; symptomatic medical care that supports vital functions is the only strategy.

As in other medical emergencies, supportive therapy is the mainstay of the treatment of drug poisoning. The adage, “Treat the patient, not the poison,” remains the most basic and important principle of clinical toxicology. Maintenance of respiration and circulation takes precedence. Serial measurement and charting of vital signs and important reflexes help to judge the progress of intoxication, response to therapy, and need for additional treatment. This monitoring usually requires hospitalization. The classification in Table 64–3 often is used to indicate the severity of CNS intoxication. Treatment with large doses of stimulants and sedatives often causes more harm than the poison. Chemical antidotes should be used judiciously; heroic measures seldom are necessary.

Treatment of acute poisoning must be prompt. The first goal is to maintain the vital functions if their impairment is imminent. The second goal is to keep the concentration of poison in the crucial tissues as low as possible by preventing absorption and enhancing elimination. The third goal is to combat the pharmacological and toxicological effects at the effector sites.

Prevention of Further Absorption of Poison

Emesis. Historically, emesis was one of the major tools of gastric decontamination in the management of acute poi-

Table 64-3
Signs and Symptoms of CNS Intoxication

DEGREE OF SEVERITY	CHARACTERISTICS
<i>Depressants</i>	
0	Asleep, but can be aroused and can answer questions
I	Semicomatose, withdraws from painful stimuli, reflexes intact
II	Comatose, does not withdraw from painful stimuli, no respiratory or circulatory depression, most reflexes intact
III	Comatose, most or all reflexes absent, but without depression of respiration or of circulation
IV	Comatose, reflexes absent, respiratory depression with cyanosis or circulatory failure and shock, or both
<i>Stimulants</i>	
I	Restlessness, irritability, insomnia, tremor, hyperreflexia, sweating, mydriasis, flushing
II	Confusion, hyperactivity, hypertension, tachypnea, tachycardia, extrasystoles, sweating, mydriasis, flushing, mild hyperpyrexia
III	Delirium, mania, self-injury, marked hypertension, tachycardia, arrhythmias, hyperpyrexia
IV	As in III, plus convulsions, coma, and circulatory collapse

soning. However, its routine use in the emergency room is declining. According to the annual report of the Toxic Exposure Surveillance System (TESS) (Watson *et al.*, 2004), emesis accounted for only 0.7% of the therapy provided in human exposure cases in 2003 compared with 7.5% in 1993 (Litovitz *et al.*, 1994) and 13.8% in 1983 (Veltri *et al.*, 1984). Although emesis still may be indicated for immediate intervention after poisoning by oral ingestion of chemicals, it is contraindicated in certain situations: (1) If the patient has ingested a corrosive poison, such as a strong acid or alkali (*e.g.*, drain cleaners), emesis increases the likelihood of gastric perforation and further necrosis of the esophagus; (2) if the patient is comatose or in a state of stupor or delirium, emesis may cause aspiration of the gastric contents; (3) if the patient has ingested a CNS stimulant,

further stimulation associated with vomiting may precipitate convulsions; and (4) if the patient has ingested a petroleum distillate (*e.g.*, kerosene, gasoline, or petroleum-based liquid furniture polish), regurgitated hydrocarbons can be aspirated readily and cause chemical pneumonitis (Ervin, 1983). In contrast, emesis should be considered if the ingested solution contains potentially dangerous compounds, such as pesticides.

There are marked differences in the capabilities of various petroleum distillates to produce hydrocarbon pneumonia, which is an acute hemorrhagic necrotizing process. In general, the ability of various hydrocarbons to produce pneumonitis is inversely proportional to their viscosity: If the viscosity is high, as with oils and greases, the risk is limited; if the viscosity is low, as with mineral seal oil found in liquid furniture polishes, the risk of aspiration is high.

Vomiting can be induced mechanically by stroking the posterior pharynx. However, this technique is not as effective as the administration of *ipecac* or *apomorphine*.

Ipecac. The most common household emetic is syrup of *ipecac* (not *ipecac* fluid extract, which is 14 times more potent and may cause fatalities). Syrup of *ipecac* is available in 0.5- and 1-fluid ounce containers (approximately 15 and 30 ml), which may be purchased without prescription. The drug can be given orally, but it takes 15 to 30 minutes to produce emesis; this compares favorably with the time usually required for adequate gastric lavage. The oral dose is 15 ml in children from 6 months to 12 years of age and 30 ml in older children and adults. Because emesis may not occur when the stomach is empty, administration of *ipecac* should be followed by a drink of water.

In 2004, the American Academy of Clinical Toxicology and the European Association of Poisons Control Centers and Clinical Toxicologists issued position papers on the use of *ipecac* syrup in poisonings (Anonymous, 2004). *After careful review of the medical literature, these groups concluded that syrup of ipecac should not be administered routinely in the management of poisoned patients.* In studies with various marker substances, the beneficial effects of *ipecac*-induced emesis were highly variable and diminished rapidly with time. Another concern was that initial use of *ipecac* in fact may be counterproductive by reducing the efficacy of other, later, and presumably more effective treatments such as use of activated charcoal, oral antidotes, and whole-bowel irrigation. *Ipecac* may be indicated when it can be administered to conscious, alert patients within 60 minutes of poisoning.

Ipecac acts as an emetic because of its local irritant effect on the enteric tract and its effect on the chemoreceptor trigger zone (CTZ) in the area postrema of the medulla. Syrup of *ipecac* may be effective even when antiemetic drugs (such as *phenothiazines*) have been

ingested. Ipecac can produce toxic effects on the heart because of its content of emetine, but this usually is not a problem with the dose used for emesis. If emesis does not occur, ipecac should be removed by gastric lavage. Chronic abuse of ipecac for weight reduction can result in cardiomyopathy, ventricular fibrillation, and death.

Apomorphine. Apomorphine stimulates the CTZ and causes emesis. The drug is unstable in solution and must be prepared just prior to use and thus is not often readily available. Apomorphine is not effective orally and must be given parenterally, usually by the subcutaneous route, 6 mg for adults and 0.06 mg/kg for children (Goldfrank *et al.*, 2002). However, this can be an advantage over ipecac in that it can be administered to an uncooperative patient and produces vomiting in 3 to 5 minutes. Because apomorphine is a respiratory depressant, it should not be used if the patient has been poisoned by a CNS depressant or if the patient's respiration is slow and labored. At present, apomorphine is used rarely as an emetic.

Gastric Lavage. Gastric lavage is accomplished by inserting a tube into the stomach and washing the stomach with water, normal saline, or one-half normal saline to remove the unabsorbed poison. The procedure should be performed as soon as possible, but only if vital functions are adequate or supportive procedures have been implemented. The contraindications to this procedure generally are the same as for emesis, and there is the additional potential complication of mechanical injury to the throat, esophagus, and stomach. A position statement on the use of gastric lavage by American and European clinical toxicologists (Anonymous, 1997) concluded that *gastric lavage should not be used routinely in the management of the poisoned patient but should be reserved for patients who have ingested a potentially life-threatening amount of poison and when the procedure can be undertaken within 60 minutes of ingestion.*

The only equipment needed for gastric lavage is a tube and a large syringe. The tube should be as large as possible so that the wash solution, food, and poison (whether in the form of a capsule, pill, or liquid) will flow freely, and lavage can be accomplished quickly. A 36-French tube or larger should be used in adults and a 24-French tube or larger in children. Orogastric lavage is preferred over nasogastric lavage because a larger tube can be employed. To prevent aspiration, an endotracheal tube with an inflatable cuff should be positioned before lavage is initiated if the patient is comatose, having seizures, or has lost the gag reflex. During gastric lavage, the patient should be placed on his or her left side because of the anatomical asymmetry of the stomach, with the head hanging face down over the edge of the examining table. If possible, the foot of the table should be elevated. This technique minimizes chances of aspiration.

The contents of the stomach should be aspirated with an irrigating syringe and saved for chemical analysis. The stomach then may be washed with saline solution. Saline solution is safer than water in young children because of the risk of water intoxication, manifested by tonic-clonic seizures and coma. Only small volumes (120 to 300 ml) of lavage solution should be instilled into the stomach at one time so that the poison is not pushed into the intestine. Lavage is

repeated until the returns are clear, which usually requires 10 to 12 washings and a total of 1.5 to 4 L of lavage fluid. When the lavage is complete, the stomach may be left empty, or an antidote may be instilled through the tube. If no specific antidote for the poison is known, an aqueous suspension of activated charcoal and a cathartic often is given.

Chemical Adsorption. Activated charcoal avidly adsorbs drugs and chemicals on the surfaces of the charcoal particles, thereby preventing absorption and toxicity. Many, but not all, chemicals are adsorbed by charcoal. For example, alcohols, hydrocarbons, metals, and corrosives are not well adsorbed by activated charcoal, and charcoal therefore is of little value in treating these poisonings. The effectiveness of charcoal also depends on the time since the ingestion and on the dose of charcoal; one should attempt to achieve a charcoal–drug ratio of at least 10:1. Activated charcoal also can interrupt the enterohepatic circulation of drugs and enhance the net rate of diffusion of the chemical from the body into the gastrointestinal tract. For example, serial doses of activated charcoal have been shown to enhance the elimination of *theophylline* and phenobarbital.

During the last two decades, there has been an increase in the use of activated charcoal and a corresponding decrease in the use of ipecac-induced emesis and gastric lavage in the treatment of poisoning. Studies in patients with drug overdoses and in normal subjects fail to show a benefit of treatment with ipecac or lavage plus activated charcoal as compared with charcoal alone. Based on these findings, American and European clinical toxicologists issued a position paper in 1999 on the use of multidose activated charcoal in treatment of acute poisoning (Anonymous, 1999). They concluded that while experimental and clinical trials demonstrate that elimination of some drugs can be enhanced by treatment with activated charcoal in volunteer studies, rarely has it been demonstrated to reduce morbidity or mortality in a controlled study. The position paper recommends consideration of activated charcoal treatment only if a patient has ingested a life-threatening amount of *carbamazepine*, *dapsone*, phenobarbital, *quinine*, or theophylline. Even then, there are certain contraindications, such as an unprotected airway, the presence of intestinal obstruction, or if the gastrointestinal tract is not intact or there is decreased peristalsis. There is a need for ongoing study of the efficacy of this treatment for other drugs and to establish optimal dosage regimens.

Activated charcoal usually is prepared as a mixture of at least 50 g (about 10 heaping tablespoons) in a glass of water. The mixture is then administered either orally or *via* a gastric tube. Because most poisons do not appear to desorb from the charcoal if charcoal is

present in excess, the adsorbed poison need not be removed from the gastrointestinal tract. Activated charcoal should not be used simultaneously with ipecac because charcoal can adsorb the emetic agent in ipecac and thus reduce the drug's emetic effect. Charcoal also may adsorb and decrease the effectiveness of specific antidotes.

Activated charcoal must be distinguished from the so-called universal antidote, which consists of two parts burned toast (not activated charcoal), one part tannic acid (strong tea), and one part magnesium oxide. In practice, the universal antidote is ineffective.

As mentioned earlier, the presence of an adsorbent in the intestine may interrupt enterohepatic circulation of a toxicant, thus enhancing its excretion. Activated charcoal is useful in interrupting the enterohepatic circulation of drugs such as tricyclic antidepressants and *glutethimide*. A nonabsorbable *polythiol resin* has been used to treat poisoning by methylmercury owing to its capacity to bind mercury excreted into the bile (see Chapter 65). *Cholestyramine* hastens the elimination of cardiac glycosides by a similar mechanism.

Chemical Inactivation. Antidotes can change the chemical nature of a poison by rendering it less toxic or preventing its absorption. Formaldehyde poisoning can be treated with ammonia to form hexamethylenetetramine; sodium formaldehyde sulfoxylate can convert mercuric ion to the less soluble metallic mercury; and sodium bicarbonate converts ferrous iron to ferrous carbonate, which is poorly absorbed. Chemical inactivation techniques seldom are used today, however, because valuable time may be lost, whereas emetics, activated charcoal, and gastric lavage are rapid and effective.

In the past, neutralization was the usual treatment of poisoning with acids or bases. Vinegar, orange juice, or lemon juice has been used often for the patient who has ingested alkali, and various antacids often have been advocated for treatment of acid burns. The use of neutralizing agents is controversial because they may produce excessive heat. Carbon dioxide gas produced from bicarbonates used to treat oral poisoning with acids can cause gastric distension and even perforation. The treatment of choice for ingestion of either acids or alkalis is dilution with water or milk. Similarly, burns produced by acid or alkali on the skin should be treated with copious amounts of water.

Purgation. The rationale for using an osmotic cathartic is to minimize absorption by hastening the passage of the toxicant through the gastrointestinal tract. Few, if any, controlled clinical data are available on the effectiveness of cathartics in the treatment of poisoning. Cathartics generally are considered harmless unless the poison has injured the gastrointestinal tract. Cathartics are indicated after the ingestion of enteric-coated tablets, when the time after ingestion is greater than 1 hour, and for poisoning by volatile hydrocarbons. *Sorbitol* is the most effective, but *sodium sulfate* and *magnesium sulfate* also are used; all act promptly and usually have minimal toxicity. However, magnesium sulfate should be used cautiously in patients with renal failure or in those likely to develop renal dysfunction, and Na⁺-containing cathartics should be avoided in patients with congestive heart failure.

Whole-bowel irrigation (WBI) is a technique that not only promotes defecation but also eliminates the entire contents of the intestines. This technique uses a high-molecular-weight *polyethylene glycol* and *isosmolar electrolyte* solution (PEG-E S) that does not alter serum electrolytes. It is available commercially as GOLYTELY and COLYTE. A position statement on WBI, issued by the American Academy of Clinical Toxicology and the European Association of

Poisons Centres and Clinical Toxicologists, indicates that *WBI should not be used routinely in the management of the poisoned patient*. Even though volunteer studies have shown substantial decreases in the bioavailability of certain ingested drugs, evidence from controlled clinical trials is lacking. WBI may be considered in cases of acute poisoning by sustained-release or enteric-coated drugs and possibly toxic ingestions of iron, lead, zinc, or packets of illicit drugs.

Inhalation and Dermal Exposure to Poisons. When a poison has been inhaled, the first priority is to remove the patient from the source of exposure. Similarly, if the skin has had contact with a poison, it should be washed thoroughly with water. Contaminated clothing should be removed. Initial treatment of all types of chemical injuries to the eye must be rapid; thorough irrigation of the eye with water for 15 minutes should be performed immediately.

Enhanced Elimination of the Poison

Biotransformation. Once a chemical has been absorbed, procedures sometimes can be employed to enhance its rate of elimination. Many drugs are metabolized by hepatic CYPs, and components of this system can be induced by a number of compounds (see Chapter 3). However, induction of these oxidative enzymes is too slow (days) to be valuable in the treatment of acute poisoning by most chemical agents.

Many chemicals are toxic because they are biotransformed into more toxic chemicals. Thus inhibition of biotransformation should decrease the toxicity of such drugs. For example, ethanol is used to inhibit the conversion of methanol to its highly toxic metabolite, formic acid, by alcohol dehydrogenase (see Chapter 22). Acetaminophen is converted by the CYP system to an electrophilic metabolite that is detoxified by glutathione, a cellular nucleophile (Figure 64-3). Acetaminophen does not cause hepatotoxicity until glutathione is depleted, whereupon the reactive metabolite binds to essential macromolecular constituents of the hepatocyte, resulting in cell death. The liver can be protected by maintenance of the concentration of glutathione, and this can be accomplished by the administration of *N*-acetylcysteine (see Chapter 26).

Some drugs are detoxified by conjugation with glucuronic acid or sulfate before elimination from the body, and the availability of the endogenous cosubstrates for conjugation may limit the rate of elimination; such is the case in the detoxication of acetaminophen. Methods to replete these compounds will provide an additional mechanism to treat poisoning. Similarly, detoxication of cyanide by conversion to thiocyanate can be accelerated by the administration of *thiosulfate*.

Biliary Excretion. The liver excretes many drugs and other foreign chemicals into bile, but little is known about efficient ways to enhance biliary excretion of xenobiotics for the treatment of acute poisoning. Inducers of microsomal enzyme activity enhance biliary excretion of some xenobiotics, but the effect is slow in onset.

Urinary Excretion. Drugs and poisons are excreted into the urine by glomerular filtration and active tubular secretion (see

Chapter 28); they can be reabsorbed into the blood if they are in a lipid-soluble form that will penetrate the tubule or if there is an active mechanism for their transport.

There are no methods known to accelerate the active transport of poisons into urine, and enhancement of glomerular filtration is not a practical means to facilitate elimination of toxicants. However, passive reabsorption from the tubular lumen can be altered. Diuretics inhibit reabsorption by decreasing the concentration gradient of the drug from the lumen to the tubular cell and by increasing flow through the tubule. *Furosemide* is used most often, but osmotic diuretics also are employed (see Chapter 28). Forced diuresis should be used with caution, especially in patients with renal, cardiac, or pulmonary complications.

Nonionized compounds are reabsorbed far more rapidly than ionized polar molecules; therefore, a shift from the nonionized to the ionized species of the toxicant by alteration of the pH of the tubular fluid may hasten elimination (see Chapter 1). Acidic compounds such as phenobarbital and salicylates are cleared much more rapidly in alkaline than in acidic urine. In 2004, American and European clinical toxicologists issued a position paper on the use of urine alkalinization in treatment of acute poisoning (Proudfoot *et al.*, 2004). Urine alkalinization increases the urine elimination of *chlorpropamide*, *2,4-dichlorophenoxyacetic acid*, *diflunisal*, *fluoride*, *mecoprop*, *methotrexate*, phenobarbital, and salicylate. However, urine alkalinization is recommended as first-line treatment only for patients with moderately severe salicylate poisoning who do not meet the criteria for hemodialysis. Urine alkalinization and high urine flow (approximately 600 ml/h) should also be considered in patients with severe 2,4-dichlorophenoxyacetic acid and mecoprop poisoning. Even though it has been shown to be effective in enhancing elimination of phenobarbital (Figure 64–7), urine alkalinization is not recommended as first-line treatment in cases of phenobarbital poisoning because multiple-dose activated charcoal has been shown to be superior. Urine alkalinization is contraindicated in the case of compromised renal function or failure. Hypokalemia is the most common complication but can be corrected by giving potassium supplements.

Intravenous sodium bicarbonate is used to alkalinize the urine. Renal excretion of basic drugs such as *amphetamine* theoretically can be enhanced by acidification of the urine. Acidification can be accomplished by the administration of ammonium chloride or ascorbic acid. Urinary excretion of an acidic compound is particularly sensitive to changes in urinary pH if its pK_a is within the range of 3.0 to 7.5; for bases, the corresponding range is 7.5 to 10.5.

Dialysis. Hemodialysis or hemoperfusion usually has limited use in the treatment of intoxication with chemicals. However, under cer-

Figure 64–7. Renal clearance of phenobarbital in the dog as related to urinary pH and the rate of urine flow. The values designated by circles are from experiments in which diuresis was induced by administration of water orally or Na_2SO_4 intravenously and the urinary pH was below 7.0. The values designated by triangles are from experiments in which NaHCO_3 was administered intravenously and in which the urinary pH was 7.8 to 8.0. (After Waddell and Butler, 1957. Courtesy of *Journal of Clinical Investigation*.)

tain circumstances, such procedures can be lifesaving. The utility of dialysis depends on the amount of poison in the blood relative to the total-body burden. Thus, if a poison has a large volume of distribution, as is the case for the tricyclic antidepressants, the plasma will contain too little of the compound for effective removal by dialysis. Extensive binding of the compound to plasma proteins impairs dialysis greatly. The elimination of a toxicant by dialysis also depends on dissociation of the compound from binding sites in tissues; for some chemicals, this rate may be slow and limiting.

Although peritoneal dialysis requires a minimum of personnel and can be started as soon as the patient is admitted to the hospital, it is too inefficient to be of value for the treatment of acute intoxications. Hemodialysis (extracorporeal dialysis) is much more effective than peritoneal dialysis and may be essential in a few life-threatening intoxications, such as with methanol, ethylene glycol, and salicylates.

Passage of blood through a column of charcoal or adsorbent resin (hemoperfusion) is a technique for the extracorporeal removal of a poison (Winchester, 1983). Because of the high adsorptive capacity and affinity of the material in the column, some chemicals that are bound to plasma proteins can be removed. The principal side effect of hemoperfusion is depletion of platelets.

Antagonism or Chemical Inactivation of an Absorbed Poison.

The functional and pharmacological antagonism of the effects of absorbed toxicants was discussed earlier. If a patient is poisoned with a compound that acts as an agonist at a receptor for which a specific blocking agent is available, administration of the receptor antagonist may be highly effective. Functional antagonism also can

be valuable for support of the patient's vital functions. For example, anticonvulsant drugs are used to treat chemically induced convulsions. However, drugs that stimulate antagonistic physiological mechanisms are not always of clinical value and may even decrease survival because it often is difficult to titrate the effect of one drug against another when the two act on opposing systems. An example of such a complication is the use of CNS stimulants to attempt to reverse respiratory depression. Convulsions are a typical complication of such therapy, and mechanical support of respiration is preferred. In addition, the duration of action of the poison and the antidote may differ, sometimes leading to poisoning with the antidote.

Specific chemical antagonists of a toxicant, such as opioid antagonists (see Chapter 21) and *atropine* as an antagonist of pesticide-induced acetylcholine excess (see Chapter 7), are valuable but unfortunately rare. A recently approved antagonist is *fomepizole*, an inhibitor of alcohol dehydrogenase, approved for treatment for poisoning by ethylene glycol and methanol (Barceloux *et al.*, 1999; Mycyk and Leikin, 2003). Chelating agents with high selectivity for certain metal ions are used more commonly (see Chapter 65). Antibodies offer the potential for the production of specific antidotes for a host of common poisons and for drugs that frequently are abused or misused. A notable example of such success is the use of purified digoxin-specific Fab fragments of antibodies in the treatment of potentially fatal cases of poisoning with digoxin (see Chapter 33). The development of human monoclonal antibodies directed against specific toxins has significant potential therapeutic value.

HEAVY METALS AND HEAVY-METAL ANTAGONISTS

Curtis D. Klaassen

People continue to be exposed to heavy metals in the environment. Metals contaminate water and food in some areas. Metals also leach from eating utensils and cookware. The emergence of the industrial age and large-scale mining brought occupational diseases caused by various toxic metals. Metallic constituents of pesticides and even therapeutic agents (*e.g.*, antimicrobials) have been additional sources of hazardous exposure. The burning of fossil fuels containing heavy metals, the addition of tetraethyl lead to gasoline, and the increase in industrial applications of metals have made environmental pollution the major source of heavy-metal poisoning. The first part of this chapter covers the toxic properties of lead, mercury, arsenic, and cadmium, as well as radioactive heavy metals, and treatment of the consequences of toxic exposure to these metals. The second part of the chapter covers the chemical properties and therapeutic uses of several heavy-metal antagonists.

Heavy metals exert their toxic effects by combining with one or more reactive groups (ligands) essential for normal physiological functions. Heavy-metal antagonists (chelating agents) are designed specifically to compete with these groups for the metals and thereby prevent or reverse toxic effects and enhance the excretion of metals. Heavy metals, particularly those in the transition series, may react in the body with ligands containing oxygen (—OH , —COO^- , $\text{—OPO}_3\text{H}^-$, >C=O), sulfur (—SH , —S—S—), and nitrogen (—NH_2 and >NH). The resulting metal complex (or coordination compound) is formed by a coordinate bond in which both electrons are contributed by the ligand.

THE IDEAL CHELATOR

The heavy-metal antagonists discussed in this chapter share the capacity to form complexes with heavy metals and thereby prevent or reverse the binding of metallic cations to body ligands. These drugs are referred to as *chelating agents*. A *chelate* is a complex formed between a metal and a compound that contains two or more potential ligands. The product of such a reaction is a heterocyclic ring. Five- and six-membered chelate rings are the most stable, and a polydentate (multiligand) chelator typically is designed to form such a highly stable complex, far more stable than when a metal is combined with only one ligand atom.

The stability of chelates varies with the metal and the ligand atoms. For example, lead and mercury have greater affinities for sulfur and nitrogen than for oxygen ligands; calcium, however, has a greater affinity for oxygen than for sulfur and nitrogen. These differences in affinity serve as the basis of selectivity of action of a chelating agent in the body.

The effectiveness of a chelating agent for the treatment of poisoning by a heavy metal depends on several factors, including the relative affinity of the chelator for the heavy metal as compared with essential body metals, the distribution of the chelator in the body as compared with the distribution of the metal, and the capacity of the chelator to mobilize the metal from the body once chelated.

An ideal chelating agent would have the following properties: high solubility in water, resistance to biotransformation, ability to reach sites of metal storage, capacity

to form nontoxic complexes with toxic metals, ability to retain chelating activity at the pH of body fluids, and ready excretion of the chelate. A low affinity for Ca^{2+} also is desirable because Ca^{2+} in plasma is readily available for chelation, and a drug might produce hypocalcemia despite high affinity for heavy metals. The most important property of a therapeutic chelating agent is greater affinity for the metal than that of the endogenous ligands. The large number of ligands in the body is a formidable barrier to the effectiveness of a chelating agent. Observations *in vitro* on chelator–metal interactions provide only a rough guide to the treatment of heavy-metal poisoning. Empirical observations *in vivo* are necessary to determine the clinical utility of a chelating agent.

Lead

Through natural occurrence and its industrial use, lead is ubiquitous in the environment. The decreased addition of tetraethyl lead to gasoline over the past two decades has resulted in decreased concentrations of lead in blood in humans. The primary sources of environmental exposure to lead are leaded paint and drinking water; most of the overt toxicity from lead results from environmental and industrial exposures.

Acidic foods and beverages—including tomato juice, fruit juice, carbonated beverages, cider, and pickles—can dissolve the lead when packaged or stored in improperly glazed containers. Foods and beverages thus contaminated have caused fatal human lead poisoning. Lead poisoning in children is a common result of their ingestion of paint chips from old buildings. Paints applied to dwellings before World War II, when lead carbonate (white) and lead oxide (red) were common constituents of interior and exterior house paints, are primarily responsible. In such paint, lead may constitute 5% to 40% of dried solids. Young children are poisoned most often by nibbling sweet-tasting paint chips and dust from lead-painted windowsills and door frames. The American Standards Association specified in 1955 that paints for toys, furniture, and the interior of dwellings should not contain more than 1% lead in the final dried solids of fresh paint, and in 1978, the Consumer Product Safety Commission (CPSC) banned paint containing more than 0.06% lead for use in and around households. Renovation or demolition of older homes, using a physical process that would cause an airborne dispersion of lead dust or fumes, may cause substantial contamination and lead poisoning. Lead poisoning from the use of discarded automobile-battery casings made of wood and vulcanite and used as fuel during times of economic distress, such as during World Wars I and II, has been reported. Sporadic cases of lead poisoning have been traced to miscellaneous sources such as lead toys, retained bullets, drinking water that is conveyed through lead pipes, artists' paint pigments, ashes and fumes of painted wood, jewelers' wastes, home battery manufacture, and lead type. Finally, lead also is a common contaminant of illicitly distilled whiskey ("moonshine") because automobile radiators frequently are used as condensers and other components of the still are connected by lead solder.

Occupational exposure to lead has decreased markedly because of appropriate regulations and programs of medical surveillance. Workers in lead smelters have the highest potential for exposure because fumes are generated, and dust containing lead oxide is deposited in their environment. Workers in storage-battery factories face similar risks.

Dietary intake of lead also has decreased since the 1940s, when the estimate of intake was about 500 $\mu\text{g}/\text{day}$ in the U.S. population, to less than 20 $\mu\text{g}/\text{day}$ in 2000. This decrease has been due largely to (1) a decrease in the use of lead-soldered cans for food and beverages; (2) a decrease in the use of lead pipes and lead-soldered joints in water distribution systems; (3) the introduction of lead-free gasoline; and (4) public awareness of the hazards of indoor leaded paint (NRC, 1993). A decline in blood levels from 13 $\mu\text{g}/\text{dl}$ in the 1980s to less than 5 $\mu\text{g}/\text{dl}$ has been observed in the general U.S. population (Pirkle *et al.*, 1998). However, many children living in central portions of large cities still have blood lead concentrations over 10 $\mu\text{g}/\text{dl}$.

Absorption, Distribution, and Excretion. The major routes of absorption of lead are from the gastrointestinal (GI) tract and the respiratory system. GI absorption of lead varies with age; adults absorb approximately 10% of ingested lead, whereas children absorb up to 40%. Little is known about lead transport across the GI mucosa; lead and Ca^{2+} may compete for a common transport mechanism because there is a reciprocal relationship between the dietary content of Ca^{2+} and lead absorption. Iron deficiency also enhances intestinal absorption of lead apparently because in the absence of iron, the divalent metal transporter (DMT) can readily transport lead in place of iron. Absorption of inhaled lead varies with the form (vapor *versus* particle) as well as with concentration. Approximately 90% of inhaled lead particles from ambient air are absorbed (Goyer and Clarkson, 2001).

After absorption, about 99% of lead in the bloodstream binds to hemoglobin in erythrocytes. Only 1% to 3% of the circulating blood lead is in the serum available to the tissues. Inorganic lead initially distributes in the soft tissues, particularly the tubular epithelium of the kidney and in the liver. In time, lead is redistributed and deposited in bone, teeth, and hair. About 95% of the body burden of lead eventually is found in bone. Only small quantities of inorganic lead accumulate in the brain, mostly in gray matter and the basal ganglia.

The deposition of Pb^{2+} in bone closely resembles that of Ca^{2+} , but Pb^{2+} is deposited as tertiary lead phosphate, which does not contribute to toxicity. After a recent exposure, the concentration of lead often is higher in the flat bones than in the long bones, although, as a general rule, the long bones contain more lead. In the early period of deposition, the concentration of lead is highest in the epiphyseal portion of the long bones. This is especially true in growing bones, where deposits may be detected by radiography as rings of increased density in the ossification centers of the epiphyseal cartilage and as a series of transverse lines in the diaphyses, so-called lead lines. Such findings are of diagnostic significance in children.

Factors that affect the distribution of calcium similarly affect that of lead. Thus a high intake of phosphate favors skeletal storage of lead and a lower concentration in soft tissues. Conversely, a low phosphate intake mobilizes lead in bone and elevates its content in soft tissues. High intake of calcium in the absence of elevated intake of phosphate has a similar effect owing to competition with lead for available phosphate. Vitamin D tends to promote lead deposition in bone if sufficient phosphate is available; otherwise, Ca^{2+} deposition preempts that of Pb^{2+} . Parathyroid hormone mobilizes lead from the

skeleton and augments the concentration of lead in blood and the rate of its excretion in urine.

In experimental animals, lead is excreted in bile, and much more lead is excreted in feces than in urine, whereas urinary excretion is a more important route of excretion in humans (Kehoe, 1987). The concentration of lead in urine is directly proportional to that in plasma, but because most lead in blood is in the erythrocytes, only a small quantity of lead is filtered. Lead also is excreted in milk and sweat and is deposited in hair and nails. Placental transfer of lead also occurs.

The half-life of lead in blood is 1 to 2 months, and a steady state thus is achieved in about 6 months. After establishment of a steady state early in human life, the daily intake of lead normally approximates the output, and concentrations of lead in soft tissues are relatively constant. However, the concentration of lead in bone apparently increases, and its half-life in bone is estimated to be 20 to 30 years. Because the capacity for lead excretion is limited, even a slight increase in daily intake may produce a positive lead balance. The average daily intake of lead is approximately 0.2 mg; positive lead balance begins at a daily intake of about 0.6 mg, an amount that ordinarily will not produce overt toxicity within a lifetime. However, the time to accumulate toxic amounts shortens disproportionately as the amount ingested increases. For example, a daily intake of 2.5 mg lead requires nearly 4 years for the accumulation of a toxic burden, whereas a daily intake of 3.5 mg requires but a few months because deposition in bone is too slow to protect the soft tissues during rapid accumulation.

Acute Lead Poisoning. Acute lead poisoning is relatively infrequent and follows ingestion of acid-soluble lead compounds or inhalation of lead vapors. Local actions in the mouth produce marked astringency, thirst, and a metallic taste. Nausea, abdominal pain, and vomiting ensue. The vomitus may be milky from the presence of lead chloride. Although the abdominal pain is severe, it is unlike that of chronic poisoning. Stools may be black from lead sulfide, and there may be diarrhea or constipation. If large amounts of lead are absorbed rapidly, a shock syndrome may develop as the result of massive GI loss of fluid. Acute central nervous system (CNS) symptoms include paresthesias, pain, and muscle weakness. An acute hemolytic crisis sometimes causes severe anemia and hemoglobinuria. The kidneys are damaged, and oliguria and urinary changes are evident. Death may occur in 1 or 2 days. If the patient survives the acute episode, characteristic signs and symptoms of chronic lead poisoning are likely to appear.

Chronic Lead Poisoning. The medical term for lead poisoning is *plumbism*, after the Latin word for lead, *plumbum*. The chemical symbol for lead, Pb, also is derived from this Latin root, as is the modern word *plumber*, which reflects the significant prior use of metallic lead in pipes, fixtures, and gutters. Signs and symptoms of plumbism can be divided into six categories: GI, neuromuscular, CNS, hematological, renal, and other. They may occur separately or in combination. The neuromuscular and CNS syndromes usually result from intense exposure, whereas the GI syndrome more commonly reflects a very slowly and insidiously developing intoxication. The CNS syndrome is more

common among children, whereas the GI syndrome is more prevalent in adults.

Gastrointestinal Effects. Lead affects the smooth muscle of the gut, producing intestinal symptoms that are an important early sign of exposure to the metal. The abdominal syndrome often begins with vague symptoms, such as anorexia, muscle discomfort, malaise, and headache. Constipation usually is an early sign, especially in adults, but diarrhea occurs occasionally. A persistent metallic taste appears early in the course of the syndrome. As intoxication advances, anorexia and constipation become more marked. Intestinal spasm, which causes severe abdominal pain (*lead colic*), is the most distressing feature of the advanced abdominal syndrome. The attacks are paroxysmal and generally excruciating. The abdominal muscles become rigid, and tenderness is especially manifested in the region of the umbilicus. In cases where colic is not severe, removal of the patient from the environment of exposure may be sufficient for relief of symptoms. *Calcium gluconate* administered intravenously is recommended for relief of pain and usually is more effective than *morphine*.

Neuromuscular Effects. The neuromuscular syndrome (*lead palsy*) occurs with repeated lead exposure, as characterized by the house painter and other workers with excessive occupational exposure to lead more than a half century ago; it now is rare in the United States. Muscle weakness and easy fatigue occur long before actual paralysis and may be the only symptoms. Weakness or palsy may not become evident until after extended muscle activity. The muscle groups involved usually are the most active ones (extensors of the forearm, wrist, and fingers and extraocular muscles). Wrist drop and, to a lesser extent, foot drop with the appropriate history of exposure are almost pathognomonic for lead poisoning. There usually is no sensory involvement. Degenerative changes in the motoneurons and their axons have been described.

CNS Effects. The CNS syndrome, or *lead encephalopathy*, is the most serious manifestation of lead poisoning and is much more common in children than in adults. The early signs of the syndrome include clumsiness, vertigo, ataxia, falling, headache, insomnia, restlessness, and irritability. As the encephalopathy develops, the patient may first become excited and confused; delirium with repetitive tonic-clonic convulsions or lethargy and coma follow. Vomiting, a common sign, usually is projectile. Visual disturbances also are present. Although the signs and symptoms are characteristic of increased intracranial pressure, craniotomy to relieve intracranial pressure is not beneficial. However, treatment for cerebral edema may become necessary. There may be a proliferative meningitis, intense edema, punctate hemorrhages, gliosis, and areas of focal necrosis. Demyelination has been observed in nonhuman primates. The mortality rate among patients who develop cerebral involvement is about 25%. When chelation therapy is begun after the symptoms of acute encephalopathy appear, approximately 40% of survivors have neurological sequelae such as mental retardation, electroencephalographic abnormalities or frank seizures, cerebral palsy, optic atrophy, or dystonia musculorum deformans (Chisolm and Barltrop, 1979).

Exposure to lead occasionally produces clear-cut progressive mental deterioration in children. The history of these children indicates normal development during the first 12 to 18 months of life or longer, followed by a steady loss of motor skills and speech. They may have severe hyperkinetic and aggressive behavior disorders and a poorly controllable convulsive disorder. The lack of

sensory perception severely impairs learning. Concentrations of lead in whole blood exceed 60 $\mu\text{g}/\text{dl}$ (2.9 μM), and X-rays may show multiple heavy bands of increased density in the growing long bones. It once was thought that such exposure to lead was restricted largely to children in inner-city slums. However, all children are exposed chronically to low levels of lead in their diets, in the air they breathe, and in the dirt and dust in their play areas. This is reflected in elevated concentrations of lead in the blood of many children and may be a cause of subtle CNS toxicity, including learning disabilities, lowered IQ, and behavioral abnormalities. An increased incidence of hyperkinetic behavior and a statistically significant, although modest, decrease in IQ have been shown in children with higher blood lead concentrations (Needleman *et al.*, 1990; Baghurst *et al.*, 1992; Banks *et al.*, 1997; Bellinger *et al.*, 1992). Increased blood lead levels in infancy and early childhood later may be manifested as decreased attention span, reading disabilities, and failure to graduate from high school. Most studies report a 2- to 4-point IQ deficit for each microgram per deciliter increase in blood lead within the range of 5 to 35 $\mu\text{g}/\text{dl}$. As a result, the Centers for Disease Control and Prevention (CDC) considers a blood lead concentration of 10 $\mu\text{g}/\text{dl}$ or greater to indicate excessive absorption of lead in children and to constitute grounds for environmental assessment, cleanup, and/or intervention. Chelation therapy should be considered when blood lead concentrations exceed 25 $\mu\text{g}/\text{dl}$. The CDC recommends universal screening of children beginning at 6 months of age.

Hematological Effects. When the blood lead concentration is near 80 $\mu\text{g}/\text{dl}$ or greater, basophilic stippling occurs in erythrocytes; this is not pathognomonic of lead poisoning.

A more common hematological manifestation of chronic lead intoxication is a hypochromic microcytic anemia, which is observed more frequently in children and is morphologically similar to that resulting from iron deficiency. The anemia is thought to result from two factors: a decreased life span of the erythrocytes and an inhibition of heme synthesis.

Very low concentrations of lead influence the synthesis of heme. The enzymes necessary for heme synthesis are distributed widely in mammalian tissues, and each cell probably synthesizes its own heme for incorporation into such proteins as hemoglobin, myoglobin, cytochromes, and catalases. Lead inhibits heme formation at several points, as shown in Figure 65-1. Inhibition of δ -aminolevulinic acid (δ -ALA) dehydratase and ferrochelatase, which are sulfhydryl-dependent enzymes, is well documented. Ferrochelatase is the enzyme responsible for incorporating the ferrous ion into protoporphyrin to form heme. When ferrochelatase is inhibited by lead, excess protoporphyrin takes the place of heme in the hemoglobin molecule. Zinc is incorporated into the protoporphyrin molecule, resulting in the formation of zinc-protoporphyrin, which is intensely fluorescent and may be used to diagnose lead toxicity. Lead poisoning in both humans and experimental animals is characterized by accumulation of protoporphyrin IX and nonheme iron in red blood cells, by accumulation of δ -ALA in plasma, and by increased urinary excretion of δ -ALA. There also is increased urinary excretion of coproporphyrin III (the oxidation product of coproporphyrinogen III), but it is not clear whether this is due to inhibition of enzymatic activity or to other factors. Increased excretion of porphobilinogen and uroporphyrin has been reported only in severe cases. The pattern of excretion of pyrroles in lead poisoning differs from that characteristic of symptomatic episodes of acute intermittent porphyria and other hepatocellular disorders (Table 65-1). The increase in δ -ALA synthase activity is due to reduction of the cellular concentra-

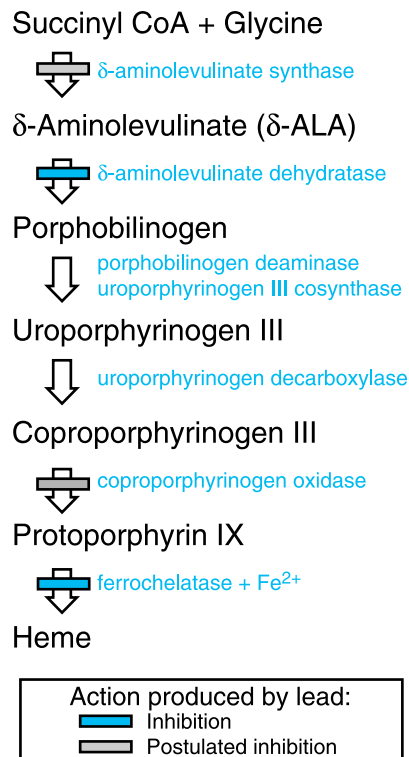

Figure 65-1. Lead interferes with the biosynthesis of heme at several enzymatic steps. Steps that definitely are inhibited by lead are indicated by blue blocks. Steps at which lead is thought to act but where evidence for this is inconclusive are indicated by gray blocks.

Table 65-1
Patterns of Increased Excretion of Pyrroles in Urine of Acutely Symptomatic Patients

tion of heme, which regulates the synthesis of δ -ALA synthase by feedback inhibition.

Measurement of heme precursors provides a sensitive index of recent absorption of inorganic lead salts. δ -ALA dehydratase activity in hemolysates and δ -ALA in urine are sensitive indicators of exposure to lead but are not as sensitive as quantification of blood lead concentrations.

Renal Effects. Although less dramatic than those in the CNS and GI tract, renal effects do occur. Renal toxicity occurs in two forms: a reversible tubular disorder (usually seen after acute exposure of children to lead) and an irreversible interstitial nephropathy (observed more commonly in long-term industrial lead exposure) (Goyer and Clarkson, 2001). Clinically, a Fanconi-like syndrome is seen with proteinuria, hematuria, and casts in the urine (Craswell, 1987; Bernard and Becker, 1988). Hyperuricemia with gout occurs more frequently in the presence of chronic lead nephropathy than in any other type of chronic renal disease. Histologically, lead nephropathy is revealed by characteristic nuclear inclusion bodies composed of a lead-protein complex; they appear early and resolve after chelation therapy. Such inclusion bodies have been reported in the urine sediment of workers exposed to lead in an industrial setting (Schumann *et al.*, 1980).

Other Effects. Other signs and symptoms of lead poisoning are an ashen color of the face and pallor of the lips; retinal stippling; appearance of "premature aging," with stooped posture, poor muscle tone, and emaciation; and a black, grayish, or blue-black "lead line" along the gingival margin. The lead line, a result of periodontal deposition of lead sulfide, may be removed by good dental hygiene. Similar pigmentation may result from the absorption of mercury, bismuth, silver, thallium, or iron. There is a relationship between the concentration of lead in blood and blood pressure, and it has been suggested that this may be due to subtle changes in calcium metabolism or renal function (Staessen, 1995). Lead also interferes with vitamin D metabolism

(Rosen *et al.*, 1980; Mahaffey *et al.*, 1982). A decreased sperm count in lead-exposed males has been described (Lerda, 1992). The human carcinogenicity of lead is not well established but has been suggested (Cooper and Gaffey, 1975), and case reports of renal adenocarcinoma in lead workers have been published.

Diagnosis of Lead Poisoning. In the absence of a positive history of abnormal exposure to lead, the diagnosis of lead poisoning is missed easily because the signs and symptoms of lead poisoning are shared by other diseases. For example, the signs of encephalopathy may resemble those of various degenerative conditions. Physical examination does not easily distinguish lead colic from other abdominal disorders. Clinical suspicion should be confirmed by determinations of the concentration of lead in blood and protoporphyrin in erythrocytes. As noted earlier, lead at low concentrations decreases heme synthesis at several enzymatic steps. This leads to buildup of the diagnostically important substrates δ -ALA, coproporphyrin (both measured in urine), and zinc protoporphyrin (measured in the red cell as erythrocyte protoporphyrin). For children, the erythrocyte protoporphyrin level is insufficiently sensitive to identify children with elevated blood lead levels below about 25 $\mu\text{g}/\text{dl}$, and the screening test of choice is blood lead measurement.

Since lead has been removed from paints and gasoline, the mean blood levels of lead in children in the United States have decreased from 17 $\mu\text{g}/\text{dl}$ in the 1970s to 6 $\mu\text{g}/\text{dl}$ in the 1990s (Schoen, 1993). The concentration of lead in blood is an indication of recent absorption of the metal (Figure 65-2). Children with concentrations of lead in blood above 10 $\mu\text{g}/\text{dl}$ are at risk of developmental disabilities. Adults with concentrations below 30 $\mu\text{g}/\text{dl}$ exhibit no known functional injury or symptoms; however, they will have a definite decrease in δ -ALA dehydratase activity, a slight increase in urinary excretion of δ -ALA, and an increase in erythrocyte protoporphyrin. Patients with a blood lead concentration of 30 to 75 $\mu\text{g}/\text{dl}$ have all

Figure 65-2. Manifestations of lead toxicity associated with varying concentrations of lead in blood of children and adults. δ -ALA = δ -aminolevulinate.

the preceding laboratory abnormalities and, usually, nonspecific, mild symptoms of lead poisoning. Clear symptoms of lead poisoning are associated with concentrations that exceed 75 $\mu\text{g}/\text{dl}$ of whole blood, and lead encephalopathy usually is apparent when lead concentrations are greater than 100 $\mu\text{g}/\text{dl}$. In persons with moderate-to-severe anemia, interpretation of the significance of concentrations of lead in blood is improved by correcting the observed value to approximate that which would be expected if the patient's hematocrit were within the normal range.

The urinary concentration of lead in normal adults generally is less than 80 $\mu\text{g}/\text{L}$ (0.4 μM). Most patients with lead poisoning show concentrations of lead in urine of 150 to 300 $\mu\text{g}/\text{L}$ (0.7 to 1.4 μM). However, in persons with chronic lead nephropathy or other forms of renal insufficiency, urinary excretion of lead may be within the normal range, even though blood lead concentrations are significantly elevated.

Because the onset of lead poisoning usually is insidious, it often is desirable to estimate the body burden of lead in individuals who are exposed to an environment that is contaminated with the metal. In the past, the edetate calcium disodium (CaNa_2EDTA) provocation test was used to determine whether there is an increased body burden of lead in those for whom exposure occurred much earlier. The provocation test is performed by intravenous administration of a single dose of CaNa_2EDTA (50 mg/kg), and urine is collected for 8 hours. The test is positive for children when the lead excretion ratio (micrograms of lead excreted in the urine per milligram of CaNa_2EDTA administered) is greater than 0.6; it also may be useful for therapeutic chelation in children with blood levels of 25 to 45 $\mu\text{g}/\text{dl}$. This test is not used in symptomatic patients or in those whose concentration of lead in blood is greater than 45 $\mu\text{g}/\text{dl}$ because these patients require the proper therapeutic regimen with chelating agents (see below). Neutron activation analysis or fluorometric assays, available only as research methods, may offer a unique *in vivo* approach to the diagnosis of lead burden in the future.

Organic Lead Poisoning. Tetraethyl lead and tetramethyl lead are lipid-soluble compounds that are absorbed readily from the skin, GI tract, and lungs. The toxicity of tetraethyl lead is believed to be due to its metabolic conversion to triethyl lead and inorganic lead.

The major symptoms of intoxication with tetraethyl lead are referable to the CNS: insomnia, nightmares, anorexia, nausea and vomiting, diarrhea, headache, muscular weakness, and emotional instability (Seshia *et al.*, 1978). Subjective CNS symptoms such as irritability, restlessness, and anxiety are next evident, usually accompanied by hypothermia, bradycardia, and hypotension. With continued exposure, or in the case of intense short-term exposure, CNS manifestations progress to delusions, ataxia, exaggerated muscular movements, and finally, a manic state.

The diagnosis of poisoning by tetraethyl lead is established by relating these signs and symptoms to a history of exposure. The urinary excretion of lead may increase markedly, but the concentration of lead in blood remains nearly normal. Anemia and basophilic stippling of erythrocytes are uncommon in organic lead poisoning. There is little effect on the metabolism of porphyrins, and erythrocyte protoporphyrin concentrations are inconsistently elevated (Garrettson, 1983). In the case of severe exposure, death may occur within a few hours or may be delayed for several weeks. If the patient survives the acute phase of organic lead poisoning, recovery usually is complete; however, instances of residual CNS damage have been reported.

Treatment of Lead Poisoning. Initial treatment of the acute phase of lead intoxication involves supportive measures. Prevention of further exposure is important. Seizures are treated with *diazepam* or *phenytoin* (see Chapter 19), fluid and electrolyte balances must be maintained, and cerebral edema is treated with *mannitol* and *dexamethasone* or controlled hyperventilation. The concentration of lead in blood should be determined or at least a blood sample obtained for analysis prior to initiation of chelation therapy.

Chelation therapy is indicated in symptomatic patients or in patients with a blood lead concentration in excess of 50 to 60 $\mu\text{g}/\text{dl}$ (about 2.5 μM). Four chelators are employed: *edetate calcium disodium* (CaNa_2EDTA), *dimercaprol* [British antilewisite (BAL)], *D-penicillamine*, and *succimer* [2,3-dimercaptosuccinic acid (DMSA), CHEMET]. CaNa_2EDTA and dimercaprol usually are used in combination for lead encephalopathy.

CaNa_2EDTA . CaNa_2EDTA is initiated at a dose of 30 to 50 mg/kg per day in two divided doses either by deep intramuscular injection or slow intravenous infusion for up to 5 consecutive days. The first dose of CaNa_2EDTA should be delayed until 4 hours after the first dose of dimercaprol. An additional course of CaNa_2EDTA may be given after an interruption of 2 days. Each course of therapy with CaNa_2EDTA should not exceed a total dose of 500 mg/kg. Urine output must be monitored because the chelator-lead complex is believed to be nephrotoxic. Treatment with CaNa_2EDTA can alleviate symptoms quickly. Colic may disappear within 2 hours; paresthesia and tremor cease after 4 or 5 days; and coproporphyrinuria, stippled erythrocytes, and gingival lead lines tend to decrease in 4 to 9 days. Urinary elimination of lead usually is greatest during the initial infusion.

Dimercaprol. Dimercaprol is given intramuscularly at a dose of 4 mg/kg every 4 hours for 48 hours, then every 6 hours for 48 hours, and finally, every 6 to 12 hours for an additional 7 days. *The combination of dimercaprol and CaNa_2EDTA is more effective than is either chelator alone* (Chisolm, 1973).

D-Penicillamine. In contrast to CaNa_2EDTA and dimercaprol, penicillamine is effective orally and may be included in the regimen at a dosage of 250 mg given four times daily for 5 days. During chronic therapy with penicillamine, the dose should not exceed 40 mg/kg per day.

Succimer. Succimer is the first orally active lead chelator available for children, with a safety and efficacy profile that surpasses that of D-penicillamine. Succimer usually is given every 8 hours (10 mg/kg) for 5 days and then every 12 hours for an additional 2 weeks.

General Principles. In any chelation regimen, the blood lead concentration should be reassessed 2 weeks after the regimen has been completed; an additional course of therapy may be indicated if blood lead concentrations rebound.

Treatment of organic lead poisoning is symptomatic. Chelation therapy will promote excretion of the inorganic lead produced from the metabolism of organic lead, but the increase is not dramatic.

Mercury

Mercury was an important constituent of drugs for centuries as an ingredient in many diuretics, antibacterials, antiseptics, skin ointments, and laxatives. More specific, effective, and safer modes of therapy now have replaced the mercurials, and drug-induced mercury poisoning has become rare. However, mercury has a number of impor-

Table 65–2
Occupational and Environmental Exposure to Mercury

Laboratory	2

tant industrial uses (Table 65–2), and poisoning from occupational exposure and environmental pollution continues to be an area of concern. There have been epidemics of mercury poisoning among wildlife and human populations in many countries. With very few exceptions and for numerous reasons, such outbreaks were misdiagnosed for months or even years. Reasons for these tragic delays included the insidious onset of the affliction, vagueness of early clinical signs, and the medical profession's unfamiliarity with the disease (Gerstner and Huff, 1977).

Chemical Forms and Sources of Mercury. With regard to the toxicity of mercury, three major chemical forms of the metal must be distinguished: mercury vapor (elemental mercury), salts of mercury, and organic mercurials. Table 65–3 indicates the estimated daily retention of various forms of mercury from various sources.

Elemental mercury is the most volatile of the metal's inorganic forms. Human exposure to mercury vapor is mainly occupational. Extraction of gold with mercury and then heating the amalgam to drive off the mercury is a technique that has been used extensively by gold miners and still is used today in some developing countries.

Table 65–3
Estimated Average Daily Retention of Total Mercury and Mercury Compounds in the General Population Not Occupationally Exposed to Mercury

EXPOSURE	ESTIMATED MEAN DAILY RETENTION OF MERCURY COMPOUNDS, μg MERCURY/DAY		
	<i>Mercury Vapor</i>	<i>Inorganic Mercury Salts</i>	<i>Methylmercury</i>
Air	0.024	0.001	0.0064
Food			
Fish	0.0	0.04	2.3
Nonfish	0.0	0.25	0.0
Drinking water	0.0	0.0035	0.0
Dental amalgams	3–17	0.0	0.0
Total	3–17	0.3	2.31

Chronic exposure to mercury in ambient air after inadvertent mercury spills in poorly ventilated rooms, often scientific laboratories, can produce toxic effects. Mercury vapor also can be released from silver–amalgam dental restorations. In fact, this is the main source of mercury exposure to the general population, but the amount of mercury released does not appear to be of significance for human health (Eley and Cox, 1993) except for allergic contact eczema seen in a few individuals.

Salts of mercury exist in two states of oxidation—as monovalent mercurous salts or as divalent mercuric salts. Mercurous chloride (Hg_2Cl_2), or *calomel*, the best-known mercurous compound, was used in some skin creams as an antiseptic and was employed as a diuretic and cathartic. Mercuric salts are the more irritating and acutely toxic form of the metal. Mercuric nitrate was a common industrial hazard in the felt-hat industry more than 400 years ago. Occupational exposure produced neurological and behavioral changes depicted by the Mad Hatter in Lewis Carroll's *Alice's Adventures in Wonderland*. Mercuric chloride (Hg_2Cl_2), once a widely used antiseptic, also was used commonly for suicidal purposes. Mercuric salts still are employed widely in industry, and industrial discharge into rivers has introduced mercury into the environment in many parts of the world. The main industrial uses of inorganic mercury today are in chloralkali production and in electronics. Other uses of the metal include the manufacturing of plastics, fungicides, and germicides and the formulation of amalgams in dentistry.

The organomercurials in use today contain mercury with one covalent bond to a carbon atom. Members of this heterogeneous group of compounds have varying abilities to produce toxic effects. The alkylmercury salts are by far the most dangerous of these compounds; methylmercury is the most common. Alkylmercury salts have been used widely as fungicides and have produced toxic effects in humans. Major incidents of human poisoning from the inadvertent consumption of mercury-treated seed grain have occurred in Iraq, Pakistan, Ghana, and Guatemala. The most catastrophic outbreak occurred in Iraq in 1972. During the fall of 1971, Iraq imported large quantities of seed (wheat and barley) treated with methylmercury and distributed the grain for spring planting. Despite official warnings, the grain was ground into flour and made into bread. As a result, 6530 victims were hospitalized, and 500 died (Bakir *et al.*, 1973, 1980).

Minamata disease also was due to methylmercury. In the Japanese town of Minamata, the major industry was a chemical plant that emptied its effluent directly into Minamata Bay. The chemical plant used inorganic mercury as a catalyst, and some of it was methylated before it entered the bay. In addition, microorganisms can convert inorganic mercury to methylmercury; the compound then is taken up rapidly by plankton algae and is concentrated in fish via the food chain. Residents of Minamata who consumed fish as a large portion of their diet were the first to be poisoned. Eventually, 121 persons were poisoned, and 46 died (McAlpine and Araki, 1958; Smith and Smith, 1975; Tamashiro *et al.*, 1985). In the United States, human poisonings have resulted from ingestion of meat from pigs fed grain treated with an organomercurial fungicide. Because of concerns about methylmercury accumulation in fish, the Food and Drug Administration (FDA) recommends that pregnant or nursing women, women of childbearing age, and young children avoid eating large fish (*e.g.*, shark, swordfish, king mackerel, and tilefish) and limit their intake of albacore tuna to 6 ounces per week.

In other instances, exposure to mercury was intentional. For example, thimerosal ($\text{CH}_3\text{CH}_2\text{—Hg—S—C}_6\text{H}_4\text{—COOH}$) has been used as an antibacterial additive to biologics and vaccines since the 1930s. However, concerns about the possibility of health risks from thimerosal in vaccines have been debated, especially the possibility that the ethylmercury thiosalicylate preservative in hepatitis B immunoglobulin (HBIG) could release ethylmercury and cause severe mercury intoxication (Lowell *et al.*, 1996; Ball *et al.*, 2001). These concerns were based on the assumption that ethylmercury, for which there is limited toxicologic information, is toxicologically similar to its close chemical relative, methyl mercury ($\text{CH}_3\text{—Hg}^+$), about which much is known (Clarkson, 2002).

