vasopressin. The clinical manifestations of plasma hypotonicity resulting from SIADH may include lethargy, anorexia, nausea and vomiting, muscle cramps, coma, convulsions, and death. A multitude of disorders can induce SIADH (Robertson, 2001), including malignancies, pulmonary diseases, CNS injuries/diseases (*e.g.*, head trauma, infections, and tumors), and general surgery. The three drug classes most commonly implicated in drug-induced SIADH include psychotropic medications (*e.g.*, *fluoxetine*, haloperidol, and *tricyclic antidepressants*), sulfonylureas (*e.g.*, chlorpropamide), and vinca alkaloids (*e.g.*, *vincristine* and *vinblastine*). Other drugs strongly associated with SIADH include thiazide diuretics, clonidine, *enalapril*, *ifosphamide*, and *methyldopa*. In a normal individual, an elevation in plasma vasopressin *per se* does not induce plasma hypotonicity because the person simply stops drinking owing to an osmotically induced aversion to fluids. Therefore, plasma hypotonicity only occurs when excessive fluid intake (oral or intravenous) accompanies inappropriate secretion of vasopressin. Treatment of hypotonicity in the setting of SIADH includes water restriction, intravenous administration of hypertonic saline, loop diuretics (which interfere with the concentrating ability of the kidneys), and drugs that inhibit the effect of vasopressin to increase water permeability in the collecting ducts. To inhibit vasopressin's action in the collecting ducts, *demeclocycline*, a tetracycline, currently is the preferred drug.

Although lithium can inhibit the renal actions of vasopressin, it is effective in only a minority of patients, may induce irreversible renal damage when used chronically, and has a low therapeutic index. Therefore, lithium should be considered for use only in patients with symptomatic SIADH who cannot be controlled by other means or in whom tetracyclines are contraindicated, *e.g.*, patients with liver disease. It is important to stress that the majority of patients with SIADH do not require therapy because plasma Na^+ stabilizes in the range of 125 to 132 mM; such patients usually are asymptomatic. Only when symptomatic hypotonicity ensues, generally when plasma Na^+ levels drop below 120 mM, should therapy with demeclocycline be initiated. Since hypotonicity, which causes an influx of water into cells with resulting cerebral swelling, is the cause of symptoms, the goal of therapy is simply to increase plasma osmolality toward normal. For a more complete description of the diagnosis and treatment of SIADH, see Robertson (2001).

Other Water-Retaining States. In patients with congestive heart failure, cirrhosis, or nephrotic syndrome, *effective* blood volume often is reduced, and hypovole-

mia frequently is exacerbated by the liberal use of diuretics. Since hypovolemia stimulates vasopressin release, patients may become hyponatremic owing to vasopressin-mediated retention of water. The development of potent orally active V_2 -receptor antagonists and specific inhibitors of water channels in the collecting duct would provide an effective therapeutic strategy not only in patients with SIADH but also in the much more common setting of hyponatremia in patients with heart failure, liver cirrhosis, and nephrotic syndrome.

CLINICAL SUMMARY; PHARMACOLOGY OF VASOPRESSIN PEPTIDES

Therapeutic Uses. Only two antidiuretic peptides are available for clinical use in the United States. (1) Vasopressin (synthetic 8-L-arginine vasopressin; PITRESSIN) is available as a sterile aqueous solution; it may be administered subcutaneously, intramuscularly, or intranasally. (2) *Desmopressin acetate* (synthetic 1-deamino-8-D-arginine vasopressin; DDAVP, others) is available as a sterile aqueous solution packaged for intravenous or subcutaneous injection, in a nasal solution for intranasal administration with either a nasal spray pump or rhinal tube delivery system, and in tablets for oral administration. The therapeutic uses of vasopressin and its congeners can be divided into two main categories according to the type of vasopressin receptor involved.

V₁-receptor-mediated therapeutic applications are based on the rationale that V_1 receptors cause contraction of gastrointestinal and vascular smooth muscle. V_1 -receptor-mediated contraction of gastrointestinal smooth muscle has been used to treat postoperative ileus and abdominal distension and to dispel intestinal gas before abdominal roentgenography to avoid interfering gas shadows. V_1 -receptor-mediated vasoconstriction of the splanchnic arterial vessels reduces blood flow to the portal system and thereby attenuates pressure and bleeding in esophageal varices (Burrhoughs, 1998). Although endoscopic variceal banding ligation is the treatment of choice for bleeding esophageal varices, V_1 -receptor agonists have been used in an emergency setting until endoscopy can be performed (Vlavianos and Westaby, 2001). Simultaneous administration of nitroglycerin with V_1 -receptor agonists may attenuate the cardiotoxic effects of V_1 agonists while enhancing their beneficial splanchnic effects. Also, V_1 -receptor agonists have been used during abdominal surgery in patients with portal hypertension to diminish the risk of hemorrhage during the procedure. Finally, V_1 -receptor-mediated vasoconstriction

has been used to reduce bleeding during acute hemorrhagic gastritis, burn wound excision, cyclophosphamide-induced hemorrhagic cystitis, liver transplant, cesarean section, and uterine myoma resection. The applications of V_1 -receptor agonists can be accomplished with vasopressin; however, the use of vasopressin for all these indications is no longer recommended because of significant adverse reactions. Although not yet available in the United States, *terlipressin* (GLYPRESSIN) is preferred for bleeding esophageal varices because of increased safety compared with vasopressin (Vlavianos and Westaby, 2001). Moreover, terlipressin is effective in patients with hepatorenal syndrome, particularly when combined with albumin (Ortega *et al.*, 2002).

Vasopressin levels in patients with vasodilatory shock are inappropriately low, and such patients are extraordinarily sensitive to the pressor actions of vasopressin (Robin *et al.*, 2003). The combination of vasopressin and *norepinephrine* is superior to norepinephrine alone in the management of catecholamine-resistant vasodilatory shock (Dunser *et al.*, 2003). Although the efficacy of vasopressin in the resuscitation of patients with ventricular fibrillation or pulseless electrical activity is similar to that of epinephrine, vasopressin followed by epinephrine appears to be more effective than epinephrine alone in the treatment of patients with asystole (Wenzel *et al.*, 2004).

V₂-receptor-mediated therapeutic applications are based on the rationale that V_2 receptors cause water conservation and release of blood coagulation factors. Central but not nephrogenic DI can be treated with V_2 -receptor agonists, and polyuria and polydipsia usually are well controlled. Some patients experience transient DI (*e.g.*, in head injury or surgery in the area of the pituitary); however, therapy for most patients with DI is lifelong. Desmopressin is the drug of choice for the vast majority of patients, and numerous clinical trials have demonstrated the efficacy and tolerability of desmopressin in both adults and children. The duration of effect from a single intranasal dose is from 6 to 20 hours; twice-daily administration is effective in most patients. There is considerable variability in the intranasal dose of desmopressin required to maintain normal urine volume, and the dosage must be tailored individually. The usual intranasal dosage in adults is 10 to 40 μg daily either as a single dose or divided into two or three doses. In view of the high cost of the drug and the importance of avoiding water intoxication, the schedule of administration should be adjusted to the minimal amount required. An initial dose of 2.5 μg can be used, with therapy first directed toward the control of nocturia. An equivalent or higher morning dose controls daytime polyuria in most patients, although a third dose occa-

sionally may be needed in the afternoon. In some patients, chronic allergic rhinitis or other nasal pathology may preclude reliable absorption of the peptide following nasal administration. Oral administration of desmopressin in doses 10 to 20 times the intranasal dose provides adequate blood levels of desmopressin to control polyuria. Subcutaneous administration of 1 to 2 μg daily of desmopressin also is effective in central DI.

Vasopressin has little, if any, place in the long-term therapy of DI because of its short duration of action and V_1 -receptor-mediated side effects. Vasopressin can be used as an alternative to desmopressin in the initial diagnostic evaluation of patients with suspected DI and to control polyuria in patients with DI who recently have undergone surgery or experienced head trauma. Under these circumstances, polyuria may be transient, and long-acting agents may produce water intoxication.

An additional V_2 -receptor-mediated therapeutic application is the use of desmopressin in bleeding disorders (Mannucci, 1997; Sutor, 1998). In most patients with type I von Willebrand's disease (vWD) and in some with type IIa vWD, desmopressin will elevate von Willebrand factor and shorten bleeding time. However, desmopressin generally is ineffective in patients with types IIa, IIb, and III vWD. Desmopressin may cause a marked transient thrombocytopenia in individuals with type IIb vWD and is contraindicated in such patients. Desmopressin also increases factor VIII levels in patients with mild to moderate hemophilia A. Desmopressin is not indicated in patients with severe hemophilia A, those with hemophilia B, or those with factor VIII antibodies. Using a test dose of nasal spray, the response of any given patient with type I vWD or hemophilia A to desmopressin should be determined at the time of diagnosis or 1 to 2 weeks before elective surgery to assess the extent of increase in factor VIII or von Willebrand factor. Desmopressin is employed widely to treat the hemostatic abnormalities induced by uremia. In patients with renal insufficiency, desmopressin shortens bleeding time and increases circulating levels of factor VIII coagulant activity, factor VIII-related antigen, and ristocetin cofactor. It also induces the appearance of larger von Willebrand factor multimers. Desmopressin is effective in some patients with liver cirrhosis-induced or drug-induced (*e.g.*, *heparin*, *hirudin*, and *antiplatelet agents*) bleeding disorders. Desmopressin, given intravenously at a dose of 0.3 $\mu\text{g}/\text{kg}$, increases factor VIII and von Willebrand factor for more than 6 hours. Desmopressin can be given at intervals of 12 to 24 hours depending on the clinical response and the severity of bleeding. Tachyphylaxis to desmopressin usually occurs after several days (owing to depletion of factor VIII and von Wille-

brand factor storage sites) and limits its usefulness to preoperative preparation, postoperative bleeding, excessive menstrual bleeding, and emergency situations.

Another V_2 -receptor-mediated therapeutic application is the use of desmopressin for primary nocturnal enuresis. Bedtime administration of desmopressin intranasal spray or tablets provides a high response rate that is sustained with long-term use, that is safe, and that accelerates the cure rate (van Kerrebroeck, 2002). Finally, desmopressin has been found to relieve post-lumbar puncture headache probably by causing water retention and thereby facilitating rapid fluid equilibration in the CNS.

Pharmacokinetics. When vasopressin and desmopressin are given orally, they are inactivated quickly by trypsin, which cleaves the peptide bond between amino acids 8 and 9. Inactivation by peptidases in various tissues (particularly the liver and kidneys) results in a plasma half-life of vasopressin of 17 to 35 minutes. Following intramuscular or subcutaneous injection, the antidiuretic effects of vasopressin last 2 to 8 hours. The plasma half-life of desmopressin has two components, a fast component of 6.5 to 9 minutes and a slow component of 30 to 117 minutes. Only 3% and 0.15%, respectively, of intranasally and orally administered desmopressin is absorbed.

Toxicity, Adverse Effects, Contraindications, Drug Interactions. Most adverse effects are mediated through the V_1 receptor acting on vascular and gastrointestinal smooth muscle; consequently, such adverse effects are much less common and less severe with desmopressin than with vasopressin. After the injection of large doses of vasopressin, marked facial pallor owing to cutaneous vasoconstriction is observed commonly. Increased intestinal activity is likely to cause nausea, belching, cramps, and an urge to defecate. Most serious, however, is the effect on the coronary circulation. Vasopressin should be administered only at low doses and with extreme caution in individuals suffering from vascular disease, especially coronary artery disease. Other cardiac complications include arrhythmia and decreased cardiac output. Peripheral vasoconstriction and gangrene have been encountered in patients receiving large doses of vasopressin.

The major V_2 -receptor-mediated adverse effect is water intoxication, which can occur with desmopressin or vasopressin. In this regard, many drugs, including carbamazepine, chlorpropamide, morphine, tricyclic antidepressants, and NSAIDs, can potentiate the antidiuretic effects of these peptides. Several drugs such as lithium, demeclocycline, and ethanol can attenuate the antidiuretic response to desmopressin. Desmopressin and vasopressin

should be used cautiously in disease states in which a rapid increase in extracellular water may impose risks (e.g., in angina, hypertension, and heart failure) and should not be used in patients with acute renal failure. Patients receiving desmopressin to maintain hemostasis should be advised to reduce fluid intake. Also, it is imperative that these peptides not be administered to patients with primary or psychogenic polydipsia because severe hypotonic hyponatremia will ensue.

Mild facial flushing and headache are the most common adverse effects associated with desmopressin. Allergic reactions ranging from urticaria to anaphylaxis may occur with desmopressin or vasopressin. Intranasal administration may cause local adverse effects in the nasal passages, such as edema, rhinorrhea, congestion, irritation, pruritus, and ulceration.

Future Directions in Vasopressin Analogues

Nonpeptide vasopressin receptor antagonists and agonists are being developed for a wide range of clinical indications, including for V_{1a} -selective antagonists: dysmenorrhea, preterm labor, and Raynaud's syndrome; for V_{1b} -selective antagonists: stress-related disorders, anxiety, depression, ACTH-secreting tumors, and Cushing's syndrome; for V_2 -selective and V_{1a}/V_2 -selective antagonists: heart failure, SIADH, cirrhosis, hyponatremia, brain edema, nephrotic syndrome, diabetic nephropathy, and glaucoma; and for V_2 -selective agonists: central DI, nocturnal enuresis, nocturnal polyuria, and urinary incontinence (Wong and Verbalis, 2001; Serradeil-Le Gal *et al.*, 2002b; Thibonnier *et al.*, 2001).

Preliminary data support several of the aforementioned indications for vasopressin receptor antagonists and agonists. SR 49059 is a V_{1a} -selective antagonist that has efficacy in primary dysmenorrhea (Brouard *et al.*, 2000), and SSR 149415 is a V_{1b} -selective antagonist that demonstrates anxiolytic activity in animal models of stress (Serradeil-Le Gal *et al.*, 2002a; Griebel *et al.*, 2002). Aquaretics are drugs that increase free-water clearance with minimal effects on electrolyte excretion. Recent randomized clinical trials demonstrate efficacy for YM 087 (CONIVAPTAN) and OPC-41067 (TOLVAPTAN), V_{1a}/V_2 -selective antagonists, respectively, as aquaretics in heart failure patients (Udelson *et al.*, 2001; Gheorghide *et al.*, 2003). The V_2 -selective antagonist VPA-985 (LIXIVAPTAN) is an effective aquaretic in patients with hyponatremia of various etiologies (Wong *et al.*, 2003). In contrast, the V_2 -selective agonist OPC-51803 has strong antidiuretic effects in animals and is being developed for central DI, nocturnal enuresis, and urinary incontinence (Naka-

mura *et al.*, 2003). It is likely that a number of nonpeptide vasopressin receptor antagonists and agonists will become available clinically in the near future.

RENIN AND ANGIOTENSIN

Edwin K. Jackson

The renin–angiotensin system participates significantly in the pathophysiology of hypertension, congestive heart failure, myocardial infarction, and diabetic nephropathy. This realization has led to a thorough exploration of the renin–angiotensin system and the development of new approaches for inhibiting its actions. This chapter discusses the biochemistry, molecular and cellular biology, and physiology of the renin–angiotensin system; the pharmacology of drugs that interrupt the renin–angiotensin system; and the clinical utility of inhibitors of the renin–angiotensin system. Therapeutic applications of drugs covered in this chapter also are discussed in Chapters 31, 32, and 33.

THE RENIN–ANGIOTENSIN SYSTEM

History. In 1898, Tiegerstedt and Bergman found that crude saline extracts of the kidney contained a pressor substance that they named *renin*. Although their discovery had an obvious bearing on the problem of arterial hypertension and its relation to kidney disease, the finding generated little interest until 1934, when Goldblatt and his colleagues demonstrated that constriction of the renal arteries produced persistent hypertension in dogs. In 1940, Braun-Menéndez and his colleagues in Argentina and Page and Helmer in the United States reported that renin was an enzyme that acted on a plasma protein substrate to catalyze the formation of the actual pressor material, a peptide, that was named *hypertensin* by the former group and *angiotenin* by the latter. These two terms persisted for nearly 20 years until it was agreed to rename the pressor substance *angiotensin* and to call the plasma substrate *angiotensinogen*. In the mid-1950s, two forms of angiotensin were recognized, a decapeptide (angiotensin I) and an octapeptide (angiotensin II) formed by proteolytic cleavage of angiotensin I by an enzyme termed *angiotensin-converting enzyme* (ACE). The octapeptide was shown to be the more active form, and its synthesis in 1957 by Schwyzer and by Bumpus made the material available for intensive study.

In 1958, Gross suggested that the renin–angiotensin system was involved in the regulation of aldosterone secretion. It was soon shown that the kidneys are important for such regulation and that synthetic angiotensin potently stimulates the production of aldoster-

one in humans. Moreover, renin secretion increased with depletion of Na^+ . Thus the renin–angiotensin system came to be recognized as a mechanism to stimulate aldosterone synthesis and secretion and an important homeostatic mechanism in the regulation of blood pressure and electrolyte composition.

In the early 1970s, polypeptides were discovered that either inhibited the formation of angiotensin II or blocked angiotensin II receptors; experimental studies with these inhibitors revealed important physiological and pathophysiological roles for the renin–angiotensin system. These findings inspired the development of a new and broadly efficacious class of antihypertensive drugs: the orally active ACE inhibitors. Subsequent studies with ACE inhibitors uncovered roles for the renin–angiotensin system in the pathophysiology of hypertension, heart failure, vascular disease, and renal failure, providing impetus for the development of additional classes of inhibitors of the renin–angiotensin system. In 1982 it was reported that derivatives of imidazole-5-acetic acid attenuated vasoconstriction induced by angiotensin II. Two of these compounds, S-8307 and S-8308, were shown subsequently to be selective and competitive antagonists of angiotensin II receptors. Refinements of these compounds yielded losartan, an orally active, highly selective, and potent nonpeptide angiotensin II receptor antagonist. Subsequently, many other angiotensin II receptor antagonists have been developed.

Components of the Renin–Angiotensin System

Overview. Angiotensin II, the most active angiotensin peptide, is derived from angiotensinogen in two proteolytic steps. First, renin, an enzyme released from the kidneys, cleaves the decapeptide angiotensin I from the amino terminus of angiotensinogen (renin substrate). Then angiotensin-converting enzyme (ACE) removes the carboxy-terminal dipeptide of angiotensin I to produce the octapeptide angiotensin II. Angiotensin II is degraded subsequently by further proteolysis. These enzymatic steps and amino acid sequences are summarized in Figure 30–1. Angiotensin II acts by binding to two heptahelical G protein–coupled receptors. All the components of the renin–angiotensin system are described below.

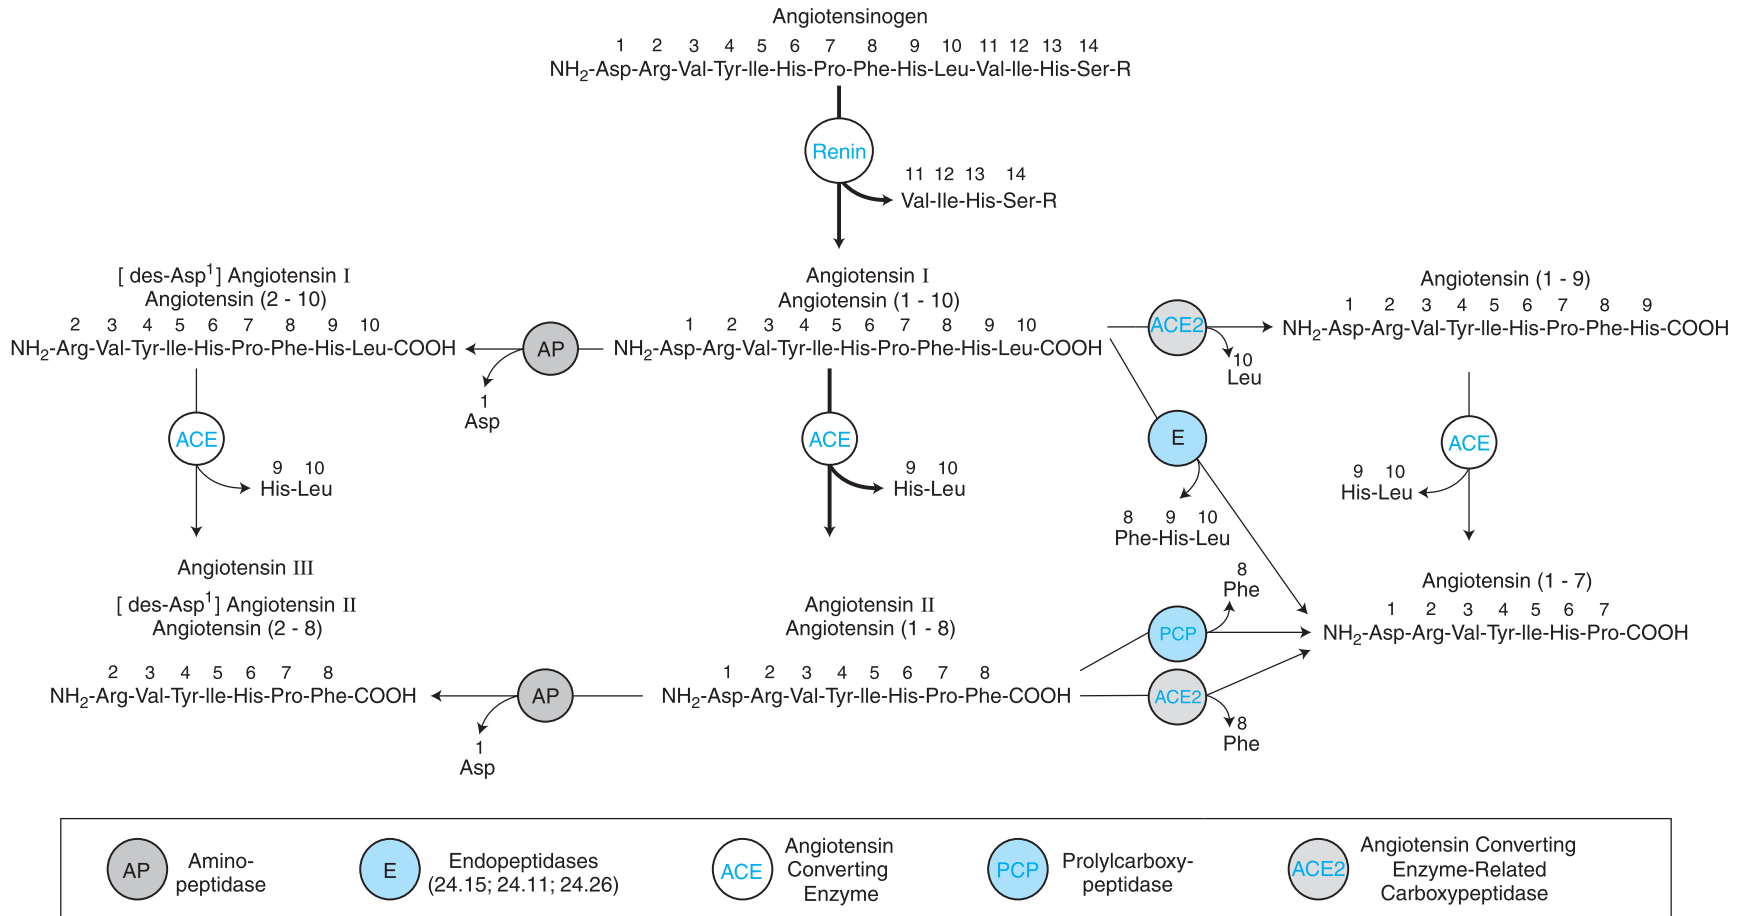

Figure 30-1. Formation of angiotensin peptides. The heavy arrows show the classical pathway, and the light arrows indicate alternative pathways. The structures of the angiotensins shown are those found in human beings, horses, rats, and pigs; the bovine form has valine in the 5 position. The N-terminal sequence of human angiotensinogen is depicted. AP, aminopeptidase; E, endopeptidases (24.15; 24.11; 24.26); ACE, angiotensin-converting enzyme; PCP, prolylcarboxylpeptidase.