A study by the FDA determined that there is a significant safety margin incorporated into all the acceptable mercury exposure limits. Furthermore, there are no data or evidence of any harm caused by the level of exposure that some children may have encountered in following the existing immunization schedule. Nevertheless, the availability of vaccines with alternate preservatives led to a statement calling for removal of all vaccines containing thimerosal (Joint Statement of the American Academy of Pediatrics and the United States Public Health Service, 1999; Ball *et al.*, 2001). This practice remains in place today, even though subsequent studies have failed to demonstrate any health risk associated with vaccines containing thimerosal (Verstraeten *et al.*, 2003; Heron *et al.*, 2004).

Chemistry and Mechanism of Action. Mercury readily forms covalent bonds with sulfur, and it is this property that accounts for most of the biological properties of the metal. When the sulfur is in the form of sulfhydryl groups, divalent mercury replaces the hydrogen atom to form mercaptides, X—Hg—SR and Hg(SR)_2 , where X is an electronegative radical and R is protein. Organic mercurials form mercaptides of the type $\text{R—Hg—SR}'$. Even in low concentrations, mercurials are capable of inactivating sulfhydryl groups of enzymes and thus interfering with cellular metabolism and function. The affinity of mercury for thiols provides the basis for treatment of mercury poisoning with such agents as dimercaprol and penicillamine. Mercury also combines with phosphoryl, carboxyl, amide, and amine groups.

Absorption, Biotransformation, Distribution, and Excretion. *Elemental Mercury.* Elemental mercury is not particularly toxic when ingested because of very low absorption from the GI tract; this is due to the formation of droplets and because the metal in this form

cannot react with biologically important molecules. However, inhaled mercury vapor is completely absorbed by the lung and then is oxidized to the divalent mercuric cation by catalase in the erythrocytes (Magos *et al.*, 1978). Within a few hours, the deposition of inhaled mercury vapor resembles that after ingestion of mercuric salts, with one important difference: Because mercury vapor crosses membranes much more readily than does divalent mercury, a significant amount of the vapor enters the brain before it is oxidized. CNS toxicity is thus more prominent after exposure to mercury vapor than to divalent forms of the metal.

Inorganic Salts of Mercury. The soluble inorganic mercuric salts (Hg^{2+}) gain access to the circulation when taken orally. GI absorption is approximately 10% to 15% of that ingested, and a considerable portion of the Hg^{2+} may remain bound to the alimentary mucosa and the intestinal contents. Insoluble inorganic mercurous compounds, such as calomel (Hg_2Cl_2), may undergo some oxidation to soluble compounds that are more readily absorbed. Inorganic mercury has a markedly nonuniform distribution after absorption. The highest concentration of Hg^{2+} is found in the kidneys, where the metal is retained longer than in other tissues. Concentrations of inorganic mercury are similar in whole blood and plasma. Inorganic mercurials do not readily pass across the blood–brain barrier or the placenta. The metal is excreted in the urine and feces with a half-life of about 60 days (Friberg and Vostal, 1972); studies in laboratory animals indicate that fecal excretion is quantitatively more important (Klaassen, 1975).

Organic Mercurials. Organic mercurials are absorbed more completely from the GI tract than are the inorganic salts because they are more lipid soluble and less corrosive to the intestinal mucosa. Their uptake and distribution are depicted in Figure 65–3A. More than 90% of methylmercury is absorbed from the human GI tract. The organic mercurials cross the blood–brain barrier and the placenta and thus produce more neurological and teratogenic effects than do the inorganic salts. Methylmercury combines with cysteine to form a structure similar to methionine, and the complex is transported by the large neutral amino acid carrier present in capillary endothelial cells (Clarkson, 1987) (Figure 65–3B). Organic mercurials are distributed more uniformly to the various tissues than are the inorganic salts (Klaassen, 1975). A significant portion of the body burden of organic mercurials is in the red blood cells. The ratio of the concentration of organomercurial in erythrocytes to that in plasma varies with the compound; for methylmercury, it approximates 20:1 (Kershaw *et al.*, 1980). Mercury concentrates in hair because of its high sulfhydryl content. The carbon–mercury bond of some organic mercurials is cleaved after absorption; with methylmercury, the cleavage is quite slow, and the inorganic mercury formed is not thought to play a major role in methylmercury toxicity. Aryl mercurials, such as mercuriophen, usually contain a labile mercury–carbon bond; their toxicity is similar to that of inorganic mercury. Methylmercury in humans is excreted mainly in the feces in the form of a glutathione conjugate; less than 10% of a dose appears in urine (Bakir *et al.*, 1980). The half-life of methylmercury in the blood of humans is between 40 and 105 days (Bakir *et al.*, 1973).

Toxicity. *Elemental Mercury.* Short-term exposure to the vapor of elemental mercury may produce symptoms within several hours, including weakness, chills, metallic taste, nausea, vomiting, diarrhea, dyspnea, cough, and a feeling of tightness in the chest. Pulmonary toxicity may progress to an interstitial pneumonitis with severe compromise of respiratory function. Recovery, although usually complete, may be complicated by residual interstitial fibrosis.

Figure 65-3. Uptake and relative distribution of organic mercurials. **A.** The intestinal uptake and subsequent distribution of organic mercurials, such as methylmercury, throughout the body. **a.** Conjugation with glutathione (GSH), shown as $\text{CH}_3\text{-Hg-SG}$. **b.** Secretion of conjugate into bile. **c.** Reabsorption in gallbladder. **d.** Remaining Hg enters intestinal tract. **B.** Uptake of the methylmercury complex by capillaries. The ability of organic mercurials to cross the blood-brain barrier and the placenta contributes to their greater neurological and teratogenic effects when compared with inorganic mercury salts. Note the structural similarity of the methylmercury complex to methionine, $\text{CH}_3\text{SCH}_2\text{CH}_2\text{-CH(NH}_3^+\text{)COO}^-$.

Chronic exposure to mercury vapor produces a more insidious form of toxicity that is dominated by neurological effects (Friberg and Vostal, 1972). The syndrome, termed the *asthenic vegetative syndrome*, consists of neurasthenic symptoms in addition to three or more of the following findings: goiter, increased uptake of radioiodine by the thyroid, tachycardia, labile pulse, gingivitis, dermatographia, and increased mercury in the urine (Goyer and Clarkson, 2001). With continued exposure to mercury vapor, tremor becomes noticeable, and psychological changes consist of depression, irritability, excessive shyness, insomnia, reduced self-confidence, emotional instability, forgetfulness, confusion, impatience, and vasomotor disturbances (such as excessive perspiration and

uncontrolled blushing, which together are referred to as *erethism*). Common features of intoxication from mercury vapor are severe salivation and gingivitis. The triad of increased excitability, tremors, and gingivitis has been recognized historically as the major manifestation of exposure to mercury vapor when mercury nitrate was used in the fur, felt, and hat industries. Renal dysfunction also has been reported to result from long-term industrial exposure to mercury vapor. The concentrations of mercury vapor in the air and mercury in urine that are associated with the various effects are shown in Figure 65-4.

Inorganic Salts of Mercury. Inorganic ionic mercury (e.g., mercuric chloride) can produce severe acute toxicity. Precipitation of mucous membrane proteins by mercuric salts results in an ash-gray appearance of the mucosa of the mouth, pharynx, and intestine and also causes intense pain, which may be accompanied by vomiting. The vomiting is perceived to be protective because it removes unabsorbed mercury from the stomach; assuming that the patient is awake and alert, vomiting should not be inhibited. The local corrosive effect of ionic inorganic mercury on the GI mucosa results in severe hematochezia with evidence of mucosal sloughing in the stool. Hypovolemic shock and death can occur in the absence of proper treatment, which can overcome the local effects of inorganic mercury.

Systemic toxicity may begin within a few hours of exposure to mercury and last for days. A strong metallic taste is followed by stomatitis with gingival irritation, foul breath, and loosening of the teeth. The most serious and frequent systemic effect of inorganic mercury is renal toxicity. Acute tubular necrosis occurs after short-term exposure, leading to oliguria or anuria. Renal injury also follows long-term exposure to inorganic mercury, where glomerular injury predominates. This results from direct effects on the glomerular basement membrane and later indirect effects mediated by immune complexes (Goyer and Clarkson, 2001).

The symptom complex of acrodynia (pink disease) also commonly follows chronic exposure to inorganic mercury ions. Acrodynia is an erythema of the extremities, chest, and face with photophobia, diaphoresis, anorexia, tachycardia, and either constipation or diarrhea. This symptom complex is seen almost exclusively after ingestion of mercury and is believed to be the result of a hypersensitivity reaction (Matheson *et al.*, 1980).

Organic Mercurials. Most human toxicological data about organic mercury concern methylmercury and have been collected as the unfortunate result of large-scale accidental exposures. Symptoms of exposure to methylmercury are mainly neurological and consist of visual disturbance (scotoma and visual-field constriction), ataxia, paresthesias, neurasthenia, hearing loss, dysarthria, mental deterioration, muscle tremor, movement disorders, and with severe exposure, paralysis and death (Table 65-4). Effects of methylmercury on the fetus can occur even when the mother is asymptomatic; mental retardation and neuromuscular deficits have been observed.

Diagnosis of Mercury Poisoning. A history of exposure to mercury, either industrial or environmental, is obviously valuable in making the diagnosis of mercury poisoning. Otherwise, clinical suspicions can be confirmed by laboratory analysis. The upper limit of a nontoxic concentration of mercury in blood generally is considered to be 3 to 4 $\mu\text{g/dl}$ (0.15 to 0.20 μM). A concentration of mercury in blood in excess of 4 $\mu\text{g/dl}$ (0.20 μM) is unexpected in normal, healthy adults and suggests the need for environmental evaluation and medical examination to assess the possibility of adverse health effects. Because methylmercury is concentrated in erythrocytes and inorganic mercury is not, the

Figure 65-4. The concentration of mercury vapor in the air and related concentrations of mercury in urine associated with a variety of toxic effects.

distribution of total mercury between red blood cells and plasma may indicate whether the patient has been poisoned with inorganic or organic mercury. Measurement of total mercury in red blood cells gives a better estimate of the body burden of methylmercury than it does for inorganic mercury. A rough guide to the relationship between concentrations of mercury in blood and the frequency of symptoms that result from exposure to methylmercury is shown in Table 65-4. Concentrations of mercury in plasma provide a better index of the body burden of inorganic mercury, but the relationship between body burden and the concentration of inorganic mercury in plasma is not well documented. This may relate to the importance of timing of measurement of the blood sample relative to the last expo-

sure to mercury. The relationship between the concentration of inorganic mercury in blood and toxicity also depends on the form of exposure. For example, exposure to vapor results in concentrations in brain approximately 10 times higher than those that follow an equivalent dose of inorganic mercuric salts.

The concentration of mercury in the urine also has been used as a measure of the body burden of the metal. The normal upper limit for excretion of mercury in urine is $5 \mu\text{g}/\text{L}$. There is a linear relationship between plasma concentration and urinary excretion of mercury after exposure to vapor; in contrast, the excretion of mercury in urine is a poor indicator of the amount of methylmercury in the blood because it is eliminated mainly in feces (Bakir *et al.*, 1980).

Table 65-4

Frequency of Symptoms of Methylmercury Poisoning in Relation to Concentration of Mercury in Blood

CONCENTRATION OF MERCURY IN BLOOD, $\mu\text{g}/\text{ml}$ (μM)	CASES WITH SYMPTOMS (%)					
	<i>Paresthesias</i>	<i>Ataxia</i>	<i>Visual Defects</i>	<i>Dysarthria</i>	<i>Hearing Defects</i>	<i>Death</i>
0.1–0.5 (0.5–2.5)	5	0	0	5	0	0
0.5–1 (2.5–5)	42	11	21	5	5	0
1–2 (5–10)	60	47	53	24	5	0
2–3 (10–15)	79	60	56	25	13	0
3–4 (15–20)	82	100	58	75	36	17
4–5 (20–25)	100	100	83	85	66	28

SOURCE: Based on data in Bakir *et al.*, 1973.

Hair is rich in sulfhydryl groups, and the concentration of mercury in hair is about 300 times that in blood. Human hair grows about 20 cm a year, and a history of exposure may be obtained by analysis of different segments of hair.

Treatment of Mercury Poisoning. Measurement of the concentration of mercury in blood should be performed as soon as possible after poisoning with any form of the metal.

Elemental Mercury Vapor. Therapeutic measures include immediate termination of exposure and close monitoring of pulmonary status. Short-term respiratory support may be necessary. Chelation therapy, as described below for inorganic mercury, should be initiated immediately and continued as indicated by the clinical condition and the concentrations of mercury in blood and urine.

Inorganic Mercury. Prompt attention to fluid and electrolyte balance and hematological status is of critical importance in moderate-to-severe oral exposures. Emesis can be induced if the patient is awake and alert, although emesis should not be induced where there is corrosive injury. If ingestion of mercury is more than 30 to 60 minutes before treatment, emesis may have little efficacy. With corrosive agents, endoscopic evaluation may be warranted, and coagulation parameters are important. *Activated charcoal* is recommended by some, although it lacks proven efficacy. Administration of charcoal may make endoscopy difficult or impossible.

Chelation Therapy. Chelation therapy with dimercaprol (for high-level exposures or symptomatic patients) or penicillamine (for low-level exposures or asymptomatic patients) is used routinely to treat poisoning with either inorganic or elemental mercury. Recommended treatment includes dimercaprol 5 mg/kg intramuscularly initially, followed by 2.5 mg/kg intramuscularly every 12 to 24 hours for 10 days. Penicillamine (250 mg orally every 6 hours) may be used alone or following treatment with dimercaprol. The duration of chelation therapy will vary, and progress can be monitored by following concentrations of mercury in urine and blood. The orally effective chelator succimer appears to be an effective chelator for mercury (Campbell *et al.*, 1986; Fournier *et al.*, 1988; Bluhm *et al.*, 1992), although it has not been approved by the FDA for this purpose.

The dimercaprol–mercury chelate is excreted into both bile and urine, whereas the penicillamine–mercury chelate is excreted only into urine. Thus penicillamine should be used with extreme caution when renal function is impaired. In fact, hemodialysis may be necessary in the poisoned patient whose renal function declines. Chelators still may be used because the dimercaprol–mercury complex is removed by dialysis (Giunta *et al.*, 1983).

Organic Mercury. The short-chain organic mercurials, especially methylmercury, are the most difficult forms of mercury to mobilize from the body presumably because of their poor reactivity with chelating agents. Dimercaprol is contraindicated in methylmercury poisoning because it increases brain concentrations of methylmercury in experimental animals. Although penicillamine facilitates the removal of methylmercury from the body, it is not clinically efficacious, and large doses (2 g/day) are needed (Bakir *et al.*, 1980). During the initial 1 to 3 days of administration of penicillamine, the concentration of mercury in the blood increases before it decreases, probably reflecting the mobilization of metal from tissues to blood at a rate more rapid than that for excretion of mercury into urine and feces.

Methylmercury compounds undergo extensive enterohepatic recirculation in experimental animals. Therefore, introduction of a nonabsorbable mercury-binding substance into the intestinal tract should facilitate their removal from the body. A *polythiol resin* has been used for this purpose in humans and appears to be effective

(Bakir *et al.*, 1973). The resin has certain advantages over penicillamine. It does not cause redistribution of mercury in the body with a subsequent increase in the concentration of mercury in blood, and it has fewer adverse effects than do sulfhydryl agents that are absorbed. Clinical experience with various treatments for methylmercury poisoning in Iraq indicates that penicillamine, *N*-acetylpenicillamine, and an oral nonabsorbable thiol resin all can reduce blood concentrations of mercury; however, clinical improvement was not clearly related to reduction of the body burden of methylmercury (Bakir *et al.*, 1980).

Conventional hemodialysis is of little value in the treatment of methylmercury poisoning because methylmercury concentrates in erythrocytes, and little is contained in the plasma. However, it has been shown that *L*-cysteine can be infused into the arterial blood entering the dialyzer to convert methylmercury into a diffusible form. Both free cysteine and the methylmercury–cysteine complex form in the blood and then diffuse across the membrane into the dialysate. This method has been shown to be effective in humans (Al-Abbasi *et al.*, 1978). Studies in animals indicate that succimer may be more effective than cysteine in this regard (Kostyniak, 1982).

Arsenic

Arsenic was used more than 2400 years ago in Greece and Rome as a therapeutic agent and as a poison. The foundations of many modern concepts of chemotherapy derive from Ehrlich's early work with organic arsenicals, and such drugs once were a mainstay of chemotherapy. Although use of arsenicals as chemotherapeutics has declined, reports still emerge about their effectiveness, as shown by the use of *arsenic trioxide* in the treatment of acute promyelocytic leukemia (Chen *et al.*, 1996; Soignet *et al.*, 1998) (*see* Chapter 51). Arsenicals also remain important in the treatment of certain tropical diseases, such as African trypanosomiasis (*see* Chapter 40). In the United States, the impact of arsenic on health is predominantly from industrial and environmental exposures. (For a review, *see* NRC, 1999.)

Arsenic is found in soil, water, and air as a common environmental toxicant. Well water in sections of Argentina, Chile, and Taiwan has especially high concentrations of arsenic, which results in widespread poisoning. Large numbers of people in Bangladesh and West Bengal, India, are exposed to high concentrations of arsenic in their well water used for drinking. There also are high concentrations of arsenic in the water in many parts of the western United States. The element usually is not mined as such but is recovered as a by-product from the smelting of copper, lead, zinc, and other ores. This can release arsenic into the environment. Mineral-spring waters and the effluent from geothermal power plants leach arsenic from soils and rocks containing high concentrations of the metal. Arsenic also is present in coal at variable concentrations and is released into the environment during combustion. Application of pesticides and herbicides containing arsenic has increased its environmental dispersion. The major source of occupational exposure to arsenic-containing compounds is from the manufacture of arsenical herbicides and pesticides (Landrigan, 1981). Fruits and vegetables sprayed

with arsenicals may be a source of this element, and it is concentrated in many species of fish and shellfish. Arsenicals sometimes are added to the feed of poultry and other livestock to promote growth. The average daily human intake of arsenic is about 10 μg . Almost all this is ingested with food and water.

Arsenic is used as arsine and as arsenic trioxide in the manufacture of most computer chips using silicon-based technology. Gallium arsenide is used in the production of compound (types III to V) semiconductors that are used for making light-emitting diodes (LEDs), as well as laser and solar devices. In the manufacture of both computer chips and semiconductors, metallic arsenic also may be used or produced as a by-product of the reaction chambers. Chromated copper arsenate (CCA) was used as a common treatment for outdoor lumber until 2004, although this should not pose a health risk unless treated wood is burned in fireplaces or woodstoves (Hall, 2002).

Chemical Forms of Arsenic. The arsenic atom exists in the elemental form and in trivalent and pentavalent oxidation states. The toxicity of a given arsenical is related to the rate of its clearance from the body and therefore to its degree of accumulation in tissues. In general, toxicity increases in the sequence of organic arsenicals $< \text{As}^{5+} < \text{As}^{3+} < \text{arsine} (\text{AsH}_3)$.

The organic arsenicals contain arsenic covalently linked to a carbon atom, where arsenic exists in the trivalent or pentavalent state. Arsphenamine contains trivalent arsenic; sodium arsenilate contains arsenic in the pentavalent form. The organic arsenicals usually are excreted more rapidly than are the inorganic forms.

ARSPHENAMINE

SODIUM ARSANILATE

The pentavalent oxidation state is found in arsenates (such as lead arsenate, PbHAsO_4), which are salts of arsenic acid, H_3AsO_4 . The pentavalent arsenicals have very low affinity for thiol groups, in contrast to the trivalent compounds, and are much less toxic. The arsenites [e.g., potassium arsenite (KAsO_2)] and salts of arsenious acid contain trivalent arsenic. Arsine (AsH_3) is a gaseous hydride of trivalent arsenic; it produces toxic effects that are distinct from those of the other arsenic compounds.

Mechanism of Action. Arsenate (pentavalent) uncouples mitochondrial oxidative phosphorylation. The mechanism is thought to be related to competitive substitution of arsenate for inorganic phosphate in the formation of adenosine triphosphate, with subsequent formation of an unstable arsenate ester that is hydrolyzed rapidly. This process is termed *arsenolysis*.

Trivalent arsenicals, including inorganic arsenite, are regarded primarily as sulfhydryl reagents. As such, trivalent arsenicals inhibit many enzymes by reacting with biological ligands containing available $-\text{SH}$ groups. The pyruvate dehydrogenase system is especially

sensitive to trivalent arsenicals because of their interaction with two sulfhydryl groups of lipoic acid to form a stable six-membered ring, as shown below:

Absorption, Distribution, and Excretion. The absorption of poorly water-soluble arsenicals, such as As_2O_3 , depends on the physical state of the compound. Coarsely powdered material is less toxic because it can be eliminated in feces before it dissolves. The arsenite salts are more soluble in water and are better absorbed than the oxide. Experimental evidence has shown a high degree of GI absorption (80% to 90%) of both trivalent and pentavalent forms of arsenic.

The distribution of arsenic depends on the duration of administration and the particular arsenical involved. Arsenic is stored mainly in liver, kidney, heart, and lung. Much smaller amounts are found in muscle and neural tissue. Because of the high sulfhydryl content of keratin, the highest concentrations of arsenic are found in hair and nails. Deposition in hair starts within 2 weeks of administration, and arsenic stays fixed at this site for years. Because of its chemical similarity to phosphorus, it is deposited in bone and teeth and is retained there for long periods. Arsenic readily crosses the placenta, and fetal damage has been reported. Concentrations of arsenic in human umbilical cord blood are equivalent to those in the maternal circulation.

Arsenic is readily biotransformed in both laboratory animals and humans (Figure 65-5). The pentavalent arsenic (arsenate) is coupled to the oxidation of glutathione (GSH) to GSSG to form the trivalent arsenic (arsenite). Arsenite undergoes oxidative methylation to pentavalent methylarsonic acid (MMA^{V}) catalyzed by arsenite methyltransferase. MMA^{V} is reduced by MMA^{V} reductase to trivalent monomethyl arsonous acid (MMA^{III}), which can undergo further oxidative methylation *via* MMA methyltransferase to dimethylarsenic acid (DMA^{V}).

Arsenic is eliminated by many routes (e.g., feces, urine, sweat, milk, hair, skin, and lungs), although most is excreted in urine in humans. The half-life for the urinary excretion of arsenic is 3 to 5 days, much shorter than those of the other metals discussed. While it once was thought that the methylated forms of arsenic are less reactive with tissue constituents, less cytotoxic, and more readily excreted in urine than inorganic arsenic, studies have shown that methylation to monomethylarsonous (III) acid or reduction of dimethylarsenic acid to its trivalent state actually increases the toxicity and carcinogenicity of arsenic owing to increased affinity for sulfhydryl groups (Petrick *et al.*, 2000; Thomas *et al.*, 2001). In humans, the urinary content of metabolites is 10% to 30% inorganic arsenic, 10% to 20% monomethylarsenite, and 60% to 80% dimethylarsenite (Vahter and Concha, 2001). Formation of trivalent mono- or dimethyl arsenic metabolites promotes biliary rather than renal excretion (Gregus *et al.*, 2000).

Pharmacological and Toxicological Effects of Arsenic. Arsenicals have varied effects on many organ systems, as summarized below.

Cardiovascular System. Acute and subacute doses of inorganic arsenic induce mild vasodilation. This may lead to an occult edema,

Figure 65–5. The biotransformation of arsenic in human beings.

particularly facial, which has been mistaken for a healthy weight gain and misinterpreted as a “tonic” effect of arsenic. Larger acute and subacute doses evoke capillary dilation; increased capillary permeability may occur in all capillary beds but is most pronounced in the splanchnic area. Transudation of plasma also may occur, and the decrease in intravascular volume may be significant. Serious cardiovascular effects include hypotension, congestive heart failure, and cardiac arrhythmias. Long-term exposure results in peripheral vascular disease (Engel *et al.*, 1994), more specifically gangrene of the extremities, especially of the feet, often referred to as *blackfoot disease*. Myocardial damage and hypotension may become evident after more prolonged exposure to arsenic.

Gastrointestinal Tract. Acute or subacute exposure to arsenic can produce GI disturbances that range from mild abdominal cramping and diarrhea to severe hemorrhagic gastroenteritis associated with shock. With chronic exposure to arsenic, GI effects usually are not observed. Small doses of inorganic arsenicals, especially the trivalent compounds, cause mild splanchnic hyperemia. Capillary transudation of plasma, resulting from larger doses, produces vesicles under the GI mucosa. These eventually rupture, epithelial fragments slough off, and plasma is discharged into the lumen of the intestine, where it coagulates. Tissue damage and the bulk cathartic action of the increased fluid in the lumen lead to increased peristalsis and characteristic watery diarrhea. Normal proliferation of the epithelium is suppressed, which accentuates the damage. Soon the feces become bloody. Damage to the upper GI tract usually results in hematemesis. Stomatitis also may be evident. The onset of GI symptoms may be so gradual that the possibility of arsenic poisoning may be overlooked.

Kidneys. The action of arsenic on the renal capillaries, tubules, and glomeruli may cause severe renal damage. Initially, the glomeruli are affected, and proteinuria results. Varying degrees of tubular necrosis and degeneration occur later. Oliguria with proteinuria, hematuria, and casts frequently results from arsenic exposure.

Skin. Skin is a major target organ of arsenic. Diffuse or spotted hyperpigmentation over the trunk and extremities usually is the first effect observed with chronic arsenic ingestion. Depending on the amount of exposure to arsenic, hyperpigmentation can be observed within 6 months. The hyperpigmentation of chronic arsenic expo-

sure commonly appears in a finely freckled “raindrop” pattern, progressing within a period of years to palmar-plantar hyperkeratosis. Long-term ingestion of low doses of inorganic arsenicals causes cutaneous vasodilation and a “milk and roses” complexion. Eventually, skin cancer is observed, as described below.

Nervous System. High-dose acute or subacute exposure to arsenic can cause encephalopathy; however, the most common arsenic-induced neurological lesion is a peripheral neuropathy with a stocking/glove distribution of dysesthesia. The syndrome is similar to acute inflammatory demyelinating polyradiculoneuropathy (Guillain-Barré syndrome) (Donofrio *et al.*, 1987). This is followed by muscular weakness in the extremities, and with continued exposure, deep-tendon reflexes diminish, and muscular atrophy follows. The cerebral lesions are mainly vascular in origin and occur in both the gray and white matter; characteristic multiple symmetrical foci of hemorrhagic necrosis occur.

Blood. Inorganic arsenicals affect the bone marrow and alter the cellular composition of the blood. Hematological evaluation usually reveals anemia with slight-to-moderate leukopenia; eosinophilia also may be present. Anisocytosis becomes evident with increasing exposure to arsenic. The vascularity of the bone marrow is increased. Some of the chronic hematological effects may result from impaired absorption of folic acid. Serious, irreversible blood and bone marrow disturbances from organic arsenicals are rare.

Liver. Inorganic arsenicals and a number of now-obsolete organic arsenicals are particularly toxic to the liver and produce fatty infiltration, central necrosis, and cirrhosis. The damage may be mild or so severe that death may ensue. The injury generally is to the hepatic parenchyma, but in some cases the clinical picture may closely resemble occlusion of the common bile duct, the principal lesions being pericholangitis and bile thrombi in the finer biliary radicles.

Carcinogenesis. The association of arsenic exposure and skin tumors was noted more than 100 years ago in patients treated with arsenicals. The International Agency for Research on Cancer concluded that inorganic arsenic is a skin and lung (*via* inhalation) carcinogen in humans (International Agency for Research on Cancer, 1980). Studies indicate that in Taiwan, Argentina, and Chile, where drinking water contained very high concentrations of arsenic (at least several hundred micrograms per deciliter), an increased incidence of bladder and lung cancer was due to arsenic exposure. Increased risks of other cancers, such as kidney and liver cancer, also have been reported, but the association with arsenic is not as high as for the tumors just noted.

Other. Apart from the various direct toxicities already mentioned, epidemiological studies demonstrate that inorganic arsenic exerts other adverse effects, examined in a variety of population-based epidemiological studies and clinical reports, including diseases of the cerebrovascular systems and hypertension. Chronic exposure to arsenic has been associated with increased prevalence of diabetes mellitus, goiter, hepatomegaly, and respiratory system dysfunctions (Thomas *et al.*, 2001).

Acute Arsenic Poisoning. Federal restrictions on the allowable content of arsenic in food and in the occupational environment not only have improved safety procedures and decreased the number of intoxications but also have decreased the amount of arsenic in use; only the annual production of arsenic-containing herbicides is increasing.

The incidence of accidental, homicidal, and suicidal arsenic poisoning has diminished greatly in recent decades. Previously, arsenic in the form of As_2O_3 was a common cause of poisoning because it was readily available, practically tasteless, and had the appearance of sugar.

GI discomfort usually is experienced within an hour after intake of an arsenical, although it may be delayed as much as 12 hours after oral ingestion if food is in the stomach. Burning lips, constriction of the throat, and difficulty in swallowing may be the first symptoms, followed by excruciating gastric pain, projectile vomiting, and severe diarrhea. Oliguria with proteinuria and hematuria usually is present; eventually, anuria may occur. The patient often complains of marked skeletal muscle cramps and severe thirst. As the loss of fluid proceeds, symptoms of shock appear. Hypoxic convulsions may occur terminally; coma and death ensue. In severe poisoning, death can occur within an hour, but the usual interval is 24 hours. With prompt application of corrective therapy, patients may survive the acute phase of the toxicity only to develop neuropathies and other disorders. In a series of 57 such patients, 37 had peripheral neuropathy, and 5 had encephalopathy. The motor system appears to be spared only in the mildest cases; severe crippling is common (Jenkins, 1966).

Chronic Arsenic Poisoning. The most common early signs of chronic arsenic poisoning are muscle weakness and aching, skin pigmentation (especially of the neck, eyelids, nipples, and axillae), hyperkeratosis, and edema. GI involvement is less prominent in long-term exposures. Other signs and symptoms that should arouse suspicion of arsenic poisoning include garlic odor of the breath and perspiration, excessive salivation and sweating, stomatitis, generalized itching, sore throat, coryza, lacrimation, numbness, burning or tingling of the extremities, dermatitis, vitiligo, and alopecia. Poisoning may begin insidiously with symptoms of weakness, languor, anorexia, occasional nausea and vomiting, and diarrhea or constipation. Subsequent symptoms may simulate acute coryza. Dermatitis and keratosis of the palms and soles are common features. Mee's lines are found characteristically in the fingernails (white transverse lines of deposited arsenic that usually appear 6 weeks after exposure). Because the fingernail grows at a rate of 0.1 mm/day, the approximate time of exposure can be determined. Desquamation and scaling of the skin may initiate an exfoliative process involving many epithelial structures of the body. The liver may enlarge, and obstruction of the bile ducts may result in jaundice. Eventually cirrhosis may occur from the hepatotoxic action. Renal dysfunction also may be encountered. As intoxication advances, encephalopathy may develop. Peripheral neuritis results in motor and sensory paralysis of the extremities; in contrast to lead palsy, the legs usually are more severely affected than the arms. The bone marrow is seriously damaged by arsenic, and all hematological elements may be affected with severe exposure.

Treatment of Arsenic Poisoning. After short-term exposure to arsenic, routine measures are taken to stabilize the patient and prevent further absorption of the poison. In particular, attention is directed to the intravascular volume status because the effects of arsenic on the GI tract can result in fatal hypovolemic shock. Hypotension requires fluid replacement and may necessitate pharmacological support with pressor agents such as *dopamine*.

Chelation Therapy. Chelation therapy often is begun with dimercaprol (3 to 4 mg/kg intramuscularly every 4 to 12 hours) until abdominal symptoms subside and charcoal (if given initially) is passed in the feces. Oral treatment with penicillamine then may be substituted for dimercaprol and continued for 4 days. Penicillamine is given in four divided doses to a maximum of 2 g/day. If symptoms recur after cessation of chelation therapy, a second course of penicillamine may be instituted. Succimer (2,3-dimercaptosuccinic acid), a derivative of dimercaprol, is efficacious in the treatment of arsenic

poisoning (Graziano *et al.*, 1978; Lenz *et al.*, 1981; Fournier *et al.*, 1988) but is approved by the FDA only for lead chelation in children.

After long-term exposure to arsenic, treatment with dimercaprol and penicillamine also may be used, but oral penicillamine alone usually is sufficient. The duration of therapy is determined by the clinical condition of the patient, and the decision is aided by periodic determinations of urinary arsenic concentrations. Adverse effects of the chelating agents may limit the usefulness of therapy (*see below*). Dialysis may become necessary with severe arsenic-induced nephropathy; successful removal of arsenic by dialysis has been reported (Vaziri *et al.*, 1980).

Arsine. Arsine gas, generated by electrolytic or metallic reduction of arsenic in nonferrous metal products, is a rare cause of industrial intoxication. Rapid and often fatal hemolysis is a unique characteristic of arsine poisoning and probably results from arsine combining with hemoglobin and then reacting with oxygen to cause hemolysis. A few hours after exposure, headache, anorexia, vomiting, paresthesia, abdominal pain, chills, hemoglobinuria, bilirubinemia, and anuria occur. The classic arsine triad of hemolysis, abdominal pain, and hematuria is noteworthy. Jaundice appears after 24 hours. A coppery skin pigmentation is observed frequently and is thought to be due to methemoglobin. Kidneys of persons poisoned by arsine characteristically contain hemoglobin casts, and there is cloudy swelling and necrosis of the cells of the proximal tubule. If the patient survives the severe hemolysis, death may result from renal failure. Because the hemoglobin-arsine complex cannot be dialyzed, *exchange transfusion* is recommended in severe cases; *forced alkaline diuresis* also may be employed (*see Chapter 64*). Dimercaprol has no effect on the hemolysis, and beneficial effects on renal function have not been established; it therefore is not recommended.

It should be noted that arsenic is a trace contaminant of other metals, such as lead; contact of these unrefined metals with acid may produce arsine (and/or stibine from antimony).

Cadmium

Cadmium ranks close to lead and mercury as a metal of current toxicological concern. It occurs in nature in association with zinc and lead, and extraction and processing of these metals often lead to environmental contamination with cadmium. The element was discovered in 1817 but was seldom used until its valuable metallurgical properties were discovered approximately 50 years ago. A high resistance to corrosion, valuable electrochemical properties, and other useful chemical properties account for cadmium's wide applications in electroplating and galvanization and its use in plastics, paint pigments (cadmium yellow), and nickel-cadmium batteries. Applications for and production of cadmium will continue to increase. Because less than 5% of the metal is recycled, environmental pollution is an important consideration. Coal and other fossil fuels contain cadmium, and their combustion releases the element into the environment.

Workers in smelters and other metal-processing plants may be exposed to high concentrations of cadmium in the air; however, for

most of the population, food is the major source of cadmium. Untaminated foodstuffs contain less than 0.05 μg cadmium per gram wet weight, and the average daily intake is about 50 μg . Cereal grains, such as rice and wheat, concentrate cadmium; thus, when they are grown in soils with naturally high concentrations of cadmium or polluted with cadmium, these grains can have high cadmium content. Drinking water normally does not contribute significantly to cadmium intake, but cigarette smoking does because the tobacco plant also concentrates cadmium. One cigarette contains 1 to 2 μg cadmium, and with even 10% pulmonary absorption (Elinder *et al.*, 1983), the smoking of one pack of cigarettes per day results in a dose of approximately 1 mg cadmium per year from smoking alone. Shellfish and animal liver and kidney can have concentrations of cadmium higher than 0.05 $\mu\text{g}/\text{g}$, even under normal circumstances. When foods such as rice and wheat are contaminated by cadmium in soil and water in which they grew, the concentration of the metal may increase considerably (1 $\mu\text{g}/\text{g}$).

Absorption, Distribution, and Excretion. Cadmium occurs only in one valency state (2^+) and does not form stable alkyl compounds or other organometallic compounds of known toxicological significance.

Cadmium is absorbed poorly from the GI tract, in the range of 1.5% to 5% (Engstrom and Nordberg, 1979; Rahola *et al.*, 1972). Absorption from the respiratory tract is higher; cigarette smokers may absorb 10% to 40% of inhaled cadmium (Friberg *et al.*, 1974). Cadmium absorption is higher in pregnant than nonpregnant rats apparently owing to an increased expression of divalent metal transporter 1 (DMT-1). The main function of DMT-1 is to facilitate iron absorption, so its levels increase during pregnancy owing to an increased need for iron. However, DMT-1 also is capable of transporting cadmium, which explains the observed increase in cadmium absorption (Leazer *et al.*, 2002).

After absorption, cadmium is transported in blood, bound mainly to blood cells and albumin. Cadmium initially is distributed to the liver and then redistributes slowly to the kidney as cadmium-metallothionein (Cd-MT). After distribution, approximately 50% of the total-body burden is found in the liver and kidney. Metallothionein is a low-molecular-weight protein with high affinity for metals such as cadmium and zinc. One-third of its amino acid residues are cysteines. Metallothionein is inducible by exposure to several metals, including cadmium, and elevated concentrations of this metal-binding protein protect against cadmium toxicity by preventing the interaction of cadmium with other functional macromolecules (Klaassen *et al.*, 1999).

The half-life of cadmium in the body is 10 to 30 years. Thus the metal is prone to accumulation, and with continuous environmental exposure, tissue concentrations of the metal increase throughout life. The body burden of cadmium in a 50-year-old adult in the United States is about 30 mg. Overall, fecal elimination of the metal, which is quantitatively more important than urinary excretion, becomes significant only after substantial renal toxicity has occurred (*see* Goering and Klaassen, 1984).

Acute Cadmium Poisoning. Acute poisoning usually results from inhalation of cadmium dusts and fumes (usually cadmium oxide) or from the ingestion of cadmium salts. The early toxic effects are due to local irritation. In the case of oral intake, these include nausea, vomiting, salivation, diarrhea, and abdominal cramps; the vomitus and diarrhea often are bloody. In the short term, inhaled cadmium is more toxic. Signs and symptoms, which appear within a few hours, include irritation of the respiratory tract with severe, early pneumo-

nitic, chest pains, nausea, dizziness, and diarrhea. Toxicity may progress to fatal pulmonary edema or residual emphysema with peribronchial and perivascular fibrosis (Zavon and Meadows, 1970).

Chronic Cadmium Poisoning. The toxic effects of long-term exposure to cadmium differ somewhat with the route of exposure. The kidney is affected following either pulmonary or GI exposure; marked effects are observed in the lungs only after exposure by inhalation.

Kidney. Figure 65-6 illustrates how cadmium is thought to produce renal toxicity. Although some cadmium is excreted with the bile, a cadmium-metallothionein complex can transport cadmium to the kidney, where it is released as inorganic cadmium. A sufficient concentration (200 $\mu\text{g}/\text{g}$) damages the cells of the proximal tubule, resulting in proteinuria (Dudley *et al.*, 1985). With more severe exposure, glomerular injury occurs, filtration is decreased, and aminoaciduria, glycosuria, and proteinuria occur. The nature of the glomerular injury is unknown but may involve an autoimmune component.

Excretion of β_2 -microglobulin in urine is a sensitive but not specific index of cadmium-induced nephrotoxicity (Piscator and Pettersson, 1977; Lauwerys *et al.*, 1979). Although measurement of urine β_2 -microglobulin is part of the Occupational Safety and Health Administration (OSHA) standard for monitoring cadmium poisoning, the concentration of β_2 -microglobulin in the urine may not be the best marker for exposure. Retinol-binding protein may be a better marker, but its measurement generally is not available.

Lung. The consequence of excessive inhalation of cadmium fumes and dusts is loss of ventilatory capacity, with a corresponding increase in residual lung volume. Dyspnea is the most frequent complaint of patients with cadmium-induced lung disease. The pathogenesis of cadmium-induced emphysema and pulmonary fibrosis is not well understood (Davison *et al.*, 1988); however, cadmium specifically inhibits the synthesis of plasma α_1 -antitrypsin (Chowdhury and Louria, 1976), and severe α_1 -antitrypsin deficiency of genetic origin is associated with emphysema in humans.

Cardiovascular System. Perhaps the most controversial issue concerning the effects of cadmium on human beings is the suggestion that the metal plays a significant causal role in hypertension (Schroeder, 1965). An initial epidemiological study indicated that individuals dying from hypertension had significantly higher concentrations of cadmium and higher cadmium-to-zinc ratios in their kidneys than people dying of other causes. Others have found similar correlations (Thind and Fischer, 1976). However, consistent effects of cadmium on the blood pressure of experimental animals have not been observed, and hypertension is not prominent in industrial cadmium poisoning.

Bone. There may be an interaction among cadmium, nutrition, and bone disease. Body stores of calcium have been found to be decreased in subjects exposed to cadmium occupationally (Scott *et al.*, 1980). This presumed effect of cadmium may be due to interference with renal regulation of calcium and phosphate balance.

Testis. Testicular necrosis, a common characteristic of short-term exposure to cadmium in experimental animals, is uncommon with long-term low-level exposure (Kotsonis and Klaassen, 1978) and has not been observed in men.

Cancer. Cadmium produces tumors in a number of organs when administered to laboratory animals (Waalkes *et al.*, 1992). Evidence that cadmium is a human carcinogen is based mainly on epidemiological studies from workers exposed occupationally to cadmium. These investigations primarily have identified tumors of the lungs and, to a lesser extent, prostate, kidney, and stomach. The Interna-

Figure 65–6. Postulated mechanisms contributing to cadmium-induced renal toxicity. Cadmium (Cd) taken up by the liver can combine with glutathione (GSH) and be excreted into the bile or can bind to metallothionein (MT), creating a storage form for cadmium. Some cadmium–metallothionein complex (Cd–MT) leaks into the plasma. When taken up by kidney cells, Cd–MT enters the lysosomes, the MT is degraded to its component amino acids (aa), and the cadmium is released from the lysosomes into the cytosol. At concentrations of 200 $\mu\text{g/g}$ or higher, cadmium damages kidney tissue and results in proteinuria (Dudley *et al.*, 1985). Alb, albumin.

tional Agency for Cancer Research (1993) has concluded that the data are sufficient to classify cadmium as a human carcinogen.

Treatment of Cadmium Poisoning. Effective therapy for cadmium poisoning is difficult to achieve. After short-term inhalation, the patient must be removed from the source, and pulmonary ventilation should be monitored carefully. Respiratory support and steroid therapy may become necessary.

Chelation Therapy. Although there is no proven benefit, some clinicians recommend chelation therapy with CaNa_2EDTA . The dose of CaNa_2EDTA is 75 mg/kg per day in three to six divided doses for 5 days. After a minimum of 2 days without treatment, a second 5-day course is given. The total dose of CaNa_2EDTA per 5-day course should not exceed 500 mg/kg. Animal studies suggest that chelation therapy should be instituted as soon as possible after cadmium exposure because a rapid decrease in effectiveness of chelation therapy occurs in parallel with distribution to sites inaccessible to the chelators (Cantilena and Klaassen, 1982a). The use of dimercaprol and substituted dithiocarbamates appears promising for individuals chronically exposed to cadmium (Jones *et al.*, 1991).

Iron

Although iron is not an environmental poison, accidental intoxication with ferrous salts used to treat iron deficiency is a frequently encountered source of poisoning in young children. Iron is discussed further in Chapter 53.

Radioactive Heavy Metals

The widespread production and use of radioactive heavy metals for nuclear generation of electricity, nuclear weapons, laboratory research, manufacturing, and medical diagnosis have generated unique problems in dealing with accidental poisoning by such metals. Because the toxicity of radioactive metals is almost entirely a consequence of ionizing radiation, the therapeutic objective follow-

ing exposure is not only chelation of the metals but also their removal from the body as rapidly and completely as possible.

Treatment of the acute radiation syndrome is largely symptomatic. Attempts have been made to investigate the effectiveness of organic reducing agents, such as *mercaptamine* (*cysteamine*), administered to prevent the formation of free radicals. Success has been limited.

Major products of a nuclear accident or the use of nuclear weapons include ^{239}Pu , ^{137}Cs , ^{144}Ce , and ^{90}Sr . Isotopes of strontium and radium are extremely difficult to remove from the body with chelating agents. Several factors are involved in the relative resistance of radioactive metals to chelation therapy; these include the affinity of these particular metals for individual chelators and the observation that radiation from Sr and Ra in bone destroys nearby capillaries, thereby decreasing blood flow and isolating the radioisotopes. Many chelating agents have been used experimentally, including CaNa_3DTPA (*pentetic acid*; see below), which has been shown to be effective against ^{239}Pu (Jones *et al.*, 1986). One gram of CaNa_3DTPA , administered by slow intravenous drip on alternate days three times per week has enhanced excretion fifty to one hundredfold in animals and in human subjects exposed in accidents. As is seen commonly with heavy-metal poisoning, effectiveness of treatment diminishes very rapidly with an increasing delay between exposure and the initiation of therapy.

HEAVY-METAL ANTAGONISTS

Edetate Calcium Disodium

Ethylenediaminetetraacetic acid (EDTA), its sodium salt (*edetate disodium*, Na_2EDTA), and a number of closely related compounds chelate many divalent and trivalent metals. The cation used to make a water-soluble salt of EDTA has an important role in the toxicity of the chela-

tor. Na_2EDTA causes hypocalcemic tetany. However, *edetate calcium disodium* (CaNa_2EDTA) can be used for treatment of poisoning by metals that have higher affinity for the chelating agent than does Ca^{2+} .

Chemistry and Mechanism of Action. The structure of CaNa_2EDTA is as follows:

The pharmacological effects of CaNa_2EDTA result from formation of chelates with divalent and trivalent metals in the body. Accessible metal ions (both exogenous and endogenous) with a higher affinity for CaNa_2EDTA than Ca^{2+} will be chelated, mobilized, and usually excreted. Because EDTA is charged at physiological pH, it does not significantly penetrate cells; its volume of distribution approximates extracellular fluid space. Experimental studies in mice have shown that administration of CaNa_2EDTA mobilizes several endogenous metallic cations, including those of zinc, manganese, and iron (Cantilena and Klaassen, 1982b). The main therapeutic use of CaNa_2EDTA is in the treatment of metal intoxications, especially lead intoxication.

CaNa_2EDTA is available as edetate calcium disodium (CALCIUM DISODIUM VERSENATE). Intramuscular administration of CaNa_2EDTA results in good absorption, but pain occurs at the injection site; consequently, the chelator injection often is mixed with a local anesthetic or administered intravenously. For intravenous use, CaNa_2EDTA is diluted in either 5% dextrose or 0.9% saline and is administered slowly by intravenous drip. A dilute solution is necessary to avoid thrombophlebitis. To minimize nephrotoxicity, adequate urine production should be established prior to and during treatment with CaNa_2EDTA . However, in patients with lead encephalopathy and increased intracranial pressure, excess fluids must be avoided. In such cases, conservative replacement of fluid is advised, and intramuscular administration of CaNa_2EDTA is recommended.

Lead Poisoning. The successful use of CaNa_2EDTA in the treatment of lead poisoning is due, in part, to the capacity of lead to displace calcium from the chelate. Enhanced mobilization and excretion of lead indicate that the metal is accessible to EDTA. Bone provides the primary source of lead that is chelated by CaNa_2EDTA . After such chelation, lead is redistributed from soft tissues to the skeleton.

Mercury poisoning, by contrast, does not respond to the drug despite the fact that mercury displaces calcium from CaNa_2EDTA *in vitro*. Mercury is unavailable to the chelate perhaps because it is too tightly bound by sulfhydryl groups or sequestered in body compartments that are not penetrated by CaNa_2EDTA .

Suggestions appeared in the lay press in the 1980s that chelation therapy with CaNa_2EDTA could minimize development of atherosclerotic plaques, which can accumulate calcium deposits; such use of CaNa_2EDTA is without therapeutic rationale and not efficacious (Guldager *et al.*, 1992; Elihu *et al.*, 1998; Villarruz *et al.*, 2002).

Absorption, Distribution, and Excretion. Less than 5% of CaNa_2EDTA is absorbed from the GI tract. After intravenous administration, CaNa_2EDTA disappears from the circulation with a half-life of 20 to 60 minutes. In blood, all the drug is found in plasma. About 50% is excreted in urine in 1 hour and more than 95% in 24 hours. For this reason, adequate renal function is necessary for successful therapy. Renal clearance of the compound in dogs equals that of inulin, and glomerular filtration accounts entirely for urinary excretion. Altering either the pH or the rate of flow of urine has no effect on the rate of excretion. There is very little metabolic degradation of EDTA. The drug is distributed mainly in the extracellular fluids, but very little gains access to the spinal fluid (5% of the plasma concentration).

Toxicity. Rapid intravenous administration of Na_2EDTA causes hypocalcemic tetany. However, a slow infusion (<15 mg/minute) administered to a normal individual elicits no symptoms of hypocalcemia because of the ready availability of extracirculatory stores of Ca^{2+} . In contrast, CaNa_2EDTA can be administered intravenously in relatively large quantities with no untoward effects because the change in the concentration of Ca^{2+} in the plasma and total body is negligible.

Renal Toxicity. The principal toxic effect of CaNa_2EDTA is on the kidney. Repeated large doses of the drug cause hydropic vacuolization of the proximal tubule, loss of the brush border, and eventually, degeneration of proximal tubular cells (Catsch and Harmuth-Hoene, 1979). Changes in distal tubules and glomeruli are less conspicuous. The early renal effects usually are reversible, and urinary abnormalities disappear rapidly on cessation of treatment.

Renal toxicity may be related to the large amounts of chelated metals that transit the renal tubule in a relatively short period during drug therapy. Some dissociation of chelates may occur because of competition for the metal by physiological ligands or because of pH changes in the cell or the lumen of the tubule. However, a more likely mechanism of toxicity may be interaction between the chelator and endogenous metals in proximal tubular cells.

Other Side Effects. Other less serious side effects have been reported with use of CaNa_2EDTA , including malaise, fatigue, and excessive thirst, followed by the sudden appearance of chills and fever. This, in turn, may be followed by severe myalgia, frontal headache, anorexia, occasional nausea and vomiting, and rarely, increased urinary frequency and urgency. Other possible undesirable effects include sneezing, nasal congestion, and lacrimation; glycosuria; anemia; dermatitis with lesions strikingly similar to those of vitamin B₆ deficiency; transitory lowering of systolic and diastolic blood pressures; prolonged prothrombin time; and T-wave inversion on the electrocardiogram.

Pentetic Acid (DTPA)

Diethylenetriaminepentaacetic acid (DTPA), like EDTA, is a polycarboxylic acid chelator, but it has somewhat greater affinity for most heavy metals. Many investigations in animals have shown that the spectrum of clinical effectiveness of DTPA is similar to that of EDTA. Because of its relatively greater affinity for metals, DTPA has been tried in cases of heavy-metal poisoning that do not respond to EDTA, particularly poisoning by radioactive metals. Unfortunately, success has been limited probably because DTPA also has limited access to intracellular sites of metal storage. Because DTPA rapidly binds Ca^{2+} , CaNa_3DTPA is employed. The use of DTPA is investigational.

Dimercaprol

Dimercaprol was developed during World War II as an antidote to lewisite, a vesicant arsenical war gas, hence its alternative name, *British antilewisite* (BAL). Arsenicals would form a very stable and relatively nontoxic chelate ring with the dimercaprol (2,3-dimercaptopropanol). Pharmacological investigations revealed that this compound would protect against the toxic effects of other heavy metals as well.

Chemistry. Dimercaprol has the following structure:

It is an oily fluid with a pungent, disagreeable odor typical of mercaptans. Because of its instability in aqueous solutions, peanut oil is the solvent employed in pharmaceutical preparations. Dimercaprol and related thiols are readily oxidized.

Mechanism of Action. The pharmacological actions of dimercaprol result from formation of chelation complexes between its sulfhydryl groups and metals. The molecular properties of the dimercaprol–metal chelate have considerable practical significance. With metals such as mercury, gold, and arsenic, the strategy is to attain a stable complex to promote elimination of the metal. Dissociation of the complex and oxidation of dimercaprol can occur *in vivo*. Furthermore, the sulfur–metal bond may be labile in the acidic tubular urine, which may increase delivery of metal to renal tissue and increase toxicity. The dosage regimen therefore is designed to maintain a concentration of dimercaprol in plasma adequate to favor the continuous formation of the more stable 2:1 (BAL–metal) complex and its rapid excretion. However, because of pronounced and dose-related side effects, excessive plasma concentrations must be avoided. The concentration in plasma therefore must be maintained by repeated fractional dosage until the offending metal can be excreted.

Dimercaprol is much more effective when given as soon as possible after exposure to the metal because it is more effective in preventing inhibition of sulfhydryl enzymes than in reactivating them. Dimercaprol antagonizes the biological actions of metals that form mercaptides with essential cellular sulfhydryl groups, principally arsenic, gold, and mercury. It also is used in combination

with CaNa_2EDTA to treat lead poisoning, especially when evidence of lead encephalopathy exists. Intoxication by selenites, which also oxidize sulfhydryl enzymes, is not influenced by dimercaprol.

Absorption, Distribution, and Excretion. Dimercaprol cannot be administered orally; it is given by deep intramuscular injection as a 100 mg/ml solution in peanut oil, and thus it should not be used in patients who are allergic to peanuts or peanut products. Peak concentrations in blood are attained in 30 to 60 minutes. The half-life is short, and metabolic degradation and excretion are essentially complete within 4 hours.

Toxicity. In humans, the administration of dimercaprol produces a number of side effects that usually are more alarming than serious. Reactions to dimercaprol occur in approximately 50% of subjects receiving 5 mg/kg intramuscularly. The effects of repeated administration of this dose are not cumulative if an interval of at least 4 hours elapses between injections. One of the most consistent responses to dimercaprol is a rise in systolic and diastolic arterial pressures, accompanied by tachycardia. The rise in pressure may be as great as 50 mmHg in response to the second of two doses (5 mg/kg) given 2 hours apart. The pressure rises immediately but returns to normal within 2 hours.

Other signs and symptoms of dimercaprol toxicity, many of which tend to parallel the change in blood pressure in time and intensity, are the following, listed in approximate order of frequency: nausea and vomiting; headache; a burning sensation in the lips, mouth, and throat and a feeling of constriction, sometimes pain, in the throat, chest, or hands; conjunctivitis, blepharospasm, lacrimation, rhinorrhea, and salivation; tingling of the hands; a burning sensation in the penis; sweating of the forehead, hands, and other areas; abdominal pain; and the occasional appearance of painful sterile abscesses at the injection site. Symptoms often are accompanied by a feeling of anxiety and unrest. Because the dimercaprol–metal complex breaks down easily in an acidic medium, production of an alkaline urine protects the kidney during therapy. Children react as do adults, although approximately 30% also may experience a fever that disappears on withdrawal of the drug. A transient reduction in the percentage of polymorphonuclear leukocytes may be observed. Dimercaprol also may cause hemolytic anemia in patients deficient in glucose-6-phosphate dehydrogenase. Dimercaprol is contraindicated in patients with hepatic insufficiency, except when this is a result of arsenic poisoning.

Succimer

Succimer (2,3-dimercaptosuccinic acid, CHEMET) is an orally effective chelator that is chemically similar to dimercaprol but contains two carboxylic acids that modify both the distribution and chelating spectrum of the drug. Succimer has the following structure:

After its absorption in humans, succimer is biotransformed to a mixed disulfide with cysteine (Aposhian and Aposhian, 1990), the structure of which is as follows:

Succimer produces a lead diuresis with a subsequent lowering of blood lead levels and attenuation of the untoward biochemical effects of lead, manifested by normalization of δ -ALA dehydrase activity (Graziano *et al.*, 1992). The succimer-lead chelate also is eliminated in bile; the fraction eliminated undergoes enterohepatic circulation.

A desirable feature of succimer is that it does not significantly mobilize essential metals such as zinc, copper, or iron. Animal studies suggest that succimer is effective as a chelator of arsenic, cadmium, mercury, and other metals (Aposhian and Aposhian, 1990).

Toxicity with succimer is less than that with dimercaprol perhaps because its relatively lower lipid solubility minimizes its uptake into cells. Nonetheless, transient elevations in hepatic transaminases are observed following treatment with succimer. The most commonly reported adverse effects of succimer treatment are nausea, vomiting, diarrhea, and loss of appetite. Rashes also have been reported that may necessitate discontinuation of therapy.

Succimer has been approved in the United States for treatment of children with blood lead levels in excess of 45 $\mu\text{g}/\text{dl}$.

Penicillamine

Penicillamine was first isolated in 1953 from the urine of patients with liver disease who were receiving penicillin. Discovery of its chelating properties led to its use in patients with Wilson's disease and heavy-metal intoxications.