Renin. The major determinant of the rate of angiotensin II production is the amount of renin released by the kidney. Renin is synthesized, stored, and secreted into the renal arterial circulation by the granular juxtaglomerular cells that lie in the walls of the afferent arterioles that enter the glomeruli. Renin is stored in granules within juxtaglomerular cells and is secreted by exocytosis (Friis *et al.*, 1999).

Renin is an aspartyl protease that attacks a restricted number of substrates. Its principal natural substrate is a circulating α_2 -globulin, angiotensinogen, that is secreted by hepatocytes (*see below*). Renin cleaves the bond between residues 10 and 11 at the amino terminus of angiotensinogen to generate angiotensin I. The active form of renin is a glycoprotein that contains 340 amino acids. It is synthesized as a proenzyme of 406 amino acid residues that is processed to prorenin, a mature but inactive form of the protein. Prorenin then is activated by an as yet uncharacterized enzyme that removes 43 amino acids from its amino terminus to yield active renin. Similar to other aspartyl proteases, renin has a bilobal structure with a cleft that forms the active site (Sielecki *et al.*, 1989). A truncated, nonsecreted form of renin is expressed in the brain from an alternative promoter within intron I of the renin gene (Lee-Kirsch *et al.*, 1999).

Both renin and prorenin are stored in the juxtaglomerular cells and, when released, circulate in the blood. The concentration of prorenin in the circulation is approximately tenfold greater than that of the active enzyme. The half-life of circulating renin is approximately 15 minutes. The physiological status of circulating prorenin is unclear.

Control of Renin Secretion (Figure 30–2). The secretion of renin from juxtaglomerular cells is controlled predominantly by three pathways: two acting locally within the kidney and the third acting through the central nervous system (CNS) and mediated by norepinephrine release from renal noradrenergic nerves. One intrarenal mechanism controlling renin release is the *macula densa pathway* (top of Figure 30–2A). The macula densa lies adjacent to the juxtaglomerular cells and is composed of specialized columnar epithelial cells in the wall of that portion of the cortical thick ascending limb that passes between the afferent and efferent arterioles of the glomerulus. A change in NaCl reabsorption by the macula densa results in the transmission to nearby juxtaglomerular cells of chemical signals that modify renin release. Increases in NaCl flux across the macula densa inhibit renin release, whereas decreases in NaCl flux stimulate renin release. Both adenosine and prostaglandins mediate the macula densa pathway; the former is released when NaCl transport increases, and the latter is released when NaCl transport decreases. Adenosine, acting *via* the A_1 adenosine receptor, inhibits renin release, and prostaglandins stimulate renin release.

Substantial evidence exists supporting a role for inducible cyclooxygenase (COX-2) and neuronal nitric oxide synthase (nNOS) in the mechanism of macula densa–stimulated renin release. Although constitutive cyclooxygenase (COX-1) is the most abundant cyclooxygenase isoform in the mammalian kidney, inducible COX-2 is the only cyclooxygenase form expressed in the macula densa, where it is up-regulated by chronic dietary sodium restriction (Harris *et al.*, 1994), a maneuver that increases renin release in part *via* the macula densa pathway. Renin release induced by a low-sodium diet is blunted by selective inhibition of COX-2 (Kammerl *et al.*, 2001) and is attenuated in COX-2 knockout mice (Yang *et al.*, 2000). Moreover, selective inhibition of COX-2 blocks macula densa–mediated renin release in the isolated perfused juxtaglomerular preparation (Traynor *et al.*, 1999). In a similar manner, the expres-

sion of nNOS in the macula densa is up-regulated by dietary sodium restriction (Singh *et al.*, 1996), and selective inhibition of nNOS reduces renin release in response to chronic dietary sodium restriction (Beierwaltes, 1997). The nNOS/NO pathway, in part, may mediate increases in COX-2 expression induced by a low-sodium diet (Cheng *et al.*, 2000). Together these findings suggest a biochemical interplay between COX-2 and nNOS in the regulation of macula densa–mediated renin release. Since NO reacts with superoxide anion to generate peroxynitrite, which markedly activates cyclooxygenase activity (Landino *et al.*, 1996), it is plausible that activation of macula densa–mediated renin release by sodium depletion involves the following events: up-regulation of nNOS and COX-2 in the macula densa, increased biosynthesis of NO and peroxynitrite in the macula densa, peroxynitrite-induced activation of COX-2 in the macula densa, increased prostaglandin production in the macula densa, and paracrine activation of prostaglandin receptors in neighboring juxtaglomerular cells. However, COX-2 expression in the macula densa is not attenuated in nNOS knockout mice (Theilig *et al.*, 2002), which suggests that other mechanisms can compensate for nNOS in the regulation of COX-2. Possible mechanisms by which the macula densa and autonomic nervous system regulate renin release are summarized in Figure 30–2B.

Although a change in NaCl transport by the macula densa is the key event that modulates the macula densa pathway, regulation of this pathway is more dependent on the luminal concentration of Cl^- than Na^+ . NaCl transport into the macula densa is mediated by the $Na^+-K^+-2Cl^-$ symporter, and the half-maximal concentrations of Na^+ and Cl^- required for transport *via* this symporter are 2 to 3 and 40 mEq/L, respectively. Since the luminal concentration of Na^+ at the macula densa usually is much greater than the level required for half-maximal transport, physiological variations in luminal Na^+ concentrations at the macula densa have little effect on renin release (*i.e.*, the symporter remains saturated with respect to Na^+). On the other hand, physiological changes in Cl^- concentrations (20 to 60 mEq/L) at the macula densa profoundly affect macula densa–mediated renin release.

The second intrarenal mechanism controlling renin release is the *intrarenal baroreceptor pathway* (middle of Figure 30–2A). Increases and decreases in blood pressure in the preglomerular vessels inhibit and stimulate renin release, respectively. The immediate stimulus to secretion is believed to be reduced tension within the wall of the afferent arteriole. Increases and decreases in renal perfusion pressure may inhibit and stimulate, respectively, the release of renal prostaglandins, which may mediate in part the intrarenal baroreceptor pathway. In support of this conclusion, COX-2 inhibition decreases renin secretion and blood pressure in renin-dependent renovascular hypertension (Wang *et al.*, 1999). Biomechanical coupling *via* stretch-activated ion channels also may play a role in this pathway (Carey *et al.*, 1997).

The third mechanism, the *β -adrenergic receptor pathway* (bottom of Figure 30–2A), is mediated by the release of norepinephrine from postganglionic sympathetic nerves; activation of β_1 -receptors on juxtaglomerular cells enhances renin secretion.

The three mechanisms regulating renin release are embedded in a physiological network. Increased renin secretion enhances the formation of angiotensin II, and angiotensin II stimulates angiotensin subtype 1 (AT_1) receptors on juxtaglomerular cells to inhibit renin release, an effect termed *short-loop negative feedback*. Angiotensin II also increases arterial blood pressure by stimulating AT_1 receptors. Increases in blood pressure inhibit renin release by (1) activating high-pressure baroreceptors, thereby reducing renal sympathetic

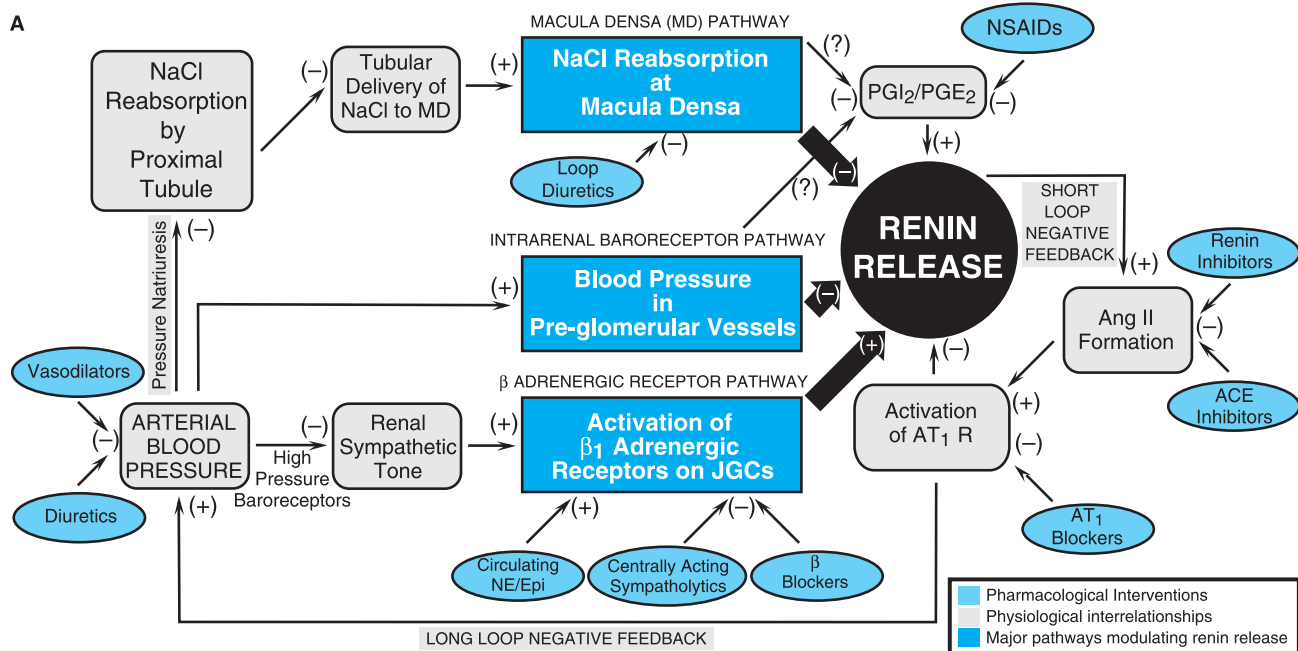

Figure 30–2. A. Schematic portrayal of the three major physiological pathways regulating renin release. See text for details. MD, macula densa; PGI₂/PGE₂, prostaglandins I₂ and E₂; NSAIDs, nonsteroidal antiinflammatory drugs; Ang II, angiotensin II; ACE, angiotensin-converting enzyme, AT₁ R, angiotensin subtype 1 receptor; NE/Epi, norepinephrine/epinephrine; JGCs, juxtaglomerular cells. B. Possible mechanisms by which the macula densa regulates renin release. Both acute changes in tubular delivery of NaCl to the macula densa and chronic changes in dietary sodium intake cause appropriate signals to be conveyed from macula densa to the juxtaglomerular cells. Chronic sodium depletion upregulates neuronal nitric oxide synthase (nNOS) and inducible cyclooxygenase (COX-2) in the macula densa. nNOS increases nitric oxide (NO) production, and NO reacts with superoxide anion (O₂⁻) to form peroxyntirite, an activator of COX-2. In addition, COX-2 may be rapidly, although indirectly, inhibited and stimulated by increases and decreases in NaCl transport, respectively, across the macula densa. Arachidonic acid (AA) is converted to prostaglandins (PGs), which diffuse to nearby juxtaglomerular cells to stimulate adenylyl cyclase (AC) via prostaglandin receptors, such as EP₄ and IP, that couple to G_s. Circulating and locally released catecholamines also stimulate adenylyl cyclase via β₁ receptors. Cyclic AMP (cAMP) augments renin release. Increased NaCl transport depletes ATP and increases adenosine (ADO) levels in the macula densa. ADO diffuses to the juxtaglomerular cells and activates the AT₁-G_i pathway, inhibiting AC and reducing cellular cAMP. Increased NaCl transport in the macula densa augments the efflux of ATP through basolateral maxianion channels, and ATP is converted to adenosine in the extracellular compartment and inhibits adenylyl cyclase via A₁ receptors. In addition, ATP released from the macula densa may inhibit renin release directly by binding to P2Y receptors coupled to G_i on juxtaglomerular cells. Activation of G_i increases intracellular Ca²⁺, which inhibits renin release. Circulating angiotensin II (Ang II) binds to AT₁ receptors on juxtaglomerular cells and inhibits renin release via G_i-induced increases in intracellular Ca²⁺.

tone, (2) increasing pressure in the preglomerular vessels, and (3) reducing NaCl reabsorption in the proximal tubule (pressure natriuresis), which increases tubular delivery of NaCl to the macula densa. The inhibition of renin release owing to angiotensin II–induced increases in blood pressure has been termed *long-loop negative feedback*.

The physiological pathways regulating renin release can be influenced by arterial blood pressure, dietary salt intake, and a number of pharmacological agents. In all these cases, renin release is affected by a complex interplay of the mechanisms summarized in Figure 30-2A. Loop diuretics (*see* Chapter 28) stimulate renin release in part by blocking the reabsorption of NaCl at the macula densa. *Nonsteroidal antiinflammatory drugs* (NSAIDs) (*see* Chapter 26) inhibit prostaglandin synthesis and thereby decrease renin release. ACE inhibitors, angiotensin-receptor blockers, and renin inhibitors interrupt both the short- and long-loop negative feedback mechanisms and therefore increase renin release. However, the effect of chronic inhibition of the renin–angiotensin system on renin release also involves COX-2 and nNOS. In this regard, chronic administration of ACE inhibitors up-regulates renocortical COX-2 and nNOS expression (Kammerl *et al.*, 2002), and the ability of chronic ACE inhibition to stimulate renin release is attenuated in COX-2 knockout mice (Cheng *et al.*, 2001). In general, diuretics and vasodilators increase renin release by decreasing arterial blood pressure. Centrally acting sympatholytic drugs, as well as β adrenergic receptor antagonists, decrease renin secretion by reducing activation of β adrenergic receptors on juxtaglomerular cells. Phosphodiesterase inhibitors stimulate renin release by increasing cyclic AMP in juxtaglomerular cells (Friis *et al.*, 2002).

Angiotensinogen. The substrate for renin is angiotensinogen, an abundant globular glycoprotein (MW = 55,000 to 60,000) containing 13% to 14% carbohydrate. High-molecular-weight (350,000 to 500,000) angiotensinogen also circulates in plasma and represents a complex of angiotensinogen with other proteins. Angiotensin I is cleaved from the amino terminus of angiotensinogen. The human angiotensinogen contains 452 amino acids and is synthesized as pre-angiotensinogen, which has a 24- or 33-amino acid signal peptide. Angiotensinogen is synthesized primarily in the liver, although angiotensinogen transcripts also are abundant in fat, certain regions of the CNS, and kidney. Angiotensinogen is synthesized and secreted continuously by the liver, and its synthesis is stimulated by inflammation, insulin, estrogens, glucocorticoids, thyroid hormone, and angiotensin II. During pregnancy, plasma levels of angiotensinogen increase severalfold owing to increased estrogen.

Circulating levels of angiotensinogen are approximately equal to the K_m of renin for its substrate (about $1 \mu M$). Consequently, the rate of angiotensin II synthesis, and therefore blood pressure, can be influenced by changes in angiotensinogen levels. For instance, knockout mice lacking angiotensinogen are hypotensive (Tanimoto *et al.*, 1994), and there is a progressive relationship among the number of copies of the angiotensinogen gene, plasma levels of angiotensinogen, and arterial blood pressure (Kim *et al.*, 1995). Also, intravenous injection of angiotensinogen increases arterial blood pressure (Klett and Granger, 2001). Oral contraceptives containing estrogen increase circulating levels of angiotensinogen and can induce hypertension. Furthermore, a missense mutation in the angiotensinogen gene (a methionine to threonine at position 235 of angiotensinogen) that increases plasma levels of angiotensinogen is associated with essential (Jeunemaitre *et al.*, 1992; Caulfield *et al.*, 1994, 1995; Kunz *et al.*, 1997; Staessen *et al.*, 1999; Sethi *et al.*,

2001, 2003) and pregnancy-induced (Ward *et al.*, 1993) hypertension. Angiotensinogen has sequence homologies with the serpin protein family, and serpins have antiangiogenic properties. Both angiotensinogen and [des-angiotensin I]angiotensinogen also inhibit angiogenesis (C el erier *et al.*, 2002).

Angiotensin-Converting Enzyme (ACE, Kininase II, Dipeptidyl Carboxypeptidase). ACE is an ectoenzyme and glycoprotein with an apparent molecular weight of 170,000. Human ACE contains 1277 amino acid residues and has two homologous domains, each with a catalytic site and a Zn^{2+} -binding region. ACE has a large amino-terminal extracellular domain, a short carboxyl-terminal intracellular domain, and a 17-amino acid hydrophobic region that anchors the ectoenzyme to the cell membrane. Circulating ACE represents membrane ACE that has undergone proteolysis at the cell surface by a secretase (Beldent *et al.*, 1995). ACE is rather nonspecific and cleaves dipeptide units from substrates with diverse amino acid sequences. Preferred substrates have only one free carboxyl group in the carboxyl-terminal amino acid, and proline must not be the penultimate amino acid; thus the enzyme does not degrade angiotensin II. ACE is identical to kininase II, the enzyme that inactivates bradykinin and other potent vasodilator peptides. Although slow conversion of angiotensin I to angiotensin II occurs in plasma, the very rapid metabolism that occurs *in vivo* is due largely to the activity of membrane-bound ACE present on the luminal surface of endothelial cells throughout the vascular system.

The ACE gene encodes both somatic and testis-specific isozymes. The testis ACE is found exclusively in developing spermatids and mature sperm and is encoded by the second half of the ACE gene, driven by a testis-specific promoter. Testis ACE is involved in the transport of sperm in the oviduct and in binding of the sperm to the zona pellucida (Hagaman *et al.*, 1998). These effects of testis-specific ACE are not mediated by angiotensin II.

The ACE gene contains an insertion deletion polymorphism in intron 16 that explains 47% of the phenotypic variance in serum ACE levels (Rigat *et al.*, 1990). The deletion allele, associated with higher levels of serum ACE and increased metabolism of bradykinin (Murphey *et al.*, 2000), may confer an increased risk of ischemic heart disease (Cambien *et al.*, 1992; Gardemann *et al.*, 1995; Mattu *et al.*, 1995; Fatini *et al.*, 2000), coronary artery spasm (Oike *et al.*, 1995), restenosis after coronary stenting (Amant *et al.*, 1997; Ribichini *et al.*, 1998), vascular endothelial dysfunction (Butler *et al.*, 1999), left ventricular hypertrophy (Iwai *et al.*, 1994; Schunkert *et al.*, 1994), exercise-induced left ventricular growth (Montgomery *et al.*, 1997), carotid artery disease (Hosoi *et al.*, 1996; Losito *et al.*, 2000), ischemic stroke (Kario *et al.*, 1996), hypertension in males (O'Donnell *et al.*, 1998; Fornage *et al.*, 1998; Higaki *et al.*, 2000), diabetic nephropathy (Marre *et al.*, 1997; Hadjadj *et al.*, 2001), deterioration of renal function in immunoglobulin A (IgA) nephropathy (Yoshida *et al.*, 1995), renal artery stenosis (Olivieri *et al.*, 1999), and thrombosis in patients undergoing hip arthroplasty (Philipp *et al.*, 1998). Surprisingly, however, the deletion allele is more frequent in centenarians (Schachter *et al.*, 1994), a finding that may be explained by the strong association of the deletion allele with protection against Alzheimer's disease (Kehoe *et al.*, 1999).

Two groups independently discovered a novel angiotensin converting enzyme–related carboxypeptidase, now termed ACE2 (Donoghue *et al.*, 2000; Tipnis *et al.*, 2000). Human ACE2 is 805 amino acids in length with a short putative signal sequence. ACE2 contains a single catalytic domain that is 42% identical to the two catalytic domains of ACE. ACE2 cleaves angiotensin I to angiotensin(1–9)

and processes angiotensin II to angiotensin(1–7). ACE2 is not inhibited by the standard ACE inhibitors described in this chapter. In animals, reduced expression of ACE2 is associated with hypertension and defects in cardiac contractility (Crackower *et al.*, 2002). ACE2 also serves as a receptor for the SARS coronavirus (Li *et al.*, 2003). The physiological significance of ACE2 still is uncertain; it may serve as a counter-regulatory mechanism to oppose the effects of ACE (Yagil and Yagil, 2003).

Angiotensin Peptides. When given intravenously, angiotensin I is converted to angiotensin II so rapidly that the pharmacological responses to these two peptides are indistinguishable. However, angiotensin I *per se* is less than 1% as potent as angiotensin II on smooth muscle, heart, and the adrenal cortex. As shown in Figure 30–1, angiotensin III, also called [des-Asp¹]angiotensin II or angiotensin (2–8), can be formed either by the action of aminopeptidase on angiotensin II or by the action of ACE on [des-Asp¹]angiotensin I. Angiotensin III and angiotensin II cause qualitatively similar effects. Angiotensin II and angiotensin III stimulate aldosterone secretion with equal potency; however, angiotensin III is only 25% and 10% as potent as angiotensin II in elevating blood pressure and stimulating the adrenal medulla, respectively.