Chemistry. Penicillamine is D- β , β -dimethylcysteine. Its structure is as follows:

The D-isomer is used clinically, although the L-isomer also forms chelation complexes. Penicillamine is an effective chelator of copper, mercury, zinc, and lead and promotes the excretion of these metals in the urine.

Absorption, Distribution, and Excretion. Penicillamine is well absorbed (40% to 70%) from the GI tract and therefore has a decided advantage over many other chelating agents. Food, antacids, and iron reduce its absorption. Peak concentrations in blood are obtained between 1 and 3 hours after administration (Netter *et al.*, 1987). Unlike cysteine, its nonmethylated parent compound, penicillamine is somewhat resistant to attack by cysteine desulfhydrase or L-amino acid oxidase. As a result, penicillamine is relatively stable *in vivo*. Hepatic biotransformation is responsible for most of the degradation of penicillamine, and very little is excreted unchanged. Metabolites are found in both urine and feces (Perrett, 1981).

Therapeutic Uses. Penicillamine (CUPRIMINE, DEPEN) is available for oral administration. For chelation therapy, the usual adult dose is 1 to 1.5 g/day in four divided doses (*see* sections under individual metals). The drug should be given on an empty stomach to avoid interference by metals in food. In addition to its use as a chelating agent for the treatment of copper, mercury, and lead poisoning, penicillamine is used in Wilson's disease (hepatolenticular degeneration owing to an excess of copper), cystinuria, and rheumatoid arthritis (rarely). For the treatment of Wilson's disease, 1 to 2 g/day usually is administered in four doses. The urinary excretion of copper should be monitored to determine whether the dosage of penicillamine is adequate.

N-Acetylpenicillamine is more effective than penicillamine in protecting against the toxic effects of mercury presumably because it is even more resistant to metabolism.

The rationale for the use of penicillamine in cystinuria is that penicillamine reacts with the poorly soluble cysteine in a thiol-disulfide exchange reaction and forms a relatively water-soluble cysteine-penicillamine mixed disulfide. In cystinuria, the urinary excretion of cystine is used to adjust dosage, although 2 g/day in four divided doses usually is employed.

The mechanism of action of penicillamine in rheumatoid arthritis remains uncertain, although suppression of the disease may result from marked reduction in concentrations of IgM rheumatoid factor. A single daily dose of 125 to 250 mg usually is used to initiate therapy, with dosage increases at intervals of 1 to 3 months as necessary to a typical range of 500 to 750 mg/day. Because of toxicity, the drug is used rarely today in this setting.

Other experimental uses of penicillamine include the treatment of primary biliary cirrhosis and scleroderma. The mechanism of action of penicillamine in these diseases also may involve effects on immunoglobulins and immune complexes (Epstein *et al.*, 1979).

Toxicity. With long-term use, penicillamine induces several cutaneous lesions, including urticaria, macular or papular reactions, pemphigoid lesions, lupus erythematosus, dermatomyositis, adverse effects on collagen, and other less serious reactions, such as dryness and scaling. Cross-reactivity with penicillin may be responsible for some episodes of urticarial or maculopapular reactions with generalized edema, pruritus, and fever that occur in as many as one-third of patients taking penicillamine. For a detailed review of the adverse dermatological effects of penicillamine, see Levy and coworkers (1983).

The hematological system also may be affected severely; reactions include leukopenia, aplastic anemia, and agranulocytosis. These may occur at any time during therapy, and they may be fatal. Patients obviously must be monitored carefully.

Renal toxicity induced by penicillamine usually is manifested as reversible proteinuria and hematuria, but it may progress to the nephrotic syndrome with membranous glomerulopathy. More rarely, fatalities have been reported from Goodpasture's syndrome (Hill, 1979).

Toxicity to the pulmonary system is uncommon, but severe dyspnea has been reported from penicillamine-induced bronchoalveolitis. Myasthenia gravis also has been induced by long-term therapy with penicillamine (Gordon and Burnside, 1977). Less serious side effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, and a transient loss of taste for sweet and salt, which is relieved by supplementation of the diet with copper. Contraindications to penicillamine therapy include pregnancy, a previous history of penicillamine-induced agranulocytosis or aplastic anemia, or the presence of renal insufficiency.

Trientine

Penicillamine is the drug of choice for treatment for Wilson's disease. However, the drug produces undesirable effects, as discussed earlier, and some patients become intolerant. For these individuals, *trientine* (triethylenetetramine dehydrochloride, CUPRID) is an acceptable alternative. Trientine is an effective cupriuretic agent in patients with Wilson's disease, although it may be less potent than penicillamine. The drug is effective orally. Maximal daily doses of 2 g for adults or 1.5 g for children are taken in two to four divided portions on an empty stomach. Trientine may cause iron deficiency; this can be overcome with short courses of iron therapy, but iron and trientine should not be ingested within 2 hours of each other.

Deferoxamine

Deferoxamine is isolated as the iron chelate from *Streptomyces pilosus* and is treated chemically to obtain the metal-free ligand. Deferoxamine has the desirable properties of a remarkably high affinity for ferric iron ($K_a = 10^{31}$) coupled with a very low affinity for calcium ($K_a = 10^2$). Studies *in vitro* have shown that it removes iron from hemosiderin and ferritin and, to a lesser extent, from transferrin. Iron in hemoglobin or cytochromes is

not removed by deferoxamine. The structure of deferoxamine is

Deferoxamine (*deferoxamine mesylate*, DESFERAL MESYLATE) is poorly absorbed after oral administration, and parenteral administration is required in most cases. For severe iron toxicity (serum iron levels greater than 500 $\mu\text{g}/\text{dl}$), the intravenous route is preferred. The drug is administered at 10 to 15 mg/kg per hour by constant infusion. Faster rates of infusion (45 mg/kg per hour) have been used in a few cases; rapid boluses usually are associated with hypotension. Deferoxamine may be given intramuscularly in moderately toxic cases (serum iron 350 to 500 $\mu\text{g}/\text{dl}$) at a dose of 50 mg/kg with a maximum dose of 1 g. Hypotension also can occur with the intramuscular route.

For chronic iron intoxication (*e.g.*, thalassemia), an intramuscular dose of 0.5 to 1.0 g/day is recommended, although continuous subcutaneous administration (1 to 2 g/day) is almost as effective as intravenous administration (Propper *et al.*, 1977). When blood is being transfused to patients with thalassemia, 2.0 g deferoxamine (per unit of blood) should be given by slow intravenous infusion (rate not to exceed 15 mg/kg per hour) during the transfusion but not by the same intravenous line. Deferoxamine is not recommended in primary hemochromatosis; phlebotomy is the treatment of choice. Deferoxamine also has been used for the chelation of aluminum in dialysis patients (Swartz, 1985).

Deferoxamine is metabolized principally by plasma enzymes, but the pathways have not yet been defined. The drug also is excreted readily in the urine.

Deferoxamine causes a number of allergic reactions, including pruritus, wheals, rash, and anaphylaxis. Other adverse effects include dysuria, abdominal discomfort, diarrhea, fever, leg cramps, and tachycardia. Occasional cases of cataract formation have been reported. Deferoxamine may cause neurotoxicity during long-term, high-dose therapy for transfusion-dependent thalassemia major; both visual and auditory changes have been described (Olivieri *et al.*, 1986). A "pulmonary syndrome" has been associated with high-dose (10 to 25 mg/kg per hour) deferoxamine therapy (Freedman *et al.*, 1990; Castriota-Scanderbeg *et al.*, 1990); tachypnea, hypoxemia, fever, and eosinophilia are prominent symptoms. Contraindications to the use of deferoxamine include renal insufficiency and anuria; during pregnancy, the drug should be used only if clearly indicated.

An orally effective iron chelator now under clinical investigation, *deferiprone* (1,2-dimethyl-3-hydroxypyridin-4-one), may be of value in patients with thalassemia major who are unable or unwilling to receive deferoxamine (Olivieri *et al.*, 1995). Combination therapy with deferoxamine also is under investigation.

PRINCIPLES OF PRESCRIPTION ORDER WRITING AND PATIENT COMPLIANCE

Iain L. O. Buxton

When the physician's treatment plan for the patient involves the prescribing of one or more medications, Robert Burns' law too often prevails: "The best-laid schemes o' mice an' men gang aft a-gley." From the wrong drug prescribed to the wrong dosage or administration schedule advised, dispensed, or administered, the impact of medication misadventures are a tremendously costly problem. This appendix provides a primer on the proper approach to the medication prescription and order process and a resource for practitioners in effectively providing pharmaceutical care for their patients.

THE MECHANICS OF PRESCRIPTION ORDER WRITING

History. Knowledge of ancient prescriptions can be found in both Chinese (Chen and Qian, 1989) and Egyptian writings (Karenberg and Leitz, 2001). The use of the symbol Rx to denote the modern prescription is rooted in ancient alchemical practice of obscure origin. Rx may be derived from the Egyptian "Eye of Horus" symbol (☉) denoting health, or may be a symbolic appeal by physicians to the god Jupiter for a prescription's success. More commonly, Rx is said to be an abbreviation for the Latin word *recipere*, meaning "take" or "take thus" as a direction to a pharmacist, preceding the physician's "recipe" for preparing a medication. What is clear is the origin of the abbreviation "Sig" for the Latin "*Signatura*," used on the prescription to mark the directions for administration of the medication.

Early medicines were made up of multiple ingredients requiring complex preparation, and Latin was adopted as the standard language of the prescription to ensure understanding and consistency. Latin is no longer the international language of medicine, but a number of commonly used abbreviations derive from old Latin usage.

Current Practice. Today, the prescription consists of the superscription, the inscription, the subscription, the signa, and the name and signature of the prescriber, all contained on a single form (Figure AI-1).

The *superscription* includes the date the prescription order is written; the name, address, weight, and age of the patient; and the Rx. The body of the prescription, or *inscription*, contains the name and amount or strength of the drug to be dispensed, or the name and strength of each ingredient to be compounded. The *subscription* is the instruction to the pharmacist, usually consisting of a short sentence such as: "make a solution," "mix and place into 30 capsules," or "dispense 30 tablets." The *signa* or "Sig" is the instruction for the patient as to how to take the prescription, interpreted and transposed onto the prescription label by the pharmacist. In the United States these should always be written in English. Many physicians continue to use Latin abbreviations; for example, "1 cap tid pc," will be interpreted by the pharmacist as "take one capsule three times daily after meals." However, the use of Latin abbreviations for these directions only mystifies the prescription. This can be a hindrance to proper patient-physician communication and is an otherwise unnecessary source of potential dispensing errors. Since the pharmacist always writes the label in English (or as appropriate in the language of the patient), the use of such abbreviations or symbols is unnecessary and discouraged.

The instruction "take as directed" is not satisfactory and should be avoided by the physician. Such directions assume an understanding on the part of the patient that may not be realized and inappropriately exclude the pharmacist from the pharmaceutical care process. Such directions can only be seen as inadequate by the pharmacist, who must determine the intent of the physi-

Superscription	Date: <u>10/01/05</u>	DEA #: _____

Figure AI-1. The prescription. The prescription must be carefully prepared to identify the patient and the medication to be dispensed, as well as the manner in which the drug is to be administered. Accuracy and legibility are essential. Use of abbreviations, particularly Latin, is discouraged, as it leads to dispensing errors. Inclusion of the purpose of the medication in the *subscription* (e.g., “for control of blood pressure”) can prevent errors in dispensing. For example, the use of losartan for the treatment of hypertension may require 100 mg/day (1.4 mg/kg per day), whereas treatment of congestive heart failure with this angiotensin II-receptor antagonist should not generally exceed 50 mg/day. Including the purpose of the prescription can also assist patients in organizing and understanding their medications. Including the patient’s weight on the prescription can be useful in avoiding dosing errors, particularly when drugs are administered to children.

cian before dispensing the medication, and who shares the responsibility for safe and proper use of the medication by the patient. The best directions to the patient will include a reminder of the intended purpose of the medication by including such phrases as “for relief of pain,” or “to relieve itching.” The correct route of administration is reinforced by the choice of the first word of the directions. For an oral dosage form, the directions would begin with “take” or “give”; for externally applied products, the word “apply”; for suppositories, “insert”; and for eye, ear, or nose drops, “place” is preferable to “instill.”

Prescriptive Authority. In many states in the United States, health care practitioners other than M.D. and D.O. physicians can write prescriptions. Licensed physician’s

assistants (P.A.), nurse practitioners, and pharmacists can prescribe medications under various circumstances.

Avoiding Confusion. Units of measure can lead to confusion and medication errors. Older systems of measure such as minims for volume (15 minims = 1 ml) and grains for weight (1 grain = 60 mg) are obscure and should not be used. Doses always should be listed by metric weight of active ingredient; doses for liquid medications should include the volume. Writing “ μg ” for micrograms can very easily be misinterpreted as milligrams (mg). Thus, if abbreviated, micrograms should be written “mcg” and milligrams as “mg”; a zero should be used before a decimal (0.X mg, rather than .X mg) but not after (use X mg rather than X.0 mg). The metric system should be used in place of common household measurements such as “drop-

perful” and “teaspoon” in the directions for the patient, and both the doctor and the pharmacist should be sure that the patient understands the measurement prescribed. For medical purposes, a “teaspoon” or “teaspoonful” dose is considered to be equivalent to 5 ml and a “tablespoon” to 15 ml, but the actual volumes held by ordinary household teaspoons and tablespoons are far too variable to be used reliably for measurement of medications. Prescribing oral medications in “drops” likewise can cause problems when accuracy of dose is important unless the patient understands that only the calibrated dropper provided by the manufacturer or pharmacist should be used to dispense the medication. Thus, one possible dosage for a pediatric iron product would be more accurately written “15 mg (0.6 ml) three times daily” instead of “one dropperful three times daily,” because a true dropperful could result in iron overdose.

Abbreviations are known to lead to dispensing errors (Teichman and Caffee, 2002). A prescription intending every-other-day dosing (qod) may be miswritten as “od” by the physician for “other-day dosing”; the pharmacist will interpret “od” as the abbreviation of the Latin for “right eye.” Once-daily dosing at bedtime (qhs) may be misinterpreted as “qhr” for every hour. The use of slash marks (/) to separate names and doses can result in the incorrect drug or dose being dispensed; the slash mark may be interpreted as a letter or number. When medications are measured in units, or international units, the abbreviation “U” or “IU” must NOT be used, as it leads to errors such as misinterpretation of “U” as zero or four, or “IU” as 10 or 14. The word “unit” should be written as such. Drug products available in the United States that are dosed in units (e.g., *corticotropin*) or international unit measures are “harmonized” by those responsible for drug standardization to avoid errors in dosing (see Drug Standards and Classification, below). Examples of confusion in the interpretation of a physician order abound (Kohn, 2001) and are considered further below. *The critical message is that practitioners in the United States must write out the Rx fully in English if errors are to be avoided.*

Proper Patient Information. The patient’s name and address are needed on the order to assure that the correct medication goes to the correct patient and also for identification and recordkeeping purposes. For medications whose dosage involves a calculation, a patient’s pertinent factors such as weight, age, or body surface area also should be listed on the prescription.

Prescribers often commit errors in dosage calculations (Lesar *et al.*, 1997) that can be prevented (Kuperman *et al.*, 2001). When prescribing a drug whose dosage

involves a calculation based on body weight or surface area, it is good practice to include both the calculated dose and the dosage formula used, such as “240 mg every 8 hours (40 mg/kg per day)” to allow another health care professional to double-check the prescribed dosage. Pharmacists always should recalculate dosage equations when filling these prescriptions. Medication orders in hospitals and some clinic settings, such as those for antibiotics or antiseizure medications that are sometimes difficult to adequately dose (e.g., *phenytoin*), can specify the patient diagnosis and desired drug and request dosing by the clinical pharmacist.

All prescriptions should be written in ink; this practice is compulsory for schedule II prescriptions under the Controlled Substances Act of 1970, as erasures on a prescription easily can lead to dispensing errors or diversion of controlled substances.

Prescription pad blanks normally are imprinted with a heading that gives the name of the physician and the address and phone number of the practice site (Figure AI-1). When using institutional blanks that do not bear the physician’s information, the physician always should print his or her name and phone number on the face of the prescription to clearly identify the prescriber and facilitate communication with other health care professionals if questions arise. United States law requires that prescriptions for controlled substances include the name, address, and Drug Enforcement Agency (DEA) registration number of the physician.

The date of the prescription is an important part of the patient’s medical record, and it can assist the pharmacist in recognizing potential problems. For example, when an opioid is prescribed for pain due to an injury, and the prescription is presented to a pharmacist 2 weeks after issuance, the drug may no longer be indicated. Compliance behavior also can be estimated using the dates when a prescription is filled and refilled. The United States Controlled Substances Act requires that all orders for controlled substances (Table AI-1) be dated as of, and signed on, the day issued, and prohibits filling or refilling orders for substances in schedules III and IV more than 6 months after their date of issuance. When writing the original prescription, the physician should designate the number of refills he or she wishes the patient to have. For maintenance medications without abuse potential, it is reasonable to write for a 1-month supply and to mark the prescription form for refills to be dispensed over a period sufficient to supply the patient until the next scheduled visit to the physician. A statement such as “refill prn” (refill as needed) is not appropriate, as it could allow the patient to misuse the medicine or neglect medical appointments. If no refills are

Table AI-1
Controlled Substance Schedules

Schedule I (examples: heroin, methylene dioxymethamphetamine, lysergic acid diethylamide, mescaline, and all salts and isomers thereof):

1. High potential for abuse.
2. No accepted medical use in the United States or lacks accepted safety for use in treatment in the United States. May be used for research purposes by properly registered individuals.

Schedule II (examples: morphine, oxycodone, fentanyl, meperidine, dextroamphetamine, cocaine, amobarbital):

1. High potential for abuse.
2. Has a currently accepted medical use in the United States.
3. Abuse of substance may lead to severe psychological or physical dependence.

Schedule III (examples: anabolic steroids, nalorphine, ketamine, certain schedule II substances in suppositories, mixtures, or limited amounts per dosage unit):

1. Abuse potential less than substances in schedule I or schedule II.
2. Has a currently accepted medical use in the United States.
3. Abuse of substance may lead to moderate or low physical dependence or high psychological dependence.

Schedule IV (examples: alprazolam, phenobarbital, meprobamate, modafinil):

1. Abuse potential less than substances in schedule III.
2. Has a currently accepted medical use in the United States.
3. Abuse of substance may lead to limited physical or psychological dependence relative to substances in schedule III.

Schedule V (examples: buprenorphine, products containing a low dose of an opioid plus a nonnarcotic ingredient such as codeine and guaifenesin cough syrup or diphenoxylate and atropine tablets):

1. Low potential for abuse relative to schedule IV.
2. Has a currently accepted medical use in the United States.
3. Some schedule V products may be sold in limited amounts without a prescription at the discretion of the pharmacist; however, if a physician wishes a patient to receive one of these products, it is preferable to provide a prescription.

desired, “zero” (not 0) should be written in the refill space to prevent alteration of the doctor’s intent. Refills for controlled substances are discussed below.

Concern about the rising cost of health care has favored the dispensing of so-called “generic” drugs. A drug is called by its generic name (in the United States this is the U.S. Adopted Name or USAN) or the manufacturer’s proprietary name, called the trademark, trade name, or brand name. In most states in the United States, pharmacists have the authority to dispense generic drugs rather than brand name medications. The physician can request that the pharmacist not substitute a generic for a branded medication by indicating this on the prescription (“do not substitute”), although this is generally unnecessary since the FDA requires that generic medications meet the same bioequivalence standards as their brand-named counterparts. In some jurisdictions, prescriptions may not be filled with a generic substitution unless specifically permitted as stated on the prescription. Occasions when substituting generic medications is discouraged are limited to products with specialized release systems and narrow therapeutic indices, or when substantial patient confusion and potential noncompliance may be associated with substitution.

Choice of Drug Product. Inappropriate choice of drugs by physicians has been noted as a problem in prescribing. As learned recently with the cyclooxygenase 2 inhibitors, it cannot be assumed that a drug’s therapeutic promise or popularity is proof of its overall clinical superiority or safety (Topol, 2004). Physicians must rely on unbiased sources when seeking drug information that will influence their prescribing habits.

The amount to be dispensed should be clearly stated and should be only that needed by the patient. Excessive amounts should never be dispensed, as this is not only expensive to the patient, but may lead to accumulation of medicines, which can lead to harm to the patient or members of the patient’s family. It is far better to have several refills of a prescription than to have more than necessary prescribed at one time.

The Prescription as a Commodity. Prescribers must be aware that patients may visit their doctor to “get” a prescription. Indeed, in an era when the time spent between physician and patient is ever shorter due to limits and pressures of physician reimbursements, patients often feel that a trip to the doctor that does not result in a new prescription is somehow a failed visit or a lost opportunity. Similarly, physicians may feel that they have fulfilled their role if the patient leaves with a prescription. Physicians must be careful to educate their patients about the

importance of viewing medicines as only to be used when really needed and that remaining on a particular medicine when their condition is stable is far preferable to seeking the newest medications available.

Prescription Drug Advertising. The Federal Food, Drug, and Cosmetic Act as amended (Federal Food and Drug Administration Modernization Act of 1997) permits the use of print and television advertising of prescription drugs. The same statute and regulations apply regardless of the audience targeted by a prescription drug advertisement. The law requires that all drug advertisements contain (among other things) information in a brief summary relating to side effects, contraindications, and effectiveness. The current advertising regulations specify that this information disclosure needs to include all the risk information in a product's approved labeling or must direct consumers to health care professionals to obtain this information. (Typically, print advertisements will include a reprinting of the risk-related sections of the product's approved labeling [package insert], while television advertising will not.) In addition, advertisements cannot be false or misleading or omit material facts. They also must present a fair balance between effectiveness and risk information. It may be that the dramatizations employed by television commercials are a disservice to the physician's ability to educate and care for the patient if such advertisements only create brand loyalty. Alternatively, patients who learn about drugs on television may interact more effectively with their health care providers by asking questions about the medicines they take.

The benefits of these types of direct-to-consumer (DTC) advertising, including internet advertising, are controversial (Findlay, 2001). Prescription drug advertising has alerted consumers to the existence of new drugs and the conditions they treat, but it has also increased consumer demand for drugs. This demand has increased the number of prescriptions being dispensed (raising sales revenues) and has contributed to the higher pharmaceutical costs borne by health insurers, government, and consumers. In the face of a growing demand for particular brand name drugs driven by advertising, physicians and pharmacists must be able to counsel patients effectively and provide evidence-based drug information to their patients.

ERRORS IN DRUG ORDERS

The Institute of Medicine (IOM) estimates that the number of medical errors in the United States annually that result in death is between 44,000 and 98,000 (Kohn *et al.*,

1999). While there is some controversy about the IOM's estimates (Sox and Woloshin, 2000), it is clear that the large number of medical errors includes medication errors resulting in adverse events, including death (Mangino, 2004). Databases of anonymously reported errors are maintained jointly by the Institute for Safe Medication Practices (ISMP), the United States Pharmacopeia Medication Errors Reporting Program (USP MERP), and the FDA's MedWatch program. Adverse drug events occur in approximately 3% of hospitalizations, and this number is larger for special populations such as those in pediatric and neonatal intensive care units (Mangino, 2004).

By examining aspects of prescription writing that can cause errors and by modifying prescribing habits accordingly, the physician can improve the chance that the patient will receive the correct prescription, whether in a hospital or an outpatient setting. By being alert to common problems that can occur with medication orders, and communicating with the patient's physician, pharmacists and other healthcare professionals can assist in reducing medication errors. Areas of particular concern in the preparation of medication orders in both the institutional and outpatient settings can be summarized as follows:

- All orders should be written using metric measurements of weight and volume.
- Arabic (decimal) numerals are preferable to Roman numerals, and in some instances it is preferable for numbers to be spelled out.
- Use leading zeros (0.125 mg, not .125 mg); never use trailing zeros (5 mg, not 5.0 mg).
- Avoid abbreviating drug names since this leads to numerous errors due to sound-alike names. For instance, NEUMEGA, an interleukin-11 product abbreviated IL-11, can be dispensed as PROLEUKIN, an interleukin-2 derivative, if Roman rather than Arabic numerals are used.
- Avoid abbreviating directions for drug administration; write directions out clearly in English.
- Some drug names sound alike when spoken and may look alike when spelled out. The United States Pharmacopeial Convention Medication Error Reporting Program maintains a current list of drug names that can be confused (<http://www.usp.org>). The list of alliterative drug names currently contains over 750 pairs of potentially confusing names that could lead to prescribing or dispensing errors harmful to patients. The alliterative drug names can be particularly problematic when giving verbal orders to pharmacists or other healthcare providers.
- The single most important measure to prevent dispensing errors based on sound-alike or look-alike drug names is for the physician to provide the patient's diag-

nosis on the prescription order. For instance, an order for administration of *magnesium sulfate* must not be abbreviated “MS,” as this may result in administration of morphine sulfate. Including the therapeutic purpose and/or the patient’s diagnosis can prevent this error.

- Poor handwriting is a well-known and preventable cause of dispensing errors. Both physician and pharmacist share in the responsibility to prevent adverse drug events by writing prescriptions clearly and questioning intent whenever an order is ambiguous or potentially ambiguous.

CONTROLLED SUBSTANCES

The Drug Enforcement Agency (DEA), an agency in the Department of Justice, is responsible for the enforcement of the Federal Controlled Substances Act (CSA). The DEA regulates each step of the handling of controlled substances from manufacture to dispensing. The act provides a system that is intended to prevent diversion of controlled substances from legitimate uses. State agencies may impose additional regulations such as requiring that prescriptions for controlled substances be printed on triplicate or state-issued prescription pads or restricting the use of a particular class of drugs for specific indications. The most stringent law always takes precedence, whether it is federal, state, or local. Substances that come under the jurisdiction of the CSA are divided into five schedules (Table AI-1), but practitioners should note that individual states may have additional schedules. Criminal offenses and penalties for misuse generally depend on the schedule of a substance as well as the amount of drug in question.

Physicians must be authorized to prescribe controlled substances by the jurisdiction in which they are licensed and they must be registered with the DEA or exempted from registration as defined under the CSA. The number on the certificate of registration must be indicated on all prescription orders for controlled substances.

Prescription Orders for Controlled Substances. To be valid, a prescription for a controlled substance must be issued for a *legitimate medical purpose* by an *individual practitioner* acting in the *usual course of his or her professional practice*. An order that does not meet these criteria, such as a prescription issued as a means to obtain controlled substances for the doctor’s office use or to maintain addicted individuals is not considered a legitimate prescription within the meaning of the law, and thus does not protect either the physician who issued it or the

pharmacist who dispensed it. Most states prohibit physicians from prescribing controlled substances for themselves; it is prudent to comply with this guideline even if it is not mandated by law.

Execution of the Order. Prescriptions for controlled substances should be dated and signed on the day of their issuance and must bear the full name and address of the patient and the printed name, address, and DEA number of the practitioner and should be signed the way one would sign a legal document. Preprinted orders are not allowed in most states, and presigned blanks are prohibited by federal law. When oral orders are not permitted (schedule II), the prescription must be written with ink or typewritten. The order may be prepared by a member of the physician’s staff, but the prescriber is responsible for the signature and any errors that the order may contain.

Oral Order. Prescriptions for schedule III, IV, and V medications may be telephoned to a pharmacy by a physician or by trusted staff in the same manner as a prescription for a noncontrolled substance, although it is in the physician’s best interest to keep his or her DEA number as private as reasonably possible (*see Preventing Diversion*, below). Schedule II prescriptions may be telephoned to a pharmacy only in *emergency* situations. To be an emergency: (1) immediate administration is necessary; (2) no appropriate alternative treatment is available; and (3) it is not reasonably possible for the physician to provide a written prescription prior to the dispensing.

For an emergency prescription, the quantity must be limited to the amount adequate to treat the patient during the emergency period, and the physician must have a written prescription delivered to the pharmacy for that emergency within 72 hours. If mailed, the prescription must be postmarked within 72 hours. The pharmacist must notify the DEA if this prescription is not received.

Refills. No prescription order for a schedule II drug may be refilled under any circumstance. For schedule III and IV drugs, refills may be issued either orally or in writing, not to exceed five refills or 6 months after the issue date, whichever comes first. Beyond this time, a new prescription must be ordered. For schedule V drugs, no restrictions are placed on the number of refills allowed, but if no refills are noted at the time of issuance, a new prescription must be made for additional drug to be dispensed.

Preventing Diversion. Prescription blanks often are stolen and used to sustain abuse of controlled substances and to divert legitimate drug products to the illicit mar-

ket. To prevent this type of diversion, prescription pads should be protected in the same manner as one would protect a personal checkbook. A prescription blank should never be presigned for a staff member to fill in at a later time. Also, a minimum number of pads should be stocked, and they should be kept in a locked, secure location except when in use. If a pad or prescription is missing, it should be reported immediately to local authorities and pharmacies; some areas have systems in place to allow the rapid dissemination of such information. Ideally, the physician's full DEA number should not be preprinted on the prescription pad, because most prescriptions will not be for controlled substances and will not require the registration number, and anyone in possession of a valid DEA number may find it easier to commit prescription fraud. Some physicians may intentionally omit part or all of their DEA number on a prescription and instead write "pharmacist call to verify" or "call for registration number." This practice works only when the pharmacist may independently verify the authenticity of the prescription, and patients must be advised to fill the prescription during the prescriber's office hours. Pharmacists can ascertain the likely authenticity of a physician's DEA number using an algorithm.

Another method employed by the drug-seeker is to alter the face of a valid prescription to increase the number of units or refills. By spelling out the number of units and refills authorized instead of giving numerals, the prescriber essentially removes this option for diversion. Controlled substances should not be prescribed excessively or for prolonged periods, as the continuance of a patient's addiction is not a legitimate medical purpose.

DRUG STANDARDS AND CLASSIFICATION

The United States Pharmacopeial Convention, Inc. is a nongovernmental organization that promotes the public health and benefits practitioners and patients by disseminating authoritative standards and information on medicines and other health care technologies. This organization is home to the United States Pharmacopeia (USP), which together with the FDA, the pharmaceutical industry, and health professions, establishes authoritative drug standards. These standards are enforceable by the FDA and the governments of other countries, and are recognized worldwide. Drug monographs are published in the USP/National Formulary (USP-NF), the official drug

standards compendia that organize drugs into categories based on pharmacological actions and therapeutic uses. The USP also provides chemical reference standards to carry out the tests specified in the USP-NF. For example, a drug to be manufactured and labeled in units must comply with the USP standard for units of that compound. Such standards are essential for agents possessing biological activity such as insulin.

The USP is also home to the USAN (The USP Dictionary of *U.S. Adopted Names* and International Drug Names). This compendium is recognized throughout the healthcare industry as the authoritative dictionary of drugs. Entries include one or more of the following: U.S. Adopted Names, official drug names for the NF (National Formulary), previously used official names, international and nonproprietary names, British Approved Names, Japanese Approved Names, trade names, and other synonyms. In addition to names, the records in this file contain other substance information such as Chemical Abstract Society (CAS), Registry Number (RN), molecular formula, molecular weight, pharmacological and/or therapeutic category, drug sponsor, reference information, and structure diagram, if available. The USP maintains an electronic Web site that can be accessed for useful drug naming, classification, and standards information (<http://www.usp.org>).

In the United States, drug products are also coded under the National Drug Code. The NDC System was originally established as an essential part of out-of-hospital drug reimbursement under Medicare. In the United States, the NDC serves as a universal product identifier for drugs used in humans. The current edition of the National Drug Code Directory is limited to prescription drugs and a few selected over-the-counter products. Each drug product listed under the Federal Food, Drug, and Cosmetic Act is assigned a unique 10-digit, 3-segment number. This number, known as the National Drug Code (NDC) number, identifies the labeler/vendor, product, and package size. The labeler code is assigned by the FDA. The second segment, the product code, identifies a specific strength, dosage form, and formulation for a particular drug company. The third segment, the package code, identifies package sizes. Both the product and package codes are assigned by the manufacturer.

In addition to classification of drugs by therapeutic category, drugs are also grouped by control schedule. Drug schedules in the United States are listed in Table AI-1 from schedule I to schedule V, and are discussed above as controlled substances. Drugs are also grouped by their potential for misuse under British and United Nations legal classifications as class A, B, or C. The classes are

linked to maximum legal penalties in a descending order of severity, from A to C.

COMPLIANCE

Compliance may be defined as the extent to which the patient follows a regimen prescribed by a healthcare professional. The assumption that the doctor tells the patient what to do and then the patient meticulously follows orders is unrealistic. It must be recognized that the patient is the final and most important determinant of how successful a therapeutic regimen will be and should be engaged as an active participant who has a vested interest in its success. Whatever term is used—*compliance*, *adherence*, *therapeutic alliance*, or *concordance*—physicians must promote a collaborative interaction between doctor and patient in which each brings an expertise that helps to determine the course of therapy. The doctor is the medical expert; the patient is the expert on himself and his beliefs, values, and lifestyle. The patient's quality-of-life beliefs may differ from the clinician's therapeutic goals, and the patient will have the last word every time when there is an unresolved conflict.

Even the most carefully prepared prescription for the ideal therapy will be useless if the patient's level of compliance is not adequate. Noncompliance may be manifest in drug therapy as intentional or accidental errors in dosage or schedule, overuse, underuse, early termination of therapy, or not having a prescription filled (Hagstrom *et al.*, 2004). Therapeutic failures can result from patient noncompliance (Hobbs, 2004). Noncompliance always should be considered in evaluating potential causes of inconsistent or nonexistent response to therapy.

The reported incidence of patient noncompliance varies widely but is usually in the range of 30% to 60% (Zyzanski and Coyne, 2000); the rate for long-term regimens is approximately 50% and tends to increase over time (Sackett and Snow, 1979). Although they complain about the illogical nature of their patients' noncompliance, healthcare professionals seem to have as much difficulty as the rest of the population in following health-related orders (Michalsen *et al.*, 1997).

Direct costs associated with noncompliance have been estimated at \$8.5 to \$50 billion. Hundreds of variables have been identified that may influence compliance behavior in a specific patient or condition. A few of the most frequently cited are discussed here along with some suggestions for improving compliance, although none provides 100% compliance (Table AI-2).

Table AI-2

Suggestions for Improving Patient Compliance

- Provide respectful communication; ask patient how they take medicine.
- Develop satisfactory, collaborative relationship between doctor and patient; encourage pharmacist involvement.
- Provide and encourage use of medication counseling.
- Give precise, clear instructions, with most important information given first.
- Support oral instructions with easy-to-read written information.
- Simplify whenever possible.
- Use mechanical compliance aids as needed (sectioned pill boxes or trays, compliance packaging, color-coding).
- Use optimal dosage form and schedule for the individual patient.
- Assess patient's literacy and comprehension and modify educational counseling as needed. Don't rely on patient knowledge about his or her disease, alone, to improve compliance.
- Find solutions when physical or sensory disabilities are present (use nonsafety caps on bottles, use large type on labels and written material, place tape marks on syringes).
- Enlist support and assistance from family or caregivers.
- Use behavioral techniques such as goal setting, self-monitoring, cognitive restructuring, skills training, contracts, and positive reinforcement.

SOURCE: Table based upon suggestions by DiMatteo, 1995; Feldman and DeTullio, 1994; Kehoe and Katz, 1998; Martin and Mead, 1982; Meichenbaum and Turk, 1987; and Salzman, 1995.

The Patient-Provider Relationship. Patient satisfaction with the physician has a significant impact on compliance behavior and is one of few factors that the physician can directly influence. Patients are more likely to follow instructions and recommendations when their expectations for the patient-provider relationship and for their treatment are met. These expectations include not only clinical but also interpersonal competence, so cultivating good interpersonal and communication skills is essential.

When deciding upon a course of therapy, it can be useful to discuss a patient's habits and daily routine as well as the therapeutic options with the patient. This information can help suggest cues for remembrance, such as storing a once-daily medicine atop the books on the bedside

table for a patient who reads nightly, or in the cabinet with the coffee cups if it is to be taken in the morning (noting that the bathroom can be the worst place to store a medication in terms of its physical and chemical preservation). The information also can help tailor the regimen to the patient's lifestyle. A lack of information about a patient's lifestyle can lead to situations such as prescribing a medication to be taken with meals three times daily for a patient who only eats twice a day or who works a night shift and sleeps during the day. Rarely is there only one treatment option for a given problem, and it may be better to prescribe an adequate regimen that the patient will follow instead of an ideal regimen that the patient will not. Involving patients in the control of any appropriate aspects of their therapy may improve compliance, not only by aiding memory and making the dosage form or schedule more agreeable or convenient, but also by giving patients a feeling of empowerment and emphasizing their responsibility for the treatment outcome.

It is not unreasonable for the physician to ask the patient whether he or she intends to adhere to the prescribed therapy and to negotiate to get a commitment to do so. Attempts should be made to resolve collaboratively any conflicts that may hinder compliance.

Patients and Their Beliefs. Behavioral models suggest that patients are more likely to be compliant when they *perceive* that they are susceptible to the disease, that the disease may have serious negative impact, that the therapy will be effective, that the benefits outweigh the costs, and they believe in their own efficacy to execute the therapy. From the standpoint of compliance, the *actual* severity of and susceptibility to an illness is not necessarily an issue; rather, the patient's perception of severity affects compliance (Buckalew and Buckalew, 1995). Education of the patient about his or her condition alone will not improve compliance (Sackett *et al.*, 1975).

Patients' beliefs can lead them to deliberately alter their therapy, whether for convenience, personal experiments, a desire to remove themselves from the sick role, a means to exercise a feeling of control over their situation, or other reasons. This reinforces the need for excellent communication and a good patient-provider relationship to facilitate the provision of additional or corrective education when the beliefs would suggest poor compliance as an outcome.

It is difficult to predict whether a particular patient will be compliant, as there is no consistent relationship with isolated demographic variables such as age, sex, education level, intelligence, personality traits, and income. Certain of these variables have been implicated in specific

situations, but they cannot be applied to the population as a whole. Social isolation generally has been found to be associated with poor compliance, although family members or other people close to the patient can undermine compliance as easily as support it. As noted above, the actual severity of the patient's disease is not predictive of compliance behavior, but characteristics of the disease can make adherence less likely, as with certain neurodegenerative or psychiatric illnesses.

Pharmacists have a legal and professional responsibility to offer medication counseling in many situations—even though practice environments are not always conducive to its provision—and can educate and support patients by discussing prescribed medications and their use. Because they often see the patient more frequently than does the physician, pharmacists who take the time to inquire about a patient's therapy can help identify compliance and other problems and notify the physician as appropriate.

Elderly patients often face a number of barriers to compliance related to their age. Such barriers include increased forgetfulness and confusion; altered drug disposition and higher sensitivity to some drug effects; decreased social and financial support; decreased dexterity, mobility, or sensory abilities; and an increased number of concurrent medicines used (both prescription and over-the-counter), whose attendant toxicities and interactions may cause decreased mental alertness or intolerable side effects. There are drugs known to be inappropriate to prescribe to elderly patients (Curtis *et al.*, 2004; Fick *et al.*, 2003) and some that may adversely impact compliance. Despite these obstacles, evidence does not show that elderly patients in general are significantly more noncompliant than any other age group. Still, the United States population is aging, and elderly patients consume a disproportionate amount of medicines and health care resources, so there is great opportunity and motivation to improve their drug-taking habits. Physicians must be careful in choosing medications for the elderly (Fick *et al.*, 2003); pharmacists must pay particular attention to thorough and compassionate counseling for elderly patients and should assist patients in finding practical solutions when problems, such as polypharmacy, are noted.

The Therapy. Increased complexity and duration of therapy are perhaps the best-documented barriers to compliance. The patient for whom multiple drugs are prescribed for a given disease or who has multiple illnesses that require drug therapy will be at higher risk for non-compliance, as will the patient whose disease is chronic.

The frequency of dosing of individual medications also can affect compliance behavior. Simplification, whenever possible and appropriate, is desirable.

The effects of the medication can make adherence less likely, as in the case of patients whose medicines cause confusion or other altered mental states. Unpleasant side effects from the medicine may influence compliance in some patients but are not necessarily predictive, especially if patient beliefs or other positive factors would tend to reinforce adherence to the regimen. A side effect that is intolerable to one patient may be of minor concern to another.

For most patients the cost of the medicine does not appear to be a major determinant of compliance (Buckalew and Buckalew, 1995), and even receiving free medicine does not guarantee clinically adequate adherence (Chisholm *et al.*, 2000). However, the cost of medicine can be a heavy burden for patients with limited economic resources, and health care providers should be sensitive to this fact. While physicians often state that drug cost is an important factor in prescribing, their actual knowledge about prices is generally low (Reichert *et al.*, 2000), even for products that they commonly prescribe (Hoffman *et al.*, 1995). The availability of this information on hand-held medical PDAs (personal digital assistants) and from dispensing pharmacists now makes it convenient for physicians to include cost as a factor and to permit appropriate generic substitution when choosing therapy for their patients. A number of other useful sources of drug information are detailed in Chapter 5.

DESIGN AND OPTIMIZATION OF DOSAGE REGIMENS: PHARMACOKINETIC DATA

Kenneth E. Thummel, Danny D. Shen, Nina Isoherranen, Helen E. Smith

This appendix provides a summary of basic pharmacokinetic information pertaining to drugs that are in common clinical use and are delivered to the systemic circulation by parenteral or nonparenteral administration. Drugs designed exclusively for topical administration and those that are not significantly absorbed into the bloodstream (e.g., ophthalmic and some dermal applications) are not included (see Chapters 62 and 63). Pharmacokinetic data for many older drugs not included in this appendix can be found in earlier editions of this book.

A major objective of this appendix is to present pharmacokinetic data in a format that informs the clinician of the essential characteristics of drug disposition that form the basis of drug-dosage regimen design. Table A-II-1 contains quantitative information about the absorption, distribution, and elimination of drugs and the effects of disease states on these processes as well as information about the correlation of efficacy and toxicity with drug concentrations in blood/plasma. The general principles that underlie the design of appropriate maintenance dose and dosing interval (and, where appropriate, the loading dose) for the average patient are described in Chapter 1. Their application using the data in Table A-II-1 for individualization of dosage regimens is presented here.

To use the data that are presented, one must understand clearance concepts and their application to drug-dosage regimens. One also must know average values of clearance as well as some measures of the extent and kinetics of drug absorption and distribution. The text below defines the eight basic parameters that are listed in the tabular material for each drug and key factors that influence these values both in normal subjects and in patients with renal or liver disease. It obviously would be more straightforward if there were a consensus on a standard

value for a given pharmacokinetic parameter; instead, literature estimates usually vary over a wide range, and a consensus set of pharmacokinetic values has been reached for only a limited number of drugs.

In Table A-II-1, a single set of values for each parameter and its variability in a relevant population has been selected from the literature, based on the scientific judgment of the authors. Most data are in the form of a study population mean value ± 1 standard deviation. However, some data are presented as mean and range of values (in parentheses) observed for the study population, *i.e.*, the lowest and highest value reported. There are times when data are reported as a geometric mean with 95% confidence interval. If sufficient data were available, we present a range of mean values obtained from different studies of similar design in parentheses, sometimes below the primary study data. Occasionally, only a single mean value for the study population was available in the literature and is reported as such. Finally, some drugs can be administered intravenously in an unmodified form and orally as a prodrug. When relevant information about both the prodrug and the active molecule are needed, we have included both, using an abbreviation to indicate the species that was measured, followed by another abbreviation in parentheses to indicate the species that was dosed (e.g., G (V) indicates a parameter for ganciclovir after valganciclovir administration).

A number of recently approved drugs are actually the active metabolite or stereoisomer of a previously marketed drug. For example, desloratidine is the *O*-desmethyl-metabolite of loratidine, and esomeprazole is the active *S*-enantiomer of omeprazole. Instead of presenting the pair of drugs in separate tables, only the more established or more commonly used drug is listed, and relevant information on its

alternate active form is presented in the same table. This approach has permitted us to include more drugs in the Appendix, hopefully without undue confusion. The only exception is with prednisone and prednisolone, which undergo inter-conversion in the body. We have also adopted this practice for inclusion of protein-based drugs (e.g., pegfilgrastim and darbepoetin) that have been modified to enhance the pharmacokinetic properties of the originally developed molecule.

Unless otherwise indicated in footnotes, data reported in the table are those determined in healthy adults. The direction of change for these values in particular disease states is noted below the average value. One or more references are provided for each of the established drugs, typically a paper or review on its clinical pharmacokinetics, which can then serve as a source for a broader range of papers for the interested reader. In some instances, we have relied on unpublished data provided by the drug sponsor in their package labeling.

TABULATED PHARMACOKINETIC PARAMETERS

Each of the eight parameters presented in Table A-II-1 has been discussed in detail in Chapter 1. The following discussion focuses on the format in which the values are presented as well as on factors (physiological or pathological) that influence the parameters.

Bioavailability. The extent of oral bioavailability is expressed as a percentage of the administered dose. This value represents the percent of administered dose that is available to the systemic circulation—the fraction of the oral dose that reaches the arterial blood in an active or prodrug form. *Fractional availability* (F), which appears elsewhere in this appendix, denotes the same parameter; this value varies from 0 to 1. Measures of both the *extent* and *rate* (see T_{\max}) of availability are presented in the table. The extent of availability is needed for the design of an oral dosage regimen to achieve a specific target blood concentration. Values for multiple routes of administration are provided, when appropriate and available. In most cases, the tabulated value represents an absolute oral bioavailability that has been determined from a comparison of area under the plasma drug concentration time curve between the oral dose and an intravenous reference dose. For those drugs where intravenous administration is not feasible, an approximate estimate of oral bioavailability based on secondary information (e.g., urinary excretion of unchanged drug) is presented, or the column is left blank

[denoted by a long dash (—)]. A dash will also appear when a drug is given by parenteral administration only.

A low bioavailability may result from a poorly formulated dosage form that fails to disintegrate or dissolve in the gastrointestinal fluids, degradative loss of drug in the gastrointestinal fluid, poor mucosal permeability, first-pass metabolism during transit through the intestinal epithelium, active efflux transport of drug back into the lumen, and first-pass hepatic metabolism or biliary excretion (see Chapter 1). In the case of drugs with extensive first-pass metabolism, hepatic disease may increase oral availability because hepatic metabolic capacity decreases and/or because vascular shunts develop around the liver.

Urinary Excretion of Unchanged Drug. The second parameter in Table A-II-1 is the amount of drug eventually excreted unchanged in the urine, expressed as a percentage of the administered dose. Values represent the percentage expected in a healthy young adult (creatinine clearance ≥ 100 ml/minute). When possible, the value listed is that determined after bolus intravenous administration of the drug, for which bioavailability is 100%. If the drug is given orally, this parameter may be underestimated due to incomplete absorption of the dose; such approximated values are indicated with a footnote. The parameter obtained after intravenous dosing is of greater utility because it reflects the relative contribution of renal clearance to total body clearance irrespective of bioavailability.

Renal disease is the primary factor that causes changes in this parameter. This is especially true when alternate pathways of elimination are available; thus, as renal function decreases, a greater fraction of the dose is available for elimination by other routes. Because renal function generally decreases as a function of age, the percentage of drug excreted unchanged also decreases with age when alternate pathways of elimination are available. In addition, for a number of weakly acidic and basic drugs with pK_a values within the normal range for urine pH, changes in urine pH will affect their rate or extent of urinary excretion (see Chapter 1).

Binding to Plasma Proteins. The tabulated value is the percentage of drug in the plasma that is bound to plasma proteins at concentrations of the drug that are achieved clinically. In almost all cases, the values are from measurements performed *in vitro* (rather than from *ex vivo* measurements of binding to proteins in plasma obtained from patients to whom the drug had been administered). When a single mean value is presented, it signifies that there is no apparent change in percent bound over the range of plasma drug concentrations resulting from the usual clinical doses. In cases in which saturation of binding to plasma proteins is

approached within the therapeutic range of plasma drug concentrations, a range of bound percentages is provided for concentrations at the lower and upper limits of the range. For some drugs, there is disagreement in the literature about the extent of plasma protein binding; in those cases, the range of reported values is given.

Plasma protein binding is affected primarily by disease states, notably hepatic disease, renal failure, and inflammatory diseases, that alter the concentration of albumin, α_1 -acid glycoprotein, or other proteins in plasma that bind drugs. Uremia also changes the binding affinity of albumin for some drugs. Disease-induced changes in plasma protein binding can dramatically affect the volume of distribution, clearance, and elimination half-life of a drug.

Plasma Clearance. Total systemic clearance of drug from plasma or blood [see Equations (1–5) and (1–6), Chapter 1] is given in Table A–II–1. Clearance varies as a function of body size and, therefore, is presented most frequently in the table in units of $\text{ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$ of body weight. Normalization to measures of body size other than weight may at times be more appropriate, such as normalization to body surface area in infants to better reflect the growth and development of the liver and kidneys. However, weight is easy to obtain, and its use often offsets any small loss in accuracy of clearance estimate, especially in adults. Exceptions to this rule are the anticancer drugs, for which dosage normalization to body surface area is conventionally used. When unit conversion was necessary, we used individual or mean body weight or body surface area (when appropriate) from the cited study, or if this was not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m^2 for healthy adults.

In some cases, separate values for renal and nonrenal clearance also are provided. For some drugs, particularly those that are excreted predominantly unchanged in the urine, equations are given that relate total or renal clearance to creatinine clearance (also expressed as $\text{ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$). For drugs that exhibit saturation kinetics, K_m and V_{max} are given and represent, respectively, the plasma concentration at which half of the maximal rate of elimination is reached (in units of mass/volume) and the maximal rate of elimination (in units of $\text{mass} \cdot \text{time}^{-1} \cdot \text{kg}^{-1}$ of body weight). K_m must be in the same units as the concentration of drug in plasma (C_p).

Intrinsic clearance from blood is the maximal possible clearance by the organ responsible for elimination when blood flow (delivery) of drug is not limiting. When expressed in terms of unbound drug, intrinsic clearance reflects clearance from intracellular water.

Intrinsic clearance is tabulated for a few drugs. It is also mathematically related to the biochemical intrinsic clearance [$V_{\text{max}}/(K_m + C)$] determined *in vitro*. In almost all cases, clearances based on plasma concentration data are presented in Table A–II–1, because drug analysis is most often performed on plasma samples. The few exceptions where clearance from blood is presented are indicated by footnote. Clearance estimates based on blood concentration may be useful when a drug concentrates in the erythrocytes.

To be accurate, clearances must be determined after intravenous drug administration. When only nonparenteral data are available, the ratio of CL/F is given; values offset by the fraction availability (F) are indicated in a footnote. When a drug, or its active isomer for racemic compounds, is a substrate for a CYP or drug transporter, this information is provided in a footnote. This information is becoming increasingly important to understand pharmacokinetic variability due to genetic polymorphisms and to predict metabolically based drug-drug interactions. [For more extensive coverage of this topic, see Chapters 2, 3, and 4 and *Metabolic Drug Interactions*. (Levy, R.H., *et al.*, eds.) Lippincott Williams & Wilkins, Philadelphia, 2000.]

Volume of Distribution. The total body volume of distribution at steady state (V_{ss}) is given in Table A–II–1 and is expressed in units of l/kg or in units of l/m^2 for some anticancer drugs. Again, when unit conversion was necessary, we used individual or mean body weights or body surface area (when appropriate) from the cited study, or if such data were not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m^2 for healthy adults.

When estimates of V_{ss} were not available, values for V_{area} were provided. V_{area} represents the volume at equilibrated distribution during the terminal elimination phase (see Equation 1-12). Unlike V_{ss} , this volume term varies when drug elimination changes, even though there is no change in the distribution space. Because we may wish to know whether a particular disease state influences either the clearance or the tissue distribution of the drug, it is preferable to define volume in terms of V_{ss} , a parameter that is theoretically independent of changes in the rate of elimination. Occasionally, the condition under which the distribution volume was obtained was not specified in the primary reference; this is denoted by the absence of a subscript.

As with clearance, V_{ss} usually is defined in the table in terms of concentration in plasma rather than blood. Further, if data were not obtained after intravenous administration of the drug, a footnote will make clear that the

apparent volume estimate, V_{ss}/F , is offset by the fractional availability.

Half-Life. Half-life ($t_{1/2}$) is the time required for the plasma concentration to decline by one-half when elimination is first-order. It also governs the rate of approach to steady state and the degree of drug accumulation during multiple dosing or continuous infusion. For example, at a fixed dosing interval, the patient will be at 50% of steady state after one half-life, 75% of steady state after two half-lives, 93.75% of steady state after four half-lives, etc. Determination of half-life is straightforward when drug elimination follows a monoexponential pattern (*i.e.*, one-compartment model). However, for a number of drugs, plasma concentration follows a multiexponential pattern of decline over time. The mean value listed in Table A-II-1 corresponds to an effective rate of elimination that covers the clearance of a major fraction of the absorbed dose from the body. In many cases, this half-life refers to the rate of elimination in the terminal exponential phase. For a number of drugs, however, the half-life of an earlier phase is presented, even though a prolonged half-life may be observed at very low plasma concentrations when extremely sensitive analytical techniques are used. If the latter component accounts for 10% or less of the total area under the plasma concentration-time curve (*AUC*), predictions of drug accumulation in plasma during continuous or repetitive dosing will be in error by no more than 10% if this longer half-life is ignored. The clinician should know the half-life that will best predict drug accumulation in the patient, which will be the appropriate half-life to use for estimating the rate constant in Equations (1-19) through (1-21) (*see* Chapter 1) to predict time to steady state. It is this half-life of accumulation during multiple dosing that is given in Table A-II-1.

Half-life is usually independent of body size because it is a function of the ratio of two parameters, clearance and volume of distribution, each of which is proportional to body size. It should also be noted that the half-life is preferably obtained from intravenous studies, if feasible, because the half-life of decline in plasma drug concentration after oral dosing can be influenced by prolonged absorption, such as when slow release formulations are given. If the half-life is derived from an oral dose, this will be indicated in a footnote of Table A-II-1.

Time to Peak Concentration. Because clearance concepts are used most often in the design of multiple dosage regimens, the extent rather than the rate of availability is more critical to estimate the average steady-state concentration of drug in the body. In some circumstances, the degree of fluctuation in plasma drug concentration, *i.e.*, peak and trough concentrations, which govern drug effi-

cacy and side effects, can be greatly influenced by modulation of drug absorption rate through the use of sustained- or extended-release formulations. Controlled-release formulations often permit a reduction in dosing frequency from 3 or 4 times daily to once or twice daily. There also are drugs that are given on an acute basis, *e.g.*, for the relief of breakthrough pain or to induce sleep, for which the rate of drug absorption is a critical determinant of onset of effect. Thus, information about the expected average time to achieve maximal plasma or blood concentration and the degree of interindividual variability in that parameter have been included in Table A-II-1.

The time required to achieve a maximal concentration (T_{max}) depends on the rate of drug absorption into blood from the site of administration and the rate of elimination. From mass balance principles, T_{max} occurs when the rate of absorption equals the rate of elimination from the reference compartment. Prior to this time, absorption rate exceeds elimination rate, and the plasma concentration of drug increases. After the peak is reached, elimination rate exceeds the absorption rate and, at some point, defines the terminal elimination phase of the concentration-time profile.

The rate of drug absorption following oral administration will depend on the formulation and physicochemical properties of the drug, its permeability across the mucosal barrier, and the intestinal villous blood flow. For an oral dose, some absorption may occur very rapidly within the buccal cavity, esophagus, and stomach, or absorption may be delayed until the drug reaches the small intestine or until the local pH in the intestine permits drug release from the dosage formulation. In the most extreme case, the rate of absorption can be sufficiently controlled by the drug formulation to permit sustained or extended delivery as the dosage form traverses the entire length of the gastrointestinal tract. In some instances, the terminal elimination of drug from the body following a peak concentration reflects the slower rate of absorption and not elimination.

When more than one type of drug formulation is available commercially, we have provided absorption information for both the immediate- and sustained-release formulations. Not surprisingly, the presence of food in the gastrointestinal tract can alter both the rate and extent of drug availability. We have indicated with footnotes when the consumption of food near the time of drug ingestion may have a significant effect on the drug bioavailability.

Peak Concentration. There is no general agreement about the best way to describe the relationship between the concentration of drug in plasma and its effect. Many different kinds of data are present in the literature, and use of a single effect parameter or effective concentration is difficult. This is particularly true for antimicrobial agents

because the effective concentration depends on the identity of the microorganism causing the infection. It also is important to recognize that concentration-effect relationships are most easily obtained at steady state or during the terminal log-linear phase of the concentration-time curve, when the drug concentration(s) at the site(s) of action are expected to parallel those in plasma. Thus, when attempting to correlate a blood or plasma level to effect, the temporal aspect of distribution of drug to its site of action must be taken into account.