Angiotensin(1–7) is formed by multiple pathways (Figure 30–1). Angiotensin I can be metabolized to angiotensin(1–7) by metalloendopeptidase 24.15, endopeptidase 24.11, and prolylendopeptidase 24.26. Angiotensin II can be converted to angiotensin(1–7) by prolylcarboxypeptidase (Ferrario *et al.*, 1997). ACE2 converts angiotensin I to angiotensin(1–9) and angiotensin II to angiotensin(1–7); ACE metabolizes angiotensin(1–9) to angiotensin(1–7). ACE inhibitors increase tissue and plasma levels of angiotensin(1–7) both because angiotensin I levels are increased and diverted away from angiotensin II formation (Figure 30–1) and because ACE contributes importantly to the plasma clearance of angiotensin(1–7) (Yamada *et al.*, 1998). The pharmacological profile of angiotensin(1–7) is distinct from that of angiotensin II: Angiotensin(1–7) does not cause vasoconstriction, aldosterone release, or facilitation of noradrenergic neurotransmission. Angiotensin(1–7) releases vasopressin, stimulates prostaglandin biosynthesis, elicits depressor responses when microinjected into certain brainstem nuclei, dilates some blood vessels, and exerts a natriuretic action on the kidneys. Angiotensin(1–7) also inhibits proliferation of vascular smooth muscle cells (Tallant *et al.*, 1999). The effects of angiotensin(1–7) may be mediated by a specific angiotensin(1–7) receptor (Tallant *et al.*, 1997). The *Mas* protooncogene encodes an orphan G protein–coupled receptor that binds angiotensin(1–7) (Santos *et al.*, 2003). Ferrario and colleagues (1997) proposed that angiotensin(1–7) serves to counterbalance the actions of angiotensin II. Angiotensin(3–8), also called *angiotensin IV*, is yet another biologically active angiotensin peptide. Putative receptors for angiotensin(3–8) are detectable in a number of tissues (Swanson *et al.*, 1992), and the peptide stimulates the expression of plasminogen activator inhibitor-1 in endothelial (Kerins *et al.*, 1995) and proximal tubular (Gesualdo *et al.*, 1999) cells, although in vascular smooth muscle cells and cardiomyocytes, angiotensin II rather than angiotensin(3–8) mediates increased expression of plasminogen activator inhibitor-1 (Chen *et al.*, 2000). Angiotensin(3–8) also may be involved in memory acquisition and, like angiotensin(1–7), appears to counteract the effects of angiotensin II (de Gasparo *et al.*, 2000). The physiological significance of angiotensin(1–7) and angiotensin(3–8) remains uncertain.

There is considerable information on the structure–activity relationships of angiotensin-related peptides with regard to activity at

receptors for angiotensin II (Samanen and Regoli, 1994). In general, phenylalanine in position 8 is critical for most agonist activity, and the aromatic residues in positions 4 and 6, the guanido group in position 2, and the C-terminal carboxyl are thought to be involved in binding to the receptor site. Position 1 is not critical, but replacement of aspartic acid in position 1 with sarcosine enhances binding to angiotensin receptors and slows hydrolysis by rendering the peptide refractory to a subgroup of aminopeptidases (angiotensinase A). Such a substitution, combined with that of alanine or isoleucine in place of phenylalanine in position 8, yields potent angiotensin II receptor antagonists.

Angiotensinases. This term is applied to various peptidases that are involved in the degradation and inactivation of angiotensin peptides; none is specific. Among them are aminopeptidases, endopeptidases, and carboxypeptidases.

Local (Tissue) Renin–Angiotensin Systems. The traditional view of the renin–angiotensin system is that of a classical endocrine system. Circulating renin from the kidney acts on circulating angiotensinogen of hepatic origin to produce angiotensin I in the plasma, circulating angiotensin I is converted by plasma ACE and by pulmonary endothelial ACE to angiotensin II, and angiotensin II then is delivered to its target organs *via* the bloodstream, where it induces a physiological response. This traditional view is an oversimplification that must be expanded to include local (tissue) renin–angiotensin systems. In this regard it is important to distinguish between *extrinsic* and *intrinsic* local renin–angiotensin systems.

Extrinsic Local Renin–Angiotensin Systems. ACE is present on the luminal face of vascular endothelial cells throughout the circulation, and circulating renin of renal origin can be taken up (sequestered) by the arterial wall and by other tissues. Thus the conversion of hepatic angiotensinogen to angiotensin I and the conversion of angiotensin I (both circulating and locally produced) to angiotensin II may occur primarily within or at the surface of the blood vessel wall, not in the circulation *per se*. Indeed, many vascular beds produce angiotensins I and II locally, and a substantial fraction of local production does not occur in the plasma as it transverse the vascular bed (Danser *et al.*, 1991, 1994; Hilgers *et al.*, 2001). Local sequestration of renal renin in both vascular and cardiac tissues reportedly participates in the local production of angiotensins (Kato *et al.*, 1993; Taddei *et al.*, 1993; Danser *et al.*, 1994), a conclusion not universally accepted (Hu *et al.*, 1998).

Intrinsic Local Renin–Angiotensin Systems. Many tissues—including the brain, pituitary, blood vessels, heart, kidney, and adrenal gland—express mRNAs for renin, angiotensinogen, and/or ACE, and various cells cultured from these tissues produce renin, angiotensinogen, ACE, and angiotensins I, II, and III (Phillips *et al.*, 1993; Saavedra, 1992; Dzau, 1993; Baker *et al.*, 1992). Thus it appears that local renin–angiotensin systems exist independently of the renal/hepatic-based system. Although these local systems do not contribute significantly to circulating levels of active renin or angiotensins (Campbell *et al.*, 1991), local production of angiotensin II by intrinsic local renin–angiotensin systems may influence vascular, cardiac, and renal function and structure.

Alternative Pathways for Angiotensin Biosynthesis. Some tissues contain nonrenin angiotensinogen-processing enzymes that convert angiotensinogen to angiotensin I (nonrenin proteases) or directly to angiotensin II (*e.g.*, cathepsin G, tonin) and non-ACE angiotensin I-processing enzymes that convert angiotensin I to angiotensin II

(*e.g.*, cathepsin G, chymostatin-sensitive angiotensin II-generating enzyme, heart chymase) (Dzau *et al.*, 1993). There is mounting evidence that chymase, possibly mast cell-derived, contributes to the local tissue conversion of angiotensin I to angiotensin II, particularly in the heart (Wolny *et al.*, 1997; Wei *et al.*, 1999) and kidneys (Hollenberg *et al.*, 1998); however, the role of chymase as a non-ACE angiotensin I-processing enzyme is species- and organ-dependent (Akasu *et al.*, 1998).

Angiotensin Receptors. The effects of angiotensins are exerted through specific heptahelical G protein-coupled receptors (de Gasparo *et al.*, 2000). The two subtypes of angiotensin receptors (Whitbread *et al.*, 1989; Chiu *et al.*, 1989) now are designated AT₁ and AT₂ (Bumpus *et al.*, 1991). The AT₁ receptor has a high affinity for losartan (and related biphenyl tetrazole derivatives), a low affinity for PD 123177 (and related 1-benzyl spinacine derivatives), and a low affinity for CGP 42112A (a peptide analog). In contrast, the AT₂ receptor has a high affinity for PD 123177 and CGP 42112A but a low affinity for losartan.

The AT₁ receptor is 359 amino acids long; the AT₂ receptor consists of 363 amino acids. The AT₁ and AT₂ receptors have little sequence homology. Most of the known biological effects of angiotensin II are mediated by the AT₁ receptor. Functional roles for the AT₂ receptors are poorly defined, but they may exert antiproliferative, proapoptotic, vasodilatory, and antihypertensive effects (Inagami *et al.*, 1999; Ardaillou, 1999; Horiuchi *et al.*, 1999; Siragy *et al.*, 2000; Moore *et al.*, 2001; Carey *et al.*, 2001). The complex effects of AT₂ receptor activation on vascular tone and biology may depend on such factors as species, organ, and vascular diameter (Henrion *et al.*, 2001). Although the AT₂ receptor generally is conceptualized as a cardiovascular protective receptor, its activation may contribute to cardiac fibrosis (Ichihara *et al.*, 2001).

The AT₂ receptor is distributed widely in fetal tissues, but its distribution is more restricted in adults. In adults, some tissues contain primarily either AT₁ receptors or AT₂ receptors, whereas other tissues contain the receptor subtypes in similar amounts. In this regard, tissue and species differences are the rule, not the exception (Timmermans *et al.*, 1993). The AT₁-receptor gene contains a polymorphism (A-to-C transversion in position 1166) that reportedly is associated with hypertension (Kainulainen *et al.*, 1999), hypertrophic cardiomyopathy (Osterop *et al.*, 1998), coronary artery vasoconstriction (Amant *et al.*, 1997), and aortic stiffness (Benetos *et al.*, 1996). Moreover, the C allele synergizes with the ACE deletion allele with regard to increased risk of coronary artery disease (Tiret *et al.*, 1994; Álvarez *et al.*, 1998). Preeclampsia is associated with the development of agonistic autoantibodies against the AT₁ receptor (Wallukat *et al.*, 1999). AT₁ receptors regulate their own expression by a mechanism involving phosphorylation of calreticulin. Phosphorylated calreticulin binds to and destabilizes AT₁-receptor mRNA (Nickenig *et al.*, 2002).

Angiotensin Receptor-Effector Coupling. AT₁ receptors activate a large array of signal-transduction systems to produce effects that vary with cell type and that are a combination of primary and secondary responses (Griendling *et al.*, 1997; Berk, 1999; Inagami, 1999; Blume *et al.*, 1999; Rocic *et al.*, 2001; Haendeler and Berk, 2000; Epperson *et al.*, 2004) (Figure 30-3). AT₁ receptors couple to several heterotrimeric G proteins, including G_q, G_{12/13} and G_i. In most cell types, AT₁ receptors couple to G_q to activate the PLCβ-IP₃-Ca²⁺ pathway (*see* Chapter 1). Secondary to G_q activation, activation of PKC, PLA₂, and PLD and eicosanoid production may occur, as well as activation of

Ca²⁺-dependent and MAP kinases and the Ca²⁺-calmodulin-dependent activation of NOS. Activation of G_i may occur and will reduce the activity of adenylyl cyclase, lowering cellular cyclic AMP content; however, there also is evidence for G_q → G_i cross-talk such that activation of the AT₁-G_q-PLC pathway enhances cyclic AMP production (Meszaros *et al.*, 2000; Epperson *et al.*, 2004). The βγ subunits of G_i and activation of G_{12/13} lead to activation of tyrosine kinases and small G proteins such as Rho. Ultimately, through a combination of direct and secondary effects, the JAK/STAT pathway is activated, and a variety of transcriptional regulatory factors is induced, as summarized by Figure 30-3. By these mechanisms, angiotensin influences the expression of a host of gene products relating to cell growth and the production of components of the extracellular matrix. AT₁ receptors also stimulate the activity of a membrane-bound NADH/NADPH oxidase that generates superoxide anion. Catalase transforms the superoxide anion to hydrogen peroxide, which may contribute to biochemical effects (MAP kinase activation), expression of monocyte chemoattractant protein-1 and physiological effects [acute effects on renal function (López *et al.*, 2003), chronic effects on blood pressure (Landmesser *et al.*, 2002), and vascular hypertrophy (Wang *et al.*, 2001)]. Angiotensin II also induces the expression of a novel redox-sensitive gene product, Id3, that depresses the amount of cell-cycle inhibitors such as p21^{WAF1}, p27^{Kip1}, and p53 and increases cell growth (Mueller *et al.*, 2002). The relative importance of these myriad signal-transduction pathways in mediating biological responses to angiotensin II is tissue-specific. The presence of other receptors may alter the response to AT₁-receptor activation. For example, AT₁ receptors heterodimerize with bradykinin B₂ receptors, a process that enhances angiotensin II sensitivity in preeclampsia (Abdalla *et al.*, 2001).

Less is known about AT₂ receptor-effector coupling. Signaling from AT₂ receptors is mediated largely by G_i (Hansen *et al.*, 2000). Consequences of AT₂-receptor activation include activation of phosphatases, potassium channels, and bradykinin and NO production and inhibition of calcium channel functions (Horiuchi *et al.*, 1999). The AT₂ receptor may bind directly to and antagonize the AT₁ receptor.

Functions and Effects of the Renin-Angiotensin System

The renin-angiotensin system plays a major role in both the short- and long-term regulation of arterial blood pressure. Modest increases in plasma concentrations of angiotensin II acutely raise blood pressure; on a molar basis, angiotensin II is approximately 40 times more potent than norepinephrine, and the EC₅₀ of angiotensin II for acutely raising arterial blood pressure is approximately 0.3 nmol/L. When a single moderate dose of angiotensin II is injected intravenously, systemic blood pressure begins to rise within seconds, peaks rapidly, and returns to normal within minutes (Figure 30-4). This *rapid pressor response* to angiotensin II is due to a swift increase in total peripheral resistance—a response that helps to maintain arterial blood pressure in the face of an acute hypotensive challenge (*e.g.*, blood loss or vasodilation). Although angiotensin II increases cardiac con-

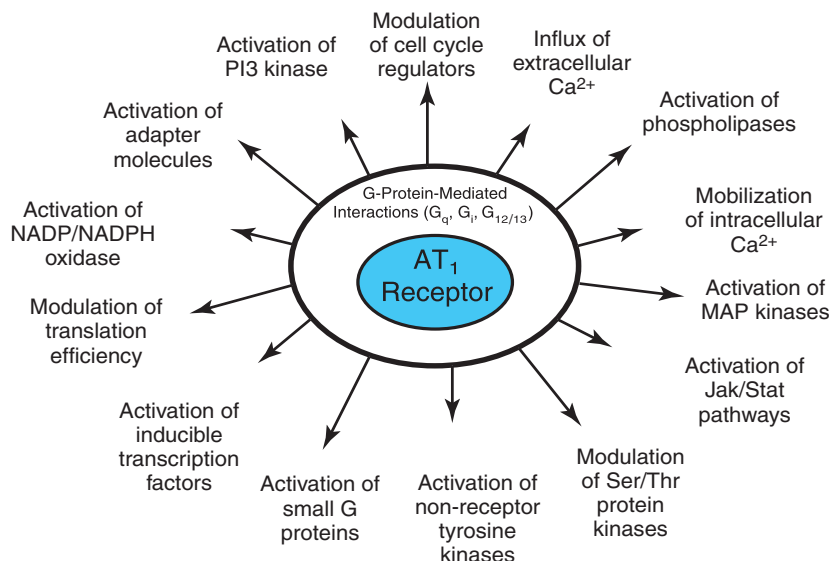

Figure 30–3. Multiple mechanisms of AT_1 receptor–effector coupling. AT_1 receptors couple to G_q , G_i , and $G_{12/13}$. Through effectors, second messengers, and signaling cascades, a large array of response pathways is subsequently engaged to produce immediate and long-term effects of angiotensin II.

tractility directly (*via* opening voltage-gated Ca^{2+} channels in cardiac myocytes) and increases heart rate indirectly (*via* facilitation of sympathetic tone, enhanced adrenergic neurotransmission, and adrenal catecholamine release), the rapid increase in arterial blood pressure activates a baroreceptor reflex that decreases sympathetic tone and increases vagal tone. Thus, depending on the physiological state, angiotensin II may increase, decrease, or not change cardiac contractility, heart rate, and cardiac output. Changes in cardiac output therefore contribute little, if at all, to the rapid pressor response induced by angiotensin II.

Angiotensin II also causes a *slow pressor response* that helps to stabilize arterial blood pressure over the long term. A continuous infusion of initially subpressor doses of angiotensin II gradually increases arterial blood pressure, with the maximum effect requiring days to achieve. This slow pressor response probably is mediated by a decrement in renal excretory function that shifts the renal pressure–natriuresis curve to the right (*see* below). Angiotensin II stimulates the synthesis of endothelin-1 and superoxide anion (Laursen *et al.*, 1997; Rajagopalan *et al.*, 1997; Ortiz *et al.*, 2001), which may contribute to the slow pressor response.

In addition to its effects on arterial blood pressure, angiotensin II significantly alters the morphology of the cardiovascular system, causing hypertrophy of vascular

and cardiac cells and increased synthesis and deposition of collagen by cardiac fibroblasts.

The effects of angiotensin II on total peripheral resistance, renal function, and cardiovascular structure are

Figure 30–4. Effect of a bolus intravenous injection of angiotensin II ($0.05 \mu\text{g}/\text{kg}$) on arterial blood pressure and renal blood flow in a conscious dog. (From Zimmerman, 1979, with permission.)

mediated by a number of direct and indirect mechanisms, as summarized by Figure 30–5.

Mechanisms by Which Angiotensin II Increases Total Peripheral Resistance. Angiotensin II increases total peripheral resistance (TPR) *via* direct and indirect effects on blood vessels.

Direct Vasoconstriction. Angiotensin II constricts precapillary arterioles and, to a lesser extent, postcapillary venules by activating AT_1 receptors located on vascular smooth muscle cells and stimulating the G_q -PLC- IP_3 - Ca^{2+} pathway. Angiotensin II has differential effects on vascular beds. Direct vasoconstriction is strongest in the kidneys (Figure 30–4) and somewhat less in the splanchnic vascular bed; blood flow in these regions falls sharply when angiotensin II is infused. Angiotensin II–induced vasoconstriction is much less in vessels of the brain and still weaker in those of the lung and skeletal muscle. In these regions, blood flow actually may increase, especially following small changes in the concentration of the peptide, because the relatively weak vasoconstrictor response is opposed by the elevated systemic blood pressure. Nevertheless, high circulating concentrations of angiotensin II may decrease cerebral and coronary blood flow.

Enhancement of Peripheral Noradrenergic Neurotransmission. Angiotensin II facilitates peripheral noradrenergic neurotransmission by augmenting norepinephrine release from sympathetic nerve terminals, by inhibiting the reuptake of norepinephrine into nerve terminals, and by enhancing the vascular response to norepinephrine. High concentrations of the peptide stimulate ganglion cells directly. Facilitation of adrenergic transmission by endogenous angiotensin II occurs in animals with renin-dependent renovascular hypertension (Zimmerman *et al.*, 1987), and in humans, intracoronary angiotensin II potentiates sympathetic nervous system–induced coronary vasoconstriction (Saino *et al.*, 1997).

Effects on the Central Nervous System. Small amounts of angiotensin II infused into the vertebral arteries cause an increase in arterial blood pressure. This response—mediated by increased sympathetic outflow—reflects effects of the hormone on circumventricular nuclei that are not protected by a blood–brain barrier (*e.g.*, area postrema, subfornical organ, and organum vasculosum of the lamina terminalis). Circulating angiotensin II also attenuates baroreceptor-mediated reductions in sympathetic discharge, thereby increasing arterial pressure. The CNS is affected both by blood-borne angiotensin II and by angiotensin II formed within the brain (Saavedra,

1992; Bunnemann *et al.*, 1993). The brain contains all components of a renin–angiotensin system. Moreover, there is angiotensinlike immunoreactivity at many sites within the CNS, suggesting that angiotensin II serves as a neurotransmitter or modulator. In addition to increasing sympathetic tone, angiotensin II also causes a centrally mediated dipsogenic effect and enhances the release of vasopressin from the neurohypophysis. Increased drinking and vasopressin secretion result more consistently from intraventricular than from intravenous injections.

Release of Catecholamines from the Adrenal Medulla. Angiotensin II stimulates the release of catecholamines from the adrenal medulla by depolarizing chromaffin cells. Although this response usually is of minimal physiological importance, intense and dangerous reactions have followed the administration of angiotensin II to individuals with pheochromocytoma.

Mechanisms by Which Angiotensin II Alters Renal Function. Angiotensin II has pronounced effects on renal function, reducing the urinary excretion of Na^+ and water while increasing the excretion of K^+ . The overall effect of angiotensin II on the kidneys is to shift the renal pressure–natriuresis curve to the right (*see* below). Like the effects of angiotensin II on TPR, its effects on renal function are multifaceted.

Direct Effects of Angiotensin II on Sodium Reabsorption in the Renal Tubules. Very low concentrations of angiotensin II stimulate Na^+/H^+ exchange in the proximal tubule—an effect that increases Na^+ , Cl^- , and bicarbonate reabsorption. Approximately 20% to 30% of the bicarbonate handled by the nephron may be affected by this mechanism (Liu and Cogan, 1987). Angiotensin II also increases the expression of the Na^+ –glucose symporter in the proximal tubule (Bautista *et al.*, 2004). Paradoxically, at high concentrations, angiotensin II may inhibit Na^+ transport in the proximal tubule. Angiotensin II also directly stimulates the Na^+ – K^+ – $2Cl^-$ symporter in the thick ascending limb (Kovács *et al.*, 2002). The proximal tubule secretes angiotensinogen, and the connecting tubule releases renin, so a paracrine tubular renin–angiotensin system may contribute to Na^+ reabsorption (Rohr-wasser *et al.*, 1999).