Despite these limitations, it is possible to define the minimum effective or toxic concentrations for some of the drugs currently in clinical use. However, in reviewing the list of drugs approved within the last five years, it is rare to find a declaration of an *effective concentration range*, even in the manufacturer's package labeling. Thus, it is necessary to infer therapeutic concentrations from concentrations observed following *effective dosage* regimens. For a given dosage regimen, a time-averaged steady-state blood or plasma concentration (*i.e.*, \bar{C}_{ss} as estimated by dividing the mean *AUC* by the duration of the dosing interval) and the associated interindividual variability might be one appropriate parameter to report; however, such data often are not available. Also, \bar{C}_{ss} does not take into account the onset and offset of effect during fluctuation of plasma drug concentration over a dosing interval. In some instances, drug efficacy may be more closely linked with peak concentration than with the average or trough concentration, and differences in peak concentration for special populations (*e.g.*, elderly) sometimes are associated with increased incidence of drug toxicity.

For practical reasons, the most commonly reported parameter, C_{max} (peak concentration), is presented in Table A-II-1, rather than effective or toxic concentrations. This provides a more consistent body of information about drug exposure from which one can infer, if appropriate, efficacious or toxic blood levels. While the value reported is the highest that would be encountered in a given dose interval, C_{max} can be related to the trough concentration (C_{min}) through appropriate mathematical predictions (*see* Equation 1-21). Because peak levels will vary with dose, we have attempted to present concentrations observed with a customary dose regimen that is recognized to be effective in the majority of patients. When a higher or lower dose rate is used, the expected peak level can be adjusted by assuming dose proportionality, unless nonlinear kinetics are indicated. In some instances, only limited data pertaining to multiple dosing are available, so single-dose peak concentrations are presented. When specific information is available about an effective therapeutic range of concentrations or about concentrations at

which toxicity occurs, it has been incorporated in a footnote. For individual drugs, the reader also is referred to the index to highlight pages where more detailed information is provided.

It is important to recognize that significant differences in C_{max} will occur when comparing similar daily-dose regimens for an immediate-release and sustained-release product. Indeed, the sustained-release product sometimes is administered to reduce peak-trough fluctuations during the dosing interval and to minimize swings between potentially toxic or ineffective drug concentrations. Again, we report C_{max} for both immediate-release and extended-release formulations, when available. In addition to parent drug concentrations, we have included information on any active metabolite that circulates at a concentration that may contribute to the overall pharmacological effect, particularly those active metabolites that accumulate with multiple dosing. Likewise, for chiral drugs whose stereoisomers differ in their pharmacological activity and clearance characteristics, we present information on the pharmacokinetics of the individual enantiomers or the active enantiomer that contributes most to the drug's efficacy.

Although total drug or metabolite concentrations are reported, it is important to recognize that the concentration of *unbound drug* often determines the degree of pharmacological effect. Accordingly, changes in protein binding due to disease may be expected to cause changes in the total plasma concentration associated with desired or unwanted effects. However, the clinical outcome is not always affected because an increase in free fraction will also increase the apparent clearance of an orally administered drug and of a low extraction drug dosed intravenously. Under such a scenario, the mean unbound plasma concentration at steady state will not change with reduced or elevated plasma protein binding, despite a significant change in mean total drug concentration.

ALTERATIONS OF PARAMETERS IN THE INDIVIDUAL PATIENT

Dose adjustments for an individual patient should be made according to the manufacturer's recommendation in the package labeling when available. This information is generally available when disease, age, or race has a significant impact on drug disposition, particularly for drugs that have been introduced within the last 10 years. In some cases, a significant difference in drug disposition from the "average" adult can be expected but may not

require dose adjustment because of a sufficiently broad therapeutic index. In other cases, dose adjustment may be necessary, but no specific information is available. Under these circumstances, an estimate of the appropriate dosing regimen can be obtained based on pharmacokinetic principles described in Chapter 1.

Unless otherwise specified, the values in Table A-II-2 represent mean values for populations of normal adults; it may be necessary to modify them for calculation of dosage regimens for individual patients. The fraction available (F) and clearance (CL) also must be estimated to compute a maintenance dose necessary to achieve a desired average steady-state concentration. To calculate the loading dose, knowledge of the volume of distribution is needed. The estimated half-life is used in deciding a dosing interval that provides an acceptable peak-trough fluctuation; note, this may be the apparent half-life following dosing of a slowly absorbed formulation. The values reported in the table and the adjustments apply only to adults; exceptions are footnoted. Although the values at times may be applied to children who weigh more than about 30 kg (after proper adjustment for size; *see* below), it is best to consult pediatrics textbooks or other sources for definitive advice.

For each drug, changes in the parameters caused by certain disease states are noted within the eight segments of the table. In all cases, the qualitative direction of changes is noted, such as “↓ LD,” which indicates a significant decrease in the parameter in a patient with liver disease. The relevant literature and the package label should be consulted for more definitive, quantitative information for dosage adjustment recommendations.

Plasma Protein Binding. Most acidic drugs that are extensively bound to plasma proteins are bound to albumin. Basic lipophilic drugs, such as propranolol, often bind to other plasma proteins (*e.g.*, α_1 -acid glycoprotein and lipoproteins). The degree of drug binding to proteins will differ in pathophysiological states that cause changes in plasma-protein concentrations. Significant pharmacokinetic effects from a change in plasma protein binding will be denoted under clearance or volume of distribution.

Clearance. For drugs that are partly or predominantly eliminated by renal excretion, plasma clearance changes in accordance with the renal function of an individual patient. This necessitates dosage adjustment that is dependent on the fraction of normal renal function remaining and the fraction of drug normally excreted unchanged in the urine. The latter quantity appears in the table; the former can be estimated as the ratio of the patient's creatinine clearance (CL_{cr}) to a normal value (100 ml/minute

per 70 kg body weight). If urinary creatinine clearance has not been measured, it may be estimated from the concentration of creatinine in serum (C_{cr}). In men:

$$CL_{cr}(\text{ml} \cdot \text{min}^{-1}) = \frac{[140 - \text{age}(\text{yr})] \cdot [\text{weight}(\text{kg})]}{72 \cdot [C_{cr}(\text{mg/dl})]} \quad (\text{A-1})$$

For women, the estimate of CL_{cr} by the above equation should be multiplied by 0.85 to reflect their smaller muscle mass. The fraction of normal renal function (rfx_{pt}) is estimated from the following:

$$rfx_{pt} = \frac{CL_{cr, pt}}{100 \text{ ml} \cdot \text{min}^{-1}} \quad (\text{A-2})$$

A more accurate measure of rfx_{pt} is seldom necessary because, given the considerable degree of interindividual variation in nonrenal clearance, the adjustment of clearance is an approximation. The following equation for adjustment of clearance uses the quantities discussed:

$$rf_{pt} = 1 - [fe_{nl} \cdot (1 - rfx_{pt})] \quad (\text{A-3})$$

where fe_{nl} is the fraction of systemic drug excreted unchanged in normal individuals (*see* Table A-II-1). The renal factor (rf_{pt}) is the value that, when multiplied by normal total clearance (CL_{nl}) from the table, gives the total clearance of the drug adjusted for the impairment in renal function.

Example. The clearance of vancomycin in a patient with reduced renal function (creatinine clearance = 25 ml/min per 70 kg) may be estimated as follows:

$$rfx_{pt} = \frac{25 \text{ ml/min}}{100 \text{ ml/min}} = 0.25$$

$$fe_{nl} = 0.79 \text{ (see listing for vancomycin)}$$

$$rf_{pt} = 1 - [0.79 \cdot (1 - 0.25)] = 0.41$$

$$CL_{pt} = (1.4 \text{ ml/minute per kg}) \cdot 0.41 \\ = 0.57 \text{ ml/minute per kg}$$

Importantly, such a clearance adjustment should be regarded only as an initial step in optimizing the dosage regimen; depending on the patient's response to the drug, further individualization may be necessary.

Conventionally, clearance is adjusted for the size of the patient to reflect a difference in the mass of the eliminating organ. For orally administered drugs, the applicability of such an adjustment may be limited by the available dosage strengths of commercial formulations. In some cases, scored tablets can be split or commercial tablet splitters are used to increase the range of available dosage strengths. However, this practice should be followed only with the recommendation of the drug manufacturer

because splitting a tablet sometimes can compromise the bioavailability of a product.

With the exception of certain oncolytic agents, the data presented in the table are normalized to weight. Thus, interindividual variability in the weight-normalized clearance reflects a variation in the intrinsic metabolic or transport clearance and not the size of the organ. Further, these differences can be attributed to variable expression/function of metabolic enzymes or transporters. However, it is important to recognize that liver mass and total enzyme/transporter content may not increase or decrease in proportion to weight in obese or malnourished individuals. Alternative approaches such as normalization by body surface area or other measures of body mass may be more appropriate. For example, many of the drugs used to treat cancer are dosed according to body surface area (*see* Chapter 51). In the tabulation, if the literature reported dose per body surface area, we present the data in the same unit. If the cited clearance data were not normalized, but the preponderance of the literature utilized body surface area, we followed the practice of using values of body surface area from the literature source or a standard of 1.73 m² for a healthy adult.

Volume of Distribution. Volume of distribution should be adjusted for the modifying factors indicated in Table A-II-1 as well as for body size. Again, the data in the table most often are normalized to weight. Unlike clearance, volume of distribution in an individual is most often proportional to weight itself. Whether this applies to a specific drug depends on the actual sites of distribution of drug; no absolute rule applies.

Whether or not to adjust volume of distribution for changes in binding to plasma proteins cannot be decided in general; the decision depends critically on whether or not the factors that alter binding to plasma proteins also alter binding to tissue proteins. Qualitative changes in volume of distribution, when they occur, are indicated in the table.

Half-Life. Half-life may be estimated from the adjusted values of clearance (CL_{pt}) and volume of distribution (V_{pt}) for the patient:

$$t_{1/2} = \frac{0.693 \cdot V_{pt}}{CL_{pt}} \quad (\text{A-4})$$

Because half-life has been the parameter most often measured and reported in the literature, qualitative changes for this parameter are almost always given in the table.

INDIVIDUALIZATION OF DOSAGE

By using the parameters for the individual patient, calculated as described above, initial dosing regimens may be chosen. The maintenance dosage rate may be calculated with Equation (1-18) using the estimated values for CL and F for the individual patient. As described above, the target concentration may have to be adjusted for changes in plasma protein binding in the patient, as described above. The loading dose may be calculated using Equation (1-22) and estimates for V_{ss} and F . A particular dosing interval may be chosen; the maximal and minimal steady-state concentrations can be calculated by using Equations (1-20) and [(1-19) or (1-21)], and these can be compared with the known efficacious and toxic concentrations for the drug. As with the target concentration, these values may need to be adjusted for changes in the extent of plasma protein binding. Use of Equations (1-19) and (1-20) also requires estimates of values for F , V_{ss} , and K ($K = 0.693/t_{1/2}$) for the individual patient.

Note that these adjustments of pharmacokinetic parameters for an individual patient are suggested for the rational choice of initial dosing regimen. As indicated in Chapter 1, steady-state measurement of drug concentrations in the patient then can be used as a guide to further adjust the dosage regimen. However, optimization of a dosage regimen for an individual patient ultimately will depend on the clinical response produced by the drug.

Table A-II-1 Pharmacokinetic Data

AVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE ($ml \cdot min^{-1} \cdot kg^{-1}$)	VOL. DIST. (liters/kg)	HALF-LIFE (hours)	PEAK TIME (hours)	PEAK CONCENTRATIONS
ACETAMINOPHEN^a (Chapter 26)

ARIPIPRAZOLE^a (Chapter 18)

87	<1	>99	0.83 ± 0.17 ^b	4.9 ^b	47 ± 10	3.0 ± 0.6 ^c	242 ± 36 ng/ml ^c
----	----	-----	--------------------------	------------------	---------	------------------------	-----------------------------

^aEliminated primarily by CYP2D6- and CYP3A4-dependent metabolism. The major metabolite, dehydro-aripiprazole, has affinity for D₂ receptors similar to parent drug; found at 40% of parent drug concentration in plasma; t_{1/2} is 94 hrs. CYP2D6 poor metabolizers exhibit increased exposure (80%) to parent drug but reduced exposure (30%) to the active metabolite. No significant gender differences. ^bCL/F and V/F at steady state reported. ^cFollowing a 15 mg oral dose given once daily for 14 days.

CARBAMAZEPINE^a (Chapter 19)

>70	<1	74 ± 3 ↔ RD, Cirr, Preg	13 ± 0.5 ^{b,c} ↑ Preg ↔ Child, Aged, Smk	1.4 ± 0.4 ^b ↔ Child, Neo, Aged	15 ± 5 ^{b,c} ↔ Child, Neo, Aged	4–8 ^d	9.3 (2–18) μg/ml ^d
-----	----	----------------------------	--	---	---	------------------	-------------------------------

^aA metabolite, carbamazepine-10,11-epoxide, is equipotent in animal studies. Its formation is catalyzed primarily by CYP3A and secondarily by CYP2C8. ^bData from oral, multiple-dose regimen; values are CL/F and V_{area}/F . ^cData from multiple-dose regimen. Carbamazepine induces its own metabolism; for a single dose, $CL/F = 0.36 \pm 0.07 \text{ ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$ and $t_{1/2} = 36 \pm 5$ hours. CL also increases with dose. ^dMean (range) steady-state concentration following a daily 18.4-mg/kg oral dose (immediate release) given to adult patients with epilepsy. Therapeutic range for control of psychomotor seizures is 4–10 μg/ml.

CHLORPHENIRAMINE^a (Chapter 24)

41 ± 16	0.3–26 ^b	70 ± 3	1.7 ± 0.1 ↑ Child	3.2 ± 0.3 ↔ Child	20 ± 5 ↓ Child	IR: 2–3 ^c SR: 5.7–8.1 ^c	IR: 16–71 ng/ml ^e SR: 17–76 ng/ml ^e
---------	---------------------	--------	----------------------	----------------------	-------------------	--	--

^aAdministered as a racemic mixture; reported parameters are for racemic drug. Activity comes predominantly from S-(+) enantiomer, which has a 60% longer $t_{1/2}$ than the R-(-) enantiomer. ^bRenal elimination increases with increased urine flow and lower pH. ^cRange of data from different studies following a 4 mg oral immediate release (IR) dose given every 4 to 6 hours to steady state or following an 8 mg oral sustained release (SR) dose given every 12 hours to steady state, both in healthy adults.

Reference: Rumore, M.M. Clinical pharmacokinetics of chlorpheniramine. *Drug Intell. Clin. Pharm.*, **1984**, 18:701–707.

CHLORPROMAZINE^a (Chapters 18, 37)

32 ± 19 ^b	<1	95–98 ↔ RD	8.6 ± 2.9 ^c ↓ Child ^d ↔ Cirr	21 ± 9 ^c	30 ± 7 ^c	1–4 ^e	25–150 ng/ml ^e
----------------------	----	---------------	--	---------------------	---------------------	------------------	---------------------------

^aActive metabolites, 7-hydroxychlorpromazine ($t_{1/2} = 25 \pm 15$ hours) and possibly chlorpromazine N-oxide, yield AUCs comparable to the parent drug (single doses). ^bAfter single dose. Bioavailability may decrease to about 20% with repeated dosing. ^cCL/F, V_{area} , and terminal $t_{1/2}$ following IM administration. ^dFollowing a 100 mg oral dose given twice a day for 33 days to adult patients. Neurotoxicity (tremors and convulsions) occurs at concentrations of 750–1000 ng/ml.

Reference: Dahl, S.G., and Strandjord, R.E. Pharmacokinetics of chlorpromazine after single and chronic dosage. *Clin. Pharmacol. Ther.*, **1977**, 21:437–448.

CHLORTHALIDONE (Chapter 28)

64 ± 10	65 ± 9 ^a	75 ± 1	0.04 ± 0.01 ↓ Aged	0.14 ± 0.07	47 ± 22 ^b ↑ Aged	13.8 ± 6.3 ^c	3.7 ± 0.9 µg/ml ^c
---------	---------------------	--------	-----------------------	-------------	--------------------------------	-------------------------	------------------------------

^aValue is for 50 and 100 mg doses; renal CL is decreased at an oral dose of 200 mg, and there is a concomitant decrease in the percentage excreted unchanged. ^bChlorthalidone is sequestered in erythrocytes. $t_{1/2}$ is longer if blood, rather than plasma, is analyzed. Parameters reported based on blood concentrations. ^cFollowing a single 50 mg oral dose (tablet) given to healthy male adults.

Reference: Williams, R.L., Blume, C.D., Lin, E.T., Holford, N.H., and Benet, L.Z. Relative bioavailability of chlorthalidone in humans: adverse influence of polyethylene glycol. *J. Pharm. Sci.*, **1982**, 71:533–535.

Pharmacokinet.*, **1989**, 16(suppl 1):5–24.

CISPLATIN^a (Chapter 51)

—	2.3 ± 9	— ^b	6.3 ± 1.2	0.28 ± 0.07	0.53 ± 0.10	—	2Hr: 3.4 ± 1.1 μg/ml ^c 7Hr: 1.0 ± 0.4 μg/ml ^c
---	---------	----------------	-----------	-------------	-------------	---	--

^aEarly studies measured total platinum, rather than the parent compound; values reported here are for parent drug in seven patients with ovarian cancer (mean CL_{cr} = 66 ± 27 ml/minute). ^bPlatinum will form a tight complex with plasma proteins (90%). ^cFollowing a single 100 mg/m² IV dose given as a ~2- or 7-hour infusion to ovarian cancer patients.

Reference: Reece, P.A., Stafford, I., Davy, M., and Freeman, S. Disposition of unchanged cisplatin in patients with ovarian cancer. *Clin. Pharmacol. Ther.*, **1987**, 42:320–325.

CITALOPRAM^a (Chapter 17)

Rac: 80 ± 13	Rac: 10.5 ± 1.4 Es: 8	Rac: 80 Es: 56	Rac: 4.3 ± 1.2 ^b Es: 8.8 ± 3.2 ^{b,c} ↓ Aged, LD ^d	Rac: 12.3 ± 2.3 Es: 15.4 ± 2.4 ^c	Rac: 33 ± 4 ^b Es: 22 ± 6 ^b ↑ Aged, LD ^d , RD ^e	Rac/Es: 4–5 ^f	Rac: 50 ± 9 ng/ml ^f Es: 21 ± 4 ng/ml ^f
--------------	--------------------------	-------------------	--	--	--	--------------------------	---

^aCitalopram is available either as a racemic mixture or as the pure active S-enantiomer escitalopram. Pharmacokinetic data after dosing of the racemate (Rac) and escitalopram (Es) are reported. No significant gender differences. Citalopram is metabolized by CYP2C19 (polymorphic) and CYP3A4 to desmethylcitalopram. ^bData from CYP2C19 extensive metabolizers. CYP2C19 poor metabolizers exhibit a lower (~44%) CL/F and longer $t_{1/2}$ than extensive metabolizers. ^c CL/F and V/F for escitalopram reported. ^dAlcoholic, viral, or biliary cirrhosis. ^eModerate renal impairment. ^fFollowing a single 40 mg (Rac) or 20 mg (Es) oral dose.

Table A-II-1 Pharmacokinetic Data (Continued)

AVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE ($ml \cdot min^{-1} \cdot kg^{-1}$)	VOL. DIST. (liters/kg)	HALF-LIFE (hours)	PEAK TIME (hours)	PEAK CONCENTRATIONS
CLARITHROMYCIN^a (Chapter 46)							
55 ± 8 ^b	36 ± 7 ^b ↔ Aged	42–50	7.3 ± 1.9 ^b ↓ Aged, RD ↔ Cirr	2.6 ± 0.5 ↔ Aged ↑ Cirr	3.3 ± 0.5 ^b ↑ Aged, RD, Cirr	C: 2.8 ^c HC: 3 ^c	C: 2.4 μg/ml ^c HC: 0.7 μg/ml ^c
^a Active metabolite, 14(R)-hydroxyclearithromycin. ^b Data generated for a 250 mg oral dose. At higher doses, metabolic <i>CL</i> saturates, resulting in increases in the % urinary excretion and $t_{1/2}$ and decrease in <i>CL</i> . ^c Mean data for clarithromycin (C) and 14-hydroxyclearithromycin (HC), following a 500 mg oral dose given twice daily to steady state in healthy adults.				<i>Reference:</i> Fraschini, F., Scaglione, F., and Demartini, G. Clarithromycin clinical pharmacokinetics. <i>Clin. Pharmacokinet.</i> , 1993 , 25:189–204.			
CLINDAMYCIN (Chapter 46)							
~87 ^a Topical: 2	13	93.6 ± 0.2	4.7 ± 1.3 ↔ Child	1.1 ± 0.3 ^b ↔ RD, Child	2.9 ± 0.7 ↔ Child, RD, Preg ↑ Prem	—	IV: 17.2 ± 3.5 μg/ml ^c Oral: 2.5 μg/ml ^d
^a Clindamycin hydrochloride given orally. ^b V_{area} reported. ^c Following a 1200 mg IV dose (30 minute infusion) of clindamycin phosphate (prodrug) given twice daily to steady state in healthy male adults. ^d Following a single 150 mg oral dose of clindamycin hydrochloride to adults.				<i>References:</i> <i>Physicians' Desk Reference</i> , 54th ed. Medical Economics Co., Montvale, NJ, 2000 , p. 2421. Plaisance, K.I., Drusano, G.L., Forrest, A., Townsend, R.J., and Standiford, H.C. Pharmacokinetic evaluation of two dosage regimens of clindamycin phosphate. <i>Antimicrob. Agents Chemother.</i> , 1989 , 33:618–620.			
CLONAZEPAM (Chapters 16, 17)							
98 ± 31	<1	86 ± 0.5 ↓ Neo	1.55 ± 0.28 ^{a,b}	3.2 ± 1.1	23 ± 5	Oral: 2.5 ± 1.3 ^c	IV: 3–29 ng/ml ^c Oral: 17 ± 5.4 ng/ml ^c
^a <i>CL/F</i> reported; this value is consistent for a number of studies but is higher than the <i>CL</i> determined in a single study of IV administration. ^b Metabolized by CYP3A. ^c Range of C_{max} values following a single 2 mg IV dose (model-fitted for bolus dose) or mean following a 2 mg oral dose (tablet) given to healthy adults. Most patients, including children, whose seizures are controlled by clonazepam have steady-state concentrations in the range of 5 to 70 ng/ml. However, patients who do not respond and those with side effects achieve similar levels.				<i>Reference:</i> Berlin, A., and Dahlstrom, H. Pharmacokinetics of the anticonvulsant drug clonazepam evaluated from single oral and intravenous doses and by repeated oral administration. <i>Eur. J. Clin. Pharmacol.</i> , 1975 , 9:155–159.			
CLONIDINE (Chapter 32)							
Oral: 95 TD: 60	62 ± 11	20	3.1 ± 1.2 ↓ RD	2.1 ± 0.4	12 ± 7 ↑ RD	Oral: 2 ^a TD: 72 ^a	Oral: 0.8 ng/ml ^a TD: 0.3–0.4 ng/ml ^a

^aMean data following a 0.1-mg oral dose given twice a day to steady state or C_{ss} following a 3.5 cm² transdermal (TD) patch administered to normotensive male adults. Concentrations of 0.2 to 2 ng/ml are associated with a reduction in blood pressure; >1 ng/ml will cause sedation and dry mouth.

Reference: Lowenthal, D.T., Matzek, K.M., and MacGregor, T.R. Clinical pharmacokinetics of clonidine. *Clin. Pharmacokinet.*, **1988**, *14*:287–310

CLORAZEPATE^a (Chapters 16, 19)

N: 91 ± 6 ^a	N: <1	N: 97.5 ↓ RD ↔ Obes, Aged ^c	N: 0.17 ± 0.02 ^b ↑ Smk ↓ Hep, Cirr, Obes, Aged ^c	N: 1.24 ± 0.09 ^b ↑ Obes, Preg ↔ Hep, Cirr, Aged	N: 93 ± 11 ^b ↑ Obes, Preg, Aged ^c ↓ Hep, Cirr, Smk	N: 0.72 ± 0.01 ^{a,d}	N: 275 ± 27 ng/ml ^{a,d}
------------------------	-------	--	---	---	--	-------------------------------	----------------------------------

^aClorazepate is essentially a prodrug for nordiazepam (N). Bioavailability, peak time, and peak concentration values for N were derived after oral administration of clorazepate. ^b CL , V_{ss} , and $t_{1/2}$ values are for IV nordiazepam. ^cSignificantly different for male subjects only.

^dData for nordiazepam following a 20 mg IM dose of clorazepate given to nonpregnant women.

References: Greenblatt, D.J., Divoll, M.K., *et al.* Desmethyldiazepam pharmacokinetics: studies following intravenous and oral desmethyldiazepam, oral clorazepate, and intravenous diazepam. *J. Clin. Pharmacol.*, **1988**, *28*:853–859. Rey, E., d'Athis, P., *et al.* Pharmacokinetics of clorazepate in pregnant and non-pregnant women. *Eur. J. Clin. Pharmacol.*, **1979**, *15*:175–180.

CLOZAPINE (Chapter 18)

55 ± 12	<1	>95	6.1 ± 1.6	5.4 ± 3.5	12 ± 4	1.9 ± 0.8 ^a	546 ± 307 ng/ml ^a
---------	----	-----	-----------	-----------	--------	------------------------	------------------------------

^aFollowing titration up to a 150 mg oral dose (tablet) given twice daily for 7 days to adult chronic schizophrenics.

References: Choc, M.G., Lehr, R.G., *et al.* Multiple-dose pharmacokinetics of clozapine in patients. *Pharm. Res.*, **1987**, *4*:402–405. Jann, M.W., Ereshefsky, L., and Saklad, S.R. Clinical pharmacokinetics of the depot antipsychotics. *Clin. Pharmacokinet.*, **1985**, *10*:315–333.

CODEINE^a (Chapter 21)

50 ± 7 ^b	Negligible	7	11 ± 2 ^c	2.6 ± 0.3 ^c	2.9 ± 0.7	C: 1.0 ± 0.5 ^d M: 1.0 ± 0.4 ^d	C: 149 ± 60 ng/ml ^d M: 3.8 ± 2.4 ng/ml ^d
---------------------	------------	---	---------------------	------------------------	-----------	--	---

^aCodeine is metabolized by CYP2D6 (polymorphic) to morphine. Analgesic effect is thought to be due largely to derived morphine. ^bOral/IM bioavailability reported. ^c CL/F and V_{area}/F reported. ^dData for codeine (C) and morphine (M) following a 60 mg oral codeine dose given three times daily for 7 doses to healthy male adults.

Reference: Quiding, H., Anderson, P., Bondesson, U., Boreus, L.O., and Hynning, P.A. Plasma concentrations of codeine and its metabolite, morphine, after single and repeated oral administration. *Eur. J. Clin. Pharmacol.*, **1986**, *30*:673–677.

CYCLOPHOSPHAMIDE^a (Chapters 51, 52)

74 ± 22	6.5 ± 4.3	13	1.3 ± 0.5 ↑ Child ↓ Cirr ↔ RD	0.78 ± 0.57 ↔ Child	7.5 ± 4.0 ↓ Child ↑ Cirr	—	121 ± 21 μM ^b
---------	-----------	----	-------------------------------------	------------------------	--------------------------------	---	--------------------------

^aCyclophosphamide is primarily activated by CYP2C9 to hydroxycyclophosphamide. The metabolite is further converted to the active alkylating species, phosphoramidate mustard ($t_{1/2}$ = 9 hours) and nornitrogen mustard (apparent $t_{1/2}$ = 3.3 hours). Kinetic parameters are for cyclophosphamide. ^bFollowing a 600 mg/m² IV (bolus) dose given to breast cancer patients.

DIGOXIN (Chapters 33, 34)

70 ± 13 ^{a,c} ↔ RD, MI, CHF, LTh, HTh, Aged	60 ± 11	25 ± 5 ↓ RD	$CL = (0.88CL_{cr} + 0.33)$ ^{b,c} ↓ LTh ↑ HTh, Neo, Child, Preg	$V = (3.12CL_{cr} + 3.84)$ ↓ LTh ↑ HTh ↔ CHF	39 ± 13 ↓ HTh ↑ RD, CHF, Aged, LTh ↔ Obes	1–3 ^d	NT: 1.4 ± 0.7 ng/ml ^d T: 3.7 ± 1.0 ng/ml ^d
--	---------	----------------	---	---	---	------------------	---

^aLANOXIN tablets; digoxin solutions, elixirs, and capsules may be absorbed more completely. ^bEquation applies to patients with some degree of heart failure. If heart failure is not present, the coefficient of CL_{cr} is 1.0. Units of CL_{cr} must be ml·min⁻¹·kg⁻¹. ^cIn the occasional patient, digoxin is metabolized to an inactive metabolite, dihydrodigoxin, by gut flora. This results in a reduced oral bioavailability. ^dFollowing an oral dose of 0.31 ± 0.19 mg/day or 0.36 ± 0.19 mg/day in patients with congestive heart failure who exhibited no signs of digitalis toxicity (NT) or signs of toxicity (T), respectively. Concentrations >0.8 ng/ml are associated with inotropic effect. Concentrations of 1.7, 2.5, and 3.3 ng/ml are associated with a 10%, 50%, and 90% probability of digoxin-induced arrhythmias, respectively.

FILGRASTIM^a (Chapter 53)

— ^b	F: — ^c PF: negligible	F/PF: —	F: 0.5–0.7 ^d ↓ RD PF: 0.23 (0.07–0.26) ^e	F: 0.15 PF: 0.48 ^e	F: 3.4–4.7 ↑ RD PF: 33 (30–54)	F: 8 ^f PF: 72 (24–96) ^f	F: 11 (9–16) ng/ml ^f PF: 114 (58–203) ng/ml ^f
----------------	-------------------------------------	---------	--	----------------------------------	--------------------------------------	--	--

^aFilgrastim (F) is a recombinant form of human G-CSF; it has an extra methionine residue and is non-glycosylated. A polyethyleneglycol conjugated analog, pegfilgrastim (PF), is also available for clinical use. In general, it is eliminated from the body more slowly than F by non-renal routes. Data from healthy male and female adults and patients with cancer following IV or SC administration. ^bFor parenteral use only. Bioavailability of F following SC dosing is 49% ± 9%. No data available for PF. ^cF is filtered, reabsorbed, and catabolized in the kidney. It also is eliminated through binding to neutrophil receptors, endocytosis, and proteolytic degradation. In contrast, PF does not undergo renal elimination, presumably because of its larger hydrodynamic size; elimination of PF occurs primarily through neutrophil-mediated CL. ^dCL of F reported for single dose at or below 4 µg/kg. CL of F increases with dose (>4 µg/kg) and with time (up to 10-fold) as absolute neutrophil count increases. ^eCL/F, V_{area} /F, and $t_{1/2}$ of PF from SC dose reported. CL/F of PF decreases with increasing dose but increases over time with increased neutrophil counts. ^fFollowing a single 5 µg/kg SC dose of F or a single 100 µg/kg SC dose of PF given 24 hours after chemotherapy.

IMPRAMINE^a (Chapter 17)

42 ± 3	<2	90.1 ± 1.4 ↑ HL, MI, Burn ↔ RA, Aged	13 ± 1.7 ^b ↓ Aged ↑ Smk ↔ Child	18 ± 2 ^c ↔ Aged, Child	16 ± 1.3 ↑ Aged ↔ Child	2–6 ^d	200 ± 137 ng/ml ^d
--------	----	--	--	--------------------------------------	-------------------------------	------------------	------------------------------

^aActive metabolite, desipramine. ^bUndergoes *N*-demethylation to desipramine, catalyzed by CYP2C19 (polymorphic), CYP1A2, and others; 2-hydroxylation is catalyzed by CYP2D6 (polymorphic). ^c V_{area} reported. ^dFollowing a 200 mg oral dose given daily for 4 weeks. Steady-state concentration reported is the sum of imipramine and desipramine (DMI/IMI = 1.4). Efficacy reported at combined levels of 100–300 ng/ml, and toxicity at combined levels >1 µg/ml.

Reference: Sallee, F.R., and Pollock, B.G. Clinical pharmacokinetics of imipramine and desipramine. *Clin. Pharmacokinet.*, **1990**, *18*:346–364.

INDOMETHACIN (Chapter 26)

~100	15 ± 8	90 ↔ Alb, Prem, Neo	1.4 ± 0.2 ↓ Prem, Neo, Aged	0.29 ± 0.04 ↔ Aged	2.4 ± 0.2 ^a ↔ RA, RD ↑ Neo, Prem, Aged	~1.3 ^b	~2.4 µg/ml ^b
------	--------	------------------------	--------------------------------	-----------------------	---	-------------------	-------------------------

^aThere is significant enterohepatic recycling (~50% after an IV dose). ^bFollowing a single 50 mg oral dose given after a standard breakfast. Effective at concentrations of 0.3–3 µg/ml and toxic at >5 µg/ml.

Reference: Oberbauer, R., Krivanek, P., and Turnheim, K. Pharmacokinetics of indomethacin in the elderly. *Clin. Pharmacokinet.*, **1993**, *24*:428–434.

Table A-II-1 Pharmacokinetic Data (Continued)

AVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE ($ml \cdot min^{-1} \cdot kg^{-1}$)	VOL. DIST. (liters/kg)	HALF-LIFE (hours)	PEAK TIME (hours)	PEAK CONCENTRATIONS
INTERFERON ALFA^a (Chapters 49, 51, 62)							
I - SC: 90	— ^b	—	I: 2.8 ± 0.6^c PI _{12kD} : 0.17 PI _{40kD} : 0.014 – 0.024	I: 0.40 ± 0.19^c PI _{12kD} : 0.44 – 1.04 PI _{40kD} : 0.11 – 0.17	I: 0.67^d PI _{12kD} : 37 (22 – 60) PI _{40kD} : 65	I: 7.3 ^e PI _{12kD} : 22 ^f PI _{40kD} : 80 ^g	I: 1.7 (1.2 – 2.3) ng/ml ^e PI _{12kD} : 0.91 ± 0.33 ng/ml ^f PI _{40kD} : 26 ± 8.8 ng/ml ^g
^a Values for recombinant interferon alfa-2a (I) and its 40 kDa pegylated form (PI _{40kD}) and the 12kDa pegylated form of interferon alfa-2b (PI _{12kD}) are reported. ^b I undergoes renal filtration, tubular reabsorption, and proteolytic degradation within tubular epithelial cells. Renal elimination of PI forms is much less significant than that of I, although not negligible. ^c CL values in 4 patients with leukemia were more than halved ($1.1 \pm 0.3 ml \cdot min^{-1} \cdot kg^{-1}$), while V_{ss} increased more than 20-fold ($9.5 \pm 3.5 l/kg$) and terminal $t_{1/2}$ changed only minimally (7.3 ± 2.4 hours). ^d A terminal $t_{1/2}$ of 5.1 ± 1.6 hours accounts for 23% of the CL of I. ^e Following a single 36×10^6 units SC dose of I. ^f Following 4 weeks of multiple SC dosing of 1 $\mu g/kg$ PI _{12kD} . ^g Following 48 weekly SC doses of 180 μg of PI _{40kD} .				<i>References:</i> Glue, P., Fang, J.W.S., <i>et al.</i> Pegylated interferon-2b: pharmacokinetics, pharmacodynamics, safety, and preliminary efficacy data. <i>Clin. LEFLUNOMIDE^a (Chapters 51, 52)

— ^b	negligible	99.4 ↓ RD	0.012 ^c ↑ RD	0.18 (0.09–0.44) ^e ↑ RD	377 (336–432) ^d ↔ RD	6–12 ^e	35 µg/ml ^e
----------------	------------	--------------	----------------------------	---------------------------------------	------------------------------------	-------------------	-----------------------

^aLeflunomide is a prodrug that is converted almost completely (~95%) to an active metabolite A77-1726 (2-cyano-3-hydroxy-N-(4-trifluoromethylphenyl)-crotonamide). All pharmacokinetic data reported are for the active metabolite. ^bAbsolute bioavailability is not known; parent drug/metabolite are well-absorbed. ^cApparent CL/F and V/F in healthy volunteers reported. Both parameters are a function of the bioavailability of leflunomide and the extent of its conversion to A77-1726. ^dIn patients with rheumatoid arthritis. ^eFollowing a 20 mg oral dose given once daily to steady state in patients with rheumatoid arthritis.

Reference: Rozman, B. Clinical pharmacokinetics of leflunomide. *Clin. Pharmacokinet.*, **2002**, *41*:421–430.

LETROZOLE^a (Chapters 51, 57)

99.9 ± 16.3	3.9 ± 1.4	60	0.58 ± 0.21 ↓ LD ^b	1.87 ± 0.46	45 ± 16	1.0 ^e	115 nM ^c
-------------	-----------	----	----------------------------------	-------------	---------	------------------	---------------------

^aData from healthy postmenopausal female subjects. Metabolized by CYP3A4 and CYP2A6. ^bCL/F reduced, severe hepatic impairment. ^cFollowing a single 2.5 mg oral dose (tablet).

References: Lamb, H.M., and Adkins, J.C. Letrozole. A review of its use in postmenopausal women with advanced breast cancer. *Drugs*, **1998**, *56*:1125–1140. METHYLPHENIDATE^a (Chapter 10)							
(+): 22 ± 8 (–): 5 ± 3	(+): 1.3 ± 0.5 (–): 0.6 ± 0.3	(+/-): 15–16	(+): 6.7 ± 2.0 ^b (–): 12 ± 4.7 ^b	(+): 2.7 ± 1.1 (–): 1.8 ± 0.9	(+): 6.0 ± 1.7 ^c (–): 3.6 ± 1.1	(+): 2.4 ± 0.8 ^{c,d} (–): 2.1 ± 0.6 ^d	(+): 18 ± 4.3 ng/ml ^d (–): 3.0 ± 0.9 ng/ml ^d
<p>^aMethylphenidate is available as a racemate and the active (+)-dextro-enantiomer, dexmethylphenidate. Methylphenidate and dexmethylphenidate are extensively metabolized, primarily through ester hydrolysis to ritalinic acid. Data are those of enantiomers following racemate administration to healthy adult male subjects. No significant gender differences. ^bThe (+)-enantiomer exhibits dose-dependent kinetics at high doses of racemate, with a ~ 50% reduction in CL/F between a 10–40-mg dose. ^cWhen dexmethylphenidate is given alone, its $t_{1/2}$ is 2.2 hours, and peak time is 1–1.5 hours. ^dFollowing a single 40 mg oral dose (immediate release). Longer peak time (3–5 hours) and lower peak concentration reported for sustained-released oral formulation.</p>				<p><i>References:</i> Aoyama, T., Kotaki, H., <i>et al.</i> Nonlinear kinetics of threo-methylphenidate enantiomers in a patient with narcolepsy and in healthy volunteers. <i>Eur. ^aMetabolically cleared by CYP2C9 (polymorphic) and CYP1A2. ^bEstimated bioavailability. ^cSaturable plasma protein binding yields apparent nonlinear elimination kinetics. ^dNo change in total CL , but significant (50%) decrease in CL of unbound drug; it is thus suggested that dosing rate be decreased. A second study in elderly patients found decreased CL and increased $t_{1/2}$ with no change in percent bound. ^e CL/F and V_{area}/F reported. ^fFollowing a single 250 mg dose of suspension (S) given orally to pediatric patients or a 250 mg immediate-release tablet (T-IR) or a 500 mg controlled-release tablet (T-CR) given to adults.

Reference: Wells, T.G., Mortensen, M.E., *et al.* Comparison of the pharmacokinetics of naproxen tablets and suspension in children. *J. Clin. Pharmacol.*, **1994**, 34:30–33.

NELFINAVIR^a (Chapter 51)

20–80 ^b ↑ Food	1–2	98–99	12.0 ± 7.2 ^c ↑ Child ^d	2–7 ^c	3–5 ^c	3.0 ± 1.1 ^e	3.2 ± 1.2 μg/ml ^e ↑ Food
------------------------------	-----	-------	---	------------------	------------------	------------------------	--

^aData from healthy subjects and patients with HIV infection. No significant gender differences. Nelfinavir is metabolized by multiple cytochrome CYP isozymes, including CYP3A4. ^bAbsolute bioavailability is unknown; reported to vary between 20% to 80% when taken without or with food. ^c CL/F , V_{ss}/F , and $t_{1/2}$ reported for oral dose. ^d CL/F increased, children 2 to 7 years and 7 to 13 years of age. ^eFollowing a 750 mg dose given three times daily for 28 days in adults.

OXALIPLATIN^a (Chapter 51)							
— ^b	— ^c	90 ^d	49 (41–64) ^e	1.5 (1.1–2.1)	0.32 (0.27–0.46) ^f	—	Ox: 0.33 (0.28–0.38) μg Pt/ml ^g PtDC: 0.008 (0.004–0.014) μg Pt/ml ^g
^a Oxaliplatin is an organoplatinum complex; Pt is coordinated with diaminocyclohexane (DACH) and an oxalate ligand as a leaving group. Oxaliplatin (Ox) undergoes nonenzymatic biotransformation to reactive derivatives, notably Pt(DACH)Cl ₂ (PtDC). Antitumor activity and toxicity are thought to relate to the concentration of oxaliplatin and PtDC in plasma ultrafiltrate (<i>i.e.</i> , unbound concentration). ^b For IV administration only. ^c Approximately 54% of the platinum eliminated is recovered in urine. ^d Binding to plasma proteins is irreversible. ^e CL of total platinum is much lower; ~2–4 ml·min ⁻¹ ·kg ⁻¹ . ^f The elimination of platinum species in plasma follows a triexponential pattern. The quoted $t_{1/2}$ reflects the $t_{1/2}$ of the first phase, which is the clinically relevant phase. The $t_{1/2}$ for the slower two phases are 17 and 391 hours. ^g Steady-state plasma ultrafiltrate concentration of Ox and PtDC after an 85 mg/m ² IV infusion over 2 hours during cycles 1 and 2.				<i>Reference:</i> <i>Physicians' Desk Reference</i> , 58th ed. Medical Economics Co., Montvale, NJ, 2004 , pp. 3024–3025. Shord, S.S., Bernard, S.A., <i>et al.</i> Oxaliplatin biotransformation and pharmacokinetics: a pilot study to determine the possible relationship to neurotoxicity. <i>Anticancer Res.</i> , 2002 , 22:2301–2309.			
OXCARBAZEPINE^a (Chapter 19)							
—	O: <1 HC: 27	— HC: 45	O: 67.4 ^b HC: ↓ RD, ^c Aged HC: ↑ Child ^d	—	O: ~2 HC: 8–15 HC: ↑ RD, Aged	HC: 2–4 ^e	HC: 8.5 ± 2.0 μg/ml ^e

^aData from healthy adult male subjects. No significant gender differences. Oxcarbazepine (O) undergoes extensive first-pass metabolism to an active metabolite, 10-hydroxycarbamazepine (HC). Reduction by cytosolic enzymes is stereoselective (80% *S*-enantiomer, 20% *R*-enantiomer), but both show similar pharmacological activity. ^b*CL/F* for O reported. HC eliminated by glucuronidation. ^c*AUC* for HC increased, moderate-to-severe renal impairment. ^d*AUC* for HC decreased, children <6 years of age. ^eFollowing a 300 mg oral oxcarbazepine dose given twice daily for 12 days.

OXYBUTYNIN^a (Chapter 7)

1.6–10.9	<1	—	8.1 ± 2.3 ^b	1.3 ± 0.4 ^b	IV: 1.9 ± 0.35 ^{b,c}	IR: 5.0 ± 4.2 ^d XL: 5.2 ± 3.7 ^d	IR: 12.4 ± 4.1 ng/ml ^d XL: 4.2 ± 1.6 ng/ml ^d
----------	----	---	------------------------	------------------------	-------------------------------	--	---

^aData from healthy female subjects. No significant gender differences. Racemic mixture; anticholinergic activity resides predominantly with *R*-enantiomer; no stereoselectivity exhibited for antispasmodic activity. Oxybutynin undergoes extensive first-pass metabolism to *N*-desethyloxybutynin (DEO), an active, anticholinergic metabolite. Metabolized primarily by intestinal and hepatic CYP3A. Racemic oxybutynin kinetic parameters reported. ^bData reported for a 1 mg IV dose, assuming a 70 kg body weight. A larger volume (2.8 l/kg) and longer $t_{1/2}$ (5.3 hours) reported for 5 mg IV dose. ^cExhibits a longer apparent $t_{1/2}$ following oral dosing due to absorption rate-limited kinetics: immediate-release (IR) $t_{1/2} = 9 \pm 2$ hours; extended-release (XL) $t_{1/2} = 14 \pm 3$ hours. The apparent $t_{1/2}$ for DEO was 4.0 ± 1.4 hours and 8.3 ± 2.5 hours for IR and XL formulations, respectively. ^dFollowing a dose of 5 mg immediate-release (IR) given three times daily or 15 mg extended-release (XL) given once daily for 4 days. Peak DEO levels at steady state were 45 and 23 ng/ml for IR and XL, respectively.

References: Gupta, S.K., and Sathyan, G. Pharmacokinetics of an oral once-a-day controlled-release oxybutynin formulation compared with immediate-release oxybutynin. *J. Clin. Pharmacol.*, **1999**, 39:289–296. *Physicians' Desk Reference*, 54th ed. Medical Economics Co., Montvale, NJ, **2000**, p. 507.

OXYCODONE^a (Chapter 21)

CR: 60–87 ^b IR: 42 ± 7 ^b	— ^c	45	12.4 (9.2–15.4)	2.0 (1.1–2.9)	2.6 (2.1–3.1) ^d	CR: 3.2 ± 2.2 ^e IR: 1.6 ± 0.8 ^e	CR: 15.1 ± 4.7 ng/ml ^e IR: 15.5 ± 4.5 ng/ml ^e
---	----------------	----	-----------------	---------------	----------------------------	--	--

^aOxycodone is metabolized primarily by CYP3A4/5, with a minor contribution from CYP2D6. Oxymorphone is an active metabolite produced by CYP2D6-mediated *O*-dealkylation. The circulating concentrations of oxymorphone are too low to contribute significantly to the opioid effects of oxycodone. Data from healthy males and females reported. ^bValues reported for OXYCONTIN[®] (oxycodone controlled release) and immediate-release tablets. ^cUp to 19% excreted unchanged after an oral dose. ^dThe apparent $t_{1/2}$ for controlled-release oral formulation is ~ 5 hours; most likely reflects absorption-limited terminal elimination kinetics. ^eFollowing 10 mg of OXYCONTIN[®] (CR) given twice daily to steady state or a 5 mg immediate-release tablet (IR) given every 6 hours to steady state.

-----------------	----	------------	-------------	------	--------------------------------	---	---

^aPenicillin G (Pen G) available in various very soluble (short acting, SA) and less soluble (long acting, LA) salt forms. Procaine and benzathine salts are two long-acting forms. Data are from adults and older children. ^bOral absorption of Pen G is irregular and variable due to its instability in stomach acid and inactivation during first-pass through the liver. Value is the maximum fraction recovered unchanged in urine following oral administration. ^cTri-exponential elimination; $t_{1/2}$ for intermediate phase reported. Terminal $t_{1/2}$ is ~3 hours and most likely reflects slow redistribution from tissues. ^dFollowing single 180 mg oral suspension of Pen G (PO), 600 mg IM dose of short-acting crystalline Pen G (SA), 187.5 mg IM dose of procaine Pen G (Pro), and 750 mg IM dose of benzathine Pen G (Benz).

PHENOBARBITAL (Chapters 16, 19)

100 ± 11	24 ± 5 ^a ↔ Cirr, AVH	51 ± 3 ↓ Neo ↔ Preg, Aged	0.062 ± 0.013 ↑ Preg, Child, Neo ↔ Smk	0.54 ± 0.03 ↑ Neo	99 ± 18 ↑ Cirr, Aged ↓ Child ↔ Epilep, Neo	2–4 ^b	13.1 ± 4.5 μg/ml ^b
----------	------------------------------------	---------------------------------	--	----------------------	---	------------------	-------------------------------

^aPhenobarbital is a weak acid ($pK_a = 7.3$); urinary excretion is increased at an alkaline pH; it also is reduced with decreased urine flow. ^bMean steady-state concentration following a 90 mg oral dose given daily for 12 weeks to patients with epilepsy. Levels of 10–25 μg/ml provide control of tonic-clonic seizures and 15 μg/ml for control of febrile convulsions in children. Levels >40 μg/ml can cause toxicity; 65–117 μg/ml produce stage III anesthesia—comatose but reflexes present; 100–134 μg/ml produce stage IV anesthesia—no deep-tendon reflexes.

RISEDRONATE (Chapter 61)							
<1 ^a	87 (73–102)	24	1.5 (1.2–1.9) ↓ RD	6.3 ± 1.5	200 (183–218) ^b	1.7 ± 1.2 ^c	2.8 ± 0.3 ng/ml ^c
<p>^aFood affects the extent of bioavailability; recommended to be taken 30 minutes prior to the first meal of the day. Data from healthy men and women reported; no significant gender differences. ^bExhibits multi-exponential elimination. The plasma $t_{1/2}$ for the first and second exponential phases is 0.9 and 13 hours, respectively. The longer terminal $t_{1/2}$ reported is thought to represent dissociation of risedronate from the surface of bone. ^cFollowing a 5 mg oral dose given once daily to healthy men.</p>				<p><i>References:</i> Mitchell, D.Y., Barr, W.H., <i>et al.</i> Risedronate pharmacokinetics and intra- and inter-subject variability upon single-dose intravenous and oral administration. <i>Pharm. Res.</i>, 2001, 18:166–170. Ogura, Y., Gonsho, A., Cyong, J.C., and Orimo, H. Clinical trial of risedronate in Japanese volunteers: single and multiple oral dose studies. <i>J. Bone Miner. Metab.</i>, 2004, 22:111–119. <i>Physicians' Desk Reference</i>, 58th ed., Medical Economics Co., Montvale, NJ, 2004, p. 2825.</p>			

RISPERIDONE^a (Chapter 18)

Oral: 66 ± 28 ^b	3 ± 2 ^b	89 ^c	5.4 ± 1.4 ^b	1.1 ± 0.2	3.2 ± 0.8 ^{a,b}	R: ~1 ^e	R: 10 ng/ml ^e
IM: 103 ± 13		↓ Cirr	↓ RD, ^a Aged ^d		↑ RD, ^a Aged ^d		TA: 45 ng/ml ^e

^aActive metabolite, 9-hydroxyrisperidone, is the predominant circulating species in extensive metabolizers and is equipotent to parent drug. 9-Hydroxyrisperidone has a $t_{1/2}$ of 20 ± 3 hours. In extensive metabolizers, 35% ± 7% of an IV dose is excreted as this metabolite; its elimination is primarily renal and therefore correlates with renal function. ^bFormation of 9-hydroxyrisperidone is catalyzed by CYP2D6. Parameters reported for extensive metabolizers. In poor metabolizers, *F* is higher; about 20% of an IV dose is excreted unchanged, 10% as the 9-hydroxy metabolite; *CL* is slightly less than 1 ml · min⁻¹ · kg⁻¹, and $t_{1/2}$ is similar to that of the active metabolite, about 20 hours. ^c77% for 9-hydroxyrisperidone. ^dChanges in elderly due to decreased renal function affecting the elimination of the active metabolite. ^eMean steady-state trough concentration for risperidone (R) and total active (TA) drug, risperidone + 9-OH-risperidone, following a 3 mg oral dose given twice daily to patients with chronic schizophrenia. No difference in total active drug levels between CYP2D6 extensive and poor metabolizers.

References: Cohen, L.J. Risperidone. *Pharmacotherapy*, **1994**, 14:253–265. Heykants, J., Huang, M.L., *et al.* The pharmacokinetics of risperidone in humans: a summary. *J. Clin. Psychiatry*, **1994**, 55(suppl):13–17.

RITONAVIR^a (Chapter 50)

— ^b	3.5 ± 1.8	98–99	SD: 1.2 ± 0.4 ^c	0.41 ± 0.25 ^c	3–5 ^c	2–4 ^e	11 ± 4 μg/ml ^e
↑ Food			MD: 2.1 ± 0.8 ^c		↑ LD ^d		
			↑ Child ↓ LD ^d				

^aRitonavir is extensively metabolized primarily by CYP3A4. It also appears to induce its own *CL* with single- (SD) to multiple-dose (MD) administration. Also used in combination with saquinavir; saquinavir has no significant effect on the pharmacokinetics of ritonavir. ^bAbsolute bioavailability unknown (>60% absorbed); food elicits a 15% increase in oral *AUC* for capsule formulation. ^c*CL/F*, V_{area}/F , and $t_{1/2}$ reported for oral dose. ^d*CL/F* reduced slightly and $t_{1/2}$ increased slightly, moderate liver impairment. ^eFollowing a 600 mg oral dose given twice daily to steady state.

References: Hsu, A., Granneman, G.R., and Bertz, R.J. Ritonavir. Clinical pharmacokinetics and interactions with other anti-HIV agents. *Clin. Pharmacokinet.*, **1998**, 35:275–291. *Physicians' Desk Reference*, 54th ed. Medical Economics Co., Montvale, NJ, **2000**, p. 465.

RIVASTIGMINE^a (Chapter 20)

72 (22–119) ^b	negligible	40	13 ± 4 ^c	1.5 ± 0.6 ^c	1.4 ± 0.4 ^{c,d}	1.2 ± 1.0 ^e	26 ± 10 ng/ml ^e
↑ Food, Dose						↑ Food	↓ Food

^aRivastigmine is metabolized by cholinesterase. No apparent gender differences. ^bFollowing a 6-mg oral dose. Bioavailability increases with dose; following a 3-mg dose, the median bioavailability is 36%. ^cIV dose of 2 mg. ^dThe pharmacodynamic $t_{1/2}$ is approximately 10 hours due to tight binding to acetylcholinesterase. ^eFollowing oral administration of 6 mg capsule. Peak concentrations increase more than proportionally at doses above 3 mg.

----------------	----	---	------------------------	------------------------	------------------------	--------------------------------------	--------------------------------------

^aData from healthy male subjects. Similar data reported for asymptomatic patients with HIV. No age or gender differences. Thalidomide undergoes spontaneous hydrolysis in blood to multiple metabolites. ^bAbsolute bioavailability is not known. Altered absorption rate and extent, Hansen's disease (HD). ^c CL/F , V_{area}/F , and $t_{1/2}$ reported for oral dose. ^dFollowing a single 200 mg oral dose.

THEOPHYLLINE (Chapter 28)

96 ± 8	18 ± 3 ↑ Neo, Prem ↔ CF, Aged	56 ± 4 ↓ Aged, Cirr, Neo, Preg, Obes ↔ CF	0.65 ± 0.20 ^{a,b} ↓ Neo, Prem, Cirr, CHF, CP, Hep, LTh, Obes, Pneu ↑ Smk, CF, HTh, Child ↔ Aged, Preg, RD, COPD	0.50 ± 0.16 ↓ Obes ↑ Prem, CF ↔ Aged, Preg, Cirr, HTh, LTh, RD	9.0 ± 2.1 ^b ↓ Smk, CF, HTh ↑ Prem, Neo, Cirr, CHF, Hep, CP, LTh ↔ Aged, RD	A: ~1.5 ^c TD: 11.5 ± 7.5 ^c T24: 11.3 ± 4.8 ^c	A: 7.9 ± 0.6 μg/ml ^c TD: 15 ± 2.8 μg/ml ^c T24: 14 ± 3.7 μg/ml ^c
--------	-------------------------------------	--	---	---	---	---	--

^aNonlinear kinetics due to saturable metabolism, especially in children at steady state. Ratio of percent increase in steady-state concentration to percent increase in dose was >1.5 in 15% of children changed to a higher dose. Metabolically cleared primarily by CYP1A2 and by CYP3A4 to a lesser extent. ^b CL increased and $t_{1/2}$ decreased as a result of enzyme induction by antiepileptic drugs. ^cFollowing a 200 mg oral dose (aminophylline) given three times daily for 5 days, a 400 mg oral dose (THEO-DUR) given twice daily for 5 days, or a 800 mg oral dose (THEO-24) given once daily for 5 days, all to healthy adults. Sustained release formulations were taken 1 hour prior to a high-fat meal. Levels of 5 to 15 μg/ml are considered therapeutic; a level >20 μg/ml is potentially toxic.