Release of Aldosterone from the Adrenal Cortex. Angiotensin II stimulates the zona glomerulosa of the adrenal cortex to increase the synthesis and secretion of aldosterone, and angiotensin II exerts trophic and permissive effects that augment responses to other stimuli (*e.g.*, ACTH and K^+). Increased output of aldosterone is elicited by concentrations of angiotensin II that have lit-

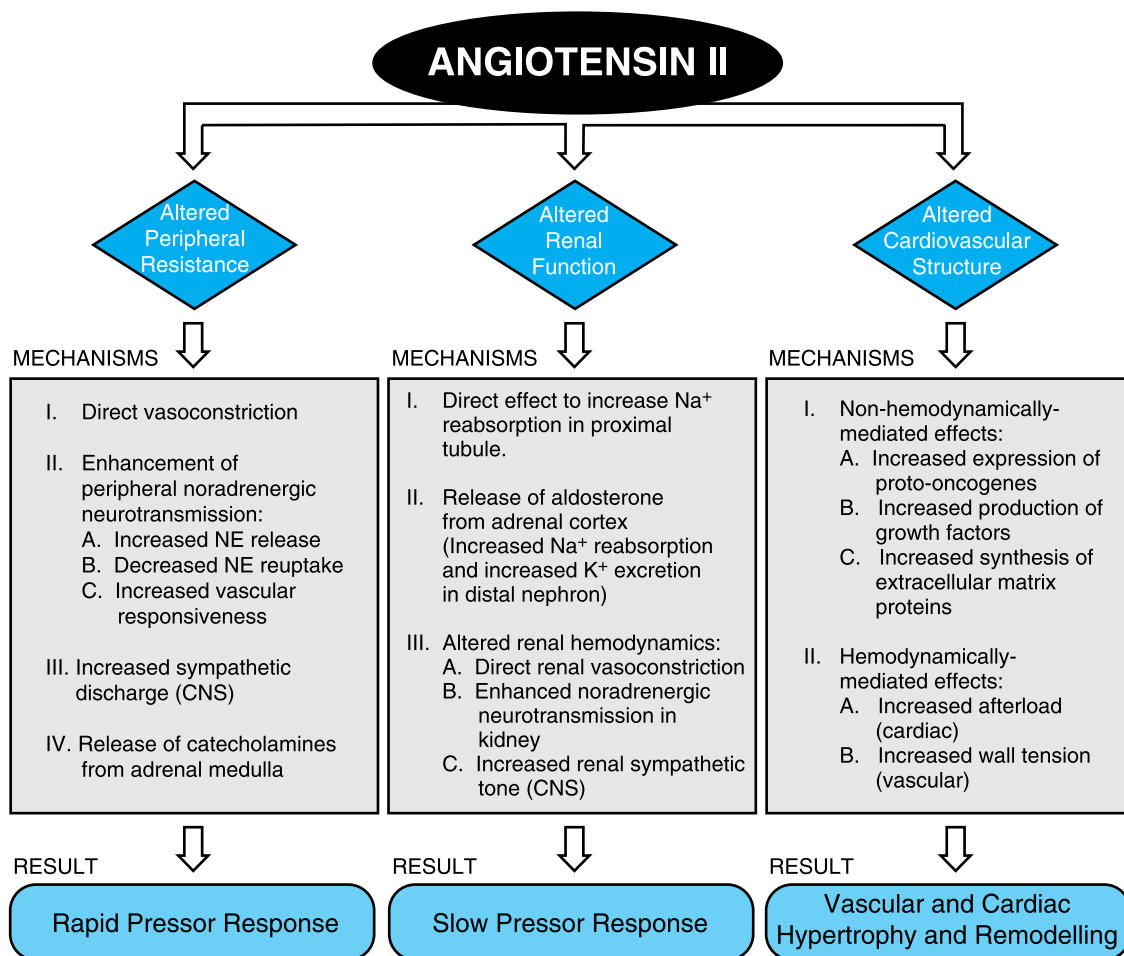

Figure 30–5. Summary of the three major effects of angiotensin II and the mechanisms that mediate them. NE, norepinephrine.

tle or no acute effect on blood pressure. As described in Chapters 28 and 59, aldosterone acts on the distal and collecting tubules to cause retention of Na^+ and excretion of K^+ and H^+ . The stimulant effect of angiotensin II on aldosterone synthesis and release is enhanced under conditions of hyponatremia or hyperkalemia and is reduced when concentrations of Na^+ and K^+ in plasma are altered in the opposite directions. Such changes in sensitivity are due in part to alterations in the number of receptors for angiotensin II on zona glomerulosa cells, as well as to adrenocortical hyperplasia in the Na^+ -depleted state.

Altered Renal Hemodynamics. Reductions in renal blood flow markedly attenuate renal excretory function, and angiotensin II reduces renal blood flow by directly constricting the renal vascular smooth muscle, by enhancing renal sympathetic tone (a CNS effect), and

by facilitating renal adrenergic transmission (an intrarenal effect). Angiotensin II–induced vasoconstriction of preglomerular microvessels is enhanced by endogenous adenosine owing to an interaction between the signal-transduction systems activated by AT_1 and the adenosine A_1 receptors (Hansen *et al.*, 2003). Autoradiographic and *in situ* hybridization studies indicate a high concentration of AT_1 receptors in the vasa recta of the renal medulla, and angiotensin II may reduce Na^+ excretion in part by diminishing medullary blood flow. Angiotensin II variably influences glomerular filtration rate (GFR) *via* several mechanisms: (1) constriction of the afferent arterioles, which reduces intraglomerular pressure and tends to reduce GFR, (2) contraction of mesangial cells, which decreases the capillary surface area within the glomerulus available for filtration and also tends to decrease GFR, and (3) constriction of efferent arteri-

oles, which increases intraglomerular pressure and tends to increase GFR. The outcome of these opposing effects on GFR depends on the physiological state. Normally, GFR is slightly reduced by angiotensin II; however, during renal artery hypotension, the effects of angiotensin II on the efferent arteriole predominate so that angiotensin II increases GFR. Thus blockade of the renin–angiotensin system may cause acute renal failure in patients with bilateral renal artery stenosis or in patients with unilateral stenosis who have only a single kidney.

Mechanisms by Which Angiotensin II Alters Cardiovascular Structure. Several cardiovascular diseases are accompanied by changes in the morphology of the heart and/or blood vessels that increase morbidity and mortality. Pathological alterations in cardiovascular structures may involve hypertrophy (an increase in tissue mass) and remodeling (redistribution of mass within a structure). Examples include (1) increased wall-to-lumen ratio in blood vessels (associated with hypertension), (2) concentric cardiac hypertrophy (also associated with hypertension), (3) eccentric cardiac hypertrophy and cardiac fibrosis (associated with congestive heart failure and myocardial infarction), and (4) thickening of the intimal surface of the blood vessel wall (associated with atherosclerosis and angioplasty). These morbid changes in cardiovascular structure are due to increased migration, proliferation (hyperplasia), and hypertrophy of cells, as well as to increased extracellular matrix. The cells involved include vascular smooth muscle cells, cardiac myocytes, and fibroblasts. The renin–angiotensin system may contribute importantly to the aforementioned morbid changes in cardiovascular structure. In this regard, angiotensin II (1) stimulates the migration (Bell and Madri, 1990; Dubey *et al.*, 1995), proliferation (Daemen *et al.*, 1991), and hypertrophy of vascular smooth muscle cells (Itoh *et al.*, 1993), (2) increases extracellular matrix production by vascular smooth muscle cells (Scott-Burden *et al.*, 1990), (3) causes hypertrophy of cardiac myocytes (Baker *et al.*, 1992), and (4) increases extracellular matrix production by cardiac fibroblasts (Villarreal *et al.*, 1993; Crawford *et al.*, 1994; Ostrom *et al.*, 2003).

Nonhemodynamically Mediated Effects of Angiotensin II on Cardiovascular Structure. Angiotensin II stimulates migration, proliferation, hypertrophy, and/or synthetic capacity of vascular smooth muscle cells, cardiac myocytes, and fibroblasts in part by acting directly on cells to induce the expression of specific proto-oncogenes. In cell culture, angiotensin II rapidly (within minutes) increases

steady-state levels of mRNA for *c-fos*, *c-jun*, *c-myc*, and *egr-1*. FOS and JUN, the proteins coded by *c-fos* and *c-jun*, combine to form AP-1, which alters the expression of several genes that stimulate cell growth (hypertrophy and hyperplasia), including basic fibroblast growth factor, platelet-derived growth factor, and transforming growth factor β . In addition, the expression of genes coding for extracellular matrix proteins, such as collagen, fibronectin, and tenascin, is increased.

Hemodynamically Mediated Effects of Angiotensin II on Cardiovascular Structure. In addition to the direct cellular effects of angiotensin II on cardiovascular structure, changes in cardiac preload (volume expansion owing to Na^+ retention) and afterload (increased arterial blood pressure) probably contribute to cardiac hypertrophy and remodeling. Arterial hypertension also contributes to hypertrophy and remodeling of blood vessels.

Role of the Renin–Angiotensin System in Long-Term Maintenance of Arterial Blood Pressure Despite Extremes in Dietary Na^+ Intake. Arterial blood pressure is a major determinant of Na^+ excretion. This is illustrated graphically by plotting urinary Na^+ excretion *versus* mean arterial blood pressure (Figure 30–6), a plot known as the *renal pressure–natriuresis curve*. Over the long term, Na^+ excretion must equal Na^+ intake; therefore, the set point for long-term levels of arterial blood pressure can be obtained as the intersection of a horizontal line representing Na^+ intake with the renal pressure–natriuresis curve (Guyton, 1991). If the renal pressure–natriuresis

Figure 30–6. Interactions among salt intake, the renal pressure–natriuresis mechanism, and the renin–angiotensin system to stabilize long-term levels of arterial blood pressure despite large variations in dietary sodium intake. (Modified from Jackson *et al.*, 1985, with permission.)

curve were fixed, then long-term levels of arterial blood pressure would be greatly affected by dietary Na^+ intake. However, as illustrated in Figure 30–6, the renin–angiotensin system plays a major role in maintaining a constant set point for long-term levels of arterial blood pressure despite extreme changes in dietary Na^+ intake. When dietary Na^+ intake is low, renin release is stimulated, and angiotensin II acts on the kidneys to shift the renal pressure–natriuresis curve to the right. Conversely, when dietary Na^+ is high, renin release is inhibited, and the withdrawal of angiotensin II shifts the renal pressure–natriuresis curve to the left. Consequently, despite large swings in dietary Na^+ intake, the intersection of salt intake with the renal pressure–natriuresis curve remains near the same set point. When modulation of the renin–angiotensin system is blocked by drugs, changes in salt intake markedly affect long-term levels of arterial blood pressure.

Other Effects of the Renin–Angiotensin System.

Expression of the renin–angiotensin system is required for the development of normal kidney morphology, particularly the maturational growth of the renal papilla (Niimura *et al.*, 1995). Angiotensin II causes a marked anorexigenic effect and weight loss, and high circulating levels of angiotensin II may contribute to the anorexia, wasting, and cachexia of heart failure (Brink *et al.*, 1996).

Angiotensin and Vascular Disease

The renin–angiotensin system induces vascular disease by multiple mechanisms, including stimulating vascular smooth muscle cell migration, proliferation, and extracellular matrix production; increasing the release of plasminogen activator inhibitor-1 from vascular smooth muscle cells; enhancing the expression of monocyte chemoattractant protein-1 in vascular smooth muscle cells; augmenting the expression of adhesion proteins, such as intercellular adhesion molecule-1 (ICAM-1), integrins, and osteopontin, in vascular cells (Pastore *et al.*, 1999; Schnee and Hsueh, 2000); and stimulating the production of inflammatory chemokines and cytokines that enhance the migration of inflammatory cells (Ruiz-Ortego *et al.*, 2001). Angiotensin II markedly accelerates the development of atherosclerosis and aortic aneurysms in apolipoprotein E–deficient mice (Daugherty *et al.*, 2000; Weiss *et al.*, 2001), an animal model of atherosclerosis. Conversely, inhibition of the renin–angiotensin system attenuates the development of atherosclerosis in diabetic apolipoprotein E–deficient mice (Candido *et al.*, 2002).

INHIBITORS OF THE RENIN–ANGIOTENSIN SYSTEM

Angiotensin II itself has limited therapeutic utility and is not available for therapeutic use in the United States. Instead, clinical interest focuses on inhibitors of the renin–angiotensin system.

Angiotensin Converting Enzyme (ACE) Inhibitors

History. In the 1960s, Ferreira and colleagues found that the venoms of pit vipers contain factors that intensify responses to bradykinin. These bradykinin-potentiating factors proved to be a family of peptides that inhibit kininase II, an enzyme that inactivates bradykinin. Erdős and coworkers established that ACE and kininase II are the same enzyme, which catalyzes both the synthesis of angiotensin II, a potent pressor substance, and the destruction of bradykinin, a potent vasodilator.

Following the discovery of bradykinin-potentiating factors, the nonapeptide teprotide was synthesized and tested in human subjects. It lowered blood pressure in many patients with essential hypertension more consistently than did peptide angiotensin II-receptor antagonists, such as saralasin, which have partial agonist activity. Teprotide also exerted beneficial effects in patients with heart failure. These key observations encouraged the search for ACE inhibitors that would be active orally.

The orally effective ACE inhibitor *captopril* was developed by a rational approach that involved analysis of the inhibitory action of teprotide, inference about the action of ACE on its substrates, and analogy with carboxypeptidase A, which was known to be inhibited by D-benzylsuccinic acid. Ondetti, Cushman, and colleagues argued that inhibition of ACE might be produced by succinyl amino acids that corresponded in length to the dipeptide cleaved by ACE. This hypothesis proved to be true and led to the synthesis of a series of carboxy alkanoyl and mercapto alkanoyl derivatives that are potent competitive inhibitors of ACE. Most active was captopril (*see* Vane, 1999, for an insider’s perspective on the discovery of ACE inhibitors).

Pharmacological Effects in Normal Laboratory Animals and Human Beings.

The essential effect of these agents on the renin–angiotensin system is to inhibit the conversion of the relatively inactive angiotensin I to the active angiotensin II (or the conversion of [des-Asp¹]angiotensin I to angiotensin III). Thus ACE inhibitors attenuate or abolish responses to angiotensin I but not to angiotensin II (Figure 30–1). In this regard, ACE inhibitors are highly selective drugs. They do not interact directly with other components of the renin–angiotensin system, and their principal pharmacological and clinical effects apparently arise from suppression of synthesis of angiotensin II. Nevertheless, ACE is an enzyme with many substrates, and inhibition of ACE may induce effects unrelated to reducing the levels of

angiotensin II. Since ACE inhibitors increase bradykinin levels and bradykinin stimulates prostaglandin biosynthesis, bradykinin and/or prostaglandins may contribute to the pharmacological effects of ACE inhibitors. Indeed, some studies demonstrate that blockade of bradykinin receptors in humans attenuates the acute blood pressure reduction (Gainer *et al.*, 1998) and increase in forearm blood flow (Wetherow *et al.*, 2001) induced by ACE inhibition. However, other studies fail to demonstrate a role for bradykinin in the vascular or cardiac effects of ACE inhibitors (Davie *et al.*, 1999; Campbell *et al.*, 1999; Rhaleb *et al.*, 1999). ACE inhibitors increase by fivefold the circulating levels of the natural stem cell regulator *N*-acetyl-seryl-aspartyl-lysyl-proline (Ac-SDKP; Azizi *et al.*, 1997), which may contribute to the cardioprotective effects of ACE inhibitors (Rhaleb *et al.*, 2001). In addition, ACE inhibitors interfere with both short- and long-loop negative feedbacks on renin release (Figure 30-2A). Consequently, ACE inhibitors increase renin release and the rate of formation of angiotensin I. Since the metabolism of angiotensin I to angiotensin II is blocked by ACE inhibitors, angiotensin I is directed down alternative metabolic routes, resulting in the increased production of peptides such as angiotensin(1-7). Whether or not biologically active peptides such as angiotensin(1-7) contribute to the pharmacological effects of ACE inhibitors is unknown.

In healthy, Na⁺-replete animals and human beings, a single oral dose of an ACE inhibitor has little effect on systemic blood pressure, but repeated doses over several days cause a small reduction in blood pressure. By contrast, even a single dose of these inhibitors lowers blood pressure substantially in normal subjects when they have been depleted of Na⁺.

Clinical Pharmacology. Many ACE inhibitors have been synthesized. These drugs can be classified into three broad groups based on chemical structure: (1) sulfhydryl-containing ACE inhibitors structurally related to captopril (*e.g.*, fentiapril, pivalopril, zofenopril, and alacepril); (2) dicarboxyl-containing ACE inhibitors structurally related to enalapril (*e.g.*, lisinopril, benazepril, quinapril, moexipril, ramipril, trandolapril, spirapril, perindopril, pentopril, and cilazapril); and (3) phosphorus-containing ACE inhibitors structurally related to fosinopril. Many ACE inhibitors are ester-containing prodrugs that are 100 to 1000 times less potent but have a much better oral bioavailability than the active molecules.

Currently, 11 ACE inhibitors are available for clinical use in the United States (Figure 30-7). In general, ACE

inhibitors differ with regard to three properties: (1) potency, (2) whether ACE inhibition is primarily a direct effect of the drug itself or the effect of an active metabolite, and (3) pharmacokinetics (*i.e.*, extent of absorption, effect of food on absorption, plasma half-life, tissue distribution, and mechanisms of elimination).

There is no compelling reason to favor one ACE inhibitor over another because all ACE inhibitors effectively block the conversion of angiotensin I to angiotensin II, and all have similar therapeutic indications, adverse-effect profiles, and contraindications. However, the Quality-of-Life Hypertension Study Group reported that although captopril and enalapril are indistinguishable with regard to antihypertensive efficacy and safety, captopril may have a more favorable effect on quality of life (Testa *et al.*, 1993). Since hypertension usually requires lifelong treatment, quality-of-life issues are an important consideration in comparing antihypertensive drugs. ACE inhibitors differ markedly in tissue distribution, and it is possible that this difference could be exploited to inhibit some local renin-angiotensin systems while leaving others relatively intact. Whether site-specific inhibition actually confers therapeutic advantages remains to be established.

With the notable exceptions of fosinopril and spirapril (which display balanced elimination by the liver and kidneys), ACE inhibitors are cleared predominantly by the kidneys. Therefore, impaired renal function significantly diminishes the plasma clearance of most ACE inhibitors, and dosages of these drugs should be reduced in patients with renal impairment. *Elevated plasma renin activity (PRA) renders patients hyperresponsive to ACE inhibitor-induced hypotension, and initial dosages of all ACE inhibitors should be reduced in patients with high plasma levels of renin (e.g., patients with heart failure and salt-depleted patients).*

Captopril (CAPOTEN). Captopril, the first ACE inhibitor to be marketed, is a potent ACE inhibitor with a K_i of 1.7 nM. It is the only ACE inhibitor approved for use in the United States that contains a sulfhydryl moiety. Given orally, captopril is absorbed rapidly and has a bioavailability of about 75%. Peak concentrations in plasma occur within an hour, and the drug is cleared rapidly with a half-life of approximately 2 hours. Most of the drug is eliminated in urine, 40% to 50% as captopril and the rest as captopril disulfide dimers and captopril-cysteine disulfide. The oral dose of captopril ranges from 6.25 to 150 mg two to three times daily, with 6.25 mg three times daily or 25 mg twice daily being appropriate for the initiation of therapy for heart failure or hypertension, respectively. Most patients should not receive daily doses in

Figure 30–7. Chemical structures of selected angiotensin-converting enzyme inhibitors. Captopril, lisinopril, and enalaprilat are active molecules. Benazepril, enalapril, fosinopril, moexipril, perindopril, quinapril, ramipril, and trandolapril are relatively inactive until converted to their corresponding diacids. The structures enclosed within blue boxes are removed by esterases and replaced with a hydrogen atom to form the active molecule *in vivo* (e.g., enalapril to enalaprilat or ramipril to ramiprilat).

excess of 150 mg. Since food reduces the oral bioavailability of captopril by 25% to 30%, the drug should be given 1 hour before meals.

Enalapril (VASOTEC). Enalapril maleate, the second ACE inhibitor approved in the United States, is a pro-drug that is hydrolyzed by esterases in the liver to produce the active dicarboxylic acid, enalaprilat. *Enalapri-*

lat is a highly potent inhibitor of ACE with a K_i of 0.2 nM. Although it also contains a “proline surrogate,” enalaprilat differs from captopril in that it is an analogue of a tripeptide rather than of a dipeptide. Enalapril is absorbed rapidly when given orally and has an oral bioavailability of about 60% (not reduced by food). Although peak concentrations of enalapril in plasma

occur within an hour, enalaprilat concentrations peak only after 3 to 4 hours. Enalapril has a half-life of only 1.3 hours, but enalaprilat, because of tight binding to ACE, has a plasma half-life of about 11 hours. Nearly all the drug is eliminated by the kidneys as either intact enalapril or enalaprilat. The oral dosage of enalapril ranges from 2.5 to 40 mg daily (single or divided dosage), with 2.5 and 5 mg daily being appropriate for the initiation of therapy for heart failure and hypertension, respectively. The initial dose for hypertensive patients who are taking diuretics, are water- or Na⁺-depleted, or have heart failure is 2.5 mg daily.

Enalaprilat (VASOTEC INJECTION). Enalaprilat is not absorbed orally but is available for intravenous administration when oral therapy is not appropriate. For hypertensive patients, the dosage is 0.625 to 1.25 mg given intravenously over 5 minutes. This dosage may be repeated every 6 hours.

Lisinopril (PRINIVIL, ZESTRIL). Lisinopril, the third ACE inhibitor approved for use in the United States, is the lysine analogue of enalaprilat; unlike enalapril, lisinopril itself is active. *In vitro*, lisinopril is a slightly more potent ACE inhibitor than is enalaprilat. Lisinopril is absorbed slowly, variably, and incompletely (about 30%) after oral administration (not reduced by food); peak concentrations in plasma are achieved in about 7 hours. It is cleared as the intact compound by the kidney, and its half-life in plasma is about 12 hours. Lisinopril does not accumulate in tissues. The oral dosage of lisinopril ranges from 5 to 40 mg daily (single or divided dosage), with 5 and 10 mg daily being appropriate for the initiation of therapy for heart failure and hypertension, respectively. A daily dose of 2.5 mg is recommended for patients with heart failure who are hyponatremic or have renal impairment.

Benazepril (LOTENSIN). Cleavage of the ester moiety by hepatic esterases transforms benazepril, a prodrug, into benazeprilat, an ACE inhibitor that *in vitro* is more potent than captopril, enalaprilat, or lisinopril. Benazepril is absorbed rapidly but incompletely (37%) after oral administration (only slightly reduced by food). Benazepril is nearly completely metabolized to benazeprilat and to the glucuronide conjugates of benazepril and benazeprilat, which are excreted into both the urine and bile; peak concentrations of benazepril and benazeprilat in plasma are achieved in about 0.5 to 1 hour and 1 to 2 hours, respectively. Benazeprilat has an effective half-life in plasma of about 10 to 11 hours. With the exception of the lungs, benazeprilat does not accumulate in tissues. The oral dosage of benazepril ranges from 5 to 80 mg daily (single or divided dosage).