Table A-II-1 Pharmacokinetic Data (Continued)

AVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE ($ml \cdot min^{-1} \cdot kg^{-1}$)	VOL. DIST. (liters/kg)	HALF-LIFE (hours)	PEAK TIME (hours)	PEAK CONCENTRATIONS
TOPOTECAN^a (Chapter 51)							
32 ± 12	40 ^b	L: 21.3 A: 6.6	28.6 ± 4.1 liters · h ⁻¹ · (m ²) ^{-1b} ↑ RD ^c ↔ Child, Cirr	74 ± 21 liters/m ^{2b}	2.4 ± 0.4 ^b ↑ RD	Oral, L: 0.92 ± 0.61 ^d Oral, A: 1.5–2 ^d	IV, L: 38 ± 8 ng/ml ^d IV, A: 19 ± 2 ng/ml ^d Oral, L: 5.9 ± 0.8 ng/ml ^d Oral, A: 7.5 ± 2.6 ng/ml ^d
^a Data from adult male and female patients (mean age, 62 years) with solid tumors. Topotecan is converted under physiological pH from a lactone (L) to a ring-opened carboxylic acid (A). Topotecan is active, but the acid metabolite is in equilibrium with parent drug. ^b CL and V _{ss} calculated assuming a 1.73 m ² body surface area. There is considerable variability in the mean parameter reported from different IV studies: urinary excretion = 23% to 93%; CL = 19 to 35 liters · h ⁻¹ · (m ²) ⁻¹ ; V _{ss} = 61 to 563 liters/m ² ; t _{1/2} = 2.9 to 8.4 hours. ^c CL of topotecan reduced, moderate renal impairment. ^d Following a single 1.5 mg/m ² IV or oral dose.				<i>References:</i> Furman, W.L., Baker, S.D., <i>et al.</i> Escalating systemic exposure of continuous infusion topotecan in children with recurrent acute leukemia. <i>J. ^aActive metabolites. ^bDose-dependent; value shown for daily doses of 250 and 500 mg. At 1 g daily, % bound = 90 ± 2 . ^cData for multiple dosing (500 mg daily) reported. Single dose value: $0.14 \pm 0.04 \text{ ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$; $t_{1/2} = 9.8 \pm 2.6$ hours. Total *CL* the same at 100 mg daily, although *CL* of free drug increases with multiple dosing. ^dIncreased *CL* and decreased $t_{1/2}$ from enzyme induction following concomitant administration of other antiepileptic drugs. ^e C_{ave} following a 250 mg oral dose (capsule, DEPAKENE) given twice daily for 15 days to healthy male adults. A therapeutic range of 50 to 150 $\mu\text{g/ml}$ is reported. T_{max} is 3 to 8 hours for enteric-coated tablets (DEPAKOTE) and 7 to 14 hours for extended-release tablet (DEPAKOTE-ER).

VALSARTAN^a (Chapters 30, 32, 33)

23 ± 7 ↓ Food	29.0 ± 5.8	95	0.49 ± 0.09 ↓ Aged, LD ^b ↔ RD	0.23 ± 0.09	9.4 ± 3.8 ↑ Aged	2 (1.5–3) ^c	$1.6 \pm 0.6 \mu\text{g/ml}^c$
----------------------	----------------	----	--	-----------------	-------------------------	------------------------	--------------------------------

^aData from healthy adult male subjects. No significant gender differences. Valsartan is cleared primarily by biliary excretion. ^b*CL/F* reduced, mild-to-moderate hepatic impairment and biliary obstruction. ^cFollowing a single 80 mg oral dose (capsule).

VENLAFAXINE^a (Chapter 17)							
10–45	V: 4.6 ± 3.0 DV: 29 ± 7 ^b	V: 27 ± 2 DV: 30 ± 12 ^b	22 ± 10 ^c ↔ Aged, Fem ↓ Cirr, RD	7.5 ± 3.7 ^c ↔ Aged, Fem, Cirr, RD	4.9 ± 2.4 10.3 ± 4.3 ^b ↔ Aged, Fem ↑ Cirr, RD	V: 2.0 ± 0.4 ^d DV: 2.8 ± 0.8 ^d	V: 167 ± 55 ng/ml ^d DV: 397 ± 81 ng/ml ^d
^a Racemic mixture; antidepressant activity resides with the <i>l</i> (-)-enantiomer and its equipotent <i>O</i> -desmethyl metabolite (formation catalyzed by CYP2D6—polymorphic). ^b Values for <i>O</i> -desmethylvenlafaxine after venlafaxine dosing. ^c <i>CL/F</i> and <i>V_{ss}/F</i> reported. ^d Mean data for venlafaxine (V) and <i>O</i> -desmethylvenlafaxine (DV), following a 75 mg oral dose (immediate-release tablet) given three times daily for 3 days to healthy adults. <i>T_{max}</i> for an extended-release formulation is 5.5 (V) and 9 (DV) hours.				<i>References:</i> Klamerus, K.J., Maloney, K., et al. Introduction of a composite parameter to the pharmacokinetics of venlafaxine and its active <i>O</i> -desmethyl metabolite. <i>J. Clin. Pharmacol.</i> , 1992 , 32:716–724. <i>Physicians' Desk Reference</i> , 54th ed. Medical Economics Co., Montvale, NJ, 2000 , p. 3237.			
VERAPAMIL^{a,b} (Chapters 31, 32, 34)							
Oral: 22 ± 8 SL: 35 ± 13 ↑ Cirr ↔ RD	<3	90 ± 2 ↑ Cirr ↔ RD, Atr Fib, Aged	15 ± 6 ^{c,d} ↑ Cirr, Aged, Obes ↑, ↔ Atr Fib ↔ RD, Child	5.0 ± 2.1 ↑ Cirr ↑, ↔ Atr Fib ↔ RD, Aged, Obes	4.0 ± 1.5 ^c ↑ Cirr, Aged, Obes ↑, ↔ Atr Fib ↔ RD, Child	IR: 1.1 ^e XR: 5.6–7.7 ^e	IR: 272 ng/ml ^e XR: 118–165 ng/ml ^e

^aRacemic mixture; (–)-enantiomer is more active. Bioavailability of (+)-verapamil is 2.5-fold greater than that for (–)-verapamil because of a lower *CL* (10 ± 2 vs. 18 ± 3 ml · min⁻¹ · kg⁻¹). Relative concentration of the enantiomers changes as a function of route of administration. ^bActive metabolite, norverapamil, is a vasodilator but has no direct effect on heart rate or P-R interval. At steady state (oral dosing), *AUC* is equivalent to that of parent drug ($t_{1/2} = 9 \pm 3$ hours). ^cMultiple dosing causes greater than twofold decrease in *CL/F* and prolongation of $t_{1/2}$ in some studies, but no change of $t_{1/2}$ in others. ^dVerapamil is a substrate for CYP3A4, CYP2C9, and other CYPs. ^eMean data following a 120 mg oral conventional tablet (IR) given twice daily or range of data following a 240 mg oral extended release (XR) dose given once daily, both for 7 to 10 days to healthy adults. *EC*₅₀ for prolongation of P-R interval after oral dose of racemate is 120 ± 20 ng/ml; value for IV administration is 40 ± 25 ng/ml. After oral administration, racemate concentrations above 100 ng/ml cause more than 25% reduction in heart rate in atrial fibrillation, more than 10% prolongation of P-R interval, and more than 50% increase in duration of exercise in angina patients. A level of 120 ± 40 ng/ml (after IV administration) was found to terminate reentrant supraventricular tachycardias.

 classification of, 675*t*
 gastrointestinal effects of, 681, 693
 hypersensitivity to, 685
 low antiinflammatory activity of, 682, 694
 mechanism of action, 673, 681, 693
 metabolism of, 82, 693, 1741, 1741*f*
 with opioids, 579–581
 overdose of, management of, 694–695
 pharmacokinetics of, 675*t*, 693, 1794*t*
 pharmacological properties of, 693
 toxicity of, 694, 1741, 1741*f*
 and alcoholic cirrhosis, 597
 and glutathione S-transferase, 83
- Acetanilide, 693
- Acetazolamide, 743–747
 absorption and elimination of, 745*t*, 746
 adverse effects of, 746
 for altitude sickness, 746–747
 chemistry of, 743, 745*t*
 extrarenal effects of, 746
 for familial periodic paralysis, 747
 for glaucoma, 1723
 and lithium, 486–487
 for seizures/epilepsy, 521, 746
 therapeutic uses of, 746–747
- Acetohexamide, 1635, 1636
 absorption, fate, and excretion of, 1636
 chemistry of, 1634, 1635*t*
- Acetorphan, for diarrhea, 997
- N-OH-2-acetylaminofluorene, metabolism of, 82
- Acetylation, in drug metabolism, 73, 77*t*, 85–86
- Acetylcholine, 183–186
 accumulation of, anticholinesterase agents and, 201. *See also* Anticholinesterase agents
 action of, 202–203, 203*f*
 in Alzheimer's disease, 539
 antagonism of, 186
 antipsychotics and, 474
 atropine and, 183, 186, 186*t*, 191, 1751
 cardiovascular effects of, 184–185
 destruction or dissipation of, 149
 interference with, 174–175
 extraneuronal, 153
 in ganglionic neurotransmission, 230, 230*f*
 and gastric acid secretion, 967–968, 968*f*
 gastrointestinal effects of, 185
 and gastrointestinal motility, 983–985
 and glucagon secretion, 1642
 and heart rate, 904
 histamine H₁ receptor antagonists and, 637
 history of, 629
 inhibition/inactivation of, 152, 201–203, 203*f*
 negative dromotropic effect of, 184
 negative inotropic effect of, 184–185
 neuromuscular blocking agents and, 222–224
 as neurotransmitter, 138–139, 140*f*–141*f*, 146, 150–157, 151*f*, 323*t*, 327, 332–333
 characteristics at various sites, 152–153
 co-transmitters with, 174–176
 pharmacological actions on, 170, 173, 174
 norepinephrine and, 153
 ophthalmic use of, 1720*t*, 1724
 opioids and, 561
 pharmacologic properties of, 184–186, 186*t*
 receptors for, 151*f*, 153–155, 158. *See also* Muscarinic receptor(s); Nicotinic cholinergic receptor(s)
 release of, 151–152, 151*f*
 storage of, 150–151, 151*f*
 structure of, 187*f*
 synergism with, 186
 synthesis of, 150, 151*f*
 as therapeutic target, 172*t*–173*t*
 therapeutic uses of, 188
 transport of, 150, 151*f*
 urinary tract effects of, 185
 and vasopressin, 775
- Acetylcholine receptor(s), 323*t*

- Acetylcholinesterase (AChE), 149, 151*f*, 152, 183
inhibition of, 152, 173, 201. *See also* Anticholinesterase agents
reactivators of, 210–211, 211*f*
structure of, 202–203, 202*f*
- Acetylcholine transporter blocker, 323*t*
- Acetyl coenzyme A
in acetylcholine synthesis, 150
in ethanol metabolism, 592*f*, 593
- Acetylglyceryl etherphosphorylcholine (AGEPC), 666
- Acetylsalicylic acid, 673. *See also* Aspirin
pharmacokinetics of, 1794*t*
- Achlorhydria, and antimicrobial therapy, 1102
- Acid(s), organic, renal secretion of, 741–742, 742*f*
- Acidification of urine, 1649
- Acidosis
compensatory renal, salicylates and, 688, 691–692
metabolic
carbonic anhydrase inhibitors and, 746
mineralocorticoid receptor antagonists and, 762
respiratory
benzodiazepines and, 407
carbonic anhydrase inhibitors and, 746
- Acid-peptic disease(s), 967. *See also* Gastroesophageal reflux disease; Peptic ulcer disease
mechanisms of drug action in, 968*f*
therapeutic strategies for, 976–980
- Acinetobacter* infection, colistin for, 1194
- ACIPHEX (rabeprazole), 969
- Acitretin, 1683, 1686, 1731
for skin cancer prevention, 1686–1687
- ACLOVATE (alclometasone dipropionate), 1602*t*, 1682*t*
- Acne
antibiotics for, 1689–1690
azelaic acid for, 1690, 1701
clindamycin for, 1190, 1690
hormonal contraceptives and, 1566
isotretinoin for, 1685–1686
oral contraceptive for, 1567
tazarotene for, 1685
tetracyclines for, 1178, 1690
tretinoin for, 1684
- Acquired immune deficiency syndrome (AIDS). *See also* Human immunodeficiency virus (HIV) infection
anemia in, erythropoietin therapy for, 1438
antimicrobial prophylaxis in, 1105
antimicrobial therapy in, 1101
CMV infection in, 1254–1255
cryptococcosis in, 1230
cryptosporidiosis in, 1051
Cyclospora cayentanensis in, 1053
HAART for, 1051
herpes simplex virus in, 1249
hyperkalemia in, 759
Isospora belli in, 1053
leishmaniasis in, 1052
mycobacterial infections in, macrolides for, 1185–1186
Mycobacterium avium complex in, 1185–1186, 1216–1218
neutropenia in, treatment of, 1440
Pneumocystis infection in, pentamidine for, 1065–1066
sulfonamide hypersensitivity in, 1116
suramin use in, 1069
toxoplasmosis in, 1051
trimethoprim-sulfamethoxazole hypersensitivity in, 1119
tuberculosis in, 1215
tuberculosis prophylaxis in, 1216
wasting in
megestrol acetate for, 1561
testosterone for, 1581
- Acridanes, 462
- Acrivastine
dosage of, 638*t*
duration of action, 638*t*
preparations of, 638*t*
- Acromegaly, 1496–1498
treatment of, 1496–1498, 1644
- ACTH. *See* Adrenocorticotropic hormone
- ACTHREL (corticotropin), 1593
- ACTICIN (permethrin), 1692
- ACTIGALL (ursodeoxycholic acid), 1701
- ACTIMMUNE (interferon- γ), 1212, 1422
- ACTINEX (masoprocol), 1703
- Actinic keratosis
imiquimod for, 1696
masoprocol for, 1703
photodynamic therapy for, 1688
prevention of, sunscreens for, 1700–1701
- Actinomycin(s), 1357
- Actinomycin D. *See* Dactinomycin
- Actinomycosis
penicillin G for, 1137
tetracyclines for, 1177
- Actinoplanes teichomyetius*, 1196
- Action potential, 147
cardiac, 899–904
differing, among cells, 901, 902*f*
initiation of, 900–901, 901*f*
as therapeutic target, 908–909, 913–914
and neurotransmission, 147–149, 148*f*
- ACTIQ (fentanyl), 571–572
- Activated charcoal, 1748–1749
for mercury poisoning, 1763
for salicylate poisoning, 693
- Activated partial thromboplastin time (aPTT), 1469–1470
in heparin therapy, 1472–1473
in lepirudin therapy, 1475
- Active immunization, 1423
- Active transport, 3, 45*f*, 46–47, 740
primary, 45*f*, 46
secondary, 45*f*, 46–47, 740
- ACTONEL (risedronate), 1668
- ACTOS (pioglitazone), 1640
- ACULAR (ketorolac), 1725
- Acute coronary syndrome, 831
- Acute dystonia, antipsychotics and, 478–479, 478*t*, 483
- Acute intermittent porphyria, increased porphyrin excretion in, 1756*t*
- Acute lymphocytic leukemia (ALL)
L-asparaginase for, 1363–1364
glucocorticoids for, 1610
methotrexate for, 1338
teniposide for, 1360–1361
- Acute myelocytic leukemia (AML)
chlorambucil and, 1328–1329
cisplatin and, 1333–1334
cytarabine for, 1344–1345
daunorubicin for, 1358
gemtuzumab ozogamicin for, 1379
glucocorticoids for, 1380–1381
interleukin-2 for, 1374
mercaptopurine and, 1346–1348
mitoxantrone for, 1357
- Acute promyelocytic leukemia (APL)
all-trans-retinoic acid for, 1315
arsenic trioxide for, 1366
differentiation in, 1365
retinoids for, 1365–1366
- Acute tubular necrosis (ATN), osmotic diuretics for, 748
- Acyclovir, 1247–1250
absorption, distribution, and elimination of, 1247
adverse effects of, 1247–1249
as antiviral prototype, 1246
antiviral spectrum of, 1247
for Bell's palsy, 1250
chemistry of, 1247
for CMV infection, 1250
drug interactions of, 1249
with mycophenolate mofetil, 1247, 1414–1415
for herpes simplex virus, 1247, 1249, 1717*t*
mechanism of action, 1247, 1248*f*
for mononucleosis, 1250
nephrotoxicity of, 1249
ophthalmic use of, 1249, 1717*t*, 1718
pharmacokinetics of, 1794*t*
resistance to, 1247
therapeutic uses of, 1249–1250, 1691
for varicella-zoster virus, 1249–1250
- Acyl coenzyme A:cholesterol acyltransferase (ACAT), 934
- ADALAT (nifedipine), 834*t*
- Adalimumab, 1419
pharmacokinetics of, 1795*t*
- Adapalene, 1683–1685
- ADAPIN (doxepin), 433*t*
- Adaptive immunity, 1405
- ADDERAL XR (amphetamine), 263
- Addiction, 563, 607–626
- Addison's disease, 1599, 1605
- Adducin polymorphism, 106*t*
- Adefovir, 1260–1261
for hepatitis B, 1260–1261
mechanism of action, 1260
resistance to, 1260
therapeutic uses of, 1261

- Adenine, 1339
- ADENOCARD (adenosine), 917
- Adenoma(s), prolactin-secreting, 1500
- Adenosine
- adverse effects of, 917–920
 - as antiarrhythmic agent, 917–920
 - electrophysiological actions of, 912*t*
 - mechanism of action, 908
 - benzodiazepines and, 406–407
 - chemistry of, 917
 - dosage of, 918*t*
 - drug interactions of, 920
 - as neurotransmitter, 146, 176, 335–336
 - pharmacokinetics of, 918*t*, 920
 - pharmacological effects of, 917
 - and renin secretion, 791
- Adenosine deaminase (ADA), pentostatin and, 1349
- Adenosine diphosphate (ADP), thromboxane A₂ and, 660
- Adenosine receptor(s), 149, 176, 335
- theophylline and, 728
- Adenosine receptor antagonist, A₁, as diuretic, 766
- Adenosine triphosphate (ATP)
- cardiac glycosides and, 886–887, 887*f*
 - and gastrointestinal motility, 984
 - hydrolysis of, and transport, 46, 58, 740
 - and insulin secretion, 1616
 - as neurotransmitter, 138, 141, 146, 174–176
 - and norepinephrine release, 163–164
- Adenosine triphosphate-binding cassette transporters. *See* ATP-binding cassette transporters
- S-Adenosylmethionine, for alcoholic liver disease, 597
- Adenovirus, ribavirin for, 1266
- Adenylyl cyclase
- β₂ adrenergic receptor agonists and, 720
 - in cyclic AMP synthesis, 29–30
 - in ethanol intoxication, 600
 - in opioid tolerance, 555
 - vasopressin receptors and, 776–777, 777*f*
- Adherence, to prescription orders, 1784
- Adhesion molecules, in inflammation, 671–672
- Administration of drugs, 4–7, 4*t*
- Adrenal cortex

 nephrotoxicity of, 1167
 neuromuscular blockade by, 1164
 ototoxicity of, 1162–1163, 1167
 pharmacokinetics of, 1797*t*
 resistance to, 1155, 1157*f*, 1158
 therapeutic uses of, 1165–1167
 for tuberculosis, 1167, 1203, 1204*t*, 1214
- AMIKIN (amikacin), 1166
- Amiloride, 757–759, 757*t*,
 for congestive heart failure, 875
 for diabetes insipidus, 759, 784
 for hypertension, 759, 850
 interaction with lithium, 488
 mechanism of action, 758, 758*f*
 site of action, 758
 therapeutic uses of, 759
- Amiloride-sensitive sodium channel (ENaC), 758
- Amino acid(s)
 and glucagon secretion, 1642
 as neurotransmitters, 330–332, 331*f*
- γ -Aminobutyric acid. *See* GABA
- Aminocaproic acid, 1480–1481
 for ophthalmic surgery, 1728
- Aminoglutethimide, 1385, 1385*f*, 1610–1611
 adverse effects of, 1611
 antiestrogen activity of, 1557, 1611
 antithyroid activity of, 1527
 mechanism of action, 1610–1611
 therapeutic uses of, 1611
- Aminoglycoside(s), 1155–1168
 absorption of, 1159
 adverse effects of, 1162–1164
 antibacterial spectrum of, 1158–1159, 1159*t*
 chemistry of, 1155–1156
 distribution of, 1159–1160
 dosing of, 1160–1161, 1161*t*
 elimination of, 1161–1162
 hypersensitivity to, 1164
 with β -lactam antibiotics, 1104, 1165
 mechanism of action, 1156–1157, 1158*f*
 metabolism of, 1100
 minimal inhibitory concentrations of, 1159*t*
 nephrotoxicity of, 1161, 1163–1164
 neuromuscular blockade by, 227, 1164
 ototoxicity of, 1160–1163
 pH and, 1101
 plasma concentrations of, 1160–1161, 1160*f*
 postantibiotic effect of, 1156
 in pregnancy, 1160
 with quinolones, 1122
 renal clearance of, 1161–1162
 impaired, 120
- resistance to, 1097, 1155, 1157–1158, 1157*f*
 therapeutic uses of, 1164–1168
 toxicity of, 1102, 1155, 1162–1164
 transport of, 1156, 1158
 with vancomycin, 1102
- α -Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid. *See* AMPA receptors
- Aminolevulinic acid
 increased excretion of, 1756*t*
 in lead poisoning, 1756–1758, 1756*t*, 1757*f*
 in photodynamic therapy, 1688–1689
- Aminolevulinic acid synthetase, barbiturates and, 417
- 6-Aminopenicillanic acid, 1128
- Aminopenicillins, 1139–1140. *See also* Amoxicillin; Ampicillin
- Aminopeptidase P, 646, 646*f*
- Aminophylline
 chemistry of, 727
 and lithium, 486–487
 toxicity of, 729
- Aminopyridine, mechanism of action, 225*f*
- Aminopyrine, 702
- 5-Aminosalicylate, 1114
- Aminosalicyclic acid, 1213
 for tuberculosis, 1203, 1204*t*, 1213
- Amiodarone, 920–921
 adverse effects of, 920, 1729
 as antiarrhythmic agent, 909, 913, 920–921
 dosage of, 918*t*
 electrophysiological actions of, 912*t*
 interactions of
 with chloroquine, 1035
 with cytochrome P450 enzyme-inhibiting agents, 122, 921
 with statins, 951
 iodine content of, 1532*t*
 mechanism of action, 909, 913
 P-glycoprotein inhibition by, 122
 pharmacokinetics of, 918*t*, 921, 1797*t*
 pharmacological effects of, 920
 and thyroid function, 921, 1527, 1532*t*
- Amisulpride, 467
- Amitriptyline
 chemistry of, 432, 433*t*
 CYP interactions of, 445*t*
 for depression, 432
 disposition of, 445*t*
 dose and dosage forms of, 433*t*
 half-life of, 445*t*
 interactions of
 with altretamine, 1329
 with morphine, 568
 mechanism of action, 312, 432
 with opioids, for analgesia, 581
 pharmacokinetics of, 1797*t*
 physical dependence on, 447
 potency of
 for receptors, 440*t*
 for transporters, 438*t*
 serum concentrations of, 444, 445*t*

- Amitriptyline—*continued*
 side effects of, 433*t*
 toxicity/poisoning by, 194
- Amlodipine, 857
 absorption, fate, and excretion of, 836
 adverse effects of, 837
 for angina, 837
 with β receptor antagonists, 839
 with atorvastatin, 953
 cardiovascular effects of, 833*t*, 834–836
 chemistry of, 832, 833*t*
 pharmacokinetics of, 1798*t*
 for Raynaud's disease, 838
- Ammonio steroids
 absorption, fate, and excretion of, 228
 as neuromuscular blocking agents, 220, 222, 222*t*, 228
- Amnesia
 in anesthetic state, 343–344
 benzodiazepines and, 404, 424
- Amobarbital, 415*t*, 419
- Amodiaquine, 1041–1042
 chemistry of, 1033*f*
 mechanism of action, 1034
 toxicity of, 1041–1042
- Amotivational syndrome, cannabinoids and, 623
- Amoxapine
 chemistry of, 432, 433*t*
 CYP interactions of, 445*t*
 disposition of, 445*t*
 dose and dosage forms of, 433*t*
 half-life of, 445*t*
 metabolism of, 444
 pharmacological properties of, 439
 potency of
 for receptors, 440*t*
 for transporters, 438*t*
 serum concentrations of, 445*t*
 side effects of, 433*t*, 447
- Amoxicillin, 1139–1140
 antimicrobial activity of, 1130*t*, 1133, 1139
 chemistry of, 1129*t*
 with ciprofloxacin, 1122
 with clarithromycin, 1185
 dosage of, intermittent, 20
 for fever, with cancer therapy, 1122
 for *Helicobacter pylori* infection, 979, 980*t*
 for Lyme disease, 1137
 major properties of, 1129*t*
 pharmacokinetics of, 1798*t*
 pharmacological properties of, 1139
 therapeutic indications for, 1139–1140
- Amoxicillin-clavulanate, 1133, 1152
 with ciprofloxacin, 1122, 1152
 prophylactic uses of, 1107*t*
 for upper respiratory tract infections, 1140
- AMOXIL (amoxicillin), 1139
- Ampakine(s), 455, 491
- AMPA receptors, 331*f*, 332
 in anxiety/depression, 455
 barbiturates and, 414–416
 in epilepsy, 503, 520
 in ethanol intoxication, 600
 in glutamate excitotoxicity, 332
- Amperozide, receptor actions of, 472*t*
- Amphetamine(s), 257–258
 abuse and dependence, 258, 429, 622
 analgesic effects of, 257, 581, 584
 antipsychotics and, 468
 appetite suppression by, 257–258, 262–263
 for attention-deficit/hyperactivity disorder, 263
 cardiovascular responses to, 257
 chemistry of, 239, 240*t*
 clinical uses of, 240*t*, 258–260
 CNS effects of, 257–258
 and dopamine transporter, 66
 drug interactions of
 with meperidine, 570
 with morphine, 568
 and fatigue/sleep, 257–258
 mechanism of action, 41–42, 173, 258
 for narcolepsy, 258, 262
 psychosis model from, 429
 reinforcing properties of, 608
 respiratory effects of, 257
 and serotonin, 258, 305, 450
 smooth muscle effects of, 257
 tolerance to, 258
 toxicity of, 258
- Amphiphic solute facilitators, 163
- AMPHOCIL (amphotericin B), 1226
- AMPHOTEC (amphotericin B), 1226
- Amphotericin B, 1225–1229
 absorption, distribution, and excretion of, 1227–1228
 adverse effects of, 1228–1229
 antifungal activity of, 1227
 antiprotozoal effects of, 1053
 chemistry of, 1225
 colloidal dispersion, 1226
 deoxycholate complex (conventional, C-AMB), 1226–1227
 with flucytosine, 1104, 1230
 fungal resistance to, 1227
 infusion reaction to, 570, 1228
 for leishmaniasis, 1052–1053
 lipid complex, 1227
 lipid formulations of, 1225–1227
 mechanism of action, 1053, 1227, 1228*f*
 ophthalmic use of, 1719*t*
 pharmacokinetics of, 1798*t*
 therapeutic uses of, 1053, 1228
 topical, 1240
 unilamellar vesicle, 1227
versus voriconazole, 1234
- Ampicillin, 1139–1140
 allopurinol and, 1141–1142
 antimicrobial activity of, 1130*t*, 1133, 1139
 chemistry of, 1129*t*
 drug interactions of
 with allopurinol, 709
 with proton pump inhibitors, 971
 hypersensitivity to, 1141–1142
 for listeriosis, 1137, 1140
 major properties of, 1129*t*
 for meningitis, 1140
 for nocardiosis, 1115
 for *Pasteurella multocida* infection, 1137
 pharmacological properties of, 1139
 resistance to, 1139–1140
 for salmonellosis, 1140
 therapeutic indications for, 1139–1140
 for upper respiratory tract infections, 1139–1140
 for urinary tract infections, 1115, 1140
- Ampicillin-sulbactam, 1133, 1140, 1152
- Ampiroxicam, 701
- Amprenavir, 1276*t*, 1305–1306
 chemistry of, 1304*f*, 1305
 in combination therapy, 1297
 drug interactions of, 122, 1295*t*, 1300*t*, 1306
 pharmacokinetics of, 1299*t*, 1305–1306
 therapeutic use of, 1306
- Amrinone. *See* Inamrinone
- Amycolatopsis mediterranei*, 1207
- Amygdaloid complex, 318
- Amyl nitrite, 625–626
 chemistry of, 825
 history of, 825
- β -Amyloid, in Alzheimer's disease, 528, 538–539
- Amyloid precursor protein, in Alzheimer's disease, 528, 539
- Amyotrophic lateral sclerosis (ALS), 542–543
 environmental triggers in, 528
 genetics of, 528, 542
 as prototypical neurodegenerative disorder, 527
 riluzole for, 542
 selective vulnerability in, 527
 spasticity of, treatment of, 542–543
 treatment of, 527, 542–544
- AMYTAL (amobarbital), 415*t*
- Anabolic steroids, 1581
- Anandamide, receptors for, 322
- ANADIN ULTRA (ibuprofen), 699
- Anaerobic infection(s)
 chloramphenicol for, 1180–1181
 penicillin G for, 1136
- ANAFRANIL (clomipramine), 433*t*
- Anal cancer
 cisplatin for, 1334
 mitomycin for, 1362
- Analgesia(s), 671–711. *See also specific agents*
 as adjuncts to anesthesia, 361–362
 in anesthetic state, 343–344
 for cancer pain, 584
 ceiling effect of, 556
 dependence on, percent and risk of, 609*t*
 ethanol for, 599–600
 in inflammatory bowel disease, 1018
 NSAIDs for, 617, 681–682
 opioids for, 547–584. *See also* Opioid(s)
 opioid sparing strategy in, 579–581
 patient-controlled, 343, 581

- poisoning from, 1745, 1745*t*–1746*t*
 postoperative, 343
 salicylates for, 688, 690
 selective CNS modification by, 336–337
 in terminal illness, 584
- Analgesic ladder, 579–581
- Analgesic nephropathy, 685
- Anandamide, 622
- Anaphylatoxins, and histamine release, 632
- Anaphylaxis
 epinephrine for, 248, 263
 histamine H₁ receptor antagonists for, 637, 640
 histamine release and, 632, 635, 637
 itraconazole and, 1232
 neuromuscular blocking agents and, 227
 penicillins and, 1141–1142
 platelet-activating factor and, 668
 slow-reacting substance of, 722–723
 tetracyclines and, 1178–1179
- Anastrozole, 75, 1385, 1386
 antiestrogen activity of, 1557–1558
 for breast cancer, 1387, 1557–1558
 chemistry of, 1385*f*, 1558
 pharmacokinetics of, 1799*t*
- ANCEF (cefazolin), 1144*t*
- ANCOBON (flucytosine), 1230
- Ancylostoma braziliense*, 1075
- Ancylostoma duodenale*, 1075, 1090
- Andrews, Edmond, 341
- ANDRIOL (testosterone undecanoate), 1578*f*
- ANDROCUR (cyproterone), 1388
- ANDRODERM (testosterone), 1578
- ANDROGEL (testosterone), 1578
- Androgen(s), 1573–1582. *See also* Testosterone
 action of, inhibitors of, 1582–1583
 in adulthood, 1576–1577
 adverse effects of, 1580
 agents targeting or inhibiting, 1582–1583. *See also* Antiandrogen(s); *specific agents*
 age patterns of, 1573, 1574*f*, 1576–1577
 alkylated, 1578*f*, 1579
 and alopecia, 1702–1703
 for angioedema, 1581
 athletes' use of, 1581
 in breast cancer, 1383
 in cancer chemotherapy, 1318*t*, 1381, 1387, 1388
 for catabolic and wasting states, 1581
 deficiency of, 1577–1578, 1580–1581
 in estrogen synthesis, 1542–1543
 for female hypogonadism, 1580–1581
 in infancy, 1576
 for male contraception, 1581
 for male hypogonadism, 1580
 pharmacological effects of, 1575–1577
 physiological effects of, 1575–1577
 in puberty, 1573, 1574*f*, 1576
 secretion of, 1588–1589, 1589*f*
 selective, design attempts for, 1579–1580
 in senescence, 1577, 1580
 therapeutic preparations of, 1578
 chemistry of, 1578*f*
 pharmacokinetics of, 1579*f*
 therapeutic uses of, 1580–1582
 in utero, 1573, 1576
- Androgen deprivation therapy (ADT), 1381, 1387
- Androgen receptor(s), 1575–1576
 and high-density lipoproteins, 940
 mineralocorticoid antagonists and, 761
 mutations of, 1576
 in prostate cancer, 1576
 structure of, 1575, 1576*f*
 testosterone effects via, 1575–1576, 1575*f*
- Androgen receptor antagonist(s), 1582–1583
 adverse effects of, 1388
 classification of, 1387
 nonsteroidal, 1388, 1388*t*
 for prostate cancer, 1387–1388
 steroidal, 1387
- Androstanediol, 1574
- Androstanedione, 1574
- Androstanol, 90
- Androstenedione
 athletes' use of, 1581
 chemistry of, 1385*f*, 1543*f*
 in estrogen synthesis, 1542, 1543*f*
- Androstenol, 48
- Androsterone, testosterone metabolism to, 1574, 1575*f*
- ANECTINE (succinylcholine), 222*t*
- Anemia(s)
 androgen therapy for, 1581
 aplastic
 carbamazepine and, 512–513
 chloramphenicol and, 1181
 ethosuximide and, 514
 felbamate and, 520
 indomethacin and, 695
 sulfonamides and, 1116
 of chronic renal failure, erythropoietin therapy for, 1438
 copper-deficiency, 1451
 darbepoetin alfa for, 1437
 eflornithine and, 1055
 epoetin alfa for, 1437–1439
 ethanol and, 598–599
 hemolytic
 androgen therapy for, 1580–1581
 corticosteroids for, 1610
 dimercaprol and, 1770
 methyl dopa and, 854
 primaquine and, 1041
 sulfonamides and, 1116
 hyperbaric oxygen for, 393
 hypochromic, treatment of, 1442–1452
 hypoplastic, chloramphenicol and, 1181
 in hypothyroidism, 1523
 and hypoxia, 390
 iron-deficiency, 1442, 1446–1451
 causes of, 10, 1446
 diagnosis of, 1446–1447
 sequential changes in, 1446, 1447*f*
 treatment of, 1447–1451
 adverse effects of, 1449
 complicating illnesses and, 1447
 duration of, 1448–1449
 effectiveness of, 1447–1448
 gastrointestinal tolerance of, 1447
 general therapeutic principles in, 1447–1448
 oral iron for, 1448–1449, 1448*t*
 parenteral iron for, 1449–1450
 toxicity/poisoning in, 1449
- in lead poisoning, 1756–1757
- macrocytic, ethanol and, 598
- megaloblastic, 1452–1461
 folic acid deficiency in, 1452–1454, 1458–1461
 nitrous oxide and, 1454
 pyrimethamine and, 1031
 vitamin B₁₂ deficiency in, 1452–1458
- microcytic, ethanol and, 598
- pernicious, 1452
- pyridoxine-deficiency, 1451
- sideroblastic, 598, 1451
- zidovudine and, 1284
- Anesthesia. *See also specific agents*

- and hypothalamus, 473–474

- Antipsychotic(s)—*continued*
 and limbic system, 470–473
 long-term treatment with, 483–484
 for mania, 481–482, 484, 489–490
 mechanism of action, 431, 469–470, 471f
 metabolic effects of, 480–481
 miscellaneous medical uses of, 484–485
 for nausea and vomiting, 484
 for negative symptoms, 482
 nervous system effects of, 469–474
 neuroleptic, 461–462, 482, 492
 and neuroleptic malignant syndrome, 467, 474, 478t, 479
 neurological effects of, 477–480
 nonresponders to, 482
 novel, 490–491
 parenteral administration of, 474, 483
 and parkinsonism, 478t, 479, 530
 in Parkinson's disease, 479, 481, 484
 and perioral tremor, 478t, 480
 pharmacogenetics of, 106t
 pharmacological properties of, 467–477
 physical dependence on, 476–477
 plasma concentrations of, 475–476
 preparations of, 477
 for psychosis, 481–484
 receptor actions of, 474, 490–491
 potencies of, 472t
 in vivo occupation in, 473
 renal effects of, 474
 and seizure threshold, 469
 selection of agent, 482
 selective CNS modification by, 336–337
 short-term treatment with, 481–483
 sites of action, 471f
 and sleep, 469
 in special populations, 483–484
 structure-activity relationships of, 462–467
 and tardive dyskinesia, 478t, 479–480, 490
 target symptoms for, 482
 and temperature, 473–474
 therapeutic indices of, 477
 therapeutic uses of, 430, 481–484
 tolerance to, 476–477
 for Tourette's syndrome, 484–485
 toxic reactions to, 477–481
 tricyclic, 461–481
 and vasopressin secretion, 775, 784
 and weight gain, 480–481
- Antipyretic(s)
 NSAIDs as, 682
 salicylates as, 687
 selective CNS modification by, 336–337
- Antipyrine, 702
 pharmacogenetics of, 93–94, 94f
- Antiresorptive agents, for osteoporosis, 1671
- Antiretroviral therapy, 1280–1310
 for HIV infection, 1273. *See also specific agents*
 access program for, 1276
 agents approved in U. S., 1276t
 combination/synergistic, 1277–1279, 1278t
 contraindicated regimes of, 1279t
 current treatment guidelines for, 1309–1310
 failed regimes in, 1279
 history of, 1275–1276
 initiation of, 1276–1277, 1278t–1279t
 and metabolic syndrome, 1279–1280

 patient characteristics and, 1278t
 preferred and alternative regimes of, 1278t
 principles of, 1276–1280
 resistance to, 1277
 structured treatment interruptions in, 1277
 hyperglycemic effects of, 1633t, 1634
- Antiseizure drug(s). *See also specific agents*
 adverse effects of, 507
 for alcohol withdrawal, 613
 barbiturates, 349, 414, 418, 510–511
 benzodiazepines, 404–405, 410, 516–517
 for benzodiazepine withdrawal, 615
 combination therapy with, 507, 521–522
 CYPs induced by, 121
 duration of therapy with, 522
 ethchlorvynol as, 421
 general considerations for, 507–508
 history of, 507
 in Huntington's disease, 541
 hydantoins, 508–510
 ideal, 507
 iminostilbenes, 512–513
 in infants and young children, 523
 interactions of
 with antipsychotics, 481
 with busulfan, 1330
 with hepatic microsomal enzymes, 509t, 522–523
 with sulfonamides, 1116
 in lead poisoning, 1758
 for mania, 485, 489–492, 512
 mechanism of action, 501, 505f
 with opioids, for analgesia, 581
 plasma concentrations of, 508, 522
 in pregnancy, 523
 propofol as, 350
 resistance to, transporters and, 43
 screening tests for, 507
 by seizure type, 502t
 selective CNS modification by, 336–337
 single-agent therapy with, 507, 521
 and sodium channels, 505, 505f, 508, 515, 518–520
 succinimides, 513–514
 therapeutic aspects of, 507–508
 toxicity of, 507–508
- Antiseptics, topical, iodine content of, 1532t
- Antithrombin, 1470
 estrogen and, 1548
 heparin and, 1471–1472, 1471f
- Antithrombotic agents, 1480–1481. *See also specific agents*
 for angina, 841
 contraindications to, 1481, 1481t
 hemorrhagic toxicity of, 1481
 in ophthalmic surgery, 1728
- Antithymocyte globulin, 1406, 1416–1417
- Antithyroid drug(s), 1526–1535, 1526t
 chemistry of, 1527, 1527f
 pharmacokinetics of, 1528, 1528t
 in pregnancy, 1530
 therapeutic uses of, 1529–1530
- Antitussive agents, centrally acting, 578–579
- ANTIVERT (meclizine), 638t
- Antiviral agent(s), 1243–1268. *See also specific agents*
 classification of, 1096
 combination therapy with, 1268
 dermatologic use of, 1691
 in development, 1267–1268, 1267t
 general principles of, 1243–1244
 mechanism of action, 1096
 nomenclature of, 1246t
 ophthalmic use of, 1717–1718, 1717t
 general considerations for, 1717
 therapeutic applications of, 1718
 resistance to, transporters and, 43
- ANTURANE (sulfapyrazone), 711
- ANUSOL (pramoxine hydrochloride), 379
- Anxiety disorder(s), 430
 antidepressants for, 430, 450–451
 benzodiazepines for, 404, 407, 410, 430, 453–454
 animal models of, 404
 histamine H₁ receptor antagonists for, 641
 insomnia with, 423
 meprobamate for, 422, 429–430
 pharmacotherapy for, 452–453
 placebo response in, 453–454
 selective serotonin reuptake inhibitors for, 453–454
 serotonin (5-HT) in, 304
 serotonin receptor agonists for, 305, 334
 vasopressin receptor antagonists for, 787
- ANZEMET (dolasetron), 1001
- Aortic dissection
 β adrenergic receptor antagonists for, 289
 sodium nitroprusside for, 864
- Apazone (azapropazone), 706
 for gout, 706–707
- Aperients, 990
- Apicoplast inhibitors, for malaria, 1045
- Aplastic anemia
 carbamazepine and, 512–513
 chloramphenicol and, 1181
 ethosuximide and, 514
 felbamate and, 520
 indomethacin and, 695
 sulfonamides and, 1116
- Apnea
 aminoglycosides and, 1164
 antipsychotics and, 480–481
 benzodiazepines and, 407, 412, 424

anti-IgE therapy for, 725–726
cromolyn sodium for, 726–727
eicosanoids in, 664
epinephrine for, 245
general anesthesia in, ketamine for, 351–353
glucocorticoids for, 721–722, 731, 1608–1609
histamine for, 636
as inflammatory disease, 717–718, 718*f*
kinins in, 647
leukotriene receptor antagonists for, 658, 664, 722–725
leukotriene-synthesis inhibitors for, 722–725
muscarinic receptor antagonists for, 193, 195–196, 730–731
nedocromil sodium for, 726–727
omalizumab for, 725–726
phosphodiesterase 4 inhibitors for, 728
platelet-activating factor in, 668
quinine and, 1039
theophylline for, 727–730
treatment of, 718–732
pharmacogenetics of, 731
- Astrocytes, 319
- ATACAND (candesartan cilexetil), 813
- Ataractic(s), 462
- ATARAX (hydroxyzine), 638*t*
- Ataxia(s)
inherited, physostigmine for, 211
phenobarbital and, 511
- Ataxia-telangiectasia and rad-related (ATR) protein, 1325
- Ataxia-telangiectasia-mutated (ATM) protein, 1325
- Atazanavir, 1276*t*, 1307–1308
chemistry of, 1304*f*, 1307
in combination therapy, 1297
drug interactions of, 1291, 1295*t*, 1300*t*, 1308
for HIV infection, 1307–1308
mechanism of action, 1307
pharmacokinetics of, 1299*t*, 1307, 1799*t*
therapeutic use of, 1308
- Atenolol, 284
absorption, fate, and excretion of, 284
for angina, 838–839
in breast milk, 11
chemistry of, 274*f*
for hypertension, 284
for hyperthyroidism, 1530
pharmacokinetics of, 278*t*, 285, 1800*t*
pharmacological properties of, 278*t*
receptor selectivity of, 272
- ATGAM (lymphocyte immune globulin), 1406
- Atherosclerosis
arterial wall biology in, 944–945
estrogen therapy and, 1553
hyperlipidemia and, 933, 940–948
leukotriene receptor antagonists for, 658
plaque stability in, 944–945
statins and, 950
- Athlete's foot, 1690–1691, 1691*t*
ciclopirox olamine for, 1239
griseofulvin for, 1236
haloprogin for, 1239
tolnaftate for, 1239
topical treatment of, 1237
undecylenic acid for, 1240
- ATIVAN (lorazepam), 360
- ATIVASE (alteplase), 1481
- Atomoxetine, 432
chemistry of, 436*t*
CYP interactions of, 445*t*, 446
disposition of, 445*t*
dose and dosage forms of, 436*t*
half-life of, 445*t*
pharmacokinetics of, 1800*t*
pharmacological properties of, 439
potency of
for receptors, 440*t*
for transporters, 438*t*
serum concentrations of, 445*t*
side effects of, 436*t*
- Atorvastatin, 58, 948–953
absorption, fate, and excretion of, 950–951
adverse effects of, 951–952
with amlodipine, 953
chemistry of, 948, 949*f*
in children, 953
clinical trials of, 942–943
dosage, for LDL-lowering effects, 949–950, 950*t*
drug interactions of, 122, 951–952
mechanism of action, 948–950
metabolism of, 950–951
induction of, 89*f*
pharmacokinetics of, 1800*t*

- in pregnancy, 952
- therapeutic uses of, 952–953
- Atosiban, 1507, 1509
- Atovaquone, 1028–1029

 with zonisamide, 521
 for mania, 485, 489–492, 512
 mechanism of action, 505, 512
 metabolism of, 79, 79*f*
 for neuralgia, 510, 512–513
 with opioids, for analgesia, 581
 pharmacokinetic properties of, 512
 pharmacokinetics of, 1805*t*
 pharmacological effects of, 512
 for seizures/epilepsy, 505, 512–513, 522
 teratogenicity of, 523–524
 therapeutic uses of, 513
 tolerance to, 512
 toxicity of, 512–513
 treatment of, 1748
 and vasopressin, 775, 779
- Carbapenems**, 1150–1151
- Carbaryl**, 204
- CARBATROL (carbamazepine)**, 512
- Carbenicillin**, 1130*t*, 1140, 1143
 antimicrobial activity of, 1131*t*, 1133, 1140
- Carbenicillin indanyl**, 1130*t*
 antimicrobial activity of, 1131*t*, 1133, 1140
- Carbenoxolone**, for gastric cytoprotection, 976
- Carbetapentane**, 579
- Carbidopa**
 dosage of, 533*t*
 with levodopa, 534
 versus muscarinic receptor antagonists, 197
 for Parkinson's disease, 533*t*, 534
 pharmacokinetics of, 1805*t*
 sustained-release, 533*t*
- Carbimazole**, 1527, 1527*f*, 1528
 in pregnancy, 1530
- Carbinoxamine**, 638*t*
- CARBOCANE (mepivacaine)**, 378
- Carbohydrate metabolism**
 β adrenergic receptor antagonists and, 276–277
 corticosteroids in, 1587, 1593, 1597–1598, 1603
 glucocorticoids and, 1587, 1593
 lithium and, 488
 salicylates and, 689, 691
- Carbon dioxide**, 394–395
- Carbonic anhydrase inhibitor(s)**, 743–747, 745*t*
 adverse effects of, 746, 1723–1724
 excretory effects of, 744*t*, 745–746
 extrarenal effects of, 746

- Carbonic anhydrase inhibitor(s)—*continued*
 for glaucoma, 212, 746, 1723
 mechanism of action, 743–745, 745f, 763f
 for metabolic alkalosis, 747
 for mountain sickness, 391
 renal hemodynamic effects of, 744t, 746
 for seizures/epilepsy, 746
 site of action, 743–745, 763f
 therapeutic uses of, 746–747
 toxicity of, 746
- Carbon monoxide poisoning
 hyperbaric oxygen for, 393
 and hypoxia, 390
- Carbon tetrachloride intoxication, 625–626
- Carboplatin, 1332–1334
 pharmacokinetics of, 1334, 1805t
 pharmacokinetic targeting of, 1321
 thrombopoietin therapy with, 1442
 toxicities of, 1326t, 1334
- Carbovir, 1289
- Carboxylesterases, 79, 79f, 209
- Carboxymethylcellulose, for diarrhea, 996
- Carboxypenicillins, 1140–1141
- Carboxypeptidase G2, for methotrexate toxicity, 1340
- Carboxypeptidase M, 646, 646f
- Carboxypeptidase N, 646
- Carbuncle, bacitracin for, 1199
- Carbutamide, history of, 1634
- Carcinogen(s), 1740, 1742–1743
 animal testing of, 1744–1745
 arsenic as, 1765
 cadmium as, 1767–1768
- Carcinogenic metabolites, 72
- Carcinoid tumor(s)
 diarrhea with, methysergide for, 313
 gastric
 histamine-secreting, 632
 proton pump inhibitors and, 971
 somatostatin analogs for, 1498, 1644
 streptozocin for, 1331
- CARDENE (nicardipine), 833t
- CARD15 gene, in Crohn's disease, 1011–1012
- Cardiac afterload, 827
 nitrates and, 827
 sodium nitroprusside and, 864
- Cardiac arrhythmia(s), 899–930
 β adrenergic receptor agonists and, 253
 β adrenergic receptor agonists for, 250
 common
 acute therapy for, 907t–908t
 chronic therapy for, 907t–908t
 mechanisms of, 906–908, 907t–908t
 drug-induced, 904, 905t, 916–917
 EEG findings in, 909f
 electrophysiology of, 899–904
 as “moving target,” 917
 epinephrine and, 245
 erythromycin and, 915, 1187
 ethanol and, 595
 isoproterenol for, 250
 mechanisms of, 899, 904–908
 pharmacotherapy for, 917–930. *See also specific agents*
 arrhythmias induced by, 916–917
 choice of approach in, 916
 clinical use of, principles in, 915–917
 contraindications to, patient specific, 916t, 917
 goals of, 899, 915–916
 mechanisms of action in, 908–915
 monitoring of, 917
 precipitating factor identification and removal before, 915
 spironolactone and, 761
 sympathomimetic agents for, 262–263
 symptoms due to, 916
 vasopressin and, 786
- Cardiac Arrhythmia Suppression Trial (CAST), 118, 915–916, 926
- Cardiac catheterization
 for congestive heart failure, 889, 893
 nitric oxide in, 396
- Cardiac cell(s)
 action potential behaviors of, differing, 901, 902f
 calcium channel antagonists and, 834–835
 electrophysiology of, 899–904
 resting, 899–900, 900f
- Cardiac conduction
 abnormalities in. *See* Cardiac arrhythmia(s)
 action potential in, 899–904
 differing behaviors, among cell types, 901, 902f
 initiation of, 900–901, 901f
 β adrenergic receptor antagonists and, 275
 β adrenergic receptors in, 167–168
 afterdepolarizations in, 904, 906f
 cholinergic transmission in, 153
 decremental, 903
 electrocardiogram of, 902f, 903, 906
 enhanced automaticity in, 904
 epinephrine and, 245
 fast-response *versus* slow-response tissue in, 903–904, 903f
 histamine and, 635

 equivalent dose of, 1594*t*
 etomidate and, 351
 Na⁺-retaining potency of, 1594*t*
 preparations of, 1602*t*
 relative potencies of, 1594*t*
 secretion of, 1588–1589, 1589*f*
 normal daily, 1593, 1593*t*
 specificity of, receptor-independent
 mechanism of, 1596, 1597*f*
 synthesis of, 1590*f*
 topical preparations of, 1682*t*
 transport, metabolism, and excretion of, 1601
- Cortisol-binding globulin (CBG), estrogen and, 1548
- Cortisol butyrate, 1602*t*, 1682*t*
- Cortisol cypionate, 1602*t*
- Cortisol sodium phosphate, 1602*t*
- Cortisol sodium succinate, 1602*t*
- Cortisone, 1587, 1594*t*, 1597*f*
 for chronic adrenal insufficiency, 1606
 metabolism of, 1601

- CORTROSYN (cosyntropin), 1592
 CORVERT (ibutilide), 924
Corynebacterium diphtheriae. See Diphtheria
Corynebacterium infection, vancomycin for, 632, 1196
 COSMEGEN (dactinomycin), 1357
 COSOPT (timolol-dorzolamide), 1723
 Costimulatory blockade, 1420–1421, 1420f
 Cosyntropin, 1592–1593
 Cotrimoxazole, 1116. See also Trimethoprim-sulfamethoxazole
 Cough
 ACE inhibitors and, 808–809, 879
 function of, 578
 opioids and, 560
 Cough suppression, centrally acting opioids for, 578–579
 COUMADIN (warfarin), 1477
 Coumestan derivatives, estrogenic activity of, 1542
 COVERA-HS (verapamil), 834t
 Covert toxocarasis, 1075
 COX. See Cyclooxygenase(s)
 Coxib(s), 658, 681, 702–705, 703f. See also specific agents
 COX inhibitors. See Cyclooxygenase inhibitor(s)
 COZAAR (losartan), 813
 CP 0127, 644t
 Crack cocaine, 608, 620
 Cranial nerve(s), 137–139
 Cranial nerve block, 381
 C-reactive protein, statins and, 950
 Creatinine clearance
 and aminoglycoside dosage, 1160–1161, 1161t
 in impaired renal clearance, 120
 topotecan and, 1356
 “Creeping eruption,” 1075, 1080
 CREMOPHOR EL (polyethoxylated castor oil), 1352
 CREON (pancreatic enzyme), 1006t
 CRESTOR (rosuvastatin), 953
 Cretinism, 1511, 1521
 treatment of, 1521, 1525
 Crigler-Najjar syndrome, 81, 97
 Crimean-Congo hemorrhagic fever, ribavirin for, 1266
 CRINONE (progesterone), 1561
 CRIXIVAN (indinavir), 1276t
 Crohn’s disease, 1009–1018
 antibiotics for, 1010t, 1017–1018
 azathioprine for, 1010t, 1015–1016
 cyclosporine for, 1010t, 1016
 genetics of, 1011–1012
 glucocorticoids for, 1010t, 1014–1015, 1609
 immunosuppressive agents for, 1009, 1010t, 1015–1016
 infliximab for, 1010t, 1016–1017, 1419
 mercaptopurine for, 1010t, 1015–1016
 mesalamine-based therapies for, 1010t, 1012–1014
 methotrexate for, 1010t, 1016
 metronidazole for, 1060
 pathogenesis of, 1009–1012, 1011f
 pharmacotherapy for, 1009, 1010t, 1012–1018
 for active disease, 1010t
 for maintenance, 1010t
 sites of action, 1011f
 in pregnancy, therapy for, 1018
 probiotics for, 1017–1018
 supportive therapy in, 1018
 thalidomide for, 1017
 CROLOM (cromolyn sodium), 1725
 Cromolyn sodium, 726–727
 for allergies, 632, 731
 for asthma, 726–727
 ophthalmic use of, 1725
 oral, for gastrointestinal symptoms, 727
 for rhinitis, 731
 Cross-tolerance, 611
 Crotamiton, 1692
 CRUDEX (calcium undecylenate), 1240
 Cruzipain, for trypanosomiasis, 1052
 Cryptococcosis (*Cryptococcus neoformans*)
 amphotericin B for, 1228
 combination therapy for, 1104
 fluconazole for, 1233
 flucytosine for, 1230
 treatment of, 1226t
 Cryptorchidism
 androgen deficiency and, 1577
 treatment of, 1507
 Cryptosporidiosis, 1051
 nitazoxanide for, 1051, 1063
 paromomycin for, 1051, 1063–1064
Cryptosporidium, 1051. See also Cryptosporidiosis
 Crystalluria
 indinavir and, 1303
 methenamine and, 1123
 sulfonamides and, 1116
 CTOP, 549t, 552t
 C-type natriuretic peptide, 885
 CUBICIN (daptomycin), 1197
 Cupric oxide, ophthalmic effects of, 1734
 Cupric sulfate, 1451
 CUPRID (trientine), 1772
 CUPRIMINE (penicillamine), 1771
 Curare, 220, 222, 225f
 absorption, fate, and excretion of, 228
 Cushing’s syndrome, 1598–1599, 1606, 1610
 aminoglutethimide for, 1611
 behavioral changes in, 1604
 ketoconazole for, 1611
 metyrapone for, 1611
 Cutaneous infections, treatment of, 1690
 Cutaneous larva migrans, 1075, 1080
 Cyanide toxicity
 and hypoxia, 390
 sodium nitroprusside and, 885
 Cyanoacrylate tissue adhesive, in ophthalmic surgery, 1726
 Cyanocobalamin, 1452, 1454, 1454f, 1456
 ophthalmic effects of, 1731t
 supplementation of, 1456–1457
 CYCLEN (norgestimate), 1563
 Cyclic adenosine monophosphate (cAMP)
 in ACTH-mediated steroidogenesis, 1589
 actions of, 30
 β_2 adrenergic receptor agonists and, 720
 β adrenergic receptors and, 167
 in allergic responses, 632
 in congestive heart failure, 872
 dopamine receptors and, 249, 531, 531f
 in ethanol intoxication, 600
 in fever, 681
 and ion channels, 322
 and norepinephrine, 333
 and parathyroid hormone, 1652
 and renin secretion, 792f
 as second messenger, 29–30, 329
 synthesis of, 29–30
 thyroid hormone and, 1522
 vasopressin receptors and, 777, 777f
 Cyclic adenosine monophosphate response element (CRE), 30
 Cyclic adenosine monophosphate response element-binding protein (CREB), 30
 selective serotonin reuptake inhibitors and, 443
 tricyclic antidepressants and, 441
 vasopressin receptors and, 777
 Cyclic AMP-regulated GTPase exchange factors, 30
 Cyclic guanosine monophosphate (cGMP)
 actions of, 30
 and ion channels, 322
 organic nitrates and, 825
 as second messenger, 30, 329
 in visual cycle, 1732–1733, 1733f
 Cyclic nucleotide(s), 29–30. See also Cyclic adenosine monophosphate; Cyclic guanosine monophosphate
 Cyclic nucleotide-gated (CNG) ion channels, 30, 321–322
 Cyclizine, 638t
 for motion sickness, 641, 1004
 for nausea/vomiting, 1004
 receptor specificity of, 1002t
 CYCLOCORT (amcinonide), 1602t, 1682t
 CYCLOGYL (cyclopentolate), 198
 Cyclooxygenase(s), 655
 in arachidonic acid metabolism, 336, 654f, 655
 COX-1, 654f, 655, 674
 gastrointestinal effects of, 661
 in inflammation, 664
 in parturition, 664
 in patent ductus arteriosus, 683
 and smooth muscle, 660–661
 COX-2, 654f, 655, 674
 and cancer, 665
 CNS effects of, 661
 in inflammation, 658, 664–665
 in parturition, 664
 in patent ductus arteriosus, 683
 and renin secretion, 791, 792f, 793

- Cyclooxygenase(s)—*continued*
 COX-3, 674, 693
 inhibition of, 657–658. *See also*
 Cyclooxygenase inhibitor(s)

 acetaminophen as, 693
 chemistry of, 674
 COX-1, 657–658, 671
 COX-2, 657–658, 671, 681, 702–705, 703*f*
 as adjuncts to anesthesia, 361
 antiinflammatory properties of, 658, 664–665
versus aspirin, 679*t*–680*t*
 for Bartter's syndrome, 682
 for bronchospasm, 661
 for cancer chemoprevention, 682–683
 cardiovascular effects of, 684, 703
 concomitant with aspirin, 685
 gastrointestinal effects of, 661, 684
 for gout, 707
 interactions of
 with antihypertensive agents, 123
 with lithium, 487
 for menstrual pain, 681
 for neurological disease, 661
 for peptic ulcer disease, 661
 pharmacokinetics of, 679*t*–680*t*, 702–703
 for postoperative pain, 343
 in pregnancy and lactation, 685
 for psychosis, 491
 renal effects of, 664, 685
 drug interactions of, 703
 enolic acids as, 700–701
 propionic acid derivatives as, 698–699
- Cyclopentolate
 ophthalmic use of, 198, 1720*t*, 1724
 for uveitis, 1724
- Cyclopentylpropionate, 1578
- Cyclophosphamide, 1322, 1323*f*, 1327–1328
 for cancer chemotherapy, 1327–1328
 cytotoxic actions of, 1327
 dermatologic use of, 1694
 with fluorouracil, 1344
 for immunosuppression, 1415
 interaction with allopurinol, 708
 metabolism of, 73, 1322, 1323*f*
 for multiple sclerosis, 1425
 pharmacokinetics of, 1327, 1813*t*
 pharmacological actions of, 1327
 therapeutic uses of, 1328
 thrombopoietin therapy with, 1442
 toxicities of, 1325–1327, 1326*t*, 1694
 for transplant rejection prevention, 1328
 and vasopressin, 775, 1327
- Cycloplegia, 1711
 muscarinic receptor antagonists for, 197–198
- Cyclopropane, 341–342, 346
- Cycloserine, 1213–1214
 for tuberculosis, 1203, 1204*t*, 1213–1214
- Cyclospora cayetanensis*, 1053
- Cyclospora* infection, trimethoprim-sulfamethoxazole for, 1118
- Cyclosporine, 1408–1412, 1409*f*
 absorption of, ABC transporters and, 57
 adverse effects of, 1695
 bioequivalence of preparations, 1408
 dermatologic use of, 1694–1695
 disposition of, 1408
 drug interactions of, 1412
 with acyclovir, 1249
 with chloroquine, 1035
 with cytochrome P450 enzyme-inducing agents, 90, 121, 1412
 with cytochrome P450 enzyme-inhibiting agents, 122, 1412
 with proton pump inhibitors, 971
 with sirolimus, 1412
 with St. John's wort, 90
 with statins, 951
 formulations, 1409–1410
 and gout, 707
 and HMG-CoA reductase inhibitors, 59
 for immunosuppression, 1409–1411
 for inflammatory bowel disease, 1009, 1010*t*, 1016
 mechanism of action, 1408, 1410*f*, 1694–1695
 for myasthenia gravis, 213
 ophthalmic use of, 1726
 and paclitaxel, 1352–1353
 pharmacokinetics of, 1408, 1814*t*
 for psoriasis, 1411–1412, 1693
 radioimmunoassays of, 1410
 for rheumatoid arthritis, 1411
 site of action, 1407*t*
 therapeutic uses of, 1411
 and transporters, 43, 45
- CYLERT (pemoline), 259
- CYMBALTA (duloxetine), 436*t*
- CYP. *See* Cytochrome P450 enzymes

- Dexloxiglumide, for GI disorders, 988
- Dexmedetomidine, 256, 361
 as adjunct to anesthesia, 361
 anatomic sites of action, 345
- Dexmethylphenidate, 259
- Dexrazoxane, for anthracycline toxicity, 1358
- Dextran, ophthalmic use of, 1734
- Dextroamphetamine, 257, 258
 abuse and dependence, 622
 for attention-deficit/hyperactivity disorder, 263
 barbiturates for antagonism of, 418
 nomenclature for, 131
 pharmacokinetics of, 1815*t*
 for weight reduction, 262–263
- Dextromethorphan, 578–579
 interactions of
 with CYP inhibitors, 122
 with MAO inhibitors, 450
 and opioid tolerance, 563, 617
 pharmacogenetics of, 98, 125
 pharmacokinetics of, 1816*t*
- Dextropropoxyphene, 573
- DHA-clozapine, 490
- DHEA. *See* Dehydroepiandrosterone
- DIABETA (glyburide), 1636*t*
- Diabetes Control and Complications Trial (DCCT), 1623–1624
- Diabetes insipidus, 783–784
 amiloride for, 759, 784
 central, 783
 desmopressin for, 780, 783, 785–786
 indomethacin for, 784
 lithium and, 488
 nephrogenic, 783–784
 thiazide diuretics for, 784

- vasopressin in, 783–784
 vasopressin V₂ receptor agonists for, 785–786
- Diabetes mellitus, 1613, 1619–1625
 β adrenergic receptor antagonists in, 276
 antimicrobial toxicity in, 1102
 autoantibodies in, 1621
 biguanides for, 1638–1639
 complications of, pathogenesis of, 1623–1624
 foot infection in, quinolones for, 1122
 forms of, 1619, 1620*t*
 gene therapy for, 1633
 genetics of, 1620–1621
 glucagon in, 1623, 1642–1643
 glucagon-like peptide 1 in, 1641–1642
 α -glucosidase inhibitors for, 1640–1641
 immune response in, 1621–1622
 insulin action in, 1619–1625, 1622*f*, 1622*t*
 insulin therapy for, 1624–1633. *See also* Insulin therapy
 maturity-onset, of youth, 1616, 1620–1621, 1620*t*
 metabolic consequences of, 1613
 metformin for, 1638–1639
 nateglinide for, 1638
 niacin in, precautions with, 956
 oral hypoglycemic agents for, 1633–1642
 pancreatic transplantation of, 1633
 protamine hypersensitivity in, 1474
 receptor malfunction in, 32
 repaglinide for, 1638
 secondary, 1620*t*
 somatostatin for, 1642–1643
 sulfonylureas for, 1635, 1637–1638
 thiazolidinediones for, 1639–1640
 type 1, 1619–1622, 1620*t*
 type 2, 1619–1622, 1620*t*
 antipsychotics and, 480
 incidence of, reduction in, 1641
 lipid-lowering therapy in, 945–946
 vascular effects of, 1623
- Diabetes Prevention Program, 1641
- Diabetic ketoacidosis, 1628, 1632–1633
- Diabetic nephropathy
 ACE inhibitors for, 808
 angiotensin II receptor antagonists for, 813–814
 renin-angiotensin system in, 789
- Diabetic retinopathy, 1624
- DIABINASE (chlorpropamide), 1636*t*
- Diacetylmorphine. *See* Heroin
- Diacylglycerol, 28
 5-HT receptors and, 301
 vasopressin receptors and, 776–777, 776*f*
- Dialysis
 aminoglycoside removal in, 1162
 for lithium intoxication, 488
 peritonitis with
 gentamicin for, 1166
 quinolones for, 1121–1122
 for poisoning, 1750
 for salicylate poisoning, 692
- Dialysis disequilibrium syndrome, osmotic diuretics for, 748
- DIAMICRON (gliclazide), 1636*t*
- Diamine oxidase (DAO), in histamine metabolism, 631
- Diaminopyrimidine(s), 1029–1031
- DIAMOX (acetazolamide), 743
- Diarrhea, 995–998, 1008
 α_2 adrenergic receptor agonists for, 997
 antibiotic-associated, bacitracin for, 1199
 antimotility and antisecretory agents for, 996–998
 bile-salt induced, 996
 Ca²⁺ channel antagonists for, 998
 causes of, 995
 chloride channel antagonists for, 998
 clonidine for, 255–256, 997
 in cryptosporidiosis, 1051
 diphenoxylate for, 570
 eflornithine and, 1055
 ethanol and, 596–597
 fenamates and, 697
 in giardiasis, 1050
 guanadrel and, 856
 hydroscopic agents for, 996
 indomethacin and, 696
 in inflammatory bowel disease, treatment of, 1018
 iodoquinol and, 1056
 in irritable bowel syndrome. *See* Irritable bowel syndrome
 loperamide for, 570–571, 997
 methysergide for, 313
 miltefosine and, 1061
 misoprostol and, 973
 muscarinic receptor antagonists for, 197
 opioids for, 561–562, 570, 996–997
 quinidine and, 928
 suramin and, 1069
 tegaserod and, 988
 traveler's, 997
 treatment of, 995–998. *See also specific agents*
- Diarylaminoethylamine(s), 832. *See also specific agents*
- DIASORB (attapulgite), 996
- Diastolic blood pressure, in hypertension, 824*t*, 845
- Diastolic heart failure, 891–892, 892*f*
- Diatrizoate meglumine sodium, 1532*t*
- Diazepam, 403*t*, 408
 abuse and dependence, 614–615
 as adjunct to anesthesia, 360–361
 adverse effects of, 516
 cardiovascular effects of, 407, 516
 context-specific half-time of, 347*f*
 dosages of, 410*t*
 in elderly, 424
 interaction with proton pump inhibitors, 971
 in lead poisoning, 1758
 metabolism of, 408, 409*t*, 516
 pharmacokinetics of, 408, 410*t*, 516, 1816*t*
- for psychedelic drug toxicity, 624
 for seizures/epilepsy, 418, 516–517, 523
 for status epilepticus, 523
 for theophylline toxicity, 729
 therapeutic uses of, 410*t*, 517
 tolerance to, 404, 610
- Diazinon, 205, 206*t*
- Diazoxide, 865, 1644
 adverse effects of, 1644
 hyperglycemic effects of, 1634*t*, 1644
 mechanism of action, 1616, 1644
 pharmacokinetics of, 1644
- Dibenzoxepin tricyclics, 638*t*, 640

 dermatologic use of, 1689
 for extrapyramidal side effects, 641
 for motion sickness, 637, 1004
 for nausea/vomiting, 1004
 in paclitaxel pretreatment, 1352
 for Parkinson's disease, 537, 641
 pharmacokinetics of, 1818*t*

- in pregnancy, 639, 642
receptor specificity of, 1002*t*
as sedative-hypnotic, 422
side effects of, 642
- Diphenoxylate, 569*f*, 570
for diarrhea, 570, 997
in inflammatory bowel disease, 1018
- Diphenoxylate-atropine, toxicity of, 194–195
- Diphenylbutylpiperidines, 461
- Diphenylhydantoin. *See* Phenytoin
- Diphenylmethane derivatives, 994
- Diphenylpiperazines, 832. *See also specific agents*
- Diphtheria
erythromycin for, 1186
penicillin G for, 1137
- Diphyllobothrium latum*, 1077
- Dipivefrin, ophthalmic use of, 1720*t*–1721*t*
- Diplopia, strabismus and, 1724
- Diprenorphine, 552*t*
- DIPRIVAN (propofol), 350
- DIPROLENE (betamethasone dipropionate), 1682*t*
- DIPROSONE (betamethasone dipropionate), 1602*t*, 1682*t*
- Dipyridamole
as antiplatelet agent, 1482
and coronary blood flow, 827
interaction with adenosine, 920
- Dipyron, 702
- Dirithromycin, 1187
- Dirofilaria immitis*, 1084
- DISALCID (salsalate), 690
- Discoid lupus erythematosus, hydroxychloroquine for, 1693
- Disinhibition, benzodiazepines and, 412
- Disopyramide, 923
for cardiac arrhythmia, 923
contraindications to, 917
dosage of, 918*t*
electrophysiological actions of, 912*t*
pharmacokinetics of, 918*t*, 923
- Dispositional antagonism, 1744
- Dispositional tolerance, 610
- Disseminated intravascular coagulation, heparin for, 1472
- Distal convoluted tubule (DCT), 739
- Distal tubule, 738*f*
- DISTOCIDE (praziquantel), 1088
- Distribution of drugs, 2*f*, 7–10. *See also specific agents*
multicompartment model of, 15*f*, 16
one-compartment model of, 14–15, 15*f*
placental, 9–10, 54
rate of, 15, 15*f*
transporters and, 41, 42*f*

 - mechanism of action, 1292, 1296
 - pharmacokinetics of, 1292, 1293*t*, 1296, 1820*t*
 - resistance to, 1292–1294, 1296
 - teratogenicity of, 1296
 - therapeutic use of, 1296–1297
- Effective concentration range, 1791

- Effective dosage, 1791
 Effective refractory period (ERP), 903
 EFFEXOR (venlafaxine), 435*t*
 Efficacy
 of agonism, 35, 35*f*
 drug metabolism and, 87, 90–91
 of drug-receptor interaction, 34–35
 maximal (clinical), 125–126, 126*f*
 monitoring for, 128–129
 proof of, and regulatory process, 132
 quantal concentration-response curve for, 128, 129*f*
 relative, 35, 35*f*
 Efflux pumps, and antibiotic resistance, 1132, 1132*f*
 Eflornithine, 1051–1055
 EFUDEX (fluorouracil), 1694
 Eicosanoid(s), 28, 653–666
 biosynthesis of, 653–657, 654*f*, 656*f*
 inhibitors of, 657–658, 665–666
 and cancer, 665
 cardiovascular effects of, 658–660
 catabolism of, 658
 chemistry of, 653
 CNS effects of, 661
 endogenous, functions of, 663–665
 gastrointestinal effects of, 661, 665
 in immune response, 660, 664–665
 in inflammation, 660, 664–665, 672–673
 mechanism of action, 662–663
 ophthalmic effects of, 661, 665
 pharmacological properties of, 658–663
 and platelets, 660, 663–664
 renal effects of, 661
 respiratory effects of, 664
 and sexual function, 665–666
 and smooth muscle, 660–661
 and urine formation, 661
 uterine effects of, 661, 664–665
 vascular effects of, 664
 Eicosanoid receptor(s), 662–663, 662*t*
 cell signaling pathways of, 663
 Eicosanoid receptor agonist(s), 665
 Eicosanoid receptor antagonist(s), 665–666
 EISMYCIN (mupirocin), 1690
 ELAVIL (amitriptyline), 433*t*
 ELDEPRYL (selegiline), 299
 Elderly
 ACE inhibitors in, 859, 879
 β adrenergic receptor antagonists in, 851
 antianxiety agents in, 453
 antidepressants in, 446, 448–449, 452
 antimicrobial agents in, 1101–1102
 antipsychotics in, 475, 484
 barbiturates in, 349
 benzodiazepines in, 360–361, 424
 Ca²⁺ channel antagonists in, 858
 compliance among, 1785
 drug response in, 124
 hypoglycemia in, 1637
 insomnia in, 424
 nitrofurantoin in, 1123
 propofol in, 350
 Electrocardiogram, 902*f*, 903, 906
 epinephrine and, 246
 normal and abnormal rhythms in, 909*f*
 Electrochemical gradient, and transport, 45–47, 45*f*
 Electroconvulsive therapy (ECT), 429
 for depression, 432
 in elderly, 452
 and serotonin syndrome, 450
 trauma prevention in, neuromuscular blocking agents for, 229
 Electroencephalogram (EEG)
 benzodiazepines and, 405
 in epilepsy, 503–506, 504*f*
 Electrolyte(s)
 antipsychotics and, 474
 corticosteroids and, 1587, 1593, 1598, 1603
 and gastrointestinal motility, 989
 loss and replacement, in diarrhea, 995
 salicylates and, 691–692
 weak, transmembrane distribution of, 3, 3*f*
 Electrophilic metabolites, 72
 Electrophorus, nicotinic receptors in, 217
 Electroshock seizure test, 507
 ELESTAT (epinastine), 1725
 ELIDEL (pimecrolimus), 1696
 ELIGARD (leuprolide), 1502*t*
 Elimination half-life, 12, 16
 pharmacogenetics of, 93–94, 94*f*
 ELIMITE (permethrin), 1692
 ELITEK (rasburicase), 710
 ELITE (Evaluation of Losartan in the Elderly) trial, 880
 ELOCON (mometasone), 1602*t*, 1682*t*
 ELSPAR (L-asparaginase), 1363–1364
 EMADINE (emedastine difumarate), 1725
 EMCYT (estramustine), 1371
 Emedastine difumarate, 1725
 EMEND (aprepitant), 1005
 Emergency contraception, 1564–1565
 adverse effects of, 1566
 Emesis
 induced, for poisoning, 1746–1748
 serotonin (5-HT) in, 303
 Emetine, 1055
 EMLA ANESTHETIC DISC (lidocaine and prilocaine), 377
 Emollients, for constipation, 993–994
 Emphysema, therapy of, 730–732
 genetics of, 732
 Empirical therapy, antimicrobial agents for, 1099, 1103
 Emtricitabine, 1265, 1267*t*, 1276*t*, 1291–1292
 antiviral activity of, 1280, 1291
 chemistry of, 1280, 1281*f*, 1291
 drug interactions of, 1292
 for hepatitis B, 1292
 for HIV infection, 1291–1292
 mechanism of action, 1291–1292
 pharmacokinetics of, 1280, 1282*t*, 1292
 phosphorylation of, 1283*f*, 1291–1292
 resistance to, 1291–1292
 therapeutic uses of, 1292
 EMTRIVA (emtricitabine), 1276*t*
 E-MYCIN (erythromycin), 1185
 ENABLEX (darifenacin), 195
 Enalapril, 801, 802*f*, 803
 adverse effects of, 808–810
 for congestive heart failure, 879, 886
 in heart disease, 806*t*
 for hypertension, 858–859
 metabolism of, 11
 pharmacokinetics of, 1820*t*
 therapeutic uses of, 804–808
 and vasopressin secretion, 784
 Enalaprilat, 802*f*, 803
 adverse effects of, 808–810
 in heart disease, 806*t*
 therapeutic uses of, 804–808
 ENBREL (etanercept), 1419
 Encainide
 adverse effects of, 916
 clinical trials of, 118
 interaction with antidepressants, 446
 Encephalitis
 herpes simplex, acyclovir for, 1246
 toxoplasmic, 1051
Encephalitozoon, 1053, 1079
 Encephalopathy
 hepatic, lactulose for, 993
 in lead poisoning, 1755–1756
 reactive, melarsoprol and, 1057
 End-diastolic volume (EDV), 870–872
 Endocannabinoids, 327–328, 654*f*, 657
 Endocarditis
 enterococcal, combination therapy for, 1104, 1136
 gentamicin for, 1166
 prophylaxis against, 1105, 1138
 macrolides for, 1186
 rifampin for, 1209
 streptococcal
 combination therapy for, 1104
 penicillin G for, 1136
 streptomycin for, 1164
 teicoplanin for, 1197
 vancomycin for, 1196
 Endocrine system
 classical, renin-angiotensin system as, 794
 eicosanoids and, 662
 interaction with autonomic nervous system, 171
 Endocrine systems
 antipsychotics and, 473–474
 opioids and, 559
 Endometrial cancer
 cisplatin for, 1334
 estrogen therapy and, 1552, 1554
 oral contraceptives and, 1565–1567
 progestins for, 1561
 tamoxifen and, 1383, 1555, 1557
 Endometrium, estrogen/progestins and, 1546–1547, 1546*f*, 1559
 Endophthalmitis, 1713, 1717
 Endorphin(s), 335, 547–550

- Ethanol, 591–604
 absorption, distribution and metabolism of, 592–593, 592*f*, 609
 abuse of, 591, 594
 acute intoxication with, 600, 612
 ion channels in, 600
 mechanisms of CNS effects in, 600
 protein kinases and signaling enzymes in, 600
 and blackouts, 612
 blood levels of, 591–592, 599, 601
 in breast milk, 11
 and cardiomyopathy, 595
 cardiovascular effects of, 594–595
 cephalosporins and, 1149
 clinical uses of, 599–600
 as CNS depressant, 591, 593–594, 612

- Ethanol—*continued*
 cocaine use with, 620–621
 content, in beverages, 591
 cross-tolerance with, 613
 dependence on, 594, 601, 612–613
 acamprosate for, 604, 614
 antimicrobial toxicity in, 1102
 detoxification for, 613
 as disease, 601
 disulfiram for, 593, 602–603, 613
 folic acid deficiency with, 1460
 genetic influences in, 601–602, 609
 lifetime prevalence of, 612
 medical complications of, 613
 4-methylprazole for, 593
 naltrexone for, 578, 602–603, 613–614
 ondansetron for, 604
 percent and risk of, 609*t*
 pharmacotherapy for, 602–604, 613–614
 social and economic impact of, 591
 topiramate for, 604
 and depression, 613
 and diuresis, 596
 and esophagus, 596
 for ethanol withdrawal, 600
 GI effects of, 596–597
 hematological effects of, 598–599
 and hypertension, 595, 865–866
 and hypoglycemia, 1632, 1633*t*
 hypoglycemic effects of, 1633*t*
 immunological effects of, 598–599
 interactions of
 with antipsychotics, 481
 with barbiturates, 419
 with benzodiazepines, 409, 412, 454
 with metronidazole, 1059
 with nitrates, 829
 and lipoprotein levels, 594–595
 and liver disease, 593, 597
 nitroglycerin and, 885
 and pancreas, 597
 pharmacological properties of, 591–593
 physiological effects of, 593–599
 reinforcing properties of, 608
 sexual effects of, 598
 and skeletal muscle, 596
 and stomach, 596
 and stroke, 595
 and temperature, 596
 teratogenic effects of, 602, 613
 tolerance to, 594, 601, 609, 612–613
 and vasopressin, 775
 and vitamins/minerals, 594, 597–598
 withdrawal from, 601, 612–613, 613*t*
 benzodiazepines for, 613
 Ethanolamines, 638*t*, 640
 Ethchlorvynol, 420–422, 421*t*
 Ether, 341
 Ethinamate, 420
 Ethinyl estradiol, 1542*t*, 1550–1551, 1554
 for acne, 1567
 in contraception, 1563–1564, 1566
 17 α -Ethinyl-estradiol, metabolism of, 82
 Ethionamide, 1212–1213
 for leprosy, 1220
 therapeutic uses of, 1212
 for tuberculosis, 1203, 1204*t*, 1212–1213
 Ethnic diversity, and pharmacogenetics, 97, 98*f*
 Ethopropazine, chemistry of, 462
 Ethosuximide, 401, 513–514
 interaction with hepatic microsomal enzymes, 509*t*
 mechanism of action, 506, 513–514
 pharmacokinetic properties of, 514
 for seizures/epilepsy, 506, 513–514, 523
 therapeutic uses of, 514
 Ethotoxin, 508
 ETHRANE (enflurane), 358
 Ethylenediamines, 638*t*, 640
 Ethylenediaminetetraacetic acid (EDTA), as chelating agent, 1768–1769
 Ethyleneimine(s), 1316*t*, 1321–1322, 1329–1330
 chemistry of, 1322–1323
 Ethylketocyclazocine, 552*t*
 Ethyl *N*-dimethylphosphoramidocyanidate, 206*t*
 Ethylnorepinephrine, 240*t*, 260
 Ethynodiol diacetate, 1559
 ETHYOL (amifostine), 1334
 Eticlopride, 467
 Etidocaine, 377–378
 Etidronate, chemistry of, 1667, 1667*f*
 Etiocholanolone, testosterone metabolism to, 1574, 1575*f*
 Etodolac, 696–697
 versus aspirin, 676*t*
 pharmacokinetics of, 676*t*, 697
 Etomidate, 346*f*, 351, 353
 context-specific half-time of, 347*f*
 effects of, 342, 351
 enantiomer selectivity of, 345
 formulations of, 348*t*, 351

 Fick's first law, 46
 Field block anesthesia, 380
 Fight or flight response, 142
 Filariasis, 1076
 lymphatic, 1076
 albendazole for, 1074, 1076, 1079, 1081
 diethylcarbamazine for, 1074, 1076, 1083–1084
 elimination of, goals for, 1074, 1076
 ivermectin for, 1074, 1076, 1085–1087
 supportive therapy in, 1084
 Filgrastim, 1440–1441
 for ganciclovir toxicity, 1255
 for paclitaxel toxicity, 1354
 pharmacokinetics of, 1440, 1825*t*
 Filtration equilibrium, 739
 FINACEA (azelaic acid), 1701
 Finasteride, 1582–1583
 adverse effects of, 1583, 1703
 for alopecia (baldness), 1583, 1702–1703
 for benign prostatic hyperplasia, 268, 272, 1583
 chemistry of, 1583, 1702
 for hirsutism, 1583
 pharmacokinetics of, 1826*t*
 FiO₂ (inspired oxygen fraction), low, and hypoxemia, 388
 First-pass effect, 4, 11, 18
 Fish-odor syndrome, 78
 Fish tapeworm, 1077
 FK453, 766
 FK506 (tacrolimus), 1016, 1412
 FK-33824, 549*t*
 Flagellin protein, in Crohn's disease, 1012
 FLAGYL (metronidazole), 7, 1058
 FLAP (5-LOX-activating protein), 655–657, 656*f*
 polymorphisms of, 658
 Flashbacks, with psychedelic drugs, 624–625
 Flatulence, pharmacotherapy for, 1007
 Flatworms, 1073, 1077–1078
 Flavin-containing monooxygenases (FMOs), 73, 74, 78
 Flavone(s), estrogenic activity of, 1542
 Flavonoid(s)
 antithyroid properties of, 1513
 estrogenic activity of, 1542, 1551
 Flavoxate hydrochloride, 197
 Flecainide, 924
 adverse effects of, 916, 924
 for cardiac arrhythmia, 118, 913, 924
 dosage of, 918*t*
 electrophysiological actions of, 912*t*
 interaction with antidepressants, 446
 mechanism of action, 913, 924
 pharmacokinetics of, 918*t*, 924, 1826*t*
 pharmacological effects of, 924
 FLEET PHOSPHO-SODA (sodium phosphate), 992
 Fleroxacin, chemistry of, 1120*f*
 FLOLAN (epoprostenol), 666
 FLOMAX (tamsulosin), 270
 FLORONE (diflorasone diacetate), 1682*t*
 FLOVENT (fluticasone propionate), 721
 FLOXIN (ofloxacin), 1119
 Floxuridine, 1341–1344, 1341*f*, 1342*f*
 FLT-3 ligand, 1436*t*
 Fluconazole, 1233–1234
 adverse effects of, 1233, 1728
 cutaneous use of, 1691*t*
 CYP inhibition by, 122
 dosage of, 1233–1234
 drug interactions of, 1233
 with celecoxib, 704
 with valdecoxib, 704
 with flucytosine, 1230
 ophthalmic use of, 1719*t*
 pharmacokinetics of, 1826*t*
 Flucytosine, 1229–1230, 1229*f*
 with amphotericin B, 1104, 1230
 metabolism of, 1100
 therapeutic uses of, 1230
 FLUDARA (fludarabine phosphate), 1348–1349
 Fludarabine phosphate, 1348–1349
 chemistry of, 1348, 1348*f*
 pharmacokinetics of, 1348, 1826*t*
 therapeutic uses of, 1348
 Fludrocortisone, 1594*t*, 1597*f*
 antiinflammatory potency of, 1594*t*
 chemistry of, 1597*f*, 1603
 for chronic adrenal insufficiency, 1606
 for congenital adrenal hyperplasia, 1607
 Flufenamic acid, 677*t*, 697
 Fluid balance, corticosteroids and, 1598, 1603
 Fluid retention, minoxidil and, 862–863
 Flukes, 1073, 1078
 Flumazenil, 402, 403*t*
 as benzodiazepine antagonist, 404–406, 413–414, 615
 pharmacokinetics of, 1827*t*
 therapeutic uses of, 413
 Flunisolide
 for asthma, 721–722, 1608–1609
 for rhinitis, 731
 Flunitrazepam
 as date rape drug, 412, 624
 metabolism of, 409, 409*t*
 Fluoborate, as antithyroid drug, 1531
 Fluocinonide, 1682*t*
 FLUONEX (fluocinonide), 1682*t*
 Fluorescein, 1729
 FLUORESOF (fluorexon), 1729
 Fluorexon, 1729
 Fluoride, 1673–1674
 Fluorodeoxyuridine. *See* Floxuridine
 Fluorometholone, ophthalmic use of, 1724
 FLUOROPLEX (fluorouracil), 1694
 Fluoroquinolone(s), 94, 105*t*, 1119–1122
 antibacterial spectrum of, 1119–1121
 for bone, joint, and soft tissue infections, 1122
 chemistry of, 1119, 1120*f*
 in children, 1102
 for diarrhea, 997
 prophylactic uses of, 1105
 resistance to, 1098, 1119
 for salmonellosis, 1140
 therapeutic uses of, 1121–1122
 for tuberculosis, 1212
 Fluorouracil, 94, 105*t*, 1342–1343
 absorption, fate, and excretion of, 1343
 activation of, 1342, 1342*f*
 chemistry of, 1341, 1341*f*
 in combination therapy, 1343–1344
 dermatologic use of, 1694
 mechanism of action, 1342–1343, 1342*f*
 ophthalmic use of, 1713, 1725–1726
 pharmacokinetics of, 1827*t*
 resistance to, 1336, 1342–1343
 therapeutic uses of, 1343
 toxicities of, 1344

- FLUOTHANE (halothane), 354
- Fluoxetine
 chemistry of, 432, 435*t*
 CYP interactions of, 445*t*
 for depression, 432
 in Huntington's disease, 541
 dose and dosage forms of, 435*t*
 drug interactions of, 446, 449–450
 with antipsychotics, 481
 with carbamazepine, 513
 metabolism of, 444–445
 pharmacogenetics of, 125
 pharmacokinetics of, 445*t*, 1827*t*
 potency of
 for receptors, 440*t*
 for transporters, 438*t*
 sexual side effects of, cyproheptadine for, 314
 side effects of, 435*t*, 448
 and vasopressin secretion, 784
- Fluoxetine/olanzapine, 453, 482
- Fluoxymesterone, chemistry of, 1578*f*
- Fluperlapine, chemistry of, 462–466
- Fluphenazine
 chemistry of, 462, 463*t*
 dose and dosage forms of, 463*t*, 477, 483
 formulations, 462, 463*t*, 475, 477
 metabolism of, 475–476
 pharmacokinetics of, 475*t*, 1827*t*
 receptor actions of, 472*t*, 474, 1002*t*
 side effects of, 463*t*
 therapeutic uses of, 481–484
 and vasopressin, 775
 and weight gain, 480
- Flurandrenolide, 1682*t*
- Flurazepam, 403*t*, 407–409
 adverse effects of, 412
 pharmacokinetics, 408–410, 411*t*
 therapeutic uses of, 411*t*, 412
- Flurbiprofen, 699–701
versus aspirin, 678*t*
 chemistry of, 699*f*
 classification of, 678*t*
 ophthalmic use of, 1725
 pharmacokinetics of, 678*t*
- Flushing
 niacin and, 683–684, 956
 vancomycin and, 632, 1196
- Fluspirilene, 466
- Flutamide, 1389–1390, 1582
 adverse effects of, 1582
 chemistry of, 1582
 for hirsutism, 1582
 pharmacokinetics of, 1390, 1828*t*
 for prostate cancer, 1387–1388, 1582
- Fluticasone propionate
 for asthma, 721–722, 1608–1609
 for rhinitis, 731
 with salmeterol, 721
- Fluvastatin, 58, 948–953
 absorption, metabolism, and excretion of, 950–951
 adverse effects of, 951–952
 chemistry of, 948, 949*f*
 dosage, for LDL-lowering effects, 949–950, 950*t*
 drug interactions of, 951–952
 mechanism of action, 948–950
 therapeutic uses of, 952–953
- Fluvoxamine, 434*t*
 CYP interactions of, 445*t*, 446
 for depression, 432
 dose and dosage forms of, 434*t*
 interaction with antipsychotics, 481
 pharmacokinetics, 445*t*
 potency of
 for receptors, 440*t*
 for transporters, 438*t*
 side effects of, 434*t*
- FOCALIN (dexmethylphenidate), 260
- Folic acid, 1335, 1452–1453, 1458–1461
 absorption, distribution, and elimination of, 1458–1459, 1459*f*
 chemistry of, 1458, 1459*f*
 daily requirements for, 1458
 deficiency of, 1452, 1459–1461
 diagnosis of, 1460
 hematopoietic effects of, 1460
 metabolic effects of, 1452–1453
 trimethoprim-sulfamethoxazole and, 1118
 metabolic role of, 1452–1454, 1453*f*, 1458
 ophthalmic effects of, 1731*t*
 relationship with vitamin B₁₂, 1452–1454, 1453*f*
 supplementation of, 1460–1461
 in inflammatory bowel disease, 1018
 in pregnancy, 524, 1458
 with pyrimethamine therapy, 1031
- Folic acid analog(s), 1335–1340
 absorption, fate, and excretion of, 1337–1338
 for cancer chemotherapy, 1316*t*
 cytotoxic action of, 1337
 mechanism of action, 1336
 pharmacogenetics of, 1338
 resistance to, 1336–1337
 sites of action, 1335–1336, 1335*f*
 structure-activity relationship of, 1335–1336, 1337*f*
 therapeutic uses of, 1338–1339
 toxicity of, 1339
 transport of, 1336
- Folinic acid, 1460. *See also* Leucovorin
- ophthalmic use of, 1719
- Follicle-stimulating hormone (FSH), 1489, 1490*t*, 1500–1507
 action of, molecular and cellular bases of, 1501–1503
 in differential diagnosis of reproductive diseases, 1505
 estrogen and, 1545–1546, 1546*f*
 in menstrual cycle, 1505, 1546*f*
 opioid receptor antagonists and, 577
 opioids and, 559
 oral contraceptives and, 1564–1565
 for ovulation induction, 1506
 physiological effects of, 1503
- pulsatile release of, 1545
 recombinant, 1505
 synthesis and secretion of, 1501, 1501*f*
 and testosterone secretion, 1573
 therapeutic uses of, 1505–1506
- Folliculitis, 1690
- FOLLISTIM (follitropin β), 1505
- Follitropin, 1505
- Fomepizole, 1751
- FOMEPIZOLE (4-methylprazole), 593
- Fomivirsen, 1253, 1268
 for CMV infection, 1253, 1717*t*
 ophthalmic use of, 1717*t*

 hyperglycemic effects of, 1634*t*
 low-molecular-weight
 preparations of, 1473
 production of, 1471
versus standard, 1472
 therapeutic use of, 1472
 mechanism of action, 1471–1472
 monitoring with, 1472–1473
 pharmacokinetics of, 1472, 1832*t*
 pharmacological effects of, 1472
 in pregnancy, 1472
 resistance to, 1473
 source of, 1471
 sulfate, 1471
 synthetic derivatives of, 1473
 thrombocytopenia with, 1474
 toxicities of, 1474
- Hepatic clearance, 13–14
 in elderly, 124
 impaired, 120–121
 in neonates and children, 123
- Hepatic encephalopathy, lactulose for, 993
- Hepatic lipase, 937
- Hepatic necrosis
 acetaminophen and, 694
 halothane and, 357
 phenytoin and, 510
- Hepatic portal osmoreceptors, and vasopressin, 774–775
- Hepatic uptake, transporters and, 59–60
- Hepatitis. *See also* *specific infections*
 acute, increased pyrrole excretion in, 1756*t*

- corticosteroids for, 1609–1610
 ethanol and, 597
 ethionamide and, 1213
 halothane, 357
 isoniazid and, 1207, 1216
 nevirapine and, 1294
 penicillins and, 1143
 rifampin and, 1209
 treatment of, 1260–1266
 in clinical development, 1267*t*
- Hepatitis B
 adefovir for, 1260–1261
 antiviral agents in development for, 1267*t*
 emtricitabine for, 1292
 famciclovir for, 1252–1253
 interferons for, 1263–1264
 lamivudine for, 1265
- Hepatitis B immune globulin, 1423, 1424*t*
- Hepatitis C
 amantadine for, 1258
 antiviral agents in development for, 1267*t*
 interferons for, 1264
 ribavirin for, 1266
 rimantadine for, 1258
- Hepatocellular carcinoma, oral contraceptives and, 1565
- Hepcidin, 1444–1445
- Hepoxilins, 657
- HERCEPTIN (trastuzumab), 1376–1378
- Hereditary hypophosphatemic rickets with hypercalciuria (HHRH), 1661
- Hereditary sideroblastic anemia, 1451
- HER2/neu, trastuzumab and, 1376, 1378
- Heroin, 564, 565*t*, 567
 adverse effects of, 567–568
 with cocaine, illicit use of, 618
 dependence on, 617–620
 detoxification for, 611
 percent and risk of, 609*t*
 history of, 547
versus methadone, 618, 618*f*
 mortality rate with, 618–619
 receptor action and selectivity of, 553
 therapeutic use of, 581
 tolerance to, 618
 withdrawal from, 619, 619*t*
 pharmacological interventions for, 619–620
- Herpes simplex virus (HSV), 1246, 1691
 acyclovir for, 1247, 1249
 acyclovir-resistant, 1247
 antiviral agents in development for, 1267*t*
 cidofovir for, 1250–1251
 docosanol for, 1251
 famciclovir for, 1252
 foscarnet for, 1253–1254
 idoxuridine for, 1256
 interferons for, 1264
 penciclovir for, 1252
 trifluridine for, 1256
 type 1, 1246
 type 2, 1246
 valacyclovir for, 1247, 1249
 vidarabine for, 1246
- Herpesvirus(es)
 replication of, 1245*f*
 treatment of, 1246–1256, 1691. *See also specific agents and infections*
- Herpesvirus KSHV, receptor action and affinity of, 38
- Herpes zoster ophthalmicus, 1717*t*, 1718
- Herpes zoster virus (HZV). *See* Varicella-zoster virus (VZV)

 recombinant, for immunostimulation, 1422
 IFN- γ , 1261–1263, 1262*f*
 corticosteroids and, 1600, 1600*t*
 in inflammation, 672
 in inflammatory bowel disease, 1011, 1011*f*
 recombinant, for immunostimulation, 1422
 for tuberculosis, 1212
 immune interactions of, 1262–1263
 for immunostimulation, 1422
 for papillomavirus, 1264
 pegylated, 1263
 therapeutic uses of, 1263–1264
 for viruses, 1263–1264
- Intergenic regions, polymorphisms in, 95–96, 96*f*
 functional effect of, 102*t*
- Interindividual variation, 120–121, 120*f*
 determinants of, 120–121
- Interleukin(s), 1436*t*
 IL-1, 1436*t*
 corticosteroids and, 1600, 1600*t*
 estrogen and, 1547
 in inflammation, 672
 in pain, 681
 receptor for, antagonism of, 672
 in rheumatoid arthritis, 673
 site of action, 1435*f*
 IL-1 α , 672
 IL-1 β , 672
 in fever, 682
 IL-2, 1374, 1436*t*
 antitumor activity of, 1374
 for cancer chemotherapy, 1374–1375
 corticosteroids and, 1600, 1600*t*
 ethanol and, 599
 for immunostimulation, 1422–1423
 pharmacokinetics of, 1374
 receptor for, antibodies against, 1418–1419
 site of action, 1435*f*
 therapeutic uses of, 1374–1375, 1423
 toxicities of, 1374, 1423
 IL-3, 1436*t*
 corticosteroids and, 1600, 1600*t*
 site of action, 1435*f*
 therapeutic role of, 1441
 IL-4, 1436*t*
 site of action, 1435*f*
 IL-5, 1436*t*
 IL-6, 1436*t*
 corticosteroids and, 1600, 1600*t*
 estrogen and, 1547
 in fever, 1681
 site of action, 1435*f*
 therapeutic role of, 1441
 IL-7, 1436*t*
 IL-8, 1436*t*
 in pain, 681
 IL-9, 1436*t*
 IL-10, 1436*t*
 in inflammation, 672
 IL-11, 1435*f*, 1436*t*, 1441
 IL-12, 1436*t*
 in inflammatory bowel disease, 1011, 1011*f*
 Interlobular arteries, 737
 Intermediate-density lipoprotein (IDL), 935*t*, 938
 Intermediate tubule, 738*f*
 International normalized ratio (INR), in anticoagulant therapy, 1477, 1479–1480
 Interstitial cells of Cajal, 141, 984

- Ketoacidosis, diabetic, 1627, 1631–1632
- Ketoconazole, 1231, 1610–1611
 for androgen inhibition, 1582
 cutaneous use of, 1691*t*
 CYP inhibition by, 77, 122
 drug interactions of
 with didanosine, 1286
 with imatinib, 1367
 with valdecoxib, 704
 interactions of
 with benzodiazepines, 408
 with gastric pH-raising agents, 121
 with proton pump inhibitors, 121, 971
 mechanism of action, 1610
 ophthalmic use of, 1718–1719, 1719*t*
 P-glycoprotein inhibition by, 122
 pharmacokinetics of, 1839*t*
 therapeutic uses of, 1611
- α -Ketoglutarate, and OAT transporters, 63–65

- Ketolide(s), 1187–1188
 therapeutic uses of, 1188
- Ketone(s)
 in diabetes mellitus, 1623
 and glucagon secretion, 1642
- Ketoprofen, 678*t*, 699*f*, 700
versus aspirin, 678*t*
 pharmacokinetics of, 678*t*, 700
- Ketorolac, 677*t*, 697–698
 adverse effects of, 698
versus aspirin, 677*t*
 chemistry of, 697, 1725
 and nausea/vomiting, 343
 ophthalmic use of, 698, 1725
 pharmacokinetics of, 677*t*, 697–698, 1840*t*
 pharmacological properties of, 697
 for postoperative pain, 343
 for systemic mastocytosis, 682
 therapeutic uses of, 698
- Ketotifen
 for allergic diseases, 640
 ophthalmic use of, 1725
- Khat, 622
- Kidney(s), 737–742
 adefovir and, 1261
 alkylating agents and, 1326
 aminoglycosides and, 1163–1164
 anatomy and physiology of, 737–742
 angiotensin II and, 797–799
 anion and cation handling in, 742
 antimicrobial agents and, 1100–1101
 antipsychotics and, 474
 arsenic and, 1765
 autonomic regulation of, 144*t*
 barbiturates and, 417
 cadmium and, 1767, 1768*f*
 calcium retention in, 1656
 cephalosporins and, 1149
 cidofovir and, 1251
 cisplatin and, 1334
 colchicine and, 708
 colistin and, 1193–1194
 COX-2 inhibitors and, 664, 685
 desflurane and, 359
 development of, renin-angiotensin system in, 800
 diuretics and, 742–766
 dopamine and, 248
 drug clearance by, 14, 1789
 alterations in individual patients, 1792–1793
 in elderly, 124
 impaired, 120–121, 1792–1793
 in neonates and children, 124
 drug metabolism in, 11
 edetate calcium disodium, 1769
 eicosanoids and, 661, 664
 excretion via, 10
 foscarnet and, 1253
 function of, overview of, 739
 halothane and, 356
 isoflurane and, 357
 kinins and, 647–648
 lead poisoning and, 1757
 lithium and, 487–488
 minoxidil and, 862
 NSAIDs and, 683*t*, 683–684
 organic acid and base secretion in, 741–742, 742*f*
 parathyroid hormone and, 1651–1652
 passive countercurrent multiplier hypothesis of, 739
 phosphate retention in, 1656
 platelet-activating factor and, 667
 polymyxin B and, 1193–1194
 prostaglandins and, 661
 salicylates and, 688
 sevoflurane and, 360
 tenofovir and, 1291
 tetracyclines and, 1178
 transport in, 43, 44*f*, 48, 48*f*, 60–64, 739–742, 740*f*–742*f*
 vancomycin and, 1196
 vasopressin and, 777–779, 778*f*
 water conservation in, 777–779, 778*f*
- Kidney disease, corticosteroids for, 1608
- Kidney failure
 acute, diuretics for, 748, 753
 chronic
 ACE inhibitors for, 808
 anemia of, erythropoietin therapy for, 1438
 diuretics for, 756, 764–765, 766*f*
 renin-angiotensin system in, 789
- Kidney stones
 carbonic anhydrase inhibitors and, 746
 indinavir and, 1303
 zonisamide and, 521
- Kinase(s), 1366–1369
- Kinase inhibitor(s), 1366–1369
- Kindling, in epilepsy, 504
- Kinin(s), 643–649
 in allergic responses, 631
 cardiovascular effects of, 647
 chemistry of, 644, 644*t*
 functions of, 647–649
 in inflammation, 647
 metabolism of, 646, 646*f*
 in pain, 647
 pharmacology of, 647–649
 renal effects of, 647–648
 in respiratory disease, 647
 synthesis and metabolism of, 643, 644*f*
 therapeutic uses of, potential, 648
- Kininase I, 643, 646*f*
- Kininase II, 643, 800. *See also* Angiotensin-converting enzyme (ACE)

 for *Campylobacter* infection, 1186
 CYP inhibition by, 122
 dosage of, 1185
 drug interactions of, 951, 1187
 with bexarotene, 1686
 for gastrointestinal motility disorders, 988
 mechanism of action, 1183–1184, 1183*f*
 for *Mycobacterium avium* complex, 1185–1186, 1204, 1204*t*, 1217–1218
 pharmacokinetics, 1184–1185
 prophylactic uses of, 1186
 for pyrimethamine toxicity, 1031
 resistance to, 1183–1184
 therapeutic uses of, 1185–1186
- Macrophage(s)
 corticosteroids and, 1600, 1600*t*
 in immune response, 1405
- Macrophage colony-stimulating factor (M-CSF), 1434, 1435*f*, 1436*t*
 therapeutic role of, 1441
- Macula densa, 739
 and renin secretion, 791, 792*f*
- Mafenide, pharmacological properties of, 1115
- Magaldrate, 975
- MAGAN (magnesium salicylate), 691
- Magnesium
 as antiarrhythmic agent, 929–930
 electrophysiological actions of, 912*t*
 calcitonin and, 1657
 diuretics and, 752, 756, 877
 ethanol and, 598
 in neurodegenerative disorders, 528–529
 parathyroid hormone and, 1652
 renal handling of, 742
- Magnesium aluminum disilicate, for diarrhea, 996

- Magnesium-containing antacids, 974*t*, 975
 Magnesium-containing laxatives, 992
 Magnesium salicylate, 690
 Magnesium sulfate
 as laxative, 992
 for purgation, 1749
 Magnetic resonance imaging, laser-polarized helium in, 397
 Ma huang, 261
 Maintenance dose, 19–20
 Major depression, 430, 454. *See also*
 Depression
 insomnia with, 423
 psychopharmacotherapy for, 431–453.

- Methadone, 566, 572–573
 for analgesia, 572–573, 617
 with benzodiazepines, illicit use of, 614
 dependence on, 572–573, 617–620
versus heroin, 618, 618*f*
 interactions of, 572
 with CYP inducers, 121
 with didanosine, 1286
 intraspinal, 582*t*
 neuroendocrine effects of, 559
 for opioid dependence, 573, 619–620
 pharmacokinetics of, 1848*t*
 pharmacological actions of, 572
 receptor action and selectivity of, 552*t*
 structure-activity relationship of, 564
 therapeutic uses of, 573
 tolerance to, 572–573
 toxicity of, 572, 574
 withdrawal from, 619, 619*t*
- Methamphetamine, 240*t*, 242, 258–259
 abuse and dependence, 622
 clinical uses of, 240*t*
 mechanism of action, 259
 for weight reduction, 262–263
- Methanol, 593
 toxicity/poisoning, ethanol for, 600
- Methazolamide, 743–747, 745*t*
 for glaucoma, 1723
- Methcathinone, 622
- Methemoglobinemia
 nitric oxide and, 396
 prilocaine and, 378
 primaquine and, 1041
 sodium nitroprusside and, 885
- Methenamine, 1122–1123
 for urinary tract infections, 1111, 1122–1123
- Methicillin, 1129*t*
 antimicrobial activity of, 1130*t*, 1133
 hypersensitivity to, 1142
 resistance to, 1096, 1098, 1117–1118, 1131–1132, 1136, 1138, 1690
- Methimazole, 1527, 1527*f*, 1528–1529
 for hyperthyroidism, 1527–1530
 pharmacokinetics of, 1528, 1528*t*
 in pregnancy, 1530
 therapeutic uses of, 1529–1530
- Methionine metabolism, 1452–1454, 1458
- Methohexital, 347–350
 chemistry of, 346*f*, 347–349, 415*t*
 dosages of, 348*t*, 349
 formulations of, 347–349, 348*t*
 as general anesthetic, 347–350, 418–419

- Methohexital—*continued*
 pharmacokinetics and metabolism of, 348*t*, 349, 415*t*, 418
 pharmacological properties of, 348*t*
 routes of administration, 415*t*
 side effects of, 349–350
 therapeutic uses of, 349, 415*t*
- Methonium compound, 220
- Methotrexate, 1335, 1335*f*, 1336
 for abortion, 665
 absorption, fate, and excretion of, 1337–1338
 for cancer chemotherapy, 1335–1340
 contraindicated in pregnancy, 1018
 cytotoxic action of, 1337
 drug interactions of, 1338, 1693–1694
 with acyclovir, 1249
 with COX-2 inhibitors, 703
 with NSAIDs, 686
 with propionic acid derivatives, 699
 with fluorouracil, 1343–1344
 high-dose, with leucovorin rescue, 1338–1339
 for immunosuppression, 1336, 1415
 for inflammatory bowel disease, 1010*t*, 1016
 mechanism of action, 1336
 with mercaptopurine, 1347–1348
 pharmacogenetics of, 105*t*–106*t*, 108, 108*f*, 1321, 1339
 pharmacokinetics of, 1848*t*
 pharmacokinetic targeting of, 1321
 probenecid and, 710
 for psoriasis, 1336, 1339, 1693–1694
 resistance to, 1337, 1338
 for rheumatoid arthritis, 690, 706
 sites of action, 1335, 1335*f*
 structure-activity relationship of, 1335–1336
 therapeutic uses of, 1338–1339
 toxicity of, 1338, 1340
 treatment of, 1694, 1750
 transport of, 64
- Methoxamine, 240*t*, 242
 for cardiac arrhythmias, 262–263
- Methoxsalen, 1687–1698
 chemistry of, 1687
 therapeutic uses of, 1688
- 3-Methoxy-4-hydroxymandelic acid, 164, 165*f*
- 5-Methoxy-*N,N*-dimethyltryptamine, 299
- Methscopolamine bromide, 190, 197
 for irritable bowel syndrome, 1000
- Methsuximide, 513
- Methylclothiazide. *See also* Thiazide diuretics
 absorption and elimination of, 754*t*
 chemistry of, 754*t*
- Methylation, in drug metabolism, 73, 77*t*, 86–87
- Methylatropine, 189
- Methylatropine nitrate, 190
- Methylbenzoniun chloride, with paromomycin, 1064
- Methylcellulose
 for constipation, 992
 for diarrhea, 996
- Methylcobalamin, 1452–1454, 1454*f*
- Methyldopa, 258, 852–854
 clinical pharmacology, 852, 852*f*, 853–854
 and hemolytic anemia, 854
 hepatotoxicity of, 854
 for hypertension, 852–854
 in pregnancy, 853–854
 mechanism of action, 171, 258, 853
 pharmacological effects of, 853
 precautions with, 853–854
 pseudotolerance to, 853
 therapeutic uses of, 854
 and vasopressin secretion, 784
- Methylene bisbenzotriazolyl tetramethylbutylphenol, 1700
- Methylenedioxymphetamine (MDA), 624–625
- Methylenetetrahydrofolate reductase (*MTHFR*) polymorphisms, 106*t*, 107–108, 108*f*, 109
- Methylethylergonovine, 309–310, 310*t*
 for postpartum hemorrhage, 311, 1509
- Methylguanine-deoxyribonucleic acid methyltransferase polymorphism, 106*t*
- (*R*)- α -Methylhistamine, 629, 630*f*, 641
- 2-Methylhistamine, chemistry of, 630*f*
- 4(5)-Methylhistamine, chemistry of, 630*f*
- α -Methyl-5-HT, 300*t*
- Methylhydrazine(s), 1317*t*, 1331–1332
- Methylmelamines, 1317*t*, 1324, 1329–1330
- Methylmercury
 poisoning
 diagnosis of, 1761–1763, 1762*t*
 treatment of, 1763
 sources of and exposure to, 1759–1760, 1759*t*
- 7 α -Methyl-19-nortestosterone, 1578*f*, 1580
- Methylparathion, 205
- Methylphenidate, 259
 abuse and dependence, 259, 622
 for attention-deficit/hyperactivity disorder, 263
 interaction with barbiturates, 419
 pharmacokinetics of, 259, 1848*t*
- 4-Methylprazole, for alcoholism, 593
- Methylprednisolone, 1594*t*, 1603
 antiinflammatory potency of, 1594*t*
 duration of action, 1594*t*
 equivalent dose of, 1594*t*
 for inflammatory bowel disease, 1014
 interactions of
 with aprepitant, 1005
 with CYP inducers, 121
 with CYP inhibitors, 122
 Na⁺-retaining potency of, 1594*t*
 pharmacokinetics of, 1849*t*
 for spinal cord injury, 1610
- Methylprednisolone sodium succinate, 1408
 for dermatologic disease, 1683
- Methyl salicylate, 687*f*, 689
- Methyltestosterone, 1578*f*
- Methyltetrahydrofolate, 1453
- Methyltransferases (MTs), 73
- α -Methyltyrosine. *See* Metyrosine
- Methylxanthine(s), 336, 727–730. *See also* Caffeine; Theobromine; Theophylline
 interaction with adenosine, 920
 mechanism of action, 177
- Methyprylon, 420
- Methysergide, 310*t*, 313
 mechanism of action, 312
 for migraine, 310, 313
 pharmacological actions of, 309*t*
 side effects of, 313
- Metiapine, chemistry of, 462
- Metipranolol
 for glaucoma, 291, 1721*t*, 1723
 ophthalmic use of, 1721*t*
- Metoclopramide, 467, 985, 1002*t*
 adverse effects of, 986
 formulations of, 986
 for gastroesophageal reflux disease, 986
 for GI motility disorders, 985–986
 for gastroparesis, 986
 mechanism of action, 985
 for nausea/vomiting, 343, 986
 and parkinsonism, 530, 986
 pharmacokinetics of, 985, 1849*t*
 pharmacological properties of, 985
 receptor specificity of, 1002*t*
 therapeutic use of, 986
- Metocurine, 220
- Metolazone, 754*t*. *See also* Thiazide diuretics
 for hypertension, 848
- METOPIRON (metyrapone), 1611
- Metoprolol, 273*t*, 278, 284
 absorption, fate, and excretion of, 284
 for angina, 838
 for anxiety, 454
 for cardiac arrhythmia, 915
 for congestive heart failure, 290, 882–883, 882*f*
 for heart failure, 284
 for hypertension, 284
 interaction with celecoxib, 703
 mechanism of action, 174
 membrane-stabilizing effects of, 272
 for migraine prophylaxis, 290
 for myocardial infarction, 289
 pharmacokinetics of, 278*t*, 284, 1849*t*
 pharmacological properties of, 278*t*
 receptor selectivity of, 272, 284
 therapeutic uses of, 284
 withdrawal from, 612
- Metoprolol in Dilated Cardiomyopathy Trial, 882–883
- Metoprolol Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF), 883
- Metrifonate, 205, 1087–1088
 for schistosomiasis, 1078, 1088
- Metrizamide, iodine content of, 1532*t*
- METROCREAM (metronidazole), 1690
- METROGEL (metronidazole), 1690