Fosinopril (MONOPRIL). Fosinopril is the only ACE inhibitor approved for use in the United States that contains a phosphinate group that binds to the active site of ACE. Cleavage of the ester moiety by hepatic esterases transforms fosinopril, a prodrug, into fosinoprilat, an ACE inhibitor that *in vitro* is more potent than captopril yet less potent than enalaprilat. Fosinopril is absorbed slowly and incompletely (36%) after oral administration (rate but not extent reduced by food). Fosinopril is largely metabolized to fosinoprilat (75%) and to the glucuronide conjugate of fosinoprilat. These are excreted in both the urine and bile; peak concentrations of fosinoprilat in plasma are achieved in about 3 hours. Fosinoprilat has an effective half-life in plasma of about 11.5 hours, and its clearance is not significantly altered by renal impairment. The oral dosage of fosinopril ranges from 10 to 80 mg daily (single or divided dosage). The dose is reduced to 5 mg daily in patients with Na⁺ or water depletion or renal failure.

Trandolapril (MAVIK). Approximately 10% and 70% of an oral dose of trandolapril is bioavailable (absorption rate but not extent is reduced by food) as trandolapril and trandolaprilat, respectively. Trandolaprilat is about eight times more potent than trandolapril as an ACE inhibitor. Trandolapril is metabolized to trandolaprilat and to inactive metabolites (mostly glucuronides of trandolapril and deesterification products), and these are recovered in the urine (33%, mostly trandolaprilat) and feces (66%). Peak concentrations of trandolaprilat in plasma are achieved in 4 to 10 hours. Trandolaprilat displays biphasic elimination kinetics with an initial half-life of about 10 hours (the major component of elimination), followed by a more prolonged half-life owing to slow dissociation of trandolaprilat from tissue ACE. Plasma clearance of trandolaprilat is reduced by both renal and hepatic insufficiency. The oral dosage ranges from 1 to 8 mg daily (single or divided dosage). The initial dose is 0.5 mg in patients who are taking a diuretic or who have renal impairment.

Quinapril (ACCUPRIL). Cleavage of the ester moiety by hepatic esterases transforms quinapril, a prodrug, into quinaprilat, an ACE inhibitor that *in vitro* is about as potent as benazeprilat. Quinapril is absorbed rapidly (peak concentrations are achieved in 1 hour, but the peak may be delayed after food), and the rate but not extent of oral absorption (60%) may be reduced by food. Quinapril is metabolized to quinaprilat and to other minor metabolites, and quinaprilat is excreted in the urine (61%) and feces (37%). Peak concentrations of quinaprilat in plasma are achieved in about 2 hours. Conversion of quinapril to quinaprilat is reduced in

patients with diminished liver function. The initial half-life of quinaprilat is about 2 hours; a prolonged terminal half-life of about 25 hours may be due to high-affinity binding of the drug to tissue ACE. The oral dosage of quinapril ranges from 5 to 80 mg daily (single or divided dosage).

Ramipril (ALTACE). Cleavage of the ester moiety by hepatic esterases transforms ramipril into ramiprilat, an ACE inhibitor that *in vitro* is about as potent as benazeprilat and quinaprilat. Ramipril is absorbed rapidly (peak concentrations of ramipril achieved in 1 hour), and the rate but not extent of its oral absorption (50% to 60%) is reduced by food. Ramipril is metabolized to ramiprilat and to inactive metabolites (glucuronides of ramipril and ramiprilat and the diketopiperazine ester and acid) that are excreted predominantly by the kidneys. Peak concentrations of ramiprilat in plasma are achieved in about 3 hours. Ramiprilat displays triphasic elimination kinetics with half-lives of 2 to 4 hours, 9 to 18 hours, and greater than 50 hours. This triphasic elimination is due to extensive distribution to all tissues (initial half-life), clearance of free ramiprilat from plasma (intermediate half-life), and dissociation of ramiprilat from tissue ACE (terminal half-life). The oral dosage of ramipril ranges from 1.25 to 20 mg daily (single or divided dosage).

Moexipril (UNIVASC). Moexipril is another prodrug whose antihypertensive activity is almost entirely due to its deesterified metabolite, moexiprilat. Moexipril is absorbed incompletely, with bioavailability as moexiprilat of about 13%. Bioavailability is markedly decreased by food; therefore, the drug should be taken 1 hour before meals. The time to peak plasma concentration of moexiprilat is almost 1.5 hours, and the elimination half-life varies between 2 and 12 hours. The recommended dosage range is 7.5 to 30 mg daily in one or two divided doses. The dosage range is halved in patients who are taking diuretics or who have renal impairment.

Perindopril (ACEON). Perindopril erbumine is a prodrug, and 30% to 50% of systemically available perindopril is transformed to perindoprilat by hepatic esterases. Although the oral bioavailability of perindopril (75%) is not affected by food, the bioavailability of perindoprilat is reduced by approximately 35%. Perindopril is metabolized to perindoprilat and to inactive metabolites (glucuronides of perindopril and perindoprilat, dehydrated perindopril, and diastereomers of dehydrated perindoprilat) that are excreted predominantly by the kidneys. Peak concentrations of perindoprilat in plasma are achieved in 3 to 7 hours. Perindoprilat displays biphasic elimination kinetics with half-lives of 3 to 10 hours (the major component of elimination) and 30 to

120 hours (owing to slow dissociation of perindoprilat from tissue ACE). The oral dosage ranges from 2 to 16 mg daily (single or divided dosage).

Therapeutic Uses of ACE Inhibitors and Clinical Summary. Drugs that interfere with the renin-angiotensin system play a prominent role in the treatment of cardiovascular disease, the major cause of mortality in modern societies.

ACE Inhibitors in Hypertension (See Chapter 32). Inhibition of ACE lowers systemic vascular resistance and mean, diastolic, and systolic blood pressures in various hypertensive states. The effects are observed readily in animal models of renal and genetic hypertension. In human subjects with hypertension, ACE inhibitors commonly lower blood pressure, except when high blood pressure is due to primary aldosteronism. The initial change in blood pressure tends to be positively correlated with plasma renin activity (PRA) and angiotensin II plasma levels prior to treatment. However, several weeks into treatment, additional patients show a sizable reduction in blood pressure, and the antihypertensive effect then correlates poorly or not at all with pretreatment values of PRA. It is possible that increased local (tissue) production of angiotensin II and/or increased responsiveness of tissues to normal levels of angiotensin II in some hypertensive patients makes them sensitive to ACE inhibitors despite normal PRA. Regardless of the mechanisms, ACE inhibitors have broad clinical utility as antihypertensive agents.

The long-term fall in systemic blood pressure observed in hypertensive individuals treated with ACE inhibitors is accompanied by a leftward shift in the renal pressure-natriuresis curve (Figure 30-6) and a reduction in total peripheral resistance in which there is variable participation by different vascular beds. The kidney is a notable exception to this variability because increased renal blood flow owing to vasodilation is a relatively constant finding. This is not surprising because the renal vessels are exceptionally sensitive to the vasoconstrictor actions of angiotensin II. Increased renal blood flow occurs without an increase in GFR; thus the filtration fraction is reduced. Both the afferent and efferent arterioles are dilated. Blood flows in the cerebral and coronary beds, where autoregulatory mechanisms are powerful, generally are well maintained.

Besides causing systemic arteriolar dilatation, ACE inhibitors increase the compliance of large arteries, which contributes to a reduction of systolic pressure. Cardiac function in patients with uncomplicated hypertension generally is little changed, although stroke volume and car-

diac output may increase slightly with sustained treatment. Baroreceptor function and cardiovascular reflexes are not compromised, and responses to postural changes and exercise are little impaired. Surprisingly, even when a substantial lowering of blood pressure is achieved, heart rate and concentrations of catecholamines in plasma generally increase only slightly, if at all. This perhaps reflects an alteration of baroreceptor function with increased arterial compliance and the loss of the normal tonic influence of angiotensin II on the sympathetic nervous system.

Aldosterone secretion in the general population of hypertensive individuals is reduced, but not seriously impaired, by ACE inhibitors. Aldosterone secretion is maintained at adequate levels by other steroidogenic stimuli, such as adrenocorticotrophic hormone and K^+ . The activity of these secretagogues on the zona glomerulosa of the adrenal cortex requires, at most, only very small trophic or permissive amounts of angiotensin II, which always are present because ACE inhibition never is complete. Excessive retention of K^+ is encountered only in patients taking supplemental K^+ , in patients with renal impairment, or in patients taking other medications that reduce K^+ excretion.

ACE inhibitors alone normalize blood pressure in approximately 50% of patients with mild to moderate hypertension. Ninety percent of patients with mild to moderate hypertension will be controlled by the combination of an ACE inhibitor and either a Ca^{2+} channel blocker, a β adrenergic receptor blocker, or a diuretic (Zusman, 1993). Diuretics in particular augment the antihypertensive response to ACE inhibitors by rendering the patient's blood pressure renin-dependent.

There is increasing evidence that ACE inhibitors are superior to other antihypertensive drugs in hypertensive patients with diabetes, in whom they improve endothelial function (O'Driscoll *et al.*, 1997) and reduce cardiovascular events more so than do Ca^{2+} channel blockers (Estacio *et al.*, 1998; Tatti *et al.*, 1998) or diuretics and β adrenergic receptor antagonists (Hansson *et al.*, 1999).

ACE Inhibitors in Left Ventricular Systolic Dysfunction (See Chapter 33). Left ventricular systolic dysfunction ranges from a modest, asymptomatic reduction in systolic performance to a severe impairment of left ventricular systolic function with New York Heart Association grade IV congestive heart failure. It is now clear that unless contraindicated, ACE inhibitors should be given to all patients with impaired left ventricular systolic function whether or not they have symptoms of overt heart failure.

Several large prospective, randomized, placebo-controlled clinical studies support the usefulness of ACE inhibitors in patients with varying degrees of left ventricular systolic dysfunction. These studies are summarized in Table 30–1 and are described in more detail in Chapter 33. Collectively, these studies demonstrate that inhibition of ACE in patients with systolic dysfunction prevents or delays the progression of heart failure, decreases the incidence of sudden death and myocardial infarction, decreases hospitalization, and improves quality of life. The more severe the ventricular dysfunction, the greater is the benefit from ACE inhibition.

Although the mechanisms by which ACE inhibitors improve outcome in patients with systolic dysfunction are not completely understood, the induction of a more favorable hemodynamic state most likely plays an important role. Inhibition of ACE commonly reduces afterload and systolic wall stress, and both cardiac output and cardiac index increase, as do indices of stroke work and stroke volume. In systolic dysfunction, angiotensin II decreases arterial compliance, and this is reversed by ACE inhibition (Lage *et al.*, 2002). Heart rate generally is reduced. Systemic blood pressure falls, sometimes steeply at the outset, but tends to return toward initial levels. Renovascular resistance falls sharply, and renal blood flow increases. Natriuresis occurs as a result of the improved renal hemodynamics, the reduced stimulus to the secretion of aldosterone by angiotensin II, and the diminished direct effects of angiotensin II on the kidney. The excess volume of body fluids contracts, which reduces venous return to the right side of the heart. A further reduction results from venodilation and an increased capacity of the venous bed. Venodilation is a somewhat unexpected effect of ACE inhibition because angiotensin II has little acute venoconstrictor activity. Nevertheless, long-term infusion of angiotensin II increases venous tone, perhaps by central or peripheral interactions with the sympathetic nervous system. The response to ACE inhibitors also involves reductions of pulmonary arterial pressure, pulmonary capillary wedge pressure, and left atrial and left ventricular filling volumes and pressures. Consequently, preload and diastolic wall stress are diminished. The better hemodynamic performance results in increased exercise tolerance and suppression of the sympathetic nervous system (Grassi *et al.*, 1997). Cerebral and coronary blood flows usually are well maintained, even when systemic blood pressure is reduced.

The beneficial effects of ACE inhibitors in systolic dysfunction also involve improvements in ventricular geometry. In heart failure, ACE inhibitors reduce ventric-

Summary of Clinical Trials with ACE Inhibitors in Heart Disease (Continued)

STUDY	REFERENCE	ACE INHIBITOR	PATIENT GROUP	OUTCOME	COMMENT
FAMIS	Borghi <i>et al.</i> , 1997	Fosinopril vs. placebo (<i>n</i> = 285)	MI	Decreased overall mortality and incidence of CHF	Early (<9 hours) initiation of treatment Treatment for 3 months
QUIET	Cashin-Hemphill <i>et al.</i> , 1999	Quinapril vs. placebo (<i>n</i> = 1750)	Undergoing angioplasty	No change in progression of atherosclerosis	Treatment for 3 years
ATLAS	Parker <i>et al.</i> , 1999	Low vs. high dose lisinopril (<i>n</i> = 3164)	NYHA II–IV CHF	Reduced hospitalization with high dose	Treatment for 39–58 months
APRES	Kjøller-Hansen <i>et al.</i> , 2000	Ramipril vs. placebo (<i>n</i> = 159)	Revascularization with moderate LV dysfunction	Reduced cardiac death, MI, or clinical CHF	Treatment for 33 months
HOPE	Heart Outcomes Prevention Study Investigators, 2000	Ramipril vs. placebo (<i>n</i> = 9297)	CAD or high risk for CVD without CHF	Decreased CVD death, MI, stroke, overall mortality	Treatment for 5 years
PEACE	Pfeffer <i>et al.</i> , 2001	Trandolapril vs. placebo (<i>n</i> = 8290)	CAD without CHF	In progress as of 02/04	Treatment for 5.2 years
HOPE	Arnold <i>et al.</i> , 2003	Ramipril vs. placebo (<i>n</i> = 9297)	CAD or high risk for CVD without CHF	Decreased rate of development of CHF	Treatment for 4.5 years
EUROPA	European Trial, 2003	Perindopril vs. placebo (<i>n</i> = 12,218)	CAD without CHF	Decreased CVD death and MI	Treatment for 4.2 years

ABBREVIATIONS: MI, myocardial infarction; CAD, coronary artery disease; CHF, congestive heart failure; CVD, cardiovascular disease; LV, left ventricular; NYHA, New York Heart Association; IV, intravenous administration.

ular dilation and tend to restore the heart to its normal elliptical shape. ACE inhibitors may reverse ventricular remodeling *via* changes in preload/afterload, by preventing the growth effects of angiotensin II on myocytes, and by attenuating cardiac fibrosis induced by angiotensin II and aldosterone. Aldosterone levels are elevated in heart failure, and aldosterone markedly increases ACE expression in cultured neonatal rat cardiac myocytes (Harada *et al.*, 2001).

Although the role of ACE inhibitors in left ventricular systolic dysfunction is firmly established, whether these drugs improve diastolic dysfunction is an important open question. Infusions of enalaprilat into the left coronary

arteries of patients with left ventricular hypertrophy significantly improve diastolic function (Friedrich *et al.*, 1994; Kyriakidis *et al.*, 1998).

ACE Inhibitors in Acute Myocardial Infarction. Several large prospective, randomized clinical studies involving thousands of patients (Table 30–1) provide convincing evidence that ACE inhibitors reduce overall mortality when treatment is begun during the peri-infarction period. The beneficial effects of ACE inhibitors in acute myocardial infarction are particularly large in hypertensive (Borghi *et al.*, 1999) and diabetic (Zuanetti *et al.*, 1997; Gustafsson *et al.*, 1999) patients. Unless contraindicated (*e.g.*, cardiogenic shock or severe hypotension), ACE inhibitors should be

started immediately during the acute phase of myocardial infarction and can be administered along with thrombolytics, aspirin, and β adrenergic receptor antagonists (ACE Inhibitor Myocardial Infarction Collaborative Group, 1998). After several weeks, ACE-inhibitor therapy should be re-evaluated. In high-risk patients (e.g., large infarct, systolic ventricular dysfunction), ACE inhibition should be continued long term.

ACE Inhibitors in Patients Who Are at High Risk of Cardiovascular Events. ACE inhibitors tilt the fibrinolytic balance toward a profibrinolytic state by reducing plasma levels of plasminogen activator inhibitor-1 (Vaughan *et al.*, 1997; Brown *et al.*, 1999) and improve endothelial vasomotor dysfunction in patients with coronary artery disease (Mancini *et al.*, 1996). The HOPE study demonstrated that patients at high risk of cardiovascular events benefited considerably from treatment with ACE inhibitors (Heart Outcomes Prevention Study Investigators, 2000). ACE inhibition significantly decreased the rate of myocardial infarction, stroke, and death in a broad range of patients who did not have left ventricular dysfunction but had evidence of vascular disease or diabetes and one other risk factor for cardiovascular disease. The EUROPA trial examined the effects of ACE inhibition in patients with coronary artery disease but without heart failure. Like the HOPE study, the EUROPA trial demonstrated that ACE inhibition reduced cardiovascular disease death and myocardial infarction (European Trial, 2003). The APRES study showed that the beneficial effects of ACE inhibition in patients at high risk of cardiovascular events were expressed even after coronary revascularization (Kjøller-Hansen *et al.*, 2000). Thus the HOPE, EUROPA, and APRES studies suggest that the use of ACE inhibitors should be expanded to the large population of patients at risk for ischemic cardiovascular events.

ACE Inhibitors in Chronic Renal Failure. Diabetes mellitus is the leading cause of renal disease. In patients with type 1 diabetes mellitus and diabetic nephropathy, captopril prevents or delays the progression of renal disease (Lewis *et al.*, 1993). Renoprotection in type 1 diabetes, as defined by changes in albumin excretion, also is observed with lisinopril (Euclid Study Group, 1997). The renoprotective effects of ACE inhibitors in type 1 diabetes is in part independent of blood pressure reduction. Specific renoprotection by ACE inhibitors is more difficult to demonstrate in type 2 diabetics, with some studies providing positive results (Ravid *et al.*, 1993, 1996, 1998), whereas others do not demonstrate blood pressure-independent renoprotection (Brenner and Zargobelny, 2003). In addition to attenuating diabetic nephropathy, ACE

inhibitors also may decrease retinopathy progression in type 1 diabetics (Chaturvedi *et al.*, 1998). ACE inhibitors also attenuate the progression of renal insufficiency in patients with a variety of nondiabetic nephropathies (Maschio *et al.*, 1996; GISEN Group, 1997; Ruggenenti *et al.*, 1998, 1999b; Kshirsagar *et al.*, 2000; Praga *et al.*, 2003) and may arrest the decline in GFR even in patients with severe renal disease (Ruggenenti *et al.*, 1999a).

Several mechanisms participate in the renal protection afforded by ACE inhibitors. Increased glomerular capillary pressure induces glomerular injury, and ACE inhibitors reduce this parameter both by decreasing arterial blood pressure and by dilating renal efferent arterioles. ACE inhibitors increase the permeability selectivity of the filtering membrane, thereby diminishing exposure of the mesangium to proteinaceous factors that may stimulate mesangial cell proliferation and matrix production, two processes that contribute to expansion of the mesangium in diabetic nephropathy. Since angiotensin II is a growth factor, reductions in the intrarenal levels of angiotensin II may further attenuate mesangial cell growth and matrix production.

ACE Inhibitors in Scleroderma Renal Crisis. Before the use of ACE inhibitors, patients with scleroderma renal crisis generally died within several weeks. ACE inhibitors have improved considerably this otherwise grim prognosis (Steen and Medsger, 1990).

Adverse Effects of ACE Inhibitors. Serious untoward reactions to ACE inhibitors are rare, and in general, ACE inhibitors are well tolerated. Metabolic side effects are not encountered during long-term therapy with ACE inhibitors. The drugs do not alter plasma concentrations of uric acid or Ca^{2+} and actually may improve insulin sensitivity in patients with insulin resistance and decrease cholesterol and lipoprotein(a) levels in proteinuric renal disease.

Hypotension. A steep fall in blood pressure may occur following the first dose of an ACE inhibitor in patients with elevated PRA. In this regard, care should be exercised in patients who are salt-depleted, in patients being treated with multiple antihypertensive drugs, and in patients who have congestive heart failure. In such situations, treatment should be initiated with very small doses of ACE inhibitors, or salt intake should be increased and diuretics withdrawn before beginning therapy.

Cough. In 5% to 20% of patients, ACE inhibitors induce a bothersome, dry cough; it usually is not dose-related, occurs more frequently in women than in men, usually develops between 1 week and 6 months after initiation of therapy, and sometimes requires cessation of therapy. This adverse effect may be mediated by the accumulation in the

lungs of bradykinin, substance P, and/or prostaglandins. Thromboxane antagonism (Malini *et al.*, 1997), aspirin (Tenenbaum *et al.*, 2000), and iron supplementation (Lee *et al.*, 2001) reduce cough induced by ACE inhibitors. Once ACE inhibitors are stopped, the cough disappears, usually within 4 days (Israili and Hall, 1992).

Hyperkalemia. Despite some reduction in the concentration of aldosterone, significant K⁺ retention is rarely encountered in patients with normal renal function who are not taking other drugs that cause K⁺ retention. However, ACE inhibitors may cause hyperkalemia in patients with renal insufficiency or in patients taking K⁺-sparing diuretics, K⁺ supplements, β adrenergic receptor blockers, or NSAIDs.

Acute Renal Failure. Angiotensin II, by constricting the efferent arteriole, helps to maintain adequate glomerular filtration when renal perfusion pressure is low. Consequently, inhibition of ACE can induce acute renal insufficiency in patients with bilateral renal artery stenosis, stenosis of the artery to a single remaining kidney, heart failure, or volume depletion owing to diarrhea or diuretics. Older patients with congestive heart failure are particularly susceptible to ACE inhibitor-induced acute renal failure. However, in nearly all patients who receive appropriate treatment, recovery of renal function occurs without sequelae (Wynckel *et al.*, 1998).

Fetopathic Potential. Although ACE inhibitors are not teratogenic during the early period of organogenesis (first trimester), continued administration of ACE inhibitors during the second and third trimesters can cause oligohydramnios, fetal calvarial hypoplasia, fetal pulmonary hypoplasia, fetal growth retardation, fetal death, neonatal anuria, and neonatal death. These fetopathic effects may be due in part to fetal hypotension. While ACE inhibitors are not contraindicated in women of reproductive age, *once pregnancy is diagnosed, it is imperative that ACE inhibitors be discontinued as soon as possible.* If necessary, an alternative antihypertensive regimen should be instituted. The fetus is not at risk of ACE inhibitor-induced pathology if ACE inhibitors are discontinued during the first trimester of pregnancy (Brent and Beckman, 1991).

Skin Rash. ACE inhibitors occasionally cause a maculopapular rash that may or may not itch. The rash may resolve spontaneously or may respond to a reduced dosage or a brief course of antihistamines. Although initially attributed to the presence of the sulfhydryl group in captopril, a rash also may occur with other ACE inhibitors, albeit less frequently.