- Metronidazole, 1058–1060
 for acne, 1690
 for amebiasis, 1050, 1058–1060
 antimicrobial effects of, 1058
 antiparasitic effects of, 1058
 for bacterial infections, 1058–1060
 carcinogenicity of, 1060
 contraindications to, 1060
 for dracunculiasis, 1077
 drug interactions of, 1059–1060
 with busulfan, 1330
 with ritonavir, 1302
 for giardiasis, 1050, 1058–1060
 for *Helicobacter pylori* infection, 979, 980*t*, 1058–1059
 for inflammatory bowel disease, 1010*t*, 1017, 1060
 pharmacokinetics of, 1059, 1850*t*
 prophylactic uses of, 1106*t*
 resistance to, 979, 1058–1059
 teratogenicity of, 1060
 therapeutic uses of, 1059–1060
 toxicity of, 1060
 for trichomoniasis, 1050, 1058–1060
- METVIX (aminolevulinic acid), 1689
- Metyrapone, 1610–1611
- Metyrosine, 857
 mechanism of action, 171
- MEVACOR (lovastatin), 952
- Mevastatin, 948–953, 949*f*
 absorption, fate, and excretion of, 950–951
 adverse effects of, 951–952
 drug interactions of, 951–952
 mechanism of action, 948–951
 in pregnancy, 952
 therapeutic uses of, 952–953
- Mexican American(s), polymorphisms in, 97
- Mexiletine, 926
 adverse effects of, 926
 for cardiac arrhythmia, 926
 electrophysiological actions of, 912*t*
 mechanism of action, 913
 pharmacokinetics of, 918*t*, 926
- MEXITIL (mexiletine), 926
- MEXORYL SX AND XL (ecamsule), 1700
- Meyer-Overton rule, 345
- MEZLIN (mezlocillin), 1140
- Mezlocillin, 1130*t*
 antimicrobial activity of, 1131*t*, 1133
 for *Klebsiella* infection, 1140
 for *Pseudomonas aeruginosa* infection, 1140
- MIACALCIN (calcitonin), 1662
- Mianserin
 mechanism of action, 443
 potency of, for transporters, 438*t*
- Mibefradil, interaction with statins, 951
- Micafungin, 1235
- MICARDIS (telmisartan), 813
- MICATIN (miconazole), 1238
- Miconazole, 1238
 cutaneous use of, 1690
 ophthalmic use of, 1718–1719, 1719*t*
 therapeutic uses of, 1238
- MICRHOGRAM (Rho(D) immune globulin), 1424*t*
- Microgels, 1681
- Microglia, 319
- Microiontophoresis, in receptor studies, 328
- Micromonospora*, 1155
- MICRONASE (glyburide), 1635*t*
- MICRONOR (norethindrone), 1564
- Microphallus, 1577
- Microsomal triglyceride transfer protein (MTP), 934, 938
- Microsporidiosis, 1053
 ciclopirox olamine for, 1239
 fumagillin for, 1053, 1055
 griseofulvin for, 1236
- Microsporium*. See Microsporidiosis
- MIDAMOR (amiloride), 757
- Midazolam
 as adjunct to anesthesia, 360–361
 cardiovascular effects of, 407
 chemistry of, 403*t*
 context-specific half-time of, 347*f*
 hepatic clearance of, impaired, 121
 interaction with CYP inhibitors, 122
 pharmacokinetics of, 408–409, 409*t*, 411*t*, 1850*t*
 routes of administration, 411*t*
 therapeutic uses of, 411*t*
- Midbrain, 318
- Midodrine, 254
 for orthostatic hypotension, 261
- MIFEPREX (mifepristone), 1562
- Mifepristone, 1561–1562, 1611–1612
 for abortion, 665, 1562
 absorption, fate, and excretion of, 1562
 adverse effects of, 1562–1563
 for depression, 452
 for labor induction, after fetal death, 1563
 mechanism of action, 1611
 pharmacological actions of, 1562
 therapeutic uses and prospects of, 1562–1563, 1612
- Miglitol, 1640
- Migraine(s), 306
 ergot and ergot alkaloids for, 310
 estrogen therapy and, 1553
 methysergide for, 310, 313
 prophylaxis against
 β adrenergic receptor antagonists for, 292
 verapamil for, 838
 serotonin receptor agonists for, 305–310, 334
 triptans for, 306, 308
- MIGRANAL (dihydroergotamine mesylate), 310
- Migrating motor complex, 983, 984*f*
- Migrating myoelectric complex, 983, 984*f*
- Milk, for chemical inactivation, 1749
- Milk-alkali syndrome, 975, 1659
- MILK OF MAGNESIA, 974*t*
- Million Women Study (MWS), 1552
- Milnacipran, 455
 potency of, for transporters, 438*t*
- Milrinone
 for congestive heart failure, 890–892, 892*f*
 withdrawal from market, 841
- Miltefosine, 1060–1061
 for leishmaniasis, 1052, 1060–1061
 in pregnancy, contraindication to, 1061
 therapeutic uses of, 1061
 toxicity and side effects of, 1061
 for trypanosomiasis, 1061
- MILTOWN (meprobamate), 421*t*
- Minamata disease, 1760
- Mineral(s), ethanol and, 594, 597–598
- Mineralocorticoid(s), 1587, 1593–1610
 cardiovascular effects of, 1598–1599
 chemistry of, 1601–1603
 classification of, 1594–1595, 1594*t*
 for congenital adrenal hyperplasia, 1607
 deficiency of, 1598
 disorders of, 1596
 in electrolyte and water balance, 1587, 1593, 1598
 excess of, 1596, 1598
 gene expression regulation by, 1596
 mechanism of action, 1595–1596
 pharmacological effects of, 1597–1600
 replacement therapy
 for adrenal insufficiency, 1604–1607
 with aminoglutethimide, 1611
 monitoring of, 1606
 secretion of, ACTH and, 1588–1589, 1589*f*
 and skeletal muscle, 1599
 specificity of, receptor-independent
 mechanism of, 1596, 1597*f*
 structure-activity relationships of, 1601–1603
 synthesis of, 1589–1591, 1590*f*
 transport, metabolism, and excretion of, 1601
- Mineralocorticoid receptor(s), 1595–1596
- Mineralocorticoid receptor antagonist(s), 759–762, 760*t*
 absorption and elimination of, 760*t*, 761–762
 adverse effects of, 762
 for congestive heart failure, 874*t*, 875–876
 drug interactions of, 762
 excretory effects of, 744*t*, 761
 extrarenal effects of, 761
 for hypertension, 762, 850
 mechanism of action, 760–761, 761*f*
 renal hemodynamic effects of, 744*t*, 761
 site of action, 760–761
 therapeutic uses of, 762
 toxicity of, 762
- Mineral oil
 for constipation, 993–994
 ophthalmic use of, 1734
- Miner's disease, 1075
- Miniature end-plate potential(s) (MEPP), neuromuscular blocking agents and, 223
- Minimum alveolar concentration (MAC), in anesthetic potency, 344, 344*t*

- Minipill, 1563–1564, 1566
 MINIPRESS (prazosin), 270, 851
 MINOCIN (minocycline), 1176
 Minocycline, 1173–1179, 1174*f*
 absorption of, 1175, 1690
 for acne, 1690
 adverse effects of, 1178–1179, 1690, 1729
 antimicrobial effects of, 1173–1174
 for coccal infections, 1177
 dosage of, 1176
 excretion of, 1175
 for leprosy, 1220–1221
 for nocardiosis, 1177–1178
 resistance to, 1174–1175
 routes of administration, 1176
 therapeutic uses of, 1176–1178
- Minoxidil, 862–863
 for alopecia, 1702
 chemistry of, 862, 1702
 clinical pharmacology, 862–863
 for hypertension, 862–863
 and hypertrichosis, 863
 precautions with, 862–863
 renal effects of, 862
 therapeutic uses of, 863
- MINTACOL (paraoxon), 206*t*
 MINTEZOL (thiabendazole), 1080
 MIOCHOL-E (acetylcholine), 188
 Miosis, 1711
 agents against, 1725–1726
 anticholinesterase agents and, 207–208
 opioids and, 559–560
- MIOSTAT (carbachol), 1720*t*
 Miotics, for glaucoma, 1723
 Mipaflox, delayed neurotoxicity of, 211
 MIRADON (anisindione), 1480
 MIRALAX (polyethylene glycol), 993
 MIRENA (levonorgestrel), 1564
 MIRPEX (pramipexole), 535
 Mirtazapine, 436*t*
 CYP interactions of, 445*t*, 446
 for depression, 453
 dose and dosage forms of, 436*t*
 mechanism of action, 443
 pharmacokinetics of, 444, 445*t*, 1850*t*
 potency of
 for receptors, 440*t*
 for transporters, 438*t*
 side effects of, 436*t*, 447–448
- Mismatch repair (MMR) proteins, and
 resistance to platinum complexes, 1333
- Misoprostol, 973
 for abortion, 665
 adverse effects of, 973
 for constipation, 995
 contraindications to, 973
 with diclofenac, 698
 for gastric cytoprotection, 973
 with NSAIDs, for gastric protection, 685
 for peptic ulcer disease, 665, 979, 979*t*
 pharmacokinetics of, 973
 for postpartum hemorrhage, 1509
 therapeutic uses of, 973
- Missense mutations, 95
 diseases associated with, 101, 101*f*
- MITHRACIN (mithramycin), 1663
 Mithramycin
 for hypercalcemia, 1663
 for Paget's disease, 1673
- Mitogen-activated kinase (MAPK), 28
 estrogen receptors and, 1550
 glutathione S-transferases and, 83–85
 opioid receptors and, 555
- Mitomycin, 1362–1363
 absorption, fate, and excretion of, 1363
 extravasation of, 1363
 mechanism of action, 1362
 ophthalmic use of, 1725–1726
 therapeutic uses of, 1363
 toxicities of, 1363
- Mitomycin C, ophthalmic use of, 1713
- Mitotane, 1373
- Mitoxantrone, 1359
 for multiple sclerosis, 1425, 1426*t*
 pharmacokinetics of, 1850*t*–1851*t*
 therapeutic use of, 1359–1360
- MIVACRON (mivacurium), 222*t*
 Mivacurium, 220, 221*f*, 222*t*
 absorption, fate, and excretion of, 229
 autonomic effects of, 226
 in electroconvulsive therapy, 229
 and histamine release, 226
 kinetics of action, 220, 222*t*
 pharmacologic properties of, 222*t*
- Mizolastine, 638*t*
 MIZOLLEN (mizolastine), 638*t*
 MK-886, 655
 MOBAN (olanzapine), 465*t*
 MOBIC (meloxicam), 701
 Moclobemide, drug interactions of, 450
 Modafinil, for cocaine dependence, 621
 Modifier polymorphisms, 106*t*, 109–110
 Modulatory effects, of neurotransmitters, 329
- Moexipril, 802*f*, 804
 adverse effects of, 808–810
 for hypertension, 858–859
 therapeutic uses of, 804–808
- Molecular cloning studies, of receptor properties, 322*f*, 328, 328*f*
- Molindone, 465*t*, 467
 dose and dosage forms of, 465*t*
 drug interactions of, 481
 half-life of, 475*t*
 receptor actions of, 472*t*
 and seizure threshold, 469
 side effects of, 465*t*
 and weight gain, 480
- Molluscum contagiosum, 1691
- MOMENTUM (magnesium salicylate), 691
- Mometasone, 1602*t*
 for rhinitis, 731
 topical preparations of, 1682*t*
- MONISTAT (miconazole), 1238
 MONISTAT-DERM (miconazole), 1238
 6-Monoacetylmorphine (MAM), 567
 Monoamine(s)
 antidepressants and, 438*t*, 439–443
 lithium and, 485–486
 as neurotransmitters, 329
 transport of, inhibition by probenecid, 710
- Monoamine oxidase(s), 443
 in catecholamine metabolism, 160*f*, 164, 165*f*
 distribution of, 164
 in histamine metabolism, 631
 MAO-A, 164, 299, 307–308, 443
 MAO-B, 164, 299, 443
 in Parkinson's disease, 529
 in serotonin metabolism, 298–299, 298*f*, 302–303, 307–308
- Monoamine oxidase inhibitor(s) (MAOI), 164, 299
 absorption and bioavailability of, 444
 chemistry of, 242, 439
 for depression, 432, 439, 452–453
 duration of treatment with, 453
 false-transmitter concept and, 243
 and histamine, 631
 interactions of
 with barbiturates, 419
 with meperidine, 450, 570
 with opioids, 566, 568
 mechanism of action, 175, 443–444
 metabolism of, 446
 for panic disorder, 451
 for Parkinson's disease, 164, 175, 529, 537
 with levodopa, 535
 pharmacological properties of, 443–444
 physical dependence on, 447
 selection of, 452
 selective MAO-B, 537
 and serotonin (5-HT), 305
 side effects of, 448
 therapeutic uses of, 432, 450–451
 toxicity/overdoses of, 449
- Monoamine transporter, 161
- Monoclonal antibodies, 1374, 1376–1380
 antigen and tumor cell targets of, 1375*t*
 for cancer chemotherapy, 1374, 1376*t*, 1377*t*
 cytotoxic conjugates with, 1375, 1379
 dose of, 1377*t*
 generation/production of, 1416, 1416*f*
 for immunosuppression, 1406–1407, 1416–1420
 immunotoxin with, 1374, 1375*t*, 1379–1380
 mechanism of action, 1377*t*
 for multiple sclerosis, 1426
 naked, 1375*t*, 1376–1379
 nomenclature for, 1376
 radioimmuno-conjugates with, 1375*t*, 1379
 toxicity of, 1377*t*
- Monocyte(s)
 corticosteroids and, 1600, 1600*t*
 in immune response, 1405
- Monoocyte/macrophage colony-stimulating factor (M-CSF), 1434, 1435*f*, 1436*t*

- Mononucleosis, acyclovir for, 1250
MONOPRIL (fosinopril), 803
Montelukast, 672, 722–725
 for asthma, 658, 722–725
 chemistry of, 723
 mechanism of action, 658
 metabolism of, 723
 pharmacokinetics of, 723, 1851*t*
 toxicity of, 724
Mood disorder(s), 430, 431. *See also* Bipolar disorder; Depression; Mania
Mood-stabilizing drugs, 429, 485–490. *See also* Lithium
Moon facies, 1598
Moonshine, lead content of, 1754
MOP (μ opioid receptor), 548, 550–556
 in analgesia, 557–558
 as clinical/therapeutic target, 556, 568–574
 cloned, properties of, 553*t*
 drug actions at and selectivity for, 551, 552*t*
 structure of, 552, 554*f*
 subtypes of, 552
MOPP regimen, 1327, 1351
Moraxella catarrhalis infection, fluoroquinolones for, 1122
Moricizine
 for cardiac arrhythmia, 118, 926
 chemistry of, 926
 dosage of, 918*t*
 electrophysiological actions of, 912*t*
 pharmacokinetics of, 918*t*, 926
Morning-after pill, 1564
Morphiceptin, 549*t*
Morphinans, 564
Morphine, 547, 552*t*, 563–568, 565*t*
 absorption of, 564
 as adjunct to anesthesia, 561, 583
 adverse effects of, 567–568
 for analgesia, 343, 557–559, 579–583
 administration of, 581–583
 degree of action, 567
 dosage of, 580*t*, 581
 duration of action, 567
 in terminal illness, 584
 biliary tract effects of, 562
 bioavailability of, 564
 cardiovascular effects of, 561
 in children, 565–566
 codeine conversion to, 566
 and convulsions, 560
 and cough, 560
 dependence on, 563
 drug interactions of, 568
 for dyspnea, 583
 effects of, 556–563
 epidural and intrathecal, 385, 581–582, 582*t*
 excretion of, 565–566
 gastrointestinal effects of, 561–562
 hepatic clearance of, impaired, 121
 and histamine release, 632
 hyperglycemic effects of, 1633*t*
 hypersensitivity to, 567–568
 immune system effects of, 562–563
 iontophoretic, 583
 metabolism of, 564–566
 and miosis, 559–560
 and nausea/vomiting, 557, 560–561
 neuroendocrine effects of, 559
 pharmacokinetics of, 564–566, 1851*t*
 precautions with, 567–568
 receptor action and selectivity of, 552*t*, 553, 555
 rectal, 582
 respiratory effects of, 560, 567
 skin effects of, 562, 567
 smooth muscle effects of, 562
 structure-activity relationship of, 564
 therapeutic uses of, 579–583
 tolerance to, 563
 toxicity of, 574
 urinary tract effects of, 562
 and vasopressin, 775
Morphine-3-glucuronide, 564, 566
Morphine-6-glucuronide, 11, 564–567
Morphine-like opioids, 563–568. *See also specific agents*
Mosapride, for gastrointestinal motility disorders, 988
Motilin, 988
Motilin agonist(s), 988
MOTILIUM (domperidone), 986
Motion sickness
 histamine H₁ receptor antagonists for, 637, 640–641, 1003–1004
 muscarinic receptor antagonists for, 198, 1004
MOTOFEN (difenoxin), 570
Motor activity, antipsychotics and, 468
Motor end plate(s), 141
Motor nerve(s), 137–142
MOTRIN (ibuprofen), 678*t*
Mottled enamel, 1674
Mountain sickness, acute, 391
Moxalactam, 1149
Moxifloxacin, 1119–1122
 for *Mycobacterium avium* complex, 1204*t*, 1218
 ophthalmic use of, 1716*t*
 pharmacokinetics of, 1851*t*
 for respiratory tract infections, 1122
 for tuberculosis, 1203, 1204*t*, 1212
Moxidine, 256
Mozavaptan, 782*t*
6-MP. *See* Mercaptopurine
M phase of cell cycle, cancer drugs targeting, 1316
MPTP (*N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), 66, 528–529, 537
MsbA transporter, 50, 50*f*
MSEL-neurophysin, 773, 773*f*
mTOR inhibitors, 1406
MUCOMYST (*N*-acetylcysteine), 881
Mucormycosis
 amphotericin B for, 1228
 treatment of, 1226*t*
Mucosa, alkylating agents and, 1326
MUCOSIL (*N*-acetylcysteine), 694
Mucous membrane(s)
 local anesthesia for, 378–380
 topical applications for, 6–7
Multicompartment model, of distribution, 15*f*, 16
Multidrug resistance associated protein 2–4 (MRP2–4). *See* ATP-binding cassette transporters, ABC2–4
Multiple myeloma
 bortezomib for, 1372–1373
 glucocorticoids for, 1380–1381
 melphalan for, 1328
 thalidomide for, 1370–1371, 1371*f*
 zoledronic acid for, 1373
Multiple Risk Factor Intervention Trial (MRFIT), 945–946
Multiple sclerosis, 1424–1426, 1426*t*
Mupirocin, 1199
MURINE PLUS (tetrahydrozoline), 1721*t*
Muromonab-CD3, 1406, 1407*t*, 1417–1418
Muscarine, 186–189
 ganglionic stimulation by, 231
 mechanism of action, 186
 in mushroom poisoning, 187, 189

 pharmacological properties of, 307
- NARCAN (naloxone), 576–578
- Narcoanalysis, barbiturates in, 419
- Narcolepsy, 263
 amphetamine for, 260, 263
 ephedrine for, 260
 sympathomimetic agents for, 263
- Narcotherapy, barbiturates in, 419
- Narcotic(s)
 opioid. *See* Opioid(s)
- NARDIL (phenelzine), 437*t*
- NAROPIN (ropivacaine), 378
- NASACORT (triamcinolone), 731
- Nasal decongestion, α adrenergic receptor
 agonists for, 263
- Nasal mucosa, drug metabolism in, 74
- NASONEX (mometasone), 731
- Nasopharyngeal glands, autonomic regula-
 tion of, 144*t*
- NATACYN (natamycin), 1718
- Natalizumab, for multiple sclerosis, 1426
- Natamycin, 1718
 ophthalmic use of, 1718, 1719*t*
- Na⁺-taurocholate cotransporting polypep-
 tide (NTCP), 44
- Nateglinide, 1638
- National Cholesterol Education Program
 (NCEP), 942*t*, 943–944
- National Drug Code, 1783
- National Formulary, 1783
- Native American(s), fetal alcohol syndrome
 in, 602
- NATRECOR (neseritide), 885
- Natural killer cells, 1405
- Natural products, in cancer chemotherapy,
 1318*t*, 1350–1364
- NATURETIN (bendroflumethiazide), 754*t*
- Nausea, 1000–1005, 1008
 antipsychotics for, 484
 benzodiazepines for, 1005
 chemotherapy-induced, regimens for,
 1001, 1003*t*
 dexmedetomidine and, 361
 dopamine receptor antagonists for, 1002*t*,
 1003
 dronabinol for, 1004
 estrogen therapy and, 1553
 etomidate and, 351
 general anesthesia and, 343

- Nausea—*continued*
 glucocorticoids for, 343, 1005
 histamine H₁ receptor antagonists for, 1002*t*, 1003–1004
 levodopa and, 534
 metoclopramide for, 343, 986
 miltefosine and, 1061
 muscarinic receptor antagonists for, 1002*t*, 1004
 neurotransmission in, 1000–1001, 1001*f*
 nifurtimox/benznidazole and, 1062
 opioids and, 557, 560–561, 571
 promethazine for, 641, 1004
 salicylates and, 692
 serotonin receptor antagonists for, 312, 334, 343, 561, 1001–1003, 1002*t*
 substance P receptor antagonists for, 1005
 sulfonamides and, 1116
 suramin and, 1069
- NAVANE (thiothixene), 464*t*
 NAVELBINE (vinorelbine), 1352
N-dealkylation, 76*t*
 NEBCIN (tobramycin), 1166
 Nebivolol, 276*t*, 286–287
 for congestive heart failure, 289
 Nebramycin, 1155
 Nebulizers, 719
Necator americanus, 1075, 1090
 Necrotizing fasciitis, 1136, 1690
 Nedocromil sodium, 726–727
 ophthalmic use of, 1725
- Nefazodone, 437*t*
 CYP interactions of, 445*t*, 446
 for depression, 453
 disposition of, 445*t*
 dose and dosage forms of, 437*t*
 drug interactions of, 446
 with antipsychotics, 481
 interactions of
 with benzodiazepines, 408
 with statins, 951
 mechanism of action, 443
 metabolism of, 444
 pharmacokinetics, 444, 445*t*, 446
 potency of
 for receptors, 440*t*
 for transporters, 438*t*
 side effects of, 437*t*, 447–448
- nef* gene, in HIV infection, 1274
 Negative inotropic effect, of acetylcholine, 184–185
 Negative reinforcement, 616
 Negative symptoms, antipsychotics for, 482
Neisseria gonorrhoeae. *See* Gonorrhea
Neisseria meningitidis. *See* Meningococcal infection(s)
- Nelfinavir, 1276*t*, 1303–1305
 adverse effects of, 1305
 antiviral activity of, 1303
 chemistry of, 1303, 1304*f*
 drug interactions of, 122, 1209, 1217, 1295*t*, 1300*t*, 1305
 for HIV infection, 1303–1305
 mechanism of action, 1303
 pharmacokinetics of, 1299*t*, 1303–1305, 1853*t*
 precautions with, 1305
 resistance to, 1303
 therapeutic use of, 1305
- Nematodes, 1073–1077
 NEMBUTAL (pentobarbital), 415*t*
 Nemonapride, 467
 Neocortex
 in Alzheimer's disease, 527
 in epilepsy, 505
 α -Neoendorphin, 549*t*, 552*t*
 β -Neoendorphin, 549*t*
 NEOLOID (castor oil), 994–995
 NEO-MERCAZOLE (carbimazole), 1528
 Neomycin, 1155, 1167–1168
 absorption and excretion of, 1168
 adverse effects of, 1168
 antibacterial spectrum of, 1167
 with bacitracin, 1168, 1199
 chemistry of, 1155
 for cutaneous infections, 1690
 hypersensitivity to, 1168
 nephrotoxicity of, 1163–1164
 neuromuscular blockade by, 1164
 ophthalmic use of, 1718–1719
 ototoxicity of, 1162–1163
 with polymyxin B, 1167–1168
 prophylactic uses of, 1106*t*
 therapeutic uses of, 1168
- Neomycin B, chemistry of, 1155
 Neonate(s). *See* Infant(s)
 NEORAL (cyclosporine), 1016, 1409–1410
 NEOSAR (cyclophosphamide), 1328
 NEOSPORIN G. U. IRRIGANT (neomycin-polymyxin B), 1167–1168
- Neostigmine, 204, 205*f*
 absorption, fate, and excretion of, 209
 and acetylcholine release, 151
 gastrointestinal effects of, 208, 985
 for gastrointestinal motility disorders, 985
 mechanism of action, 203*f*, 204
 muscarinic receptor antagonists with, 198
 for myasthenia gravis, 213
 for neuromuscular blocker toxicity, 226, 362
 for paralytic ileus and bladder atony, 212
 pharmacokinetics of, 1853*t*
 preparations of, 212
 and succinylcholine, 208, 226
 therapeutic uses of, 212
- Neostigmine bromide, 212
 Neostigmine methylsulfate, 212
 Neostriatum, 318
 in Huntington's disease, 527
 in Parkinson's disease, 531–533
- NEO-SYNEPHRINE (phenylephrine), 255, 1721*t*
 Nephrolithiasis, indinavir and, 1303
 Nephron(s), 737, 738*f*, 739
 Nephrotic syndrome
 diuretics for, 764–765, 766*f*
 vasopressin in, 784–785
- Nernst equation, 46
- Nerve(s), autonomic *versus* somatic motor, 137
 Nerve block anesthesia, 380–381
 Nerve fiber sensitivity, to local anesthetics, 373–374, 374*t*
 “Nerve gases,” 201, 205
 prophylaxis against, 214
 Nervi erigentes, 139
 NESACAINE (chlorprocaine), 378
 Neseritide, for congestive heart failure, 885–886
 Nestorone, 1559
N-ethylmaleimide-sensitive fusion protein (NSF), 163
- Netilmicin, 1155, 1167
 absorption of, 1159
 adverse effects of, 1162–1164, 1167
 antibacterial spectrum of, 1158–1159, 1159*t*, 1167
 distribution of, 1159–1160
 dosing of, 1160–1161, 1167
 elimination of, 1161–1162, 1167
 minimal inhibitory concentrations of, 1159*t*
 nephrotoxicity of, 1167
 ototoxicity of, 1162–1163, 1167
 resistance to, 1155, 1157*f*, 1158
 therapeutic uses of, 1165–1167
- NETROMYCIN (netilmicin), 1167
 NEULASTA (pegylated filgrastim), 1441
 NEUMEGA (oprelvekin), 1441
 NEUPOGEN (filgrastim), 1440
- Neuralgia
 carbamazepine for, 510, 512–513
 ethanol for, 599
 phenytoin for, 510
 postherpetic, lidocaine for, 377
- Neural tube defects, folic acid deficiency and, 1459–1460
- Neurexin, 148, 148*f*
 Neuroblastoma, vinblastine for, 1351
 Neurodegenerative disorder(s), 527–544.

 and coronary blood flow, 826–827
 cutaneous, 831
 dosage of, 826*t*
 for gastrointestinal motility disorders, 989
 hemodynamic effects of, 825–826
- interaction with PDE5 inhibitors, 123, 829–830
- mechanism of action, 824–825
- for myocardial infarction
 acute, 831–832
 non-ST-segment-elevation, 831
 and myocardial oxygen requirements, 827
- pharmacological properties of, 825–828
- plasma concentrations of, and biological activity, 828
- preparations of, 826*t*
- pseudotolerance to, 828
- routes of administration, 826*t*, 830–831
 and smooth muscle, 828
- therapeutic uses of, 830–832
- tolerance to, 828–829, 881
- toxicity of, 829–830
- Nitrazepam
 as antiseizure drug, 404–405
 chemistry of, 403*t*
 metabolism of, 409, 409*t*
- Nitric oxide, 395–397
 administration of, methods for, 397
 in cGMP synthesis, 30
 as CNS mediator/neurotransmitter, 146, 177–178, 336, 395
 diagnostic uses of, 396
 estrogen and, 1548
 functions of, 395–396
 and gastrointestinal motility, 984, 990
 in opioid tolerance, 563
 organic nitrates and, 824–825
 release of, 177
 serotonin (5-HT) and, 302
 synthesis of, 177
 therapeutic uses of, 396
 toxicity of, 396–397
- Nitric oxide donor(s)
 for congestive heart failure, 874*t*
 interaction with PDE5 inhibitors, 123
- Nitric oxide synthase (NOS), 177–178, 395
 CNS effects of, 336
 endothelial, 177, 824
 estrogen and, 1548
 inducible, 177, 824
 inhibition of, 177–178
 neuronal, 177, 824
 and renin secretion, 791, 792*f*, 793
 in opioid tolerance, 563
 organic nitrates and, 824–825
- Nitrites, organic, 825
- Nitrofurantoin, 1123–1124
 antimicrobial activity of, 1123
 hypersensitivity to, 1102
 pharmacokinetics of, 1854*t*
 pharmacology of, 1123–1124
- Nitrogen
 metabolism of, salicylates and, 692
 partial pressure of, oxygen therapy and, 393
- Nitrogen mustards, 1316*t*, 1321–1322, 1327–1329
 chemistry of, 1322, 1323*f*

- mechanism of action, 1322, 1322*f*
 toxicities of, 1325–1327, 1742
- Nitroglycerin, 823–832
 adverse effects of, 829–830
 for angina, 823, 825, 830–831
 mechanisms of relief in, 827–828
 cardiovascular effects of, 825–828
 chemistry of, 825, 826*t*
 and coronary blood flow, 826–827
 dosage of, 826*t*
 hemodynamic effects of, 825–826
 history of, 825
 interaction with phosphodiesterase 5
 inhibitors, 123
 intravenous, for congestive heart failure,
 885
 mechanism of action, 825
 for myocardial infarction, 831–832
 and myocardial oxygen requirements,
 827
 for opioid-induced biliary spasm, 562
 opioids for, 583
 pharmacokinetics of, 828, 1855*t*
 plasma concentrations of, and biological
 activity, 828
 preparations of, 826*t*
 routes of administration, 826*t*
 therapeutic uses of, 830–832
 tolerance to, 828–829
 toxicity of, 829–830
- NITROPRESS (sodium nitroprusside), 885
- Nitroprusside. *See* Sodium nitroprusside
- Nitrosoarea(s), 1316*t*, 1321–1322, 1331
 chemistry of, 1323
 metabolism of, 1323
 reactions with macromolecules, 1323,
 1324*f*
 resistance to, 1323
 toxicities of, 1325–1327
- Nitrous oxide, 341, 353*f*, 360–361
 cardiovascular effects of, 361
 clinical use of, 360
 CNS effects of, 361
versus ether, 341
 intoxication with, 625–626
 and megaloblastic anemia, 1454
 molecular actions of, 346
 muscular effects of, 361
 pharmacokinetics of, 344*t*, 354*f*, 360
 physical properties of, 360
 potency of, measurement of, 344*t*
 respiratory effects of, 361
 side effects of, 361
- Nitrovasodilator(s), 825. *See also* Nitrates,
 organic; Nitrites, organic
 for congestive heart failure, 880–881
- NIX (permethrin), 1692
- Nizatidine, 971–973, 972*f*
 adverse effects of, 972
 dermatologic use of, 1689
 for gastroesophageal reflux disease, 977*t*
 mechanism of action, 971
 for peptic ulcer disease, 979*t*–980*t*
 pharmacokinetics of, 972
 pharmacological properties of, 971
- therapeutic uses of, 972
 tolerance to and rebound with, 973
- NIZORAL (ketoconazole), 1611
- NM283, 1267*t*
- N*-methylation, 86
- N*-methyl-D-aspartate, 331*f*
 excitotoxicity of, 332
- N*-methyl-D-aspartate receptor(s), 332
 agonists, 332
 antidepressants and, 441
 antipsychotics and, 474, 491
 in epilepsy, 503
 ethanol and, 600, 614
 in excitotoxicity, 528–529
 general anesthesia and, 346
 in long-term depression, 332
 in long-term potentiation, 332
 in neurodegenerative disorders, 528–529
 phencyclidine and, 625
- N*-methyl-D-aspartate receptor antago-
 nist(s), 332
 for Alzheimer's disease, 539–540
 and opioid tolerance, 563, 617
- N*-methylhistamine, 631
- N*-methylimidazoleacetic acid, 631
- Nocardiosis
 sulfonamides for, 1115
 tetracyclines for, 1177–1178
 trimethoprim-sulfamethoxazole for,
 1115, 1118
- Nociceptin, 548–550, 549*t*
 precursor of, 549–550, 551*f*
- Nociceptin/orphanin FQ receptor, 548,
 550–551
 in pain modulation, 558–559
 selectivity and affinity for, 554–555
 structural homology of, 552, 554*f*
- Nociceptive pain, 557
- Nocistatin, 548–550
- Nocturnal acid breakthrough, 978
- Nocturnal leg cramps, quinine for, 1038
- NOLAHIST (phenindamine), 638*t*
- NOLVADEX (tamoxifen), 1382–1383, 1555
- NOLVADEX Adjuvant Trial Organization
 (NATO), 1383
- Nomegestrol, 1559
- Nomifensine, 438*t*, 443
- Noncompetitive antagonism, 37
- Noncompetitive inhibition, 47
- Noncovalent inhibitors, 204
- Non-Hodgkin's lymphoma
 cyclophosphamide for, 1328
 etoposide for, 1360
 fludarabine for, 1348
 glucocorticoids for, 1380
 immunosuppressive agents and, 1015
 infliximab and, 1017
 methotrexate for, 1339
 vincristine for, 1351–1352
- Nonnucleoside reverse transcriptase inhibi-
 tors, 1275, 1276*t*, 1292–1297.

- in bone remodeling, 1658, 1658*f*
- calcitonin and, 1657
- estrogen and, 1547–1548
- parathyroid hormone and, 1651
- Osteodystrophy, renal, 1662
- vitamin D therapy for, 1665
- Osteomalacia, 1660–1662
- bisphosphonates and, 1668
- phenobarbital and, 511
- phenytoin and, 510
- vitamin D therapy for, 1665
- Osteomyelitis
- quinolones for, 1122
- teicoplanin for, 1197
- Osteonecrosis, glucocorticoids and, 1604
- Osteoporosis, 1662
- antiresorptive agents for, 1671
- bisphosphonates for, 1668, 1671
- calcitonin for, 1672
- calcium for, 1672
- combination therapies for, 1672–1673
- corticosteroids and, 1604
- estrogen in, 1548, 1672
- estrogen therapy for, 1553–1554, 1671–1672, 1671*f*
- ethanol and, 598
- fluoride for, 1673–1674
- heparin and, 1474
- integrated approach in, 1670–1673
- prevention of, 1670–1673
- primary, 1662
- raloxifene for, 1556–1557, 1671–1673
- secondary, 1662
- teriparatide for, 1669, 1671, 1671*f*
- thiazide diuretics for, 757, 1671–1672
- treatment of, 1670–1673, 1671*f*
- vitamin D for, 1672
- Osteoprotegerin (OPG), estrogen and, 1547
- Otilonium bromide, for irritable bowel syndrome, 1000
- Otitis media
- amoxicillin for, 1139
- azithromycin for, 1185
- drug-resistant, 1117
- sulfisoxazole-erythromycin for, 1114
- trimethoprim-sulfamethoxazole for, 1117–1118

- OTRIVIN (xylometazoline), 260
- Ovarian cancer
 bleomycin for, 1362
 cisplatin for, 1333–1334
 clomiphene and, 1557
 docetaxel/paclitaxel for, 1353
 gemcitabine for, 1346
 irinotecan for, 1356
 oral contraceptives and, 1565
 topotecan for, 1356
- Ovarian hyperstimulation syndrome, 1506, 1557
- Ovary(ies)
 development of, failure of, estrogen therapy for, 1554
 estrogen synthesis in, 1542–1543
 function of, hormonal control of, 1541
- OVERTURE Trial (Omapatrilat Versus Enalapril Randomized Trial of Utility in Reducing Events), 886
- OVIDREL (choriogonadotropin alfa), 1505
- OVRETTE (norgestrel), 1564
- Ovulation
 induction of
 clomiphene for, 1556–1557
 gonadotropins for, 1505–1506
 timing of, luteinizing hormone in, 1505
- 22-Oxacalcitriol, 1664*f*, 1665
- Oxacillin, 1129*t*, 1138
 adverse effects of, 1143
 antimicrobial activity of, 1130*t*, 1133
 major properties of, 1129*t*
 pharmacological properties of, 1138
- Oxaliplatin, 1334–1335
 absorption, fate, and excretion of, 1334
 chemistry of, 1332
 with fluorouracil, 1343–1344
 history of, 1332–1333
 mechanism of action, 1333
 pharmacokinetics of, 1856*t*
 resistance to, 1333

 absorption, fate, and excretion of, 1353
 chemistry of, 1352, 1353*f*
 in endovascular stents, 842
 hypersensitivity to, 1352, 1354
 metabolism of, induction of, 89–90
 pharmacokinetics of, 1858*t*
- Padimate O, 1700
- Paget's disease, 1662
 bisphosphonates for, 1673
 calcitonin for, 1656, 1666
- Pain
 histamine and, 636
 kinins and, 647
 mechanisms of, 681–682
 neuropathic, 557
 nociceptive, 557
 prostaglandins and, 661

- as specific sensation, 557
as suffering, 557
- Pain control. *See also* Analgesia(s); *specific agents*
NSAIDs for, 681–682
opioids for, 557–559
postoperative, 343
salicylates for, 688, 691
- Paint, lead content of, 1754
- Palmar-plantar hyperkeratosis, 1765
- Palonosetron, 1001–1003
for nausea/vomiting, 1001–1003
chemotherapy-induced, 1003, 1004*t*
receptor specificity of, 1002*t*
- PALUDRINE (proguanil), 1031
- PAMELOR (nortriptyline), 434*t*
- Pamidronate, 1667, 1667*f*, 1668
clinical pharmacology of, 1668
for hypercalcemia, 1663, 1668
for osteoporosis, 1671
therapeutic uses of, 1668
- PAMINE (methscopolamine bromide), 197
- p*-Aminohippuric acid (PAH), transport of, 63–65
- Panaeolus*, 189
- Pancreas
autonomic regulation of, 144*t*
ethanol and, 597
- PANCREASE (pancreatic enzyme), 1006*t*
- Pancreatic acinar cells, 1613
- Pancreatic amylase, 1005, 1006*t*
- Pancreatic cancer
cetuximab for, 1378
gemcitabine for, 1346
streptozocin for, 1331
trastuzumab for, 1378
- Pancreatic enzyme therapy, 1005–1006, 1006*t*
- Pancreatic islet cells, 1613–1615, 1632
- Pancreatic lipase, 1005, 1006*t*
- Pancreatic polypeptide, 176
- Pancreatic protease, 1005, 1006*t*
- Pancreatic transplantation, 1634
- Pancreatin, 1005
- Pancreatitis
acute
didanosine and, 1285
indomethacin and, 696
octreotide and somatostatin for, 998
chronic, pancreatic enzyme replacement for, 1005–1006
ethanol and, 597
lamivudine and, 1289
valproic acid and, 515
- Pancrelipase, 1005
- Pancuronium, 220, 221*f*, 222*t*
absorption, fate, and excretion of, 228
as adjunct to anesthesia, 362
autonomic effects of, 226
and histamine release, 226
mechanism of action, 220
pharmacokinetics of, 220, 222*t*, 1858*t*
pharmacologic properties of, 222*t*
- Pancytopenia
chloramphenicol and, 1181
ethosuximide and, 514
- Panic disorder(s), 453
 β adrenergic receptor antagonists for, 292
antidepressants for, 450–451
- Panophthalmitis, 1717
- PANRETIN (alitretinoin), 1685
- Pantoprazole, 969–971, 970*f*
for gastroesophageal reflux disease, 977*t*
for peptic ulcer disease, 978, 979*t*–980*t*
for Zollinger-Ellison syndrome, 969
- Papaverine, 857
for dementia, 430
history of, 547
for psychosis, 491
source and composition of, 564
- Papaver somniferum*, 547, 563–564
- Papillomavirus
antiviral agents for, 1691
imiquimod for, 1267, 1696
interferons for, 1264
- Para-aminobenzoic acid, 1112. *See also* Sulfonamide(s)
- Para-aminophenol derivatives, 693–695. *See also* Acetaminophen
- Parabrachial nucleus, 138
- Paracetamol, 693
- Paracoccidioides brasiliensis* infection, itraconazole for, 1231
- Paragonimus* (paragonimiasis), 1078
- Paragonimus westermani*, 1078
- Parainfluenza virus, ribavirin for, 1266
- PARAL (paraldehyde), 421*t*
- Paraldehyde, 402, 420, 421*t*
- Paralysis
familial periodic, acetazolamide for, 747
by neuromuscular blocking agents, 222–228
respiratory, 228
sequence and characteristics of, 225
- Paralysis agitans, 529. *See also* Parkinson's disease
- Paranoia, 430
psychedelic drugs and, 623–624
- Paraoxon, 205, 206*t*, 1741, 1741*f*
- Paraoxonases, 209
- PARAPLATIN (carboplatin), 1334
- Paraquat, toxicity of, 1741, 1741*f*
- Parasitic infection(s). *See also specific infections and antiparasitic agents*
helminthic, 1073–1090
ocular, 1718–1720
protozoal, 1021–1045, 1049–1070
- Parasympathetic nervous system, 139
functions of, 142–145
versus somatic motor nervous system, 141
versus sympathetic nervous system, 141
- Parasympathin, 146
- Parathion, 205, 206*t*
biotransformation of, 1741, 1741*f*
- Parathyroid glands, 1650
- Parathyroid hormone (PTH), 1649–1658
in bone metabolism, 1651
calcitonin and, 1656–1657
in calcitriol synthesis, 1652
in calcium regulation, 1650–1652, 1650*f*
- ethanol and, 598
immunoassay for, 1650
intermittent administration of, 1669
in lead poisoning, 1754–1755
physiological functions of, 1651–1652
renal effects of, 1651
synthesis and secretion of, 1650
therapeutic uses of, 1669
- Parathyroid hormone-related protein (PTHrP), 1659–1660
- Paraventricular nucleus (PVN)
oxytocin in, 773
vasopressin in, 772–775
- Paravertebral sympathetic ganglia, 139
- Parecoxib, 702–705
chemistry of, 703*f*
clinical use of, 703–705
pharmacokinetics of, 702, 705
pharmacological properties of, 704–705
- PAREDRINE (hydroxyamphetamine), 1721*t*
- Paregoric, 997
- Parenteral administration, 4–6
- Parenteral anesthesia, 346–353
- Parenteral vasodilators, for congestive heart failure, 884–886
- Paresthesia, aminoglycosides and, 1164
- Paricalcitol, 1664*f*, 1665
- Parkin, 106*t*, 528
- Parkinsonism, 530
antiemetics and, 530
antipsychotics and, 478*t*, 479, 530
drugs causing, 530
metoclopramide and, 530, 986
muscarinic receptor antagonists for, 192, 197
- Parkinson's disease, 529–538
ABC transporters and, 57–58
amantadine for, 533*t*, 538, 1258
antipsychotics and, 479, 481, 484
basal ganglia in, 531–533, 532*f*
clinical overview of, 529–530
COMT inhibitors for, 536–537, 536*f*
COX-2 inhibitors for, 661
diphenhydramine for, 537, 641
dopamine in, 333, 469, 527, 529–533, 530*f*–532*f*, 538
dopamine receptor agonists for, 535–536, 538
environmental triggers in, 528
genetics of, 528
levodopa for, 533–535, 533*t*
limbic system in, 318
monoamine oxidase inhibitors for, 164, 175, 529, 535, 537
muscarinic receptor antagonists for, 198, 537–538
neural mechanism of, 531–533
neuroprotective therapy for, 538
on/off phenomenon in, 534
oxidative stress in, 529, 530*f*
versus parkinsonism, 479
pathophysiology of, 530–533
progression of, 529–530
as prototypical neurodegenerative disorder, 527

- Parkinson's disease—*continued*
 selective CNS modification in, 336–337
 selective vulnerability in, 527
 selegiline for, 443
 treatment of, 527, 533–538, 543
- PARLODEL (bromocriptine), 535, 1500
- PARNATE (tranylcypromine), 437*t*
- Paromomycin, 1063–1064
 for amebiasis, 1050, 1063–1064
 chemistry of, 1064, 1155
 for cryptosporidiosis, 1051, 1063–1064
 for giardiasis, 1050, 1063–1064
 for leishmaniasis, 1052–1053, 1064
 mechanism of action, 1064
 for trichomoniasis, 1064
- Paroxetine, 432, 435*t*
 chemistry of, 432, 435*t*
 CYP interactions of, 445*t*, 446
 for depression, 432
 dose and dosage forms of, 435*t*
 drug interactions of, 446
 with antipsychotics, 481
 pharmacogenetics of, 109*f*, 125
 pharmacokinetics of, 445*t*, 1858*t*
 physical dependence on, 447
 potency of
 for receptors, 440*t*
 for transporters, 438*t*
 side effects of, 435*t*
- Paroxysmal atrial tachycardia, metaraminol
 for, 254
- Paroxysmal supraventricular tachycardia, 904
 Ca²⁺ channel antagonists for, 914
 edrophonium for, 211
 EEG findings in, 909*f*
 mechanism of, 907*t*
 sympathomimetic agents for, 261–262
 treatment of, 907*t*
- Parsol 1789, 1700
- Pars plicata, 1711
- Partial agonist(s), 23, 25, 25*f*
- Partial epilepsies, 502–505
- Partial seizure, 501–505, 502*t*
- Partition coefficients, of inhalational anesthetics, 344*t*, 354
- Parturition
 Ca²⁺ channel antagonists and, 838
 oxytocin and, 1507–1509
 platelet-activating factor and, 668
 prostaglandins and, 664
- PARVOLEX (N-acetylcysteine), 694
- PASER (aminosalicylic acid), 1213
- Passive countercurrent multiplier hypothesis, 739
- Passive diffusion, 45–46, 45*f*, 1100
- Passive immunization, 1423
- Passive transport, 2, 45–46, 45*f*, 740
- Pasteurella multocida* infection
 penicillin G for, 1137
 prophylaxis against, 1107*t*
- PATANOL (olopatadine), 640
- Patch-clamp technique, in receptor studies, 328
- Patent ductus arteriosus
 indomethacin and, 695
- NSAIDs and, 683, 685
 prostaglandins and, 664, 666, 682
- Patient compliance, 22, 1784–1786, 1784*t*
- Patient-controlled analgesia, 343, 581
- Patient-provider relationship, 1784–1785
- PAVULON (pancuronium), 222*t*
- PAXIL (paroxetine), 435*t*
- PBZ (tripeleppamine), 638*t*
- PCO₂, 394
- PD 123177, 795
- Peak concentration, 1790–1791
 time to, 1790
- Pectins
 for constipation, 992, 992*t*
 for diarrhea, 996
- PEDIAPRED (prednisolone sodium phosphate), 1602*t*
- PEDIAZOLE (sulfisoxazole-erythromycin), 1114
- Pediculosis, treatment of, 1692
- Pefloxacin, 1119–1122, 1120*f*
 antibacterial spectrum of, 1119
 for leprosy, 1220
- PEGANON (ethotoin), 508
- Pegaspargase, 1363–1364
- Pegfilgrastim, 1441
- Peginterferon alfa-2a/2b, 1263
- PEG-L-ASPARGINASE (pegaspargase), 1363
- Pegvisomant, 1492, 1498
- Pelvic inflammatory disease, quinolones
 for, 1121
- Pemetrexed, 1335–1340
 cytotoxic action of, 1337
 mechanism of action, 1336
 resistance to, 1336–1337
 therapeutic use of, 1339
- Pemirolast, 1725
- Pemoline, 259
 for attention-deficit/hyperactivity disorder, 263
- Pemphigus vulgaris
 glucocorticoids for, 1683
 mycophenolate mofetil for, 1696
- Penbutolol, 276*t*, 287
- Penciclovir, 1246, 1251–1253
 therapeutic uses of, 1252–1253, 1691
- PENECORT (hydrocortisone), 1682*t*
- Penfluridol, 466
- Penicillamine, 1771–1772
 for arsenic poisoning, 1766
 for lead poisoning, 1758, 1771
 for mercury poisoning, 1763, 1771
- Penicillin(s), 1127–1143. *See also specific agents*
 adverse effects of, 1141–1143
 with aminoglycosides, 1165
 antimicrobial activity of, 1130*t*–1131*t*, 1133
 antipseudomonal, 1140–1141
 bacterial density/biofilm and, 1133
 in cerebrospinal fluid, 1133, 1135
 chemistry of, 1128, 1128*f*, 1129*t*–1130*t*
 with chlortetracycline, 1104
 classification of, 1133–1138
 for cutaneous infections, 1690
- desensitization to, 1142–1143
 with gentamicin, 1104
 history of, 1095, 1127–1128
 hypersensitivity to, 1141–1143
 management of patient with, 1142–1143
 intrathecal or intraventricular administration of, avoidance of, 1143
 isoxazoyl, 1138
 major and minor determinants of, 1141
 major properties of, 1129*t*–1130*t*
 maximal dose of, 19
 mechanism of action, 1128–1131, 1131*f*
 metabolism of, probenecid and, 711, 1134
 and microflora composition, 1143
 for mushroom poisoning, 189
 penicillinase-resistant, 1130*t*–1131*t*, 1133, 1138–1139
 pharmacological properties of, 1133
 resistance to, 1096, 1098
 mechanisms of, 1131–1133, 1132*f*
 semisynthetic, 1128
 with streptomycin, 1104
 toxicity of, 1102, 1143
 unitage of, 1128
- Penicillinase-resistant penicillins, 1130*t*–1131*t*, 1133, 1138–1139
- Penicillin-binding proteins (PBPs), 1098, 1130–1131, 1147
- Penicillin G, 1134–1138
 administration, 1134–1135
 adverse effects of, 1143
 antimicrobial activity of, 1130*t*, 1133–1134
 in cerebrospinal fluid, 1135
 chemistry of, 1128, 1128*f*, 1129*t*
 major properties of, 1129*t*
 for *Pasteurella multocida* infection, 1137
 pharmacokinetics of, 1134–1135, 1859*t*
 prophylactic uses of, 1107*t*, 1137–1138
 and seizures, 1102
 therapeutic uses of, 1135–1137
 unitage of, 1128
- Penicillin G benzathine, 1134–1135
- Penicillin G procaine, 1134
 adverse effects of, 1143
- Penicillin V, 1129*t*, 1134–1138
 antimicrobial activity of, 1130*t*, 1133
 major properties of, 1129*t*
- Penicillium citrinum*, 948
- Penicillium marneffei* infection
 amphotericin B for, 1228
 itraconazole for, 1231
- Penicilloyl moiety, 1141
- PENLAC (ciclopirox olamine), 1691
- PENLAC NAIL LACQUER (ciclopirox olamine), 1239
- Pentamidine, 1064–1066
 arrhythmia induced by, 915
 drug interactions of
 with foscarnet, 1253
 with sodium channel inhibitors, 759
 hypo- and hyperglycemic effects of, 1632, 1633*t*

- for leishmaniasis, 1052–1053, 1064–1065
- mechanism of action, 1065
- resistance to, 1065
- therapeutic uses of, 1064–1066
- toxicity and side effects of, 1066
- for trypanosomiasis, 1051–1052, 1064–1065
- PENTASA (mesalamine), 1012–1013
- Pentazocine, 575
 - for analgesia, 575
 - effects of, 556–557
 - interaction with MAO inhibitors, 450
 - mechanism of action, 574
 - pharmacological actions of, 575
- Pentetic acid (DTPA), 1768–1769
- Pentobarbital, 415*t*
 - anatomic sites of action, 345
 - half-life of, 415*t*
 - routes of administration, 415*t*
 - sites and mechanisms of action, 414–416
 - therapeutic uses of, 415*t*
- PENTOLAIR (cyclopentolate), 1720*t*
- PENTOSTAM (sodium stibogluconate), 1066
- Pentostatin, 1346, 1347*f*, 1349–1350
 - resistance to, 1336–1337
 - therapeutic uses of, 1349
- PENTOTHAL (thiopental), 349
- Pentoxifylline, for claudication, 841
- Pentylenetetrazol, 336
 - seizures induced by, 507
 - benzodiazepines for, 404–405
- PEPCID (famotidine), 971
- Peptic ulcer disease, 967, 978–980
 - COX-2 inhibitors for, 661
 - ethanol and, 596
 - glucocorticoids and, 1604
 - Helicobacter pylori* and, 978–980
 - histamine H₂ receptor antagonists for, 972, 978–980, 979*t*–980*t*
 - mechanisms of drug action in, 968*f*
 - muscarinic receptor antagonists for, 197, 968*f*
 - NSAIDs and, 684–685, 978–979
 - pathophysiology of, 978
 - platelet-activating factor and, 667
 - prostaglandins and, 665
 - proton pump inhibitors for, 971, 978–980, 979*t*–980*t*
- Peptide YY, 176
- Peptidoglycan, as antibiotic target, 1128–1131, 1131*f*
- PEPTO-BISMOL (bismuth subsalicylate), 996
- Peptococcus* infection
 - clindamycin for, 1189
 - metronidazole for, 1059
- Peptostreptococcus* infection, metronidazole for, 1059
- Peramivir, 1267*t*
- Perchlorate, 1531
- PERCOCET (codeine/acetaminophen), 581
- PERCODAN (codeine/aspirin), 581
- Perfluorocarbons, as vitreous substitute, 1726, 1727*t*
- Pergolide
 - adverse effects of, 535
 - dosage of, 533*t*
 - for hyperprolactinemia, 1500
 - for Parkinson's disease, 533*t*, 535
- PERGONAL (menotropin), 1505
- Periacetum, for dementia, 430
- PERIACTIN (cyproheptadine), 313, 638*t*
- Periaqueductal gray (PAG), opioid analgesia and, 557–558
- Pericardial effusion, minoxidil and, 863
- Perindopril, 802*f*, 804
 - absorption and elimination of, 804
 - adverse effects of, 808–810
 - in heart disease, 807*t*
 - for hypertension, 858–859
 - therapeutic uses of, 804–808
- Perineal block, 383
- Perioral tremor, antipsychotics and, 478*t*, 480

 sulindac for, 696
 tolmetin for, 697
- RHEUMATREX (methotrexate), 1339
- Rhinitis
 α adrenergic receptor agonists for, 262
 asthma drugs for, 731
 histamine H₁ receptor antagonists for, 640, 731
 kinins in, 647
 muscarinic receptor antagonists for, 195
- RHINOCORT (budesonide), 1602*t*
- Rhinovirus, antiviral agents in development for, 1267*t*
- Rhodopsin, 1732–1733, 1733*f*
- RHOGAM (Rho(D) immune globulin), 1424*t*
- Rho(D) immune globulin, 1423–1424, 1424*t*

- RHYTHMOL (propafenone), 927
- Ribavirin, 1265–1267
antiviral activity of, 1265
contraindicated in pregnancy, 1266
drug interactions of, 1266
with interferons, 1266, 1422
lethal mutagenesis by, 1266
mechanism of action, 1265–1266
pharmacokinetics of, 1867*t*
resistance to, 1265–1266
therapeutic uses of, 1266–1267
- Riboflavin deficiency, 1452
- Ricin, 995
- Ricinus communis*, 994–995
- Ricketts, 1652–1654, 1661–1662
renal, 1662
treatment of, 1665
vitamin D-dependent, 1661
vitamin D therapy for, 1665
- Rickettsia* infection
chloramphenicol for, 1181
tetracyclines for, 1174, 1176
- Rifabutin, 1207, 1209, 1217
adverse effects of, 1209, 1217, 1728
antibacterial activity of, 1217
drug interactions of, 1217
with indinavir, 1303
with voriconazole, 1234
for *Mycobacteria avium* complex, 1204, 1204*t*, 1217
resistance to, 1217
therapeutic uses of, 1217
for tuberculosis, 1209
- RIFADIN (rifampin), 1207
- RIFAMATE (rifampin-isoniazid), 1208
- Rifampicin. *See* Rifampin.
- Rifampin
absorption, distribution, and excretion of, 1208
adverse effects of, 1209, 1728
antibacterial activity of, 1208
for brucellosis, 1177
chemistry of, 1207–1208
in children, 1215
for cholestatic pruritus, 1701
combination therapy with, 1103–1104
CYPs induced by, 121
dosage and dosage forms of, 1209
drug interactions of, 1209
with atovaquone, 1029
with buprenorphine, 576
with chloramphenicol, 1182
with gefitinib, 1368
with imatinib, 1367
with indinavir, 1303
with methadone, 573
with methylxanthines, 729
with metronidazole, 1059
with probenecid, 711
with quinine/quinidine, 1039
with sirolimus, 1413–1414
with terbinafine, 1236
with voriconazole, 1234
for *Haemophilus influenzae* infection, 1209
hypersensitivity to, 1209
with isoniazid, 1203, 1208, 1214–1215
with isoniazid and pyrazinamide, 1208
for leprosy, 1203, 1204*t*, 1220–1221
mechanism of action, 1208
metabolism of, induction of, 89–90
for meningitis, 1209
for mycobacterial infections, atypical, 1215
pharmacokinetics of, 1868*t*
in pregnancy, 1215
prophylactic uses of, 1105
resistance to, 1208
for staphylococcal infections, 1138
therapeutic uses of, 1208–1210
and transporters, 45, 57
for tuberculosis, 1203, 1204*t*, 1207–1210, 1214–1215
for tuberculosis prophylaxis, 1216

 antipsychotics and, 462–467, 472*t*, 473, 491
 effector coupling of, 324*t*
 functions of, 300*t*
 in gastrointestinal tract, 986–987
 gene structure of, 300*t*
 5-HT₁, 299–301, 300*t*, 334, 441, 443
 5-HT₂, 299, 300*t*, 301, 301*f*, 334, 441–443, 472*t*, 473
 5-HT₃, 299, 300*t*, 301, 334
 in nausea/vomiting, 1000–1001, 1001*f*, 1002*t*