Proteinuria. ACE inhibitors have been associated with proteinuria (more than 1 g/day); however, a causal relationship has been difficult to establish. In general, proteinuria is

not a contraindication for ACE inhibitors because ACE inhibitors are renoprotective in certain renal diseases associated with proteinuria, *e.g.*, diabetic nephropathy.

Angioedema. In 0.1% to 0.5% of patients, ACE inhibitors induce a rapid swelling in the nose, throat, mouth, glottis, larynx, lips, and/or tongue. This untoward effect, called *angioedema*, apparently is not dose-related, and if it occurs, it does so within the first week of therapy, usually within the first few hours after the initial dose. Airway obstruction and respiratory distress may lead to death. Although the mechanism of angioedema is unknown, it may involve accumulation of bradykinin, induction of tissue-specific autoantibodies, or inhibition of complement 1-esterase inhibitor. Once ACE inhibitors are stopped, angioedema disappears within hours; meanwhile, the patient's airway should be protected, and if necessary, epinephrine, an antihistamine, and/or a glucocorticoid should be administered (Israili and Hall, 1992). African-Americans have a 4.5 times greater risk of ACE inhibitor-induced angioedema than do Caucasians (Brown *et al.*, 1996). Although it is rare, angioedema of the intestine (visceral angioedema) also has been reported in association with ACE inhibitors. Visceral angioedema is characterized by emesis, watery diarrhea, and abdominal pain. Most cases of visceral angioedema occur in the absence of oropharyngeal edema, and because the symptoms are non-specific, diagnosis can be elusive.

Dysgeusia. An alteration in or loss of taste can occur in patients receiving ACE inhibitors. This adverse effect, which may occur more frequently with captopril, is reversible.

Neutropenia. Neutropenia is a rare but serious side effect of ACE inhibitors. Although the frequency of neutropenia is low, it occurs predominantly in hypertensive patients with collagen-vascular or renal parenchymal disease. If the serum creatinine concentration is 2 mg/dl or greater, the dose of ACE inhibitor should be kept low, and the patient should be counseled to seek medical evaluation if symptoms of neutropenia (*e.g.*, sore throat, fever) develop.

Glycosuria. An exceedingly rare and reversible side effect of ACE inhibitors is spillage of glucose into the urine in the absence of hyperglycemia (Cressman *et al.*, 1982). The mechanism is unknown.

Hepatotoxicity. Also exceedingly rare and reversible is hepatotoxicity, usually of the cholestatic variety (Hagley *et al.*, 1993). The mechanism is unknown.

Drug Interactions. Antacids may reduce the bioavailability of ACE inhibitors; capsaicin may worsen ACE inhibitor-induced cough; NSAIDs, including aspirin (Guazzi *et al.*, 1998), may reduce the antihypertensive

response to ACE inhibitors; and K⁺-sparing diuretics and K⁺ supplements may exacerbate ACE inhibitor-induced hyperkalemia. ACE inhibitors may increase plasma levels of digoxin and lithium and may increase hypersensitivity reactions to allopurinol.

NONPEPTIDE ANGIOTENSIN II RECEPTOR ANTAGONISTS

History. Attempts to develop therapeutically useful angiotensin II receptor antagonists date to the early 1970s, and these initial endeavors concentrated on angiotensin peptide analogs. Saralasin, 1-sarcosine, 8-isoleucine angiotensin II, and other 8-substituted angiotensins were potent angiotensin II receptor antagonists but were of no clinical value because of lack of oral bioavailability and because all peptide angiotensin II receptor antagonists expressed unacceptable partial agonist activity.

Although initial efforts to develop nonpeptide angiotensin-receptor antagonists were unsuccessful, a breakthrough came in the early 1980s with the issuance of patents on a series of imidazole-5-acetic acid derivatives that attenuated pressor responses to angiotensin II in rats. Two compounds described in the patents, S-8307 and S-8308, later were found to be highly specific, albeit very weak, nonpeptide angiotensin II receptor antagonists that were devoid of partial agonist activity (Wong *et al.*, 1988; Chiu *et al.*, 1988). In an instructive example of drug design, molecular modeling of these lead compounds gave rise to the hypothesis that their structures would have to be extended to mimic more closely the pharmacophore of angiotensin II (Figure 30-8A). Through an insightful series of stepwise modifications (Figure 30-8B), the orally active, potent, and selective nonpeptide AT₁-receptor antagonist *losartan* was developed (Timmermans *et al.*, 1993). Losartan was approved for clinical use in the United States in 1995. Since then, six additional AT₁-receptor antagonists (Figure 30-9) have been approved. AT₁-receptor antagonists approved in the United States are either biphenylmethyl derivatives or thienylmethylacrylic acid derivatives (Figure 30-9). Although these AT₁-receptor antagonists are devoid of partial agonist activity, nonpeptide AT₁-receptor agonists have been synthesized, and structural modifications as minor as a methyl group can transform a potent antagonist into an agonist (Perlman *et al.*, 1997).

Pharmacological Effects. The angiotensin II receptor blockers (ARBs) available for clinical use bind to the AT₁ receptor with high affinity and generally are more than 10,000-fold selective for the AT₁ receptor *versus* the AT₂ receptor. The rank-order affinity of the AT₁ receptor for ARBs is candesartan = omesartan > irbesartan = eprosartan > telmisartan = valsartan = EXP 3174 (the active metabolite of losartan) > losartan. Although binding of ARBs to the AT₁ receptor is competitive, the inhibition by ARBs of biological responses to angiotensin II often is insurmountable; *i.e.*, the maximal response to angiotensin II cannot be restored in the presence of the ARB regard-

less of the concentration of angiotensin II added to the experimental preparation. Of the currently available ARBs, candesartan suppresses the maximal response to angiotensin II the most, whereas insurmountable blockade by irbesartan, eprosartan, telmisartan, and valsartan is less. Although losartan antagonism is surmountable, its active metabolite, EXP 3174, causes some degree of insurmountable blockade. The mechanism of insurmountable antagonism by ARBs may be due to slow dissociation kinetics of the compounds from the AT₁ receptor; however, a number of other factors may contribute, such as ARB-induced receptor internalization and alternative binding sites for ARBs on the AT₁ receptor (McConaughy *et al.*, 1999). Regardless of the mechanism, insurmountable antagonism has the theoretical advantage of sustained receptor blockade even with increased levels of endogenous ligand and with missed doses of drug. Whether this theoretical advantage translates into an enhanced clinical performance remains to be determined.

The pharmacology of ARBs is well described (Timmermans *et al.*, 1993; Csajka *et al.*, 1997). ARBs potently and selectively inhibit, both *in vitro* and *in vivo*, most of the biological effects of angiotensin II, including angiotensin II-induced (1) contraction of vascular smooth muscle, (2) rapid pressor responses, (3) slow pressor responses, (4) thirst, (5) vasopressin release, (6) aldosterone secretion, (7) release of adrenal catecholamines, (8) enhancement of noradrenergic neurotransmission, (9) increases in sympathetic tone, (10) changes in renal function, and (11) cellular hypertrophy and hyperplasia. ARBs reduce arterial blood pressure in animals with renovascular and genetic hypertension, as well as in transgenic animals overexpressing the renin gene. ARBs, however, have little effect on arterial blood pressure in animals with low-renin hypertension (*e.g.*, rats with hypertension induced by NaCl and deoxycorticosterone).

A critical issue is whether or not ARBs are equivalent to ACE inhibitors with regard to therapeutic efficacy. Although both classes of drugs block the renin-angiotensin system, ARBs differ from ACE inhibitors in several important aspects: (1) *ARBs reduce activation of AT₁ receptors more effectively than do ACE inhibitors.* ACE inhibitors reduce the biosynthesis of angiotensin II produced by the action of ACE on angiotensin I but do not inhibit alternative non-ACE angiotensin II-generating pathways. Because ARBs block the AT₁ receptor, the actions of angiotensin II *via* the AT₁ receptor are inhibited regardless of the biochemical pathway leading to angiotensin II formation. (2) In contrast to ACE inhibitors, *ARBs permit activation of AT₂ receptors.* ACE inhibitors increase renin release; however, because ACE inhibitors

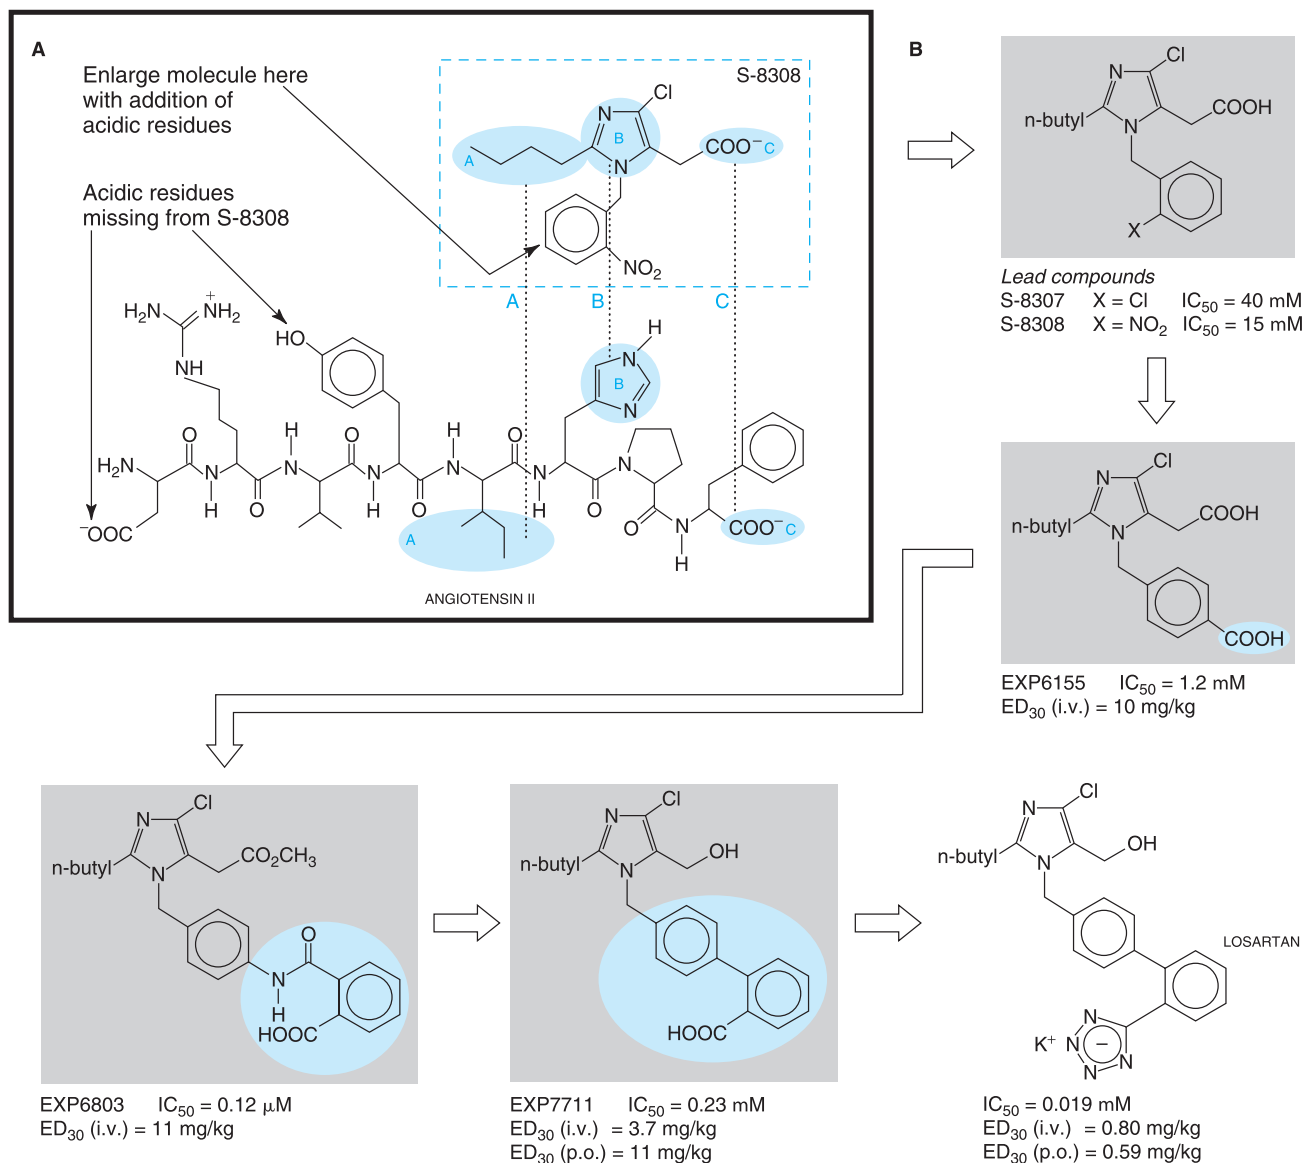

Figure 30-8. A. Hypothesized relationship between S-8308 (Takeda lead compound) and angiotensin II, and design strategies to enhance binding affinity of nonpeptide antagonists to the angiotensin II receptor. Letters indicate corresponding regions of S-8308 and angiotensin II. B. Pathway leading to the discovery of losartan. (Modified from Timmermans *et al.*, 1993, with permission.)

block the conversion of angiotensin I to angiotensin II, ACE inhibition is not associated with increased levels of angiotensin II. ARBs also stimulate renin release; however, with ARBs, this translates into a several-fold increase in circulating levels of angiotensin II. Because AT₂ receptors are not blocked by clinically available ARBs, this increased level of angiotensin II is available to activate AT₂ receptors. (3) *ACE inhibitors may increase angiotensin(1–7) levels more than do ARBs.* ACE is involved in the clearance of angiotensin(1–7), so inhibition of ACE

may increase angiotensin(1–7) levels more so than do ARBs. (4) *ACE inhibitors increase the levels of a number of ACE substrates, including bradykinin and Ac-SDKP.* ACE is a nondiscriminating enzyme that processes an array of substrates; inhibiting ACE therefore increases the levels of ACE substrates and decreases the levels of their corresponding products. Whether the pharmacological differences between ARBs and ACE inhibitors result in significant differences in therapeutic outcomes is an open question.

excretion (67%). The plasma clearance of candesartan is affected by renal insufficiency but not by mild to moderate hepatic insufficiency. Candesartan cilexetil should be administered orally once or twice daily for a total daily dosage of 4 to 32 mg.

Eprosartan (TEVETEN). Peak plasma levels are obtained approximately 1 to 2 hours after oral administration, and the plasma half-life ranges from 5 to 9 hours. Eprosartan is metabolized in part to the glucuronide conjugate, and the parent compound and its glucuronide conjugate are cleared by renal elimination and biliary excretion. The plasma clearance of eprosartan is affected by both renal insufficiency and hepatic insufficiency. The recommended dosage of eprosartan is 400 to 800 mg/day in one or two doses.

Irbesartan (AVAPRO). Peak plasma levels are obtained approximately 1.5 to 2 hours after oral administration, and the plasma half-life ranges from 11 to 15 hours. Irbesartan is metabolized in part to the glucuronide conjugate, and the parent compound and its glucuronide conjugate are cleared by renal elimination (20%) and biliary excretion (80%). The plasma clearance of irbesartan is unaffected by either renal or mild to moderate hepatic insufficiency. The oral dosage of irbesartan is 150 to 300 mg once daily.

Losartan (COZAAR). Approximately 14% of an oral dose of losartan is converted to the 5-carboxylic acid metabolite EXP 3174, which is more potent than losartan as an AT₁-receptor antagonist. The metabolism of losartan to EXP 3174 and to inactive metabolites is mediated by CYP2C9 and CYP3A4. Peak plasma levels of losartan and EXP 3174 occur approximately 1 to 3 hours after oral administration, respectively, and the plasma half-lives are 2.5 and 6 to 9 hours, respectively. The plasma clearances of losartan and EXP 3174 (600 and 50 ml/min, respectively) are due to renal clearance (75 and 25 ml/min, respectively) and hepatic clearance (metabolism and biliary excretion). The plasma clearance of losartan and EXP 3174 is affected by hepatic but not renal insufficiency. Losartan should be administered orally once or twice daily for a total daily dose of 25 to 100 mg. In addition to being an ARB, losartan is a competitive antagonist of the thromboxane A₂ receptor and attenuates platelet aggregation (Levy *et al.*, 2000). Also, EXP3179, an active metabolite of losartan, reduces COX-2 mRNA up-regulation and COX-dependent prostaglandin generation (Krämer *et al.*, 2002).

Olmesartan Medoxomil (BENICAR). Olmesartan medoxomil is an inactive ester prodrug that is completely hydrolyzed to the active form, olmesartan, during absorption from the gastrointestinal tract. Peak plasma

levels are obtained 1.4 to 2.8 hours after oral administration, and the plasma half-life is between 10 and 15 hours. Plasma clearance of olmesartan is due to both renal elimination and biliary excretion. Although renal impairment and hepatic disease decrease the plasma clearance of olmesartan, no dose adjustment is required in patients with mild to moderate renal or hepatic impairment. The oral dosage of olmesartan medoxomil is 20 to 40 mg once daily.

Telmisartan (MICARDIS). Peak plasma levels are obtained approximately 0.5 to 1 hour after oral administration, and the plasma half-life is about 24 hours. Telmisartan is cleared from the circulation mainly by biliary secretion of intact drug. The plasma clearance of telmisartan is affected by hepatic but not renal insufficiency. The recommended oral dosage of telmisartan is 40 to 80 mg once daily.

Valsartan (DIOVAN). Peak plasma levels occur approximately 2 to 4 hours after oral administration, and the plasma half-life is about 9 hours. Food markedly decreases absorption. Valsartan is cleared from the circulation by the liver (about 70% of total clearance). The plasma clearance of valsartan is affected by hepatic but not renal insufficiency. The oral dosage of valsartan is 80 to 320 mg once daily.

Therapeutic Uses of Angiotensin II-Receptor Antagonists. All ARBs are approved for the treatment of hypertension. In addition, irbesartan and losartan are approved for diabetic nephropathy, losartan is approved for stroke prophylaxis, and valsartan is approved for heart failure patients who are intolerant of ACE inhibitors. The efficacy of ARBs in lowering blood pressure is comparable with that of other established antihypertensive drugs, with an adverse-effect profile similar to that of placebo (Mimran *et al.*, 1999). ARBs also are available as fixed-dose combinations with hydrochlorothiazide.

Losartan is well tolerated in patients with heart failure and is comparable to enalapril with regard to improving exercise tolerance (Lang *et al.*, 1997). The Evaluation of Losartan in the Elderly (ELITE) study reported that in elderly patients with heart failure, losartan was as effective as captopril in improving symptoms and reduced mortality more than did captopril (Pitt *et al.*, 1997). However, the greater reduction in mortality by losartan was not confirmed in the larger Losartan Heart Failure Survival Study (ELITE II) trial (Pitt *et al.*, 2000); in fact, captopril tended to have a more favorable effect on several outcome measures. The results of the OPTIMAAL trial support the conclusions of the ELITE II study favoring captopril over losartan (Dickstein *et al.*, 2002). However, the Valsartan in

Acute Myocardial Infarction (VALIANT) trial demonstrated that valsartan is as effective as captopril in patients with myocardial infarction complicated by left ventricular systolic dysfunction with regard to all-cause-mortality (Pfeffer *et al.*, 2003a). Both valsartan and candesartan reduce mortality and morbidity in heart failure patients (Cohn *et al.*, 2001; Maggioni *et al.*, 2002; Pfeffer *et al.*, 2003a, 2003b; Granger *et al.*, 2003). Current recommendations are to use ACE inhibitors as first-line agents for the treatment of heart failure and to reserve ARBs for treatment of heart failure in patients who cannot tolerate or have an unsatisfactory response to ACE inhibitors. At present, there is conflicting evidence regarding the advisability of combining an ARB and an ACE inhibitor in heart failure patients (Pfeffer *et al.*, 2003a; McMurray *et al.*, 2003).

In part *via* blood pressure-independent mechanisms, ARBs are renoprotective in type 2 diabetes mellitus (Brenner *et al.*, 2001; Lewis *et al.*, 2001; Parving *et al.*, 2001; Viberti *et al.*, 2002). Based on these results, many experts now consider them the drugs of choice for renoprotection in diabetic patients. The Losartan Intervention For Endpoint (LIFE) Reduction in Hypertension Study demonstrated the superiority of an ARB compared with a β_1 adrenergic receptor antagonist with regard to reducing stroke in hypertensive patients with left ventricular hypertrophy (Dahlöf *et al.*, 2002). Also, irebesartan appears to maintain sinus rhythm in patients with persistent, long-standing atrial fibrillation (Madrid *et al.*, 2002). Losartan is reported to be safe and highly effective in the treatment of portal hypertension in patients with cirrhosis and portal hypertension (Schneider *et al.*, 1999) without compromising renal function.

Adverse Effects. The incidence of discontinuation of ARBs owing to adverse reactions is comparable with that of placebo. Unlike ACE inhibitors, ARBs do not cause cough, and the incidence of angioedema with ARBs is much less than with ACE inhibitors. As with ACE inhibitors, ARBs have teratogenic potential and should be discontinued before the second trimester of pregnancy. ARBs should be used cautiously in patients whose arterial blood pressure or renal function is highly dependent on the renin-angiotensin system (*e.g.*, renal artery stenosis). In such patients, ARBs can cause hypotension, oliguria, progressive azotemia, or acute renal failure. ARBs may cause hyperkalemia in patients with renal disease or in patients taking K^+ supplements or K^+ -sparing diuretics. ARBs enhance the blood pressure-lowering effect of other antihypertensive drugs, a desirable effect but one that may necessitate dosage adjustment.