- 5-HT₄, 299, 300*t*, 301, 334
 5-HT₅, 300*t*, 302, 334
 5-HT₆, 300*t*, 301–302, 334
 5-HT₇, 300*t*, 301–302, 334
 localization of, 300*t*
 physiological effects of, 303*t*
 polymorphisms in, 106*t*, 108, 109*f*
 psychedelic drugs and, 624
 signal transduction by, 300*t*
 SSRIs and, 441–443
 subtypes of, 297, 299–302, 300*t*, 334
 tricyclic antidepressants and, 441
- Serotonin receptor agonist(s), 300*t*, 305–311, 324*t*, 334. *See also specific agents*
 for anxiety, 455
 for constipation, 995
 diversity of, 305
 ergot/ergot alkaloids, 308–311
 for gastrointestinal motility disorders, 986–988, 987*f*
 for irritable bowel syndrome, 999
 lysergic acid diethylamide, 311
 for migraine, 305–310, 334
 primary actions of, 306*t*
 therapeutic uses of, 306*t*
 triptans, 306–308, 307*f*
- Serotonin receptor antagonist(s), 300*t*, 312–314, 324*t*, 334. *See also specific agents*
 for depression, 455
 with dopamine receptor antagonists, for psychosis, 490–491
 for gastrointestinal disorders, 312, 987*f*
 5-HT₃, 1001–1003
 for chemotherapy-induced emesis, 1003, 1004*t*
 for irritable bowel syndrome, 999–1000
 for nausea/vomiting, 1001–1003, 1002*t*
 pharmacokinetics of, 1001–1003
 therapeutic uses of, 1003
 mechanism of action, 312
 for nausea/vomiting, 312, 334, 343, 561, 1001–1003, 1002*t*
 negative intrinsic activity of, 312
- Serotonin syndrome, 447, 450, 570
- Serotonin transporter(s), 41, 65–66, 298
 antidepressant potencies at, 438*t*
 polymorphisms in, 106*t*
- Serotonin transporter blocker, 324*t*
- Serratia* infection
 amikacin for, 1167
 cephalosporins for, 1150
- Sertaconazole, 1239
- Sertindole, 467, 472*t*
- Sertraline, 432, 435*t*
 in children, 448
 CYP interactions of, 445*t*, 449
 for depression, 432
 dose and dosage forms of, 435*t*
 drug interactions of, 449, 481
 pharmacokinetics of, 444–445, 445*t*, 1872*t*
- potency of
 for receptors, 440*t*
 for transporters, 438*t*
 sexual side effects of, cyproheptadine for, 314
 side effects of, 435*t*
- Serum sickness, 1743
 histamine H₁ receptor antagonists for, 641
 penicillins and, 1141–1142
- SERZONE (nefazodone), 437*t*
- Sevelamer hydrochloride, 1665
- SEVIN (carbaryl), 204
- Sevoflurane, 353*f*, 359–360
 clinical use of, 359
 effects on organ systems, 355*f*, 356*f*, 360
 pharmacokinetics of, 344*t*, 354*f*, 359
 physical properties of, 359
 potency of, measurement of, 344*t*
 side effects of, 360
- Sex hormone-binding globulin (SHBG)
 estrogen and, 1548, 1551
 testosterone and, 1573
- Sexual function
 β adrenergic receptor antagonists, 288
 amyl nitrite/butyl nitrite and, 626
 androgen deficiency and, 1577–1578
 antidepressants and, 433*t*–437*t*, 448
 antipsychotics and, 474
 autonomic regulation of, 144*t*
 clonidine and, 256
 cocaine and, 621
 ethanol and, 598
 guanadrel and, 856
 PDE5 and, 665–666
 phenoxybenzamine and, 268
 phentolamine and, 268
 prostaglandins and, 665–666
 yohimbine and, 271
- Sézary syndrome
 cladribine for, 1349
 photopheresis for, 1688
- Shigellosis
 drug-resistant, 1117
 sulfonamides for, 1112
 tetracyclines for, 1177
 trimethoprim-sulfamethoxazole for, 1118
- Shivering, postanesthesia, 343, 570
- Shock, 260–261
 adrenergic receptor agonists for, 254, 260–261
 cardiogenic, 261
 dopamine for, 250, 261
 circulatory insufficiency in, 121
 histamine, 635
 hypotensive, 261
 hypovolemic, 869–870
 opioids and, 561
 septic, 261
 dopamine for, 249
 glucocorticoids for, 1609
 treatment of, 259–260
 vasodilatory, 785
- Short-loop negative feedback, 791, 792*f*
- Shunt(s), 388–389, 390*f*
- Shy-Drager syndrome, 261
- Sibutramine
 mechanism of action, 305
 for weight reduction, 262–263
- sICAM-1, 1267*t*
- Sick euthyroid syndrome, 1524
- Sickle cell anemia
 azacitidine for, 1345
 epoetin alfa for, 1438
 hydroxyurea for, 1364–1365
- Sideroblastic anemia
 ethanol and, 598
 pyridoxine therapy for, 1451
- Signa (Sig), in prescription order, 1777
- Sildenafil
 adverse effects of, 830, 1728
 for impotence, 665–666, 829–830
 interaction with nitric oxide donors, 123, 829–830
 pharmacokinetics of, 830, 1872*t*
- Silibinin, for mushroom poisoning, 189
- Silicone oil, as vitreous substitute, 1726–1727, 1727*t*
- SILVADENE (silver sulfadiazine), 1115
- Silver sulfadiazine, pharmacological properties of, 1114*t*, 1115
- Simethicone, 975
 for flatulence, 1007
- Simple seizure, 501, 502*t*, 522–523
- SIMULECT (basiliximab), 1418
- Simvastatin, 58, 948–953, 949*f*
 adverse effects of, 951–952
 clinical trials of, 941*t*, 942
 in diabetes mellitus, 946
 dosage, for LDL-lowering effects, 949–950, 950*t*
 drug interactions of, 122, 951–952
 with imatinib, 1367
 with ezetimibe, 953, 959
 mechanism of action, 948–950
 pharmacokinetics of, 950–951, 1872*t*–1873*t*
 therapeutic uses of, 952–953
- SINARTROL (cinnocicam), 701
- SINEMET (carbidopa/levodopa), 534
- SINEQUAN (doxepin), 433*t*
- Single-nephron glomerular filtration rate (SNGFR), 737–739
- Single Nucleotide Polymorphism Database (dbSNP), 100*t*
- Single nucleotide polymorphisms (SNPs), 95, 96*f*
 in coding region (cSNPs), 95, 96*f*
 diseases associated with, 101, 101*f*
 functional studies of, 101–104, 102*t*, 103*f*–104*f*
 mapping onto protein structures, 103
 in noncoding regions, 95–96, 96*f*
 predictive algorithms for, 102–103
- SINGULAIR (montelukast), 722
- Sinoatrial (SA) node
 acetylcholine and, 184–185
 Ca²⁺ channel antagonists and, 834–836, 858
 cardiac glycosides and, 887, 889

- Sinoatrial (SA) node—*continued*
 epinephrine and, 245
 histamine and, 635
- SINTHROME (acenocoumarol), 1480
- Sinus bradycardia, drug-induced, 905*t*
- Sinusitis
 amoxicillin and ampicillin for, 1139
 trimethoprim-sulfamethoxazole for, 1118
- Sinus tachycardia, drug-induced, 905*t*
- Sirolimus, 1409*f*, 1413
 drug interactions of, 1413
 with cyclosporine, 1412
 with voriconazole, 1234
 in endovascular stents, 842
 mechanism of action, 1410*f*, 1413
 pharmacokinetics of, 1413, 1873*t*
 site of action, 1407*t*
 therapeutic uses of, 1413
 and tolerance, 1420
 toxicity of, 1413
- Sisomicin, 1155
- Sitosterolemia, transporters in, 54*t*
- Sjögren's syndrome, xerostomia in, pilocarpine for, 188
- Skeletal muscle(s)
 anticholinesterase agents and, 208
 autonomic regulation of, 144*t*
 cholinergic transmission in, 152–153
 corticosteroids and, 1599, 1604
 enflurane and, 358
 epinephrine and, 246
 ethanol and, 596
 halothane and, 356
 isoflurane and, 357
 neuromuscular blocking agents and, 223–224
 nicotinic cholinergic receptors in, 154, 155*t*
 nitrous oxide and, 360
 quinine and, 1037–1038
 sevoflurane and, 360
- Skeleton, 1657–1659
- SKELID (tiludronate), 1668
- Skin, 1679–1703
 ACE inhibitors and, 809
 antipsychotics and, 481
 arsenic and, 1765
 autonomic regulation of, 144*t*
 drug excretion via, 11
 function of, 1679–1680
 local anesthesia for, 378–380
 opioids and, 562, 567
 penicillin hypersensitivity and, 1141–1142
 as pharmacological target, 1679, 1680*f*
 protection of, sunscreens for, 1700–1701
 structure of, 1679–1680
 topical application to, 6–7, 1679–1681
- Skin cancer
 imiquimod for, 1696
 photodynamic therapy for, 1688
 prevention of
 retinoids for, 1686–1687
 sunscreens for, 1700–1701
- Skin disorder(s), 1679–1703
 antimicrobial agents for, 1689–1692
 biological response modifiers for, 1697–1700
 cytotoxic drugs for, 1693–1696
 drug delivery in, 1680–1681
 glucocorticoids for, 1609, 1679, 1681–1683, 1682*t*
 histamine receptor antagonists for, 1689
 immunosuppressant drugs for, 1693–1697
 intralesional therapy for, 1681
 photochemotherapy for, 1687–1688
 photodynamic therapy for, 1688–1689
 photopheresis for, 1688
 retinoids for, 1683–1687
 systemic therapy for, 1681
 topical therapy for, 1680–1681
- Skin necrosis, warfarin and, 1478–1479
- SKIN SHIELD (dyclonine hydrochloride), 379
- Sleep. *See also* Insomnia
 β adrenergic receptor antagonists and, 288
 amphetamine and, 257
 antipsychotics and, 469, 480–481
 barbiturates and, 414, 424–425
 benzodiazepines and, 405, 407, 410–412, 423–425
 chloral hydrate and, 420–421
 drug dependence and, 615
 ethchlorvynol and, 420–422
 histamine H₁ receptor antagonists and, 641
 meprobamate and, 420, 422
 nonprescription aids and, 422
 novel benzodiazepine receptor agonists and, 412–414
 paraldehyde and, 420
 sedative-hypnotics and, 401
- Sleeping sickness. *See* Trypanosomiasis

 - for osteoporosis, 757, 1671–1672
 - in pregnancy, 849
 - and quinidine, 756, 849

- Thiazide diuretics—*continued*
 renal hemodynamic effects of, 744*t*, 756
 site of action, 755, 763*f*
 sodium channel inhibitors with, 759
 as surrogate markers, 849
 therapeutic uses of, 756–757
 toxicity of, 756
 and vasopressin secretion, 784
- Thiazolidinediones, 1639–1640
 history of, 1639
- Thienamycin, 1151
- Thienylmethylacrylic acid derivatives, 812*f*
- Thiethylperazine, 477
 for nausea/vomiting, 1003
- Thimerosal, 1760
 hypersensitivity to, 1715
- Thiobarbiturate(s), 414. *See also* Barbiturate(s)
 metabolism of, 418
- Thioctic acid, for mushroom poisoning, 189
- Thiocyanate, as antithyroid drug, 1530–1531
- Thioguanine, 1346–1347
 chemistry of, 1346, 1347*f*
 metabolism of, 87
- Thioguanine derivatives. *See also* Azathioprine; Mercaptopurine
 for inflammatory bowel disease, 1015–1016
 in pregnancy, 1018
- Thiol methyltransferase (TMT), 86
- Thiopental, 346*f*, 347–350, 352–353, 416*t*
 antithyroid activity of, 1527
 cardiovascular effects of, 349, 417
 clinical use of, 349
 CNS effects of, 349
 context-specific half-time of, 347, 347*f*
 formulations and dosages of, 347–349, 348*t*
 as general anesthetic, 347–350, 352–353, 418–419
 pharmacokinetics of, 348*t*, 349, 416*t*
 pharmacological effects of, 353*t*
 pharmacological properties of, 348*t*
 routes of administration, 416*t*, 418
 side effects of, 349–350
 single bolus administration of, 347, 347*f*
 therapeutic uses of, 416*t*
 for trauma prevention, in electroconvulsive therapy, 229
- Thioperamide, 641–642
- THIOPLEX (thiotepa), 1329
- Thiopurine, pharmacogenetics of, 105*t*, 107, 110, 111*f*
- 6-Thiopurine analog(s), 1346–1348. *See also* Mercaptopurine; Thioguanine
- Thiopurine methyltransferase (TPMT), 86–87, 1015*f*, 1016
 fraction of clinically used drugs metabolized by, 78*f*
 polymorphism of, 94–95, 100, 105*t*, 107, 110, 111*f*, 124–125, 1016
- Thioridazine, 462
 arrhythmia induced by, 915
 cardiovascular effects of, 474, 477
 in children, 484
 drug interactions of, 481
 half-life of, 475*t*
 metabolism of, 476
 neurological effects of, 477
 ophthalmic effects of, 1729
 receptor actions of, 472*t*, 474
 therapeutic index of, 477
- Thiotepa, 1323–1324, 1329–1330
 absorption, fate, and excretion of, 1329–1330
 cytotoxic effects of, 1329
 pharmacological effects of, 1329
 toxicities of, 1325–1327, 1326*t*, 1330
- Thiothixene, 462, 464*t*
 dose and dosage forms of, 464*t*
 half-life of, 475*t*
 receptor actions of, 472*t*
 side effects of, 464*t*
- Thiourea, 1527
- Thioureylenes, 1527, 1527*f*
 adverse effects of, 1528–1529
 mechanism of action, 1527–1528
 pharmacokinetics of, 1528, 1528*t*
 structure-activity relationship of, 1527
 therapeutic uses of, 1529–1530
- Thioxanthenes, 461, 462, 464*t*
 biotransformation of, 476
 drug interactions of, 481
 and seizure threshold, 469
- 2-Thiozolyethylamine, chemistry of, 630*f*
- Thoracic surgery, antibiotic prophylaxis in, 1106*t*
- Thorazine (chlorpromazine), 463*t*
- Threadworm, 1075–1076
- Thrombanolic acid, 655
- Thrombin, 1467, 1468*f*, 1469
 heparin and, 1471–1472, 1471*f*
 thromboxane A₂ and, 660
- Thrombin-activatable fibrinolysis inhibitor (TAFI), 1480
- Thrombin inhibitor(s), for angina, 841
- Thrombocytopenia, essential, hydroxyurea for, 1365
- Thrombocytopenia
 carbamazepine and, 512
 chloramphenicol and, 1181
 colchicine and, 708
 corticosteroids for, 1610
 ethanol and, 598
 ethosuximide and, 514
 flucytosine and, 1230
 heparin-induced, 1474
 indomethacin and, 696
 interleukin-11 (oprelvekin) for, 1441
 linezolid and, 1193
 quinidine and, 928
 suramin and, 1069
 thrombopoietin for, 1441–1442
- Thromboembolism
 antiplatelet drugs for, 1481–1484
 erythropoietin therapy and, 1438
 estrogen therapy and, 1552
 fibrinolytic drugs for, 1480–1481
 heparin for, 1472–1473, 1479
 oral anticoagulants for, 1479–1480
 oral contraceptives and, 1565–1566
- Thrombolysis, 1470
- Thrombolytic therapy, 1480–1481
 contraindications to, 1481, 1481*t*
 hemorrhagic toxicity of, 1481
 in ophthalmic surgery, 1728
- Thrombomodulin, 1470
- Thrombophlebitis
 erythropoietin therapy and, 1437
 tetracyclines and, 1178
- Thrombopoietic growth factor(s), 1441–1442
- Thrombopoietin, 1436*t*, 1441–1442
 history of, 1434
 site of action, 1435*f*
 therapeutic uses of, 1441–1442
- Thrombosis
 pharmacogenetics of, 109
 serotonin (5-HT) in, 302, 302*f*
- Thrombotic thrombocytopenic purpura-hemolytic uremic syndrome (TTP-HUS), ticlopidine and, 1483
- Thromboxane(s), 336, 654*f*, 655, 658, 659*f*
 A₂ (TxA₂)
 and cancer, 665
 cardiovascular effects of, 660
 catabolism of, 658, 659*f*
 CNS effects of, 661
 discovery of, 653
 endogenous, functions of, 663–665
 gastrointestinal effects of, 661
 in inflammation, 660
 inhibition of, 658
 and platelets, 660, 663–664
 renal effects of, 661, 664
 in rheumatoid arthritis, 673
 and smooth muscle, 660–661
 synthesis of, 654*f*, 655
 therapeutic uses of, 665–666
 uterine effects of, 661, 664
 inhibition of, 657–658
 PGD₂, in inflammation, 660
 pharmacological properties of, 658–663
- Thromboxane receptor(s), for TxA₂ (TP), 662–663, 662*t*
- Thrush. *See* Candidiasis
- Thymidylate synthesis, 1453, 1458
- Thymidylate synthetase, polymorphisms in, 106*t*, 108, 108*f*, 110
- Thymine, 1337*f*, 1340
- THYMOGLOBULIN (antithymocyte globulin), 1406
- THYREL (protirelin), 1524
- THYROGEN (thyrotropin alfa), 1524
- Thyroglobulin, 1513, 1513*f*, 1514–1515
 antibodies against, and hypothyroidism, 1523
- Thyroid cancer
 medullary, diagnosis of, 1666
 radioactive iodine for, 1534–1535
 TSH suppression therapy for, 1524, 1526
- Thyroid C cells, 1656

- Thyroid function tests, 1523–1524
- Thyroid gland, 1511–1526
- amiodarone and, 921, 1527, 1532*t*
 - disorders of, 1511
 - function of
 - iodine and, 1519, 1531, 1532*t*
 - regulation of, 1517–1519
 - hyperfunction of. *See* Hyperthyroidism
 - hypofunction of. *See* Hypothyroidism
 - lithium and, 487, 1531
 - salicylates and, 689
- Thyroid hormone(s), 1511–1526, 1512*f*–1513*f*
- actions of, 1519–1524

dose-response in, 1739–1740, 1740*f*
risk and assessment in, 1740–1741
- Toxic shock, streptococcal, penicillin G for, 1136
- Toxiferines, 220
- Toxocara canis*, 1074–1075
- Toxocariasis, 1074–1075
- Toxoplasma gondii*, 1050–1051. *See also* *Toxoplasmosis*
- Toxoplasmosis, 1050–1051
artemisinin for, 1027
atovaquone for, 1028–1029
clindamycin for, 1051, 1190
macrolides for, 1186
ophthalmic, 1718–1719
pyrimethamine for, 1030–1031, 1051, 1115
sulfonamides for, 1030–1031, 1051, 1115
treatment of, 1051
- Trabecular bone, 1658
- Tracheal muscle, eicosanoids and, 660–661

- Trachoma, tetracyclines for, 1177
- TRACRIUM (atracturium), 222*t*
- TRACTOTILE (atosiban), 1507
- “Train of four” stimulus schedule, 229
- Tramadol, 566, 580*t*
 pharmacokinetics of, 1880*t*–1881*t*
- TRANDATE (labetalol), 852
- Trandolapril, 802*f*, 803
 absorption and elimination of, 803
 adverse effects of, 808–810
 dosage of, 803
 in heart disease, 806*t*–807*t*
 for hypertension, 858–859
 therapeutic uses of, 804–808
- Tranilast, in Gilbert’s syndrome, 81
- Transdermal opioids, 582–583
- TRANSDERM SCOP (scopolamine), 197, 1004
- Transducer(s), 24–25
- Transducin, 1732
- Transduction, and drug resistance, 1098
- Transferrin, 1443
- Transfersomes, 1681
- Transformation, and drug resistance, 1098
- Transforming growth factor- β
 cyclosporine and, 1409
 in inflammation, 672
- Transient receptor potential (TRP) ion channels, 322
- Transplantation
 ganciclovir and, 1255
 general approach to, 1406
 rejection of
 prevention of
 corticosteroids for, 1610
 cyclophosphamide for, 1328
 immunosuppression for, 1406–1407
 sargramostim for, 1439
 tolerance and, 1420–1421
- Transport, of drugs
 across membranes, 1–3
 active, 3, 45*f*, 46–47
 primary, 45*f*, 46
 secondary, 45*f*, 46–47
 basic mechanisms of, 45–47

 β adrenergic receptor antagonists and,
 277
 bile acid sequestrants and, 954
 in diabetes mellitus, 1623
 elevated levels of, 933–934
 treatment for, 946–947
 estrogen and, 1548, 1552
 fibric acid derivatives and, 957–959
 levels of
 classification of, 943, 943*t*
 goals and therapeutic indications of,
 944*t*
 statins and, 948–949
 metabolism of, 937–938, 937*f*, 938
 niacin and, 955–956
 oral contraceptives and, 1565
 synthesis of, 934
 in very-low-density lipoproteins, 938
- Trihexyphenidyl hydrochloride, 197
 dosage of, 533*t*
 for Parkinson's disease, 533*t*, 537
- Triiodothyronine. *See* Thyroid hormone(s)
- TRILAFON (perphenazine), 463*t*
- TRILEPTAL (oxcarbazepine), 513
- TRILISATE (choline salicylate-magnesium
 salicylate), 690
- Trilostane, 1610–1611
- Trimegestone, 1559
- Trimethadione, history of, 402
- Trimethaphan, 233*f*
 and acetylcholine actions, 186
 mechanism of action, 174, 231
- Trimethoprim, 1113*f*, 1116, 1117
 antibacterial spectrum of, 1116–1117
 for diarrhea, 997
 hypersensitivity to, 1102
 pharmacokinetics of, 1881*t*
 and sodium channel inhibitors, 759
 with sulfonamides, 1104, 1111–1112
 for urinary tract infections, 1115
- Trimethoprim-sulfamethoxazole, 1104,
 1116–1119
 absorption, fate, and excretion of, 1117
 for acne, 1690
 adverse effects of, 1118–1119
 for cutaneous infections, 1690
 for diarrhea, 997, 1118
 efficacy of, 1117
 for gastrointestinal infections, 1118
 hypersensitivity to, 1119
 interaction with lamivudine, 1289
 mechanism of action, 1117
 for nocardiosis, 1115, 1118
 ophthalmic use of, 1719
 for *Pneumocystis jirovecii* infection,
 1104, 1118
 prophylactic uses of, 1105, 1118
 resistance to, 1117
 for respiratory tract infections, 1118
 for salmonellosis, 1118, 1140
 therapeutic uses of, 1117–1118
 for typhoid fever, 1118, 1140
 for urinary tract infections, 1115, 1117–
 1118
- Trimethylamine *N*-oxide (TMAO), 78
- Trimetrexate, 1336
- Trimipramine, 432, 433*t*
 CYP interactions of, 445*t*
 dose and dosage forms of, 433*t*
 pharmacokinetics of, 445*t*
 pharmacological properties of, 439
 potency of
 for receptors, 440*t*
 for transporters, 438*t*
 serum concentrations of, 445*t*
 side effects of, 433*t*
- Triorthocresylphosphate (TOCP), delayed
 neurotoxicity of, 211
- Trioxsalen, 1687–1688
- Tripamide, 750*t*
- Tripelennamine, 636, 638*t*
- Tripitramine
 affinity/selectivity of, 184
 mechanism of action, 174
 therapeutic uses of, 195
- Triple product, and angina, 827
- Triple response, to histamine, 635–637
- Triptan(s), 306–308, 307*f*
 absorption, fate, and excretion of, 307–
 308
 adverse effects of, 308
 contraindications to, 308
 mechanism of action, 307
 pharmacological properties of, 307
- Triptorelin, 1502*t*
 for prostate cancer, 1387
 therapeutic uses of, 1504
- Trisalicylate, 690
- Troglitazone, 1639–1640
 metabolism of, induction of, 89–90
 for prediabetic conditions, 1641
 toxicity of, 44–45, 1639
 withdrawal from market, 1639
- Troleandomycin, metabolism of, induction
 of, 89–90
- TRONOTHANE (pramoxine hydrochloride),
 379
- Trophoblastic tumors, methotrexate for,
 1338
- TROPICACYL (tropicamide), 1720*t*
- Tropical pulmonary eosinophilia, 1076, 1083
- Tropicamide, 189, 196
 ophthalmic use of, 1720*t*
- Tropisetron, 300*t*, 1001–1003
 for irritable bowel syndrome, 999–1000
 mechanism of action, 1001
 for nausea/vomiting, 1001–1003, 1002*t*
 pharmacokinetics of, 1001–1003
 therapeutic uses of, 1003
- Trospium chloride, 195–196
- Trovafloxacin, withdrawal from market,
 1119
- TRUSOPT (dorzolamide), 1723
- Trypan blue, 1068
- Trypanosoma*, 1050–1052
- Trypanosomiasis, 1051–1052
 African, 1051–1057
 American, 1052
 benznidazole for, 1052, 1058, 1061–1062
 eflornithine for, 1051–1055
 melarsoprol for, 1051–1052, 1056–1057
 miltefosine for, 1061
 nifurtimox for, 1052, 1061–1063
 pentamidine for, 1051–1052, 1064–1065
 rimantadine for, 1257
 suramin for, 1051–1052, 1068–1070
 treatment of, 1051–1057
- Trypan red, 1068
- Trypomastigotes, 1052
- Tryptamine, 298*f*
- Tryptophan, 297–298, 298*f*
 dietary, effects of, 305
- Tryptophan hydroxylase, 297–298, 298*f*,
 305
- Tuberculin test, 1216
- Tuberculosis, 1203–1216
 amikacin for, 1167, 1203, 1204*t*, 1214
 aminosalicilic acid for, 1203, 1204*t*,
 1213
 capreomycin for, 1203, 1204*t*, 1214
 causative agent of, 1203
 chemoprophylaxis of, 1216
 chemotherapy for, 1203–1215, 1204*t*
 combination therapy for, 1203, 1214
 cycloserine for, 1203, 1204*t*, 1213–1214
 drug resistance in, 1096–1098, 1214–
 1215
 ethambutol for, 1203, 1204*t*, 1210, 1214–
 1215
 ethionamide for, 1203, 1204*t*, 1212–1213
 first-line agents for, 1203, 1204*t*
 gatifloxacin for, 1203, 1204*t*, 1212

- glucocorticoids and, 1603–1604
 in HIV/AIDS, 1215–1216
 interferon- γ for, 1212
 isoniazid for, 1203–1207, 1204*t*, 1214–1215
 linezolid for, 1203, 1204*t*, 1212
 moxifloxacin for, 1203, 1204*t*, 1212
 pyrazinamide for, 1203, 1204*t*, 1211–1212, 1214–1215
 quinolones for, 1122, 1203, 1204*t*, 1212, 1218
 reactivation of, infliximab and, 1017
 rifabutin for, 1209
 rifampin for, 1203, 1204*t*, 1207–1210, 1214–1215
 rifapentine for, 1209–1210
 second-line agents for, 1203, 1204*t*
 streptomycin for, 1165, 1203, 1204*t*, 1210–1211, 1215
- Tubocurarine, 219*f*, 220, 221*f*, 222*t*
 and acetylcholine release, 151
 autonomic effects of, 226
 barbiturates and, 417
 CNS effects of, 226
versus decamethonium, 222*t*
 and histamine release, 226, 632
 L-isomer *versus* D-isomer of, 222
 mechanism of action, 153, 222–223
 pharmacokinetics, 220, 222*t*, 228
 pharmacologic properties of, 223–228, 222*t*
 therapeutic uses of, 229
- Tubuloglomerular (TGF) feedback, 739
- Tularemia
 ciprofloxacin for, 1122
 streptomycin for, 1164–1165
 tetracyclines for, 1177
- Tumor lysis syndrome, prevention of, allopurinol for, 708–709
- Tumor necrosis factor, 672
 TNF- α , 672
 corticosteroids and, 1600, 1600*t*
 estrogen and, 1547
 in fever, 682
 in inflammatory bowel disease, 1011, 1011*f*, 1016–1017
 reagents against, 1419
 in rheumatoid arthritis, 673
 TNF- β , 672
- Tumor necrosis factor α -converting enzyme (TACE), 27
- TUMS EX, 974*t*
- Tunnel disease, 1075
- Turner's syndrome, estrogen therapy for, 1554
- T wave, of electrocardiogram, 902*f*, 909*f*
 chloroquine and, 1035
 epinephrine and, 245
- Two-pore domain channels, general anesthesia and, 346
- TYLENOL (acetaminophen), 676*t*
- TYLOX (oxycodone), 580*t*
- Typhoid fever
 ampicillin for, 1140
 chloramphenicol for, 1180
 ciprofloxacin for, 1140
 trimethoprim-sulfamethoxazole for, 1118, 1140
- Typhus
 chloramphenicol for, 1181
 tetracyclines for, 1174, 1176
- Tyramine, 240*t*
 clinical uses of, 240*t*
 mechanism of action, 173, 239
 and tachyphylaxis, 162–163
- Tyrosine hydroxylase, 158, 158*f*, 159*t*, 163
 deficiencies of, 158, 174

- ULTRAVATE (halobetasol propionate), 1682*t*
- Ultraviolet radiation, 1679, 1687
 protection from, sunscreens for, 1700–1701
 therapeutic uses of, 1687–1688, 1701
- UVA, 1687
 agents filtering, 1700
 psoralens with (PUVA), 1687–1688
- UVB, 1687
 agents filtering, 1700–1701
- UNASYN (sulbactam-ampicillin), 1152
- Unconsciousness
 in anesthetic state, 343–344
 sedative-hypnotics and, 401
- Undecylenic acid, 1240
- Unitary theory, of anesthesia, 344–345
- United States Pharmacopeia, 130, 131, 1783
- United States Pharmacopeia Convention, Inc., 1783
- UNIVASC (moexipril), 804
- University Group Diabetes Program (UGDP), 1637
- Unoprostone, for glaucoma, 1722–1723
- Uracil, 1340
- Urapidil, 272
- URAT1 transporter, 65
- Urea, 747–749, 747*t*
 absorption and elimination of, 747*t*, 748
 adverse effects of, 748
 in breast milk, 11
 contraindications to, 748
 for dialysis disequilibrium syndrome, 748
 for glaucoma, 748–749
 for hyperkeratotic disorders, 1702
 therapeutic uses of, 748–749
 vasopressin receptors and, 777, 779
- UREAPHIL (urea), 747*t*
- Urea transporter(s), 777
- URECHOLINE (bethanechol), 188
- Ureidopenicillins, 1140–1141
- Uremia, pruritus with, 1701
- Ureter(s)
 anticholinesterase agents and, 208
 autonomic regulation of, 144*t*
 opioids and, 562
- Urethane, 402
- Urethritis, treatment of, 1177
- UREX (mandelic acid), 1123
- Uric acid
 cyclosporine and, 1412
 elevated levels of, treatment for, 707–710
 ethambutol and, 1210
 excretion of, agents increasing, 710–712
 in gout, 706–707
 mercaptopurine and, 1348
 pyrazinamide and, 1212
 salicylates and, 689
- Uricosuric agents, 710–712
- Uridine diphosphate(s), as neurotransmitter, 335
- Uridine diphosphate-glucuronosyltransferases, 72, 72*f*, 73, 80–82
 antiseizure drugs and, 509*t*, 511–512, 515
 in Crigler-Najjar syndrome, 81, 97
 expression of, 81–82
 fraction of clinically used drugs metabolized by, 78*f*
 in Gilbert's syndrome, 81–82, 81*f*–82*f*, 88
 sites of action, 74–75
 UGT isoforms, 80–81, 80*f*

- Uridine triphosphate(s), as neurotransmitter, 335
- Urinary excretion, 1788. *See also* Excretion of drugs; *specific drugs*
enhanced, for poisoning, 1749–1750, 1750*f*
- Urinary incontinence, ephedrine for, 259
- Urinary tract
acetylcholine and, 185, 186*t*
anticholinesterase agents and, 208
autonomic regulation of, 144*t*
disturbances of, sulfonamides and, 1116
eicosanoids and, 661
muscarinic receptor agonists and, 185, 186*t*, 187
muscarinic receptor antagonists and, 194
opioids and, 562
prostaglandins and, 661
- Urinary tract infection(s)
ampicillin for, 1115, 1140
antiseptic and analgesic agents for, 1122–1124
carbenicillin indanyl for, 1140
gentamicin for, 1165
methenamine for, 1111, 1122–1123
nitrofurantoin for, 1123–1124
phenazopyridine for, 1124
quinolones for, 1111, 1121
sulfonamides for, 1111, 1115
tetracyclines for, 1177
trimethoprim-sulfamethoxazole for, 1115, 1117–1118
- Urine acidification, 1649, 1750
- Urine alkalization, 1750
- Urine osmolality, vasopressin and, 774, 774*f*
- URISPAS (flavoxate hydrochloride), 197
- Urofollitropin, 1505
- Urogenital atrophy, estrogen for, 1553
- Urologic surgery, antibiotic prophylaxis in, 1107*t*
- Uroporphyrin, increased excretion of, 1756, 1756*t*
- UROXATRAL (alfuzosin), 270
- Ursodeoxycholic acid, 1006–1007, 1007*f*
for cholestatic pruritus, 1701
- Ursodiol, 1007
- Urticaria
antipsychotics and, 481
antithyroid drugs and, 1529
chronic, doxepin for, 639, 641
ethosuximide and, 514
H₁ receptor antagonists for, 640–641
histamine release in, 632
- Urticaria pigmentosa, mast cell and basophil proliferation in, 632
- USP/National Formulary (USP-NF), 1783
- Uterus
eicosanoids and, 661, 664–665
epinephrine, 246
estrogen/progestins and, 1546–1547, 1546*f*
halothane and, 356
histamine and, 636
kinins and, 648
meperidine and, 568–569
NSAIDs and, 683*t*, 685–686
opioids and, 562
oxytocin and, 661, 1507
platelet-activating factor and, 667–668
prostaglandins and, 661–662, 664–665
ritodrine and, 253
- Uveitis, 1718, 1724
- Vaccine(s), 1423
mercury content of, 1760
- Vaccinia virus, ribavirin for, 1266
- VAGIFEM (estradiol), 1551
- Vaginal atrophy, estrogen therapy for, 1553
- Vaginal cancer, diethylstilbestrol and, 1552
- Vaginal dryness, estrogen for, 1553
- Vaginal infection(s)
bacterial, clindamycin for, 1190
fungal, treatment of, 1237–1240
- VAGISTAT 1 (tioconazole), 1239
- Vagus nerve (CNX), 137–139
- Valacyclovir, 1247–1250
adverse effects of, 1247–1249
for herpes simplex virus, 1247, 1249
ophthalmic use of, 1717*t*, 1718
pharmacokinetics of, 1247, 1882*t*
therapeutic uses of, 1249–1250, 1691
- Valdecoxib, 679*t*–680*t*, 702–704, 703*f*
adverse effects of, 704
versus aspirin, 679*t*
cardiovascular risk with, 684, 687, 703
clinical use of, 703
COX-2 selectivity of, 681, 702
drug interactions of, 703
gastrointestinal effects of, 683–684
pharmacokinetics of, 679*t*–680*t*, 702–704, 1882*t*
pharmacological properties of, 704
therapeutic uses of, 704
withdrawal from market, 702, 704
- Valganciclovir, 1254–1256
adverse effects of, 1255
antiviral activity of, 1254
pharmacokinetics of, 1254, 1882*t*
therapeutic uses of, 1255–1256
- VALISONE (betamethasone valerate), 1602*t*
- VALIUM (diazepam), 360
- Valnoctamide, interaction with carbamazepine, 79
- Valproic acid, 514–516
adverse effects of, 515
competition with phenytoin, 509
interactions of, 515
with benzodiazepines, 412
with carbamazepine, 79, 513
with hepatic microsomal enzymes, 509*t*, 515
for mania, 485–486, 489–491
mechanism of action, 505–506, 515
pharmacokinetic properties of, 515
pharmacokinetics of, 515, 1883*t*
pharmacological effects of, 514–515
for seizures/epilepsy, 412, 506, 514–516, 522–523
in Huntington's disease, 541
- teratogenicity of, 515, 523–524
therapeutic uses of, 515–516
toxicity of, 515
- Valrubicin, 1359
- Valsartan, 812*f*, 813
adverse effects of, 814
for congestive heart failure, 880
for hypertension, 859–860
pharmacokinetics of, 813, 1883*t*
pharmacological effects of, 810
therapeutic uses of, 813–814
- Valsartan Heart Failure Trial (Val-HeFT), 880
- Valsartan in Acute Myocardial Infarction (VALIANT), 814
- VALSTAR (valrubicin), 1359
- VALTRES (valacyclovir), 1717*t*
- Valvular heart disease, surgery for, prophylaxis in, 1138
- VAMC Trial (Vasodilation in the Acute Management of CHF), 885–886
- VANCERIL (beclomethasone), 721, 1602*t*
- VANOCIN (vancomycin), 1196
- Vancomycin, 1194–1196
adverse effects of, 1196
with aminoglycoside, 1102
antibacterial activity of, 1194
history and source of, 1194
hypersensitivity to, 1196
mechanism of action, 1194–1195, 1195*f*
ototoxicity of, 1196
peak concentration of, 1196
pharmacokinetics of, 1100, 1196, 1883*t*
prophylactic uses of, 1106*t*–1107*t*
and “red-man syndrome,” 632, 1196
renal clearance of, impaired, 120
resistance to, 1099, 1194–1195, 1197
Van phenotypes of, 1195, 1197
for staphylococcal infections, 1136, 1138, 1196
therapeutic uses of, 1196
- Vanillylmandelic acid (VMA), 164, 165*f*
- VANSIL (oxamniquine), 1088
- VANTIN (cefpodoxime proxetil), 1145*t*
- Vapreotide, 1496, 1497*f*
for diarrhea, 998
- Vardenafil
adverse effects of, 830, 1728
for impotence, 665–666, 829–830
interaction with nitric oxide donors, 123, 829–830
metabolism of, 830
- Variceal bleeding
prevention of, β adrenergic receptor antagonists for, 292
somatostatin and octreotide for, 998, 1498
vasopressin V₁ receptor agonists for, 785, 998
- Varicella-zoster immune globulin, 1423
- Varicella-zoster virus (VZV), 1691
acyclovir for, 1249–1250
acyclovir-resistant, 1247
famciclovir for, 1252
foscarnet for, 1254

- penciclovir for, 1252
 valacyclovir for, 1249–1250
 vidarabine for, 1246
- Vascular adhesion molecule-1 (VCAM-1),
 in inflammation, 671–672
- Vascular disease
 peripheral, treatment of, 841–842
 renin-angiotensin system in, 800
- Vascular-endothelial growth factor (VEGF),
 bevacizumab and, 1378
- Vascular system, eicosanoids and, 664
- Vasculitis
 isoniazid and, 1207
 leukotriene receptor antagonists and,
 724
 lithium and, 488
 penicillins and, 1142
- Vasoactive intestinal polypeptide (VIP),
 335
 and gastrointestinal motility, 984
 as neurotransmitter, 138, 146, 176–177
 and prolactin, 1499
 and vasopressin, 775
- VASOCLEAR (naphazoline), 1721*t*
- VASOCON REGULAR (naphazoline), 1721*t*
- Vasoconstriction
 angiotensin II and, 797, 797*f*
 epinephrine and, 244–245
 hypoxia and, 391
 of large vessels, histamine and, 635
 opioids and, 561
 serotonin (5-HT) in, 302, 302*f*
 thromboxanes and, 660
 vasopressin and, 779
 vasopressin V₁ receptor agonists and, 785
- Vasoconstrictor(s), and local anesthesia,
 375, 383
- Vasodilation
 acetazolamide and, 746
 acetylcholine and, 184–185
 β adrenergic receptor antagonists and,
 275–277, 276*f*, 276*t*
 Ca²⁺ channel antagonists and, 835–836
 general anesthesia and, 342
 histamine and, 635
 kinins and, 647
 nitric oxide and, 395–396
 organic nitrates and, 826–827
 platelet-activating factor and, 667
 prostaglandins and, 658–660
 serotonin (5-HT) in, 302, 302*f*
 spinal anesthesia and, 382
 vasopressin and, 771
- Vasodilator(s). *See also specific agents*
 for congestive heart failure, 873, 874*t*,
 877
 for dementia, 430
 for hypertension, 846*t*, 860–865
 parenteral, for congestive heart failure,
 884–886
- Vasodilatory shock. *See Shock*
- Vasomotor symptoms, in menopause, treat-
 ment of, 1553–1554
- Vasopeptidase inhibitors, for congestive
 heart failure, 886
- Vasopressin, 771–787, 772*t*, 1489–1490

 Visceral larva migrans, 1075
 Visceral leishmaniasis, 1052
 Visceral nervous system. *See* Autonomic nervous system
 Viscoelastic substances, 1726
 VISICOL (phosphate salts), 992
 VISINE MOISTURIZING (tetrahydrozoline), 1721*t*
 VISKEN (pindolol), 278
 VISTARIL (hydroxyzine), 638*t*
 VISTIDE (cidofovir), 1717*t*
 Visual cycle, 1732–1733, 1733*f*–1734*f*
 retinal and, 1732–1733
 VISUDYNE (verteporfin), 1729–1730
 Vitamin(s)
 D₂/D₃, 1653*f*
 ethanol and, 594, 597–598
 iodine-containing, 1532*t*
 ophthalmic effects/uses of, 1730–1734
 Vitamin A, 1683, 1686–1687
 chemistry of, 1730–1731
 and epithelial structures, 1733–1734
 ethanol and, 598
 history of, 1730
 mechanism of action, 1734
 ophthalmic effects/uses of, 1730–1734
 pharmacological actions of, 1731–1732
 physiological functions of, 1731–1732
 and visual cycle, 1732–1733, 1733*f*
 Vitamin B₁ (thiamine)
 with altretamine, 1329
 for isoniazid toxicity, 1102, 1206–1207
 ophthalmic effects of, 1731*t*
 Vitamin B₆ (pyridoxine)
 with altretamine, 1329
 deficiency of, 1451–1452
 hypoglycemic effects of, 1634*t*
 for isoniazid toxicity, 1102, 1206–1207
 ophthalmic effects of, 1731*t*
 Vitamin B₁₂, 1452–1458, 1454*f*
 absorption, distribution, and elimination of, 1454–1455, 1455*f*
 daily requirements for, 1454–1455
 deficiency of, 1455–1456
 metabolic role of, 1452–1454, 1453*f*, 1454
 ophthalmic effects of, 1731*t*
 relationship with folic acid, 1452–1454, 1453*f*
 sources in nature, 1454
 supplementation of, 1456–1458
 in inflammatory bowel disease, 1018
 therapeutic uses of, 1458
 Vitamin C
 and iron absorption, 1448
 ophthalmic effects of, 1731*t*, 1734
 Vitamin D, 1652–1656, 1653*f*
 absorption, fate, and excretion of, 1654
 adverse effects of, 1666
 in bone metabolism, 1652–1656
 and calcium transport, 1648
 D₂, 1652
 D₃, 1653
 deficiency of, 1652–1654, 1661–1662
 disorders of, 1661–1662
 ethanol and, 598

- excess of, and hypercalcemia, 1660
forms and preparations of, 1663–1664, 1664*f*
human requirements for, 1652–1654
hydroxylation of, 1654–1655, 1655*f*
for hypoparathyroidism, 1665–1666
lead poisoning and, 1757
mechanism of action, 1655–1656
metabolic activation of, 1654–1655
mobilization in bone, 1656
for nutritional rickets, 1665
occurrence of, 1652
for osteomalacia, 1665
for osteoporosis, 1672
phenobarbital and, 511
phenytoin and, 510
physiological actions of, 1655–1656
receptors for, 29
receptor polymorphism, 106*t*
for renal osteodystrophy, 1665
therapeutic uses of, 1663–1666
toxicity of, 1661, 1666
units of, 1652–1654
- Vitamin E
for anthracycline toxicity, 1358
for ethanol toxicity, 598
ophthalmic effects of, 1731*t*, 1734
- Vitamin K, 1484
absorption of, 1485
antagonists of, 1476–1477
antiseizure drugs and, 510–511, 523–524
in coagulation, 1484–1486
cycle of, 1476, 1477*f*
deficiency of, 1485–1486
 symptoms of, 1485
fate and excretion of, 1485
human requirements for, 1485
inadequate intake of, 1485–1486
inadequate utilization of, 1486
occurrence of, 1484
ophthalmic effects of, 1731*t*
pharmacological actions of, 1484–1485
physiological functions of, 1484–1485
therapeutic uses of, 1485–1486
toxicity of, 1485
for warfarin toxicity, 1478
- Vitiligo, PUVA for, 1688
- VITRASERT (ganciclovir), 1255, 1717*t*
- VITRAVENE (fomivirsen), 1717*t*
- Vitreous, 1710*f*, 1712
- Vitreous substitutes, 1726–1728, 1727*t*
- VIVACTIL (protriptyline), 434*t*
- VIVELLE (estradiol), 1551
- VLDL. *See* Very-low-density lipoprotein
- Voltage-dependent ion channels, 321, 322*f*.
See also specific channels
- VOLTARIN (diclofenac), 677*t*, 1725
- VOLTARIN-XR (diclofenac), 698
- VOLTAROL (diclofenac), 698
- Volume of distribution, 12, 14–17, 1789–1790
 alterations in individual patients, 1793
- Vomiting, 1000–1005, 1008
 antipsychotics for, 484
 benzodiazepines for, 1005
 chemotherapy-induced, regimens for, 1001, 1003*t*
 dopamine receptor antagonists for, 1002*t*, 1003
 dronabinol for, 1004
 ergot alkaloids and, 310
 estrogen therapy and, 1553
 etomidate and, 351
 general anesthesia and, 343
 glucocorticoids for, 343, 1005
 H₁ receptor antagonists for, 1002*t*, 1003–1004
 induced, for poisoning, 1746–1748
 levodopa and, 534
 metoclopramide for, 343, 986
 miltefosine and, 1061
 muscarinic receptor antagonists for, 1002*t*, 1004
 neurotransmission in, 1000–1001, 1001*f*
 nicotine and, 251
 nifurtimox/benznidazole and, 1062
 opioids and, 557, 560–561, 571
 promethazine for, 641, 1004
 salicylates and, 692
 serotonin receptor antagonists for, 311, 334, 343, 561, 1001–1003, 1002*t*
 substance P receptor antagonists for, 1005
 sulfonamides and, 1116
 suramin and, 1069
- von Hippel-Lindau (VHL) protein, 1435
- von Willebrand factor, 1468*f*, 1469
 vasopressin and, 780, 786
- von Willebrand's disease, desmopressin for, 786
- Voriconazole, 1234–1235
 versus amphotericin B, 1234
 dosage of, 1234–1235
 drug interactions of, 1234
 pharmacokinetics of, 1234, 1886*t*
 teratogenicity of, 1234
 therapeutic use of, 1234
- Vorzole, antiestrogen activity of, 1557
- VPA-985, 781*t*, 787
- VP-glycopeptide, 773, 773*f*
- VP-neurophysin, 773, 773*f*
- vpr* gene, in HIV infection, 1274
- Vulval atrophy, estrogen therapy for, 1553
- VUMON (teniposide), 1360
- VYTORIN (simvastatin-ezetimibe), 953
- Waldenström's macroglobulinemia
 chlorambucil for, 1328–1329
 cladribine for, 1349
 fludarabine for, 1348
- Warfarin, 1475–1479, 1476*f*
 absorption of, 1477
 biotransformation and elimination of, 1477
 bleeding with, 1478
 clinical use of, 1479–1480
 dosage of, 1477
 drug interactions of, 1477–1478
 with allopurinol, 709
 with antibiotics, 123, 1478
 with antidepressants, 446
 with aprepitant, 1005
 with bile acid sequestrants, 955
 with COX-2 inhibitors, 703
 with cytochrome P450 enzyme-inducing agents, 121, 1477
 with cytochrome P450 enzyme-inhibiting agents, 122, 1477–1478
 with disulfiram, 603
 with ethanol, 593
 with indomethacin, 695
 with leukotriene receptor antagonists, 724
 with leukotriene-synthesis inhibitors, 724
 with metronidazole, 1060
 with nonsteroidal antiinflammatory drugs, 123
 with NSAIDs, 123, 685–686
 with propionic acid derivatives, 699
 with proton pump inhibitors, 971
 with rifampin, 1209
 with statins, 951
 with valdecoxib, 704
- international normalized ratio (INR) of, 1477, 1479–1480
 mechanism of action, 1476–1477
 pharmacogenetics of, 105*t*, 107, 125
 pharmacokinetics of, 1477, 1886*t*
 plasma protein binding of, 8
 resistance to, 1478
 sensitivity to, 1478
 skin necrosis with, 1478–1479
 teratogenicity of, 1478
 toxicities of, 1478–1479
 and vitamin K, 1476–1477, 1477*f*
- Warts, genital
 antiviral agents for, 1691
 imiquimod for, 1267, 1696
 interferons for, 1264
- Wasting syndromes
 megestrol acetate for, 1561
 testosterone for, 1581
- Water
 for chemical inactivation, 1749
 and gastrointestinal motility, 989
- Water balance, corticosteroids and, 1598, 1603
- Water channel-containing vesicles (WCVs), 777, 777*f*
- Water homeostasis, vasopressin and, 771, 777–779, 778*f*
- Water intoxication, vasopressin V₂ receptor agonists and, 785–787
- WAY 100135, 300*t*
- Wegener's granulomatosis, trimethoprim-sulfamethoxazole for, 1118
- Weight gain
 antidepressants and, 433*t*–437*t*, 448
 antipsychotics and, 480–481
 histamine H₁ receptor antagonists and, 639
- Weight loss
 angiotensin II and, 800
 for hypertension, 865

- WELCHOL (colesevelam), 955
 WELLBUTRIN (bupropion), 436*t*
 Wernicke's encephalopathy, 594, 598
 WESTCORT (hydrocortisone valerate), 1682*t*
 Wetting agents, ophthalmic, 1734–1735
 Wheel and flare response, 639, 647, 667
 Whipple's disease, trimethoprim-sulfamethoxazole for, 1118
 Whipworm, 1075
 Whitfield's ointment, 1240
 Whole-bowel irrigation (WBI), 1749
 Wilms' tumor, dactinomycin for, 1357
 Wilson's disease, 1771, 1772
 WIN64338, 649
 WINRHO SDF (Rho(D) immune globulin), 1424*t*
 WINSTROL (stanozolol), 1578*f*
 Withdrawal-emergent dyskinesias, 480
 Withdrawal syndrome, 611–612. *See also specific drugs*

 YOCON (yohimbine), 271
 YODOXIN (iodoquinol), 1056
 Yohimbine, 266*f*, 271
 and clonidine, 255
 mechanism of action, 174
 receptor selectivity of, 264, 271
 therapeutic uses of, 271
⁹⁰Yttrium, 1379
 Yuzpe contraception method, 1564
- ZADITOR (ketotifen), 640
 Zafirlukast, 672, 722–725
 for asthma, 658, 722–725
 mechanism of action, 658
 metabolism of, 723
 pharmacokinetics of, 723
 toxicity of, 724
 Zalcitabine, 1276*t*, 1280, 1281*f*, 1287, 1288
 adverse effects of, 1288
 antiviral activity of, 1280, 1287
 drug interactions of, 1288
 with ganciclovir, 1255
 with lamivudine, 1288–1289
 for HIV infection, 1287–1288
 mechanism of action, 1287
 pharmacokinetics of, 1280, 1282*t*, 1287–1288
 phosphorylation of, 1283*f*, 1287
 resistance to, 1287
 therapeutic uses of, 1288
 toxicity of, 1280, 1288
 Zaldaride maleate, for diarrhea, 998
 Zaleplon, 412–413
 history of, 402
 for insomnia, 412–413, 424
 pharmacokinetics of, 412–413, 1886*t*
 ZANAFLEX (tizanidine), 257
 Zanamivir, 1259–1260
 absorption, distribution, and elimination of, 1259–1260
 adverse effects of, 1260
 antiviral activity of, 1259
 for influenza, 1259–1260
 mechanism of action, 1259
 pharmacological characteristics of, 1257*t*
 resistance to, 1259
 therapeutic uses of, 1260
 ZANOSAR (streptozocin), 1331
 ZANTAC (famotidine), 971
 ZARONTIN (ethosuximide), 513
 ZAROXOLYN (metolazone), 754*t*
 ZEBETA (bisoprolol), 286, 883
 ZEGERID (omeprazole), 969
 ZELNORM (tegaserod maleate), 987
 ZEMURON (rocuronium), 222*t*
 ZENAPAX (daclizumab), 1418
- ZENTEL (albendazole), 1074
 ZERIT (stavudine) preparations, 1276*t*
 ZESTRIL (lisinopril), 803
 ZETIA (ezetimibe), 960
 ZEVALIN (ibritumomab tiuxetan), 1375
 ZIAGEN (abacavir), 1276*t*
 Zidovudine, 1276*t*, 1280, 1281*f*, 1283, 1284–1285
 adverse effects of, 1284
 anemia with, treatment of, 1438
 antiviral activity of, 1283
 in combination therapy, 1284, 1290
 drug interactions of, 1284
 with acyclovir, 1249
 with cidofovir, 1251
 with ganciclovir, 1255
 with ribavirin, 1266
 for HIV infection, 1283–1285
 for HIV prophylaxis, 1284–1285
 mechanism of action, 1283–1284
 neutropenia with, treatment of, 1440
 pharmacokinetics of, 1280, 1282*t*, 1284, 1887*t*
 phosphorylation of, 1283, 1283*f*
 precautions with, 1284
 principles for use, 1276–1277
 resistance to, 1280, 1283–1284
 therapeutic uses of, 1284–1285
 toxicity of, 1280, 1284
 Zileuton, 722–725
 mechanism of action, 656*f*, 658
 withdrawal from market, 658
 Zimelidine, 432, 438*t*
 ZINACEF (cefuroxime), 1144*t*
 Zinc
 content in insulin therapy, 1625–1627, 1626*t*–1627*t*
 ophthalmic effects of, 1731*t*, 1734
 Zinc oxide, 1700
 Zinc-protoporphyrin, in lead poisoning, 1757
 Zinc undecylenate, 1240
 ZINECARD (dexrazoxane), 1358
 Ziprasidone, 461, 466, 466*t*, 467
 for bipolar disorder, 490
 cardiovascular effects of, 474, 477
 dose and dosage forms of, 466*t*, 483
 endocrine effects of, 473
 for mania, 490
 mechanism of action, 467
 neurological effects of, 477, 479–480
 for Parkinson's disease, 484
 pharmacokinetics of, 475*t*, 476, 1887*t*
 receptor actions of, 470, 472*t*, 473
 and seizure threshold, 469
 side effects of, 466*t*, 482
 therapeutic uses of, 481–484
 and weight gain, 480
 ZITHROMAX (azithromycin), 1185
 ZOCOR (simvastatin), 952
 Zofenopril, in heart disease, 806*t*
 ZOFRAN (ondansetron), 1001
 ZOLADEX (goserelin), 1387, 1502*t*
 Zoledronate, 1373, 1667, 1667*f*, 1668
 for hypercalcemia, 1663, 1668

- for Paget's disease, 1673
- therapeutic uses of, 1668
- Zollinger-Ellison syndrome, 980
 - proton pump inhibitors for, 969, 971
- Zolmitriptan, 306–308, 307*f*
 - for migraine, 305–306, 308
 - pharmacological properties of, 307
- ZOLOFT (sertraline), 435*t*
- Zolpidem, 412–413
 - for insomnia, 412–413, 424
 - pharmacokinetics of, 408, 412, 413, 1887*t*
 - side effects of, 412
- ZOMETA (zoledronate), 1373
- ZOMIG (zolmitriptan), 305
- Zona fasciculata, 1588–1589, 1589*f*
- ZONALON (doxepin), 1689
- Zona reticularis, 1588–1589, 1589*f*
- Zone glomerulosa, 1588–1589, 1589*f*
- ZONEGRAN (zonisamide), 520–521
- Zonisamide, 520–521
 - interactions of, 521
 - with hepatic microsomal enzymes, 509*t*
 - for mania, 490, 492
 - mechanism of action, 505, 520
 - pharmacokinetics of, 521, 1888*t*
 - pharmacological effects of, 520, 521
 - for seizures/epilepsy, 505, 520–521
 - therapeutic use of, 521
- Zonules (ocular), 1711
- Zopiclone, 408, 412, 424
- ZOSTRIX (capsaicin), 1703
- ZOSYN (piperacillin-tazobactam), 1140
- Zotepine, 462, 472*t*