TREATMENT OF MYOCARDIAL ISCHEMIA

Thomas Michel

PATHOPHYSIOLOGY OF ISCHEMIC HEART DISEASE

Angina pectoris, the primary symptom of ischemic heart disease, is caused by transient episodes of myocardial ischemia that are due to an imbalance in the myocardial oxygen supply–demand relationship. This imbalance may be caused by an increase in myocardial oxygen demand (which is determined by heart rate, ventricular contractility, and ventricular wall tension) or by a decrease in myocardial oxygen supply (primarily determined by coronary blood flow but occasionally modified by the oxygen-carrying capacity of the blood) or sometimes by both (Figure 31–1). Since blood flow is inversely proportional to the fourth power of the artery’s luminal radius, the progressive decrease in vessel radius that characterizes coronary atherosclerosis can impair coronary blood flow and lead to symptoms of angina when myocardial oxygen demand increases, as with exertion (so-called typical angina pectoris). In some patients, anginal symptoms may occur without any increase in myocardial oxygen demand but rather as a consequence of abrupt reduction in blood flow, as might result from coronary thrombosis (unstable angina) or vasospasm (variant or Prinzmetal angina). Regardless of the precipitating factors, the sensation of angina is similar in most patients. Typical angina is experienced as a heavy, pressing substernal discomfort (rarely called “pain”), often radiating to the left shoulder, flexor aspect of the left arm, jaw, or epigastrium. However, a significant minority of patients notes discomfort in a different location or of a different character. Women, the elderly, and diabetics are more likely to have ischemia with atypical symptoms. In most patients with typical angina, whose symptoms are provoked by exertion, the symptoms are relieved by rest or by administration of sublingual *nitroglycerin*.

Angina pectoris is a common symptom, affecting more than 6 million Americans (Gibbons *et al.*, 2002). Angina pectoris may occur in a stable pattern over many years or may become unstable, increasing in frequency or severity and even occurring at rest. In typical stable angina, the pathological substrate is usually fixed atherosclerotic narrowing of an epicardial coronary artery, on which exertion or emotional stress superimposes an increase in myocardial oxygen consumption. In variant angina, focal or diffuse coronary vasospasm episodically reduces coronary flow. Patients also may display a mixed pattern of angina with the addition of altered vessel tone on a background of atherosclerotic narrowing. In most patients with unstable angina, rupture of an atherosclerotic plaque, with consequent platelet adhesion and aggregation, decreases coronary blood flow. Plaques with thinner fibrous caps are more “vulnerable” to rupture.

Myocardial ischemia also may be *silent*, with electrocardiographic, echocardiographic, or radionuclide evidence of ischemia appearing in the absence of symptoms. While some patients have only silent ischemia, most patients who have silent ischemia have symptomatic episodes as well. The precipitants of silent ischemia appear to be the same as those of symptomatic ischemia. We now know that the *ischemic burden*, *i.e.*, the total time a patient is ischemic each day, is greater in many patients than was recognized previously. In most trials, the agents that are efficacious in conventional angina are also efficacious in reducing silent ischemia. β Adrenergic receptor antagonists appear to be more effective than the Ca^{2+} channel blockers in the prevention of episodes. Therapy directed at abolishing all silent ischemia has not been shown to be of additional benefit over conventional therapy.

This chapter describes the pharmacological agents used in the treatment of angina. The major drugs are nitrovasodilators (*see* Chapter 33), β adrenergic receptor antagonists (*see* Chapter 10), Ca^{2+} channel antagonists (*see* Chapter 32), and in both stable and unstable angina, antiplatelet agents (*see* Chapters 26 and 54) as well as statins (HMG CoA-reductase inhibitors) (*see* Chapter 35), which may have a role in stabilizing the vulnerable plaque. All approved antianginal agents improve the balance of myocardial oxygen supply and demand, increasing supply by dilating the coronary vasculature or decreasing demand by

Figure 31–1. Pharmacological modification of the major determinants of myocardial O₂ supply. When myocardial O₂ requirements exceed O₂ supply, an ischemic episode results. This figure shows the primary hemodynamic sites of actions of pharmacological agents that can reduce O₂ demand (*left side*) or enhance O₂ supply (*right side*). Some classes of agents have multiple effects (*see text*). Stents, angioplasty, and coronary bypass surgery are mechanical interventions that increase O₂ supply. Both pharmacotherapy and mechanotherapy attempt to restore a dynamic balance between O₂ demand and O₂ supply.

reducing cardiac work (Figure 31–1). Increasing the cardiac extraction of oxygen from the blood is not a practical therapeutic goal. Drugs used in typical angina function principally by reducing myocardial oxygen demand by decreasing heart rate, myocardial contractility, and/or ventricular wall stress. By contrast, the principal therapeutic goal in unstable angina is to increase myocardial blood flow; strategies include the use of antiplatelet agents and *heparin* to reduce intracoronary thrombosis and coronary stents or coronary bypass surgery to restore flow by mechanical means. The therapeutic aim in variant or Prinzmetal angina is to prevent coronary vasospasm.

Antianginal agents may provide prophylactic or symptomatic treatment, but β adrenergic receptor antagonists also reduce mortality apparently by decreasing the incidence of sudden cardiac death associated with myocardial ischemia and infarction. The treatment of cardiac risk factors can reduce the progression or even lead to the regression of atherosclerosis. *Aspirin* is used routinely in patients with myocardial ischemia, and daily aspirin use reduces the incidence of clinical events (Gibbons *et al.*, 2002; Libby *et al.*, 2002). Other antiplatelet agents such as oral *clopidogrel* and intravenous anti-integrin drugs such as *abciximab*, *tirofiban*, and *eptifibatid* have been shown to reduce morbidity in patients with angina who undergo coronary artery stenting (Yeghizarians *et al.*, 2000). Lipid-lowering drugs such as the statins reduce mortality in patients with hypercholesterolemia with or without known coronary artery disease (Libby *et al.*, 2002). Angiotensin-converting enzyme (ACE) inhibitors (*see Chapter 29*) also reduce mortality in patients with coronary disease (Yusuf *et al.*, 2000). Coronary artery bypass surgery and percutaneous coronary interventions such as angioplasty and coronary artery stent deployment can complement pharmacological treatment. In some subsets of patients, percutaneous or surgical revascularization may have a survival advantage over medical treatment

alone. Intracoronary drug delivery using drug-eluting coronary stents represents an intersection of mechanical and pharmacological approaches in the treatment of coronary artery disease. Novel therapies that modify the expression of vascular or myocardial cell genes eventually may become an important part of the therapy of ischemic heart disease.

ORGANIC NITRATES

These agents are prodrugs that are sources of nitric oxide (NO). NO activates the soluble isoform of guanylyl cyclase, thereby increasing intracellular levels of cyclic GMP. In turn, this promotes the dephosphorylation of the myosin light chain and the reduction of cystolic (Ca²⁺) and leads to the relaxation of smooth muscle cells in a broad range of tissues. The NO-dependent relaxation of vascular smooth muscle leads to vasodilation; NO-mediated guanylyl cyclase activation inhibits platelet aggregation and relaxes smooth muscle in the bronchi and gastrointestinal (GI) tract (Murad, 1996; Molina *et al.*, 1987; Thadani, 1992).

The broad biological response to nitrovasodilators suggests the existence of endogenous NO-modulated regulatory pathways; more than a century after the therapeutic use of nitrovasodilators, the enzymes responsible for endogenous NO synthesis were isolated and characterized. The endogenous synthesis of NO in humans is catalyzed by a family of NO synthases that oxidize the amino acid L-arginine to form NO (plus L-citrulline as a coproduct). There are three distinct mammalian NO synthase isoforms termed *nNOS*, *eNOS*, and *iNOS* (*see Chapter 1*), and they are involved in processes as diverse as neurotransmission, vasomotion, and immunomodulation (Lowenstein *et al.*, 1994). In several vascular disease states, pathways of endogenous NO-dependent reg-

ulation appear to be deranged (reviewed in Dudzinski *et al.*, 2005).

History. Nitroglycerin was first synthesized in 1846 by Sobrero, who observed that a small quantity placed on the tongue elicited a severe headache. In 1857, T. Lauder Brunton of Edinburgh administered *amyl nitrite*, a known vasodepressor, by inhalation and noted that anginal pain was relieved within 30 to 60 seconds. The action of amyl nitrite was transitory, however, and the dosage was difficult to adjust. Subsequently, William Murrell surmised that the action of nitroglycerin mimicked that of amyl nitrite and established the use of sublingual nitroglycerin for relief of the acute anginal attack and as a prophylactic agent to be taken prior to exertion. The empirical observation that organic nitrates could dramatically and safely alleviate the symptoms of angina pectoris led to their widespread acceptance by the medical profession. Basic investigations defined the role of NO in both the vasodilation produced by nitrates and endogenous vasodilation. The importance of NO as a signaling molecule in the cardiovascular system and elsewhere was recognized by the awarding of the 1998 Nobel Prize in medicine/physiology to Robert Furchgott, Louis Ignarro, and Ferid Murad.

Chemistry. Organic nitrates are polyol esters of nitric acid, whereas organic nitrites are esters of nitrous acid (Table 31-1). Nitrate esters (—C—O—NO_2) and nitrite esters (—C—O—NO) are characterized by a sequence of carbon–oxygen–nitrogen, whereas nitro compounds possess carbon–nitrogen bonds (C—NO_2). Thus *glyceryl trinitrate* is not a nitro compound, and it is erroneously called *nitroglycerin*; however, this nomenclature is both widespread and official. Amyl nitrite is a highly volatile liquid that must be administered by inhalation and is of limited therapeutic utility. Organic nitrates of low molecular mass (such as nitroglycerin) are moderately volatile, oily liquids, whereas the high-molecular-mass nitrate esters (*e.g.*, *erythryl tetranitrate*, *isosorbide dinitrate*, and *isosorbide mononitrate*) are solids. In the pure form (without an inert carrier such as lactose), nitroglycerin is explosive. The organic nitrates and nitrites, collectively termed *nitrovasodilators*, must be metabolized (reduced) to produce NO, the active principle of this class of compounds.

Pharmacological Properties

Mechanism of Action. Nitrites, organic nitrates, nitroso compounds, and a variety of other nitrogen oxide-containing substances (including *nitroprusside*; see Chapter 32) lead to the formation of the reactive free radical NO. The exact mechanism(s) of denitration of the organic nitrates to liberate NO remains an active area of investigation (Chen *et al.*, 2002). NO can activate guanylyl cyclase, increase the cellular level of cyclic GMP, activate PKG (the cyclic GMP-dependent protein kinase), and modulate the activities of cyclic nucleotide phosphodiesterases (PDEs 2, 3, and 5) in a variety of cell types. In smooth muscle, the net result is reduced phosphorylation of myosin light chain, reduced Ca^{2+} concentration in the cytosol, and relaxation. One important consequence of the NO-mediated increase in intracellular cyclic GMP is the activation of PKG, which catalyzes the phosphorylation

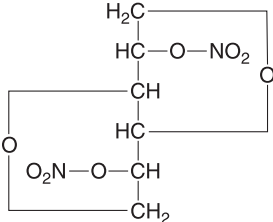

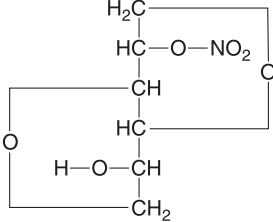

of various proteins in smooth muscle. Another important target of this kinase is the myosin light-chain phosphatase, which is activated on binding PKG (Surks *et al.*, 1999) and leads to dephosphorylation of the myosin light chain and thereby promotes vasorelaxation (Waldman and Murad, 1987). Phosphorylation of the myosin light chain regulates the maintenance of the contractile state in smooth muscle. The pharmacological and biochemical effects of the nitrovasodilators appear to be identical to those of an endothelium-derived relaxing factor now known to be NO (Ignarro *et al.*, 1987; Murad, 1996; Furchgott, 1996). Although the soluble isoform of guanylyl cyclase remains the most extensively characterized molecular “receptor” for NO, it is increasingly clear that NO also forms specific adducts with thiol groups in proteins and with reduced glutathione to form nitrosothiol compounds with distinctive biological properties (Stamler *et al.*, 2001). The enzyme mitochondrial aldehyde dehydrogenase has been shown to catalyze the reduction of nitroglycerin to yield bioactive NO metabolites (Chen *et al.*, 2002), providing a potentially important clue to the biotransformation of organic nitrates in intact tissues. The regulation and pharmacology of eNOS have been reviewed recently (Dudzinski *et al.*, 2005).

Cardiovascular Effects. Hemodynamic Effects. The nitrovasodilators promote vascular smooth muscle relaxation. Low concentrations of nitroglycerin preferentially dilate the veins more than the arterioles. This venodilation decreases left and right ventricular chamber size and end-diastolic pressures but results in little change in systemic vascular resistance. Systemic arterial pressure may fall slightly, and heart rate is unchanged or may increase slightly in response to a decrease in blood pressure. Pulmonary vascular resistance and cardiac output are slightly reduced. Doses of nitroglycerin that do not alter systemic arterial pressure often produce arteriolar dilation in the face and neck, resulting in a flush, or dilation of meningeal arterial vessels, causing headache. The molecular basis for the differential response of arterial *versus* venous tissues to nitroglycerin remains incompletely understood; venous smooth muscle may be enriched in the enzyme that converts nitroglycerin to NO compared with arterial smooth muscle (Bauer and Fung, 1996).

Higher doses of organic nitrates cause further venous pooling and may decrease arteriolar resistance as well, thereby decreasing systolic and diastolic blood pressure and cardiac output and causing pallor, weakness, dizziness, and activation of compensatory sympathetic reflexes. The reflex tachycardia and peripheral arteriolar vasoconstriction tend to restore systemic vascular resistance;

Table 31-1

Organic Nitrates Available for Clinical Use

NONPROPRIETARY NAMES AND TRADE NAMES	CHEMICAL STRUCTURE	PREPARATIONS, USUAL DOSES, AND ROUTES OF ADMINISTRATION*
Nitroglycerin (glyceryl trinitrate; NITRO-BID, NITROSTAT, NITROL, NITRO-DUR, others)	$\begin{array}{c} \text{H}_2\text{C}-\text{O}-\text{NO}_2 \\ \\ \text{HC}-\text{O}-\text{NO}_2 \\ \\ \text{H}_2\text{C}-\text{O}-\text{NO}_2 \end{array}$	T: 0.3 to 0.6 mg as needed S: 0.4 mg per spray as needed C: 2.5 to 9 mg two to four times daily B: 1 mg every 3 to 5 h O: 2.5 to 5 cm, topically to skin every 4 to 8 h D: 1 disc (2.5 to 15 mg) for 12 to 16 h per day IV: 10–20 $\mu\text{g}/\text{min}$; increments of 10 $\mu\text{g}/\text{min}$ to a maximum of 400 $\mu\text{g}/\text{min}$
Isosorbide dinitrate (ISORDIL, SORBITRATE, DILATRATE-SR, others)		T: 2.5 to 10 mg every 2 to 3 h T(C): 5 to 10 mg every 2 to 3 h T(O): 5 to 40 mg every 8 h C: 40 to 80 mg every 12 h
Isosorbide-5-mononitrate (IMDUR, ISMO, others)		T: 10 to 40 mg twice daily C: 60 to 120 mg daily

*B, buccal (transmucosal) tablet; C, sustained-release capsule or tablet; D, transdermal disc or patch; Inh, inhalant; IV, intravenous injection; O, ointment; S, lingual spray; T, tablet for sublingual use; T(C), chewable tablet; T(O), oral tablet or capsule.

this is superimposed on sustained venous pooling. Coronary blood flow may increase transiently as a result of coronary vasodilation but may decrease subsequently if cardiac output and blood pressure decrease sufficiently.

In patients with autonomic dysfunction and an inability to increase sympathetic outflow (multiple-system atrophy and pure autonomic failure are the most common forms, much less commonly seen in the autonomic dysfunction associated with diabetes), the fall in blood pressure consequent to the venodilation produced by nitrates cannot be compensated. In these clinical contexts, nitrates may reduce arterial pressure and coronary perfusion pressure significantly, producing potentially life-threatening hypotension and even aggravating angina. The appropriate therapy in patients with orthostatic angina and normal coronary arteries is to correct the orthostatic hypotension by

expanding volume (*fludrocortisone* and a high-sodium diet), to prevent venous pooling with fitted support garments, and to carefully titrate use of oral vasopressors. Since patients with autonomic dysfunction occasionally may have coexisting coronary artery disease, the coronary anatomy should be defined before therapy is undertaken.

Effects on Total and Regional Coronary Blood Flow. Ischemia is a powerful stimulus to coronary vasodilation, and regional blood flow is adjusted by autoregulatory mechanisms. In the presence of atherosclerotic coronary artery narrowing, ischemia distal to the lesion stimulates vasodilation; if the stenosis is severe, much of the capacity to dilate is used to maintain resting blood flow. When demand increases, further dilation may not be possible. After demonstration of direct coronary artery vasodilation in experimental animals, it became generally accepted that

nitrates relieved anginal pain by dilating coronary arteries and thereby increasing coronary blood flow. In the presence of significant coronary stenoses, there is a disproportionate reduction in blood flow to the subendocardial regions of the heart, which are subjected to the greatest extravascular compression during systole; organic nitrates tend to restore blood flow in these regions toward normal.

The hemodynamic mechanisms responsible for these effects are not entirely clear. Most hypotheses have focused on the ability of organic nitrates to cause dilation and prevent vasoconstriction of large epicardial vessels without impairing autoregulation in the small vessels, which are responsible for about 90% of the overall coronary vascular resistance. The vessel diameter is an important determinant of the response to nitroglycerin; vessels larger than 200 μm in diameter are highly responsive, whereas those less than 100 μm respond minimally (Sellke *et al.*, 1990). Experimental evidence in patients undergoing coronary bypass surgery indicates that nitrates do have a relaxant effect on large coronary vessels. Collateral flow to ischemic regions also is increased. Moreover, analyses of coronary angiograms in humans have shown that sublingual nitroglycerin can dilate epicardial stenoses and reduce the resistance to flow through such areas (Brown *et al.*, 1981; Feldman *et al.*, 1981). The resulting increase in blood flow would be distributed preferentially to ischemic myocardial regions as a consequence of vasodilation induced by autoregulation. An important indirect mechanism for a preferential increase in subendocardial blood flow is the nitroglycerin-induced reduction in intracavitary systolic and diastolic pressures that oppose blood flow to the subendocardium (*see below*). To the extent that organic nitrates decrease myocardial requirements for oxygen (*see below*), the increased blood flow in ischemic regions could be balanced by decreased flow in non-ischemic areas, and an overall increase in coronary artery blood flow need not occur. Dilation of cardiac veins may improve the perfusion of the coronary microcirculation. Such redistribution of blood flow to subendocardial tissue is *not* typical of all vasodilators. *Dipyridamole*, for example, dilates resistance vessels nonselectively by distorting autoregulation and is ineffective in patients with typical angina.

In patients with angina owing to coronary artery spasm, the ability of organic nitrates to dilate epicardial coronary arteries, and particularly regions affected by spasm, may be the primary mechanism by which they are of benefit.

Effects on Myocardial Oxygen Requirements. By their effects on the systemic circulation, the organic nitrates also can reduce myocardial oxygen demand. The major determinants of myocardial oxygen consumption include left ventricular wall tension, heart rate, and myocardial contractility. Ventricular wall tension is affected by a number of factors that may be considered under the categories of preload and afterload. *Preload* is determined by the diastolic pressure that distends the ventricle (ventricular end-diastolic pressure). Increasing end-diastolic volume augments the ventricular wall tension (by the law of Laplace, tension is proportional to pressure times radius). Increasing venous capacitance with nitrates decreases

venous return to the heart, decreases ventricular end-diastolic volume, and thereby decreases oxygen consumption. An additional benefit of reducing preload is that it increases the pressure gradient for perfusion across the ventricular wall, which favors subendocardial perfusion. *Afterload* is the impedance against which the ventricle must eject. In the absence of aortic valvular disease, afterload is related to peripheral resistance. Decreasing peripheral arteriolar resistance reduces afterload and thus myocardial work and oxygen consumption.

Organic nitrates decrease both preload and afterload as a result of respective dilation of venous capacitance and arteriolar resistance vessels. They do not directly alter the inotropic or chronotropic state of the heart. Since nitrates reduce the primary determinants of oxygen demand, their net effect usually is to decrease myocardial oxygen consumption. In addition, an improvement in the lusitropic state of the heart may be seen with more rapid early diastolic filling (Brisblatt *et al.*, 1988). This may be secondary to the relief of ischemia rather than primary, or it may be due to a reflex increase in sympathetic activity. Nitrovasodilators also increase cyclic GMP in platelets, with consequent inhibition of platelet function (De Caterina *et al.*, 1988; Lacoste *et al.*, 1994) and decreased deposition of platelets in animal models of arterial wall injury (Lam *et al.*, 1988). While this may contribute to their antianginal efficacy, the effect appears to be modest and in some settings may be confounded by the potential of nitrates to alter the pharmacokinetics of heparin, reducing its antithrombotic effect.

When nitroglycerin is injected or infused directly into the coronary circulation of patients with coronary artery disease, anginal attacks (induced by electrical pacing) are not aborted even when coronary blood flow is increased. However, sublingual administration of nitroglycerin does relieve anginal pain in the same patients. Furthermore, venous phlebotomy that is sufficient to reduce left ventricular end-diastolic pressure can mimic the beneficial effect of nitroglycerin.

Patients are able to exercise for considerably longer periods after the administration of nitroglycerin. Nevertheless, with or without nitroglycerin, angina occurs at the same value of the *triple product* (aortic pressure \times heart rate \times ejection time, which is proportional to myocardial consumption of oxygen). The observation that angina occurs at the same level of myocardial oxygen consumption suggests that the beneficial effects of nitroglycerin result from reduced cardiac oxygen demand rather than an increase in the delivery of oxygen to ischemic regions of myocardium. However, these results do not preclude the possibility that a favorable redistribution of blood flow to ischemic subendocardial myocardium may contribute to relief of pain in a typical anginal attack, nor do they preclude the possibility that direct coronary vasodilation may be the major effect of nitroglycerin in situations where vasospasm compromises myocardial blood flow.

Mechanism of Relief of Symptoms of Angina Pectoris. The nitrate-induced relief of anginal pain has been ascribed to a decrease in cardiac work secondary to the fall in systemic arterial pressure. As described earlier, the ability of nitrates to dilate epicardial coronary arteries, even in areas of atherosclerotic stenosis, is modest, and

the bulk of evidence continues to favor a reduction in myocardial work, and thus in myocardial oxygen demand, as their primary effect in chronic stable angina.

Paradoxically, high doses of organic nitrates may reduce blood pressure to such an extent that coronary flow is compromised; reflex tachycardia and adrenergic enhancement of contractility also occur. These effects may override the beneficial action of the drugs on myocardial oxygen demand and can aggravate ischemia. Additionally, sublingual nitroglycerin administration may produce bradycardia and hypotension probably owing to activation of the Bezold-Jarisch reflex.

Other Effects. The nitrovasodilators act on almost all smooth muscle. Bronchial smooth muscle is relaxed irrespective of the cause of the preexisting tone. The muscles of the biliary tract, including those of the gallbladder, biliary ducts, and sphincter of Oddi, are effectively relaxed. Smooth muscle of the GI tract, including that of the esophagus, can be relaxed and its spontaneous motility decreased by nitrates both *in vivo* and *in vitro*. The effect may be transient and incomplete *in vivo*, but abnormal “spasm” frequently is reduced. Indeed, many incidences of atypical chest pain and “angina” are due to biliary or esophageal spasm, and these too can be relieved by nitrates. Similarly, nitrates can relax ureteral and uterine smooth muscle, but these responses are of uncertain clinical significance.

Absorption, Fate, and Excretion. More than a century after the first use of organic nitrates to treat angina pectoris, their biotransformation remains the subject of active investigation. Studies in the 1970s suggested that nitroglycerin is reductively hydrolyzed by hepatic glutathione–organic nitrate reductase. More recent studies have implicated a mitochondrial aldehyde dehydrogenase enzyme in the biotransformation of nitroglycerin (Chen *et al.*, 2002). Other enzymatic and nonenzymatic pathways also may contribute to the biotransformation of nitrovasodilators. Despite uncertainties about the quantitative importance of the various pathways involved in nitrovasodilator metabolism, the pharmacokinetic properties of nitroglycerin and isosorbide dinitrate have been studied in some detail (Parker and Parker, 1998).

Nitroglycerin. In humans, peak concentrations of nitroglycerin are found in plasma within 4 minutes of sublingual administration; the drug has a half-life of 1 to 3 minutes. The onset of action of nitroglycerin may be even more rapid if it is delivered as a sublingual spray rather than as a sublingual tablet. Dinitrate metabolites, which have about one-tenth the vasodilator potency, appear to have half-lives of approximately 40 minutes.

Isosorbide Dinitrate. The major route of metabolism of isosorbide dinitrate in humans appears to be by enzymatic denitration followed by glucuronide conjugation. Sublingual administration produces maximal plasma concentrations of the drug by 6 minutes, and the fall in concentration is rapid (half-life of approximately 45 minutes). The primary initial metabolites, isosorbide-2-mononitrate and isosorbide-5-mononitrate, have longer half-lives (3 to 6 hours) and are presumed to contribute to the therapeutic efficacy of the drug.

Isosorbide-5-Mononitrate. This agent is available in tablet form. It does not undergo significant first-pass metabolism and so has excellent bioavailability after oral administration. The mononitrate has a significantly longer half-life than does isosorbide dinitrate and has been formulated as a plain tablet and as a sustained-release preparation; both have longer durations of action than the corresponding dosage forms of isosorbide dinitrate.

Correlation of Plasma Concentrations of Drug and Biological Activity. Intravenous administration of nitroglycerin or long-acting organic nitrates in anesthetized animals produces the same transient (1 to 4 minutes) decrease in blood pressure. Since denitration markedly reduces the activity of the organic nitrates, their rapid clearance from blood indicates that the transient duration of action under these conditions correlates with the concentrations of the parent compounds. The rate of hepatic denitration is characteristic of each nitrate and is influenced by hepatic blood flow or the presence of hepatic disease. In experimental animals, injection of moderate amounts of organic nitrates into the portal vein results in little or no vasodepressor activity, indicating that a substantial fraction of drug can be inactivated by first-pass metabolism in the liver (isosorbide mononitrate is an exception).

Tolerance

Sublingual organic nitrates should be taken at the time of an anginal attack or in anticipation of exercise or stress. Such intermittent treatment provides reproducible cardiovascular effects. However, frequently repeated or continuous exposure to high doses of organic nitrates leads to a marked attenuation in the magnitude of most of their pharmacological effects (Thadani, 1994). The magnitude of tolerance is a function of dosage and frequency of use.

Tolerance may result from a reduced capacity of the vascular smooth muscle to convert nitroglycerin to NO, *true vascular tolerance*, or to the activation of mechanisms extraneous to the vessel wall, *pseudotolerance* (Münzel *et al.*, 1996). Multiple mechanisms have been proposed to account for nitrate tolerance, including volume expansion, neurohumoral activation, cellular depletion of sulfhydryl groups, and the generation of free radicals (Thadani, 1994; Rutherford, 1995; Parker and Parker, 1998). Inactivation of mitochondrial aldehyde dehydrogenase, an enzyme implicated in biotransformation of nitroglycerin, is seen in models of nitrate tolerance (Sydow *et al.*, 2004), potentially associated with oxidative stress (Parker, 2004). A reactive intermediate formed during the generation of NO from organic nitrates may itself damage and inactivate the enzymes of the activation pathway; tolerance could involve endothelium-derived superoxide (Münzel *et al.*, 1995). Clinical data relating to the ability of agents that modify the renin–angiotensin–aldosterone system to prevent nitrate tolerance are contradictory (Parker and Parker, 1998). Important to the interpretation of clinical trials, factors that may influence the ability

of such modification to prevent nitrate tolerance include the dose, whether the ACE inhibitors or angiotensin-receptor antagonists were administered prior to the initiation of nitrates, and the tissue specificity of the agent. Despite experimental evidence that depletion of sulfhydryl groups may lead to impaired biotransformation of nitrates to NO and thereby result in nitrate tolerance, experimental results to date with sulfhydryl donors have been disappointing. Other changes that are observed in the setting of nitroglycerin tolerance include an enhanced response to vasoconstrictors such as angiotensin II, serotonin, and phenylephrine. Administration of nitroglycerin is associated with plasma volume expansion, which may be reflected by a decrease in hematocrit. Although diuretic therapy with *hydrochlorothiazide* can improve a patient's exercise duration, appropriately designed crossover trials have failed to demonstrate an effect of diuretics on nitrate tolerance (Parker *et al.*, 1996).

A more effective approach to restoring responsiveness is to interrupt therapy for 8 to 12 hours each day, which allows the return of efficacy. It is usually most convenient to omit dosing at night in patients with exertional angina either by adjusting dosing intervals of oral or buccal preparations or by removing cutaneous nitroglycerin. However, patients whose anginal pattern suggests its precipitation by increased left ventricular filling pressures (*i.e.*, occurring in association with orthopnea or paroxysmal nocturnal dyspnea) may benefit from continuing nitrates at night and omitting them during a quiet period of the day. Tolerance also has been seen with *isosorbide-5-mononitrate*; an eccentric twice-daily dosing schedule appears to maintain efficacy (Parker and Parker, 1998; Thadani *et al.*, 1992).

While these approaches appear to be effective, some patients develop an increased frequency of nocturnal angina when a nitrate-free interval is employed using nitroglycerin patches; such patients may require another class of antianginal agent during this period. Tolerance is not universal, and some patients develop only partial tolerance. The problem of anginal rebound during nitrate-free intervals is especially problematic in the treatment of unstable angina with intravenous nitroglycerin. As tolerance develops, increasing doses are required to achieve the same therapeutic effects; eventually, despite dose escalation, the drug loses efficacy.

A special form of nitroglycerin tolerance is observed in individuals exposed to nitroglycerin in the manufacture of explosives. If protection is inadequate, workers may experience severe headaches, dizziness, and postural weakness during the first several days of employment. Tolerance then develops, but headache and other symptoms may reappear after a few days away from the job—the

“Monday disease.” The most serious effect of chronic exposure is a form of organic nitrate dependence. Workers without demonstrable organic vascular disease have been reported to have an increase in the incidence of acute coronary syndromes during the 24- to 72-hour periods away from the work environment (Parker *et al.*, 1995). Coronary and digital arteriospasm during withdrawal and its relaxation by nitroglycerin also have been demonstrated radiographically. Because of the potential problem of nitrate dependence, it seems prudent not to withdraw nitrates abruptly from a patient who has received such therapy chronically.

Toxicity and Untoward Responses

Untoward responses to the therapeutic use of organic nitrates are almost all secondary to actions on the cardiovascular system. Headache is common and can be severe. It usually decreases over a few days if treatment is continued and often can be controlled by decreasing the dose. Transient episodes of dizziness, weakness, and other manifestations associated with postural hypotension may develop, particularly if the patient is standing immobile, and may progress occasionally to loss of consciousness, a reaction that appears to be accentuated by *alcohol*. It also may be seen with very low doses of nitrates in patients with autonomic dysfunction. Even in severe nitrate syncope, positioning and other measures that facilitate venous return are the only therapeutic measures required. All the organic nitrates occasionally can produce drug rash.

Interaction of Nitrates with Phosphodiesterase 5 Inhibitors. Erectile dysfunction is a frequently encountered problem whose risk factors parallel those of coronary artery disease. Thus many men desiring therapy for erectile dysfunction already may be receiving (or may require, especially if they increase physical activity) antianginal therapy. The combination of *sildenafil* and other *phosphodiesterase 5* (PDE5) inhibitors with organic nitrate vasodilators can cause extreme hypotension.

Cells in the corpus cavernosum produce NO during sexual arousal in response to nonadrenergic, noncholinergic neurotransmission (Burnett *et al.*, 1992). NO stimulates the formation of cyclic GMP, which leads to relaxation of smooth muscle of the corpus cavernosum and penile arteries, engorgement of the corpus cavernosum, and erection. The accumulation of cyclic GMP can be enhanced by inhibition of the cyclic GMP-specific PDE5 family (Beavo *et al.*, 1994). *Sildenafil* (VIAGRA) and congeners inhibit PDE5 and have been demonstrated to improve erectile function in patients with erectile dysfunction (Goldstein *et al.*, 1998). Not surprisingly, PDE5 inhibitors have assumed the status of widely used recreational drugs. Since the introduction of *sildenafil*, two additional PDE5 inhibitors have been developed for use in therapy of erectile dysfunction. *Tadalafil* (CIALIS) and *vardenafil* (LEVITRA) share similar therapeutic efficacy and side-effect profiles with *sildenafil*; *tadalafil* has a longer time to onset of action and a longer therapeutic

half-life than the other PDE5 inhibitors. Sildenafil has been the most thoroughly characterized of these compounds, but all three PDE5 inhibitors are contraindicated for patients taking organic nitrate vasodilators or α adrenergic receptor antagonists (see Chapter 10).

The side effects of sildenafil and other PDE5 inhibitors are largely predictable on the basis of their effects on PDE5. Headache, flushing, and rhinitis may be observed, as may dyspepsia owing to relaxation of the lower esophageal sphincter. Sildenafil and vardenafil also weakly inhibit PDE6, the enzyme involved in photoreceptor signal transduction (Beavo *et al.*, 1994), and can produce visual disturbances, most notably changes in the perception of color hue or brightness (Wallis *et al.*, 1999). Tadalafil inhibits PDE11, a widely distributed phosphodiesterase isoform, but the clinical importance of this effect is not clear. The most important toxicity of all these PDE5 inhibitors is hemodynamic. When given alone to men with severe coronary artery disease, these drugs have modest effects on blood pressure, producing less than a 10% fall in systolic, diastolic, and mean systemic pressures and in pulmonary artery systolic and mean pressures (Herrmann *et al.*, 2000). However, sildenafil, tadalafil, and vardenafil all have a significant and potentially dangerous interaction with organic nitrates, the therapeutic actions of which are mediated *via* their conversion to NO with resulting increases in cyclic GMP. In the presence of a PDE5 inhibitor, nitrates cause profound increases in cyclic GMP and can produce dramatic reductions in blood pressure. Compared with controls, healthy male subjects pretreated with sildenafil or the other PDE5 inhibitors exhibit a much greater decrease in systolic blood pressure when treated with sublingual *glyceryl trinitrate*, and in many subjects a fall of more than 25 mmHg was detected (Webb *et al.*, 1999). This drug class toxicity is the basis for the warning that PDE5 inhibitors should not be prescribed to patients receiving any form of nitrate (Cheitlin *et al.*, 1999) and dictates that patients should be questioned about the use of PDE5 inhibitors within 24 hours before nitrates are administered. A period of longer than 24 hours may be needed following administration of a PDE5 inhibitor for safe use of nitrates, especially with tadalafil because of its prolonged half-life. In the event that patients develop significant hypotension following combined administration of sildenafil and a nitrate, fluids and α adrenergic receptor agonists, if needed, should be used for support (Cheitlin *et al.*, 1999).

Sildenafil, tadalafil, and vardenafil are metabolized *via* cytochrome P450 (CYP3A4), and their toxicity may be enhanced in patients who receive other substrates of this enzyme, including macrolide and imidazole antibiotics, some statins, and antiretroviral agents (see individual chapters and Chapter 3). PDE5 inhibitors also may prolong cardiac repolarization by blocking the I_{Kr} (Geelen *et al.*, 2000). Although these interactions and effects are important clinically, the overall incidence and profile of adverse events observed with PDE5 inhibitors, when used without nitrates, are consistent with the expected background frequency of the same events in the treated population (Zusman *et al.*, 1999). In patients with coronary artery disease whose exercise capacity indicates that sexual activity is unlikely to precipitate angina and who are not currently taking nitrates, the use of PDE5 inhibitors can be considered. Such therapy needs to be individualized, and appropriate warnings must be given about the risk of toxicity if nitrates are taken subsequently for angina; this drug interaction may persist for approximately 24 hours for sildenafil and vardenafil and for considerably longer with tadalafil. Alternative nonnitrate antianginal therapy, such as β adrenergic receptor antagonists, should be used during these time periods (Cheitlin *et al.*, 1999).

Therapeutic Uses

Angina. Diseases that predispose to angina should be treated as part of a comprehensive therapeutic program with the primary goal being to prolong life. Conditions such as hypertension, anemia, thyrotoxicosis, obesity, heart failure, cardiac arrhythmias, and acute anxiety can precipitate anginal symptoms in many patients. The patient should be asked to stop smoking and overeating; hypertension and hyperlipidemia should be corrected (see Chapters 32 and 35); and daily aspirin (or clopidogrel or *ticlopidine* if aspirin is not tolerated) (see Chapter 54) should be prescribed. Exposure to sympathomimetic agents (*e.g.*, those in nasal decongestants) should be avoided. The use of drugs that modify the perception of pain is a poor approach to the treatment of angina because the underlying myocardial ischemia is not relieved.

Table 31–1 lists the preparations and dosages of the nitrites and organic nitrates. The rapidity of onset, the duration of action, and the likelihood of developing tolerance are related to the method of administration.

Sublingual Administration. Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug of the organic nitrates given sublingually. The onset of action is within 1 to 2 minutes, but the effects are undetectable by 1 hour after administration. An initial dose of 0.3 mg nitroglycerin often relieves pain within 3 minutes. Absorption may be limited in patients with dentures or with dry mouths. Nitroglycerin tablets are stable but should be dispensed in glass containers and protected from moisture, light, and extremes of temperature. Active tablets usually produce a burning sensation under the tongue, but the absence of this sensation does not reliably predict loss of activity; elderly patients especially may be unable to detect the burning sensation. Anginal pain may be prevented when the drug is used prophylactically immediately prior to exercise or stress. The smallest effective dose should be prescribed. Patients should be instructed to seek medical attention immediately if three tablets taken over a 15-minute period do not relieve a sustained attack because this situation may be indicative of myocardial infarction or another cause of the pain. Patients also should be advised that there is no virtue in trying to avoid taking sublingual nitroglycerin for anginal pain. Other nitrates that can be taken sublingually do not appear to be longer acting than nitroglycerin because their half-lives depend only on the rate at which they are delivered to the liver. They are no more effective than nitroglycerin and often are more expensive.

Oral Administration. Oral nitrates often are used to provide prophylaxis against anginal episodes in patients who have more than occasional angina. They must be given in sufficient dosage to provide effective plasma levels after first-pass hepatic degradation. Low doses (*e.g.*, 5 to 10 mg isosorbide dinitrate) are no more effective than placebo in decreasing the frequency of anginal attacks or increasing exercise tolerance. In clinical studies, higher doses of either isosorbide dinitrate (*e.g.*, 20 mg or more orally every 4 hours) or sustained-release preparations of nitroglycerin decreased the frequency of anginal attacks and improved exercise tolerance. Effects peak at 60 to 90 minutes and last for 3 to 6 hours. Under these cir-

cumstances, the activities of less potent metabolites also may contribute to the therapeutic effect. Chronic oral administration of isosorbide dinitrate (120 to 720 mg daily) results in persistence of the parent compound and higher plasma concentrations of metabolites. However, these doses are more likely to cause troublesome side effects and tolerance. Prolonged (up to 4 hours) improvement of exercise tolerance can be demonstrated with a sustained-release oral form of nitroglycerin, but high doses (*e.g.*, 6.5 mg) of nitroglycerin are required.

Cutaneous Administration. Application of nitroglycerin ointment can relieve angina, prolong exercise capacity, and reduce ischemic ST-segment depression with exercise for 4 hours or more. Nitroglycerin ointment (2%) is applied to the skin (2.5 to 5 cm) as it is squeezed from the tube and then spread in a uniform layer; the dosage must be adjusted for each patient. Effects are apparent within 30 to 60 minutes (although absorption is variable) and last for 4 to 6 hours. The ointment is particularly useful for controlling nocturnal angina, which commonly develops within 3 hours after the patient goes to sleep. Transdermal nitroglycerin disks use a nitroglycerin-impregnated polymer (bonded to an adhesive bandage) that permits gradual absorption and a continuous plasma nitrate concentration over 24 hours. The onset of action is slow, with peak effects occurring at 1 to 2 hours. To avoid tolerance, therapy should be interrupted for at least 8 hours each day. With this regimen, long-term prophylaxis of ischemic episodes often can be attained.

Transmucosal or Buccal Nitroglycerin. This formulation is inserted under the upper lip above the incisors, where it adheres to the gingiva and dissolves gradually in a uniform manner. Hemodynamic effects are seen within 2 to 5 minutes, and it is therefore useful for short-term prophylaxis of angina. Nitroglycerin continues to be released into the circulation for a prolonged period, and exercise tolerance may be enhanced for up to 5 hours.

Congestive Heart Failure. The utility of nitrovasodilators to relieve pulmonary congestion and to increase cardiac output in congestive heart failure is addressed in Chapter 33.

Unstable Angina Pectoris and Non-ST-Segment-Elevation Myocardial Infarction. The term *unstable angina pectoris* has been used to describe a broad spectrum of clinical entities characterized by an acute or subacute worsening in a patient's anginal symptoms. The variable prognosis of unstable angina no doubt reflects the broad range of clinical entities subsumed by the term. More recently, efforts have been directed toward identifying patients with unstable angina on the basis of their risks for subsequent adverse outcomes such as myocardial infarction or death. The term *acute coronary syndrome* has been useful in this context: Common to most clinical presentations of acute coronary syndrome is disruption of a coronary plaque leading to local platelet aggregation and thrombosis at the arterial wall with subsequent partial or total occlusion of the vessel. There is some variability in the pathogenesis of unstable angina, with gradually progressive atherosclerosis accounting for some cases of

new-onset exertional angina. Less commonly, vasospasm in minimally atherosclerotic coronary vessels may account for some cases where rest angina has not been preceded by symptoms of exertional angina. For the most part, the pathophysiological principles that underlie therapy for exertional angina—which are directed at decreasing myocardial oxygen *demand*—have limited efficacy in the treatment of acute coronary syndromes characterized by an insufficiency of myocardial oxygen (blood) *supply*.

Notably, the degree of coronary stenosis correlates poorly with the likelihood of plaque rupture. Drugs that reduce myocardial oxygen consumption by reducing ventricular preload (nitrates) or by reducing heart rate and ventricular contractility (using β adrenergic receptor antagonists) are efficacious, but additional therapies are directed at the atherosclerotic plaque itself and the consequences (or prevention) of its rupture. As discussed below, these therapies include combinations of (1) antiplatelet agents, including aspirin and clopidogrel; (2) antithrombin agents such as heparin and the thrombolytics; (3) anti-integrin therapies that directly inhibit platelet aggregation mediated by glycoprotein (GP)IIb/IIIa; (4) mechanopharmacological approaches with percutaneously deployed drug-delivering intracoronary stents; or (5) coronary bypass surgery for selected patients.

Along with nitrates and β adrenergic receptor antagonists, antiplatelet agents represent the cornerstone of therapy for acute coronary syndrome (Lange and Hills, 2004). Aspirin (*see below*) inhibits platelet aggregation and improves survival (Yeghiazarians *et al.*, 2000). Heparin (either unfractionated or low-molecular-weight) also appears to reduce angina and prevent infarction. These and related agents are discussed in detail in Chapters 26 and 54. Anti-integrin agents directed against the platelet integrin GPIIb/IIIa (including abciximab, tirofiban, and eptifibatid) are effective in combination with heparin, as discussed below. Nitrates are useful both in reducing vasospasm and in reducing myocardial oxygen consumption by decreasing ventricular wall stress. Intravenous administration of nitroglycerin allows high concentrations of drug to be attained rapidly. Because nitroglycerin is degraded rapidly, the dose can be titrated quickly and safely using intravenous administration. If coronary vasospasm is present, intravenous nitroglycerin is likely to be effective, although the addition of a Ca^{2+} channel blocker may be required to achieve complete control in some patients. Because of the potential risk of profound hypotension, nitrates should be withheld and alternate antianginal therapy administered if patients have consumed a PDE5 inhibitor within 24 hours (*see above*).

Acute Myocardial Infarction. Therapeutic maneuvers in myocardial infarction (MI) are directed at reducing the size of the infarct; preserving or retrieving viable tissue by reducing the oxygen demand of the myocardium; and preventing ventricular remodeling that could lead to heart failure.

Nitroglycerin is commonly administered to relieve ischemic pain in patients presenting with MI, but evidence that nitrates improve mortality in MI is sparse. Because they reduce ventricular preload through vasodilation, nitrates are effective in relief of pulmonary congestion. A decreased ventricular preload should be avoided in patients with right ventricular infarction because higher right-sided

heart filling pressures are needed in this clinical context. Nitrates are relatively contraindicated in patients with systemic hypotension. According to the American Heart Association/American College of Cardiology (AHA/ACC) guidelines, “nitrates should not be used if hypotension limits the administration of β -blockers, which have more powerful salutary effects” (Antman *et al.*, 2004).

Since the proximate cause of MI is intracoronary thrombosis, reperfusion therapies are critically important, employing, when possible, direct percutaneous coronary interventions (PCIs) for acute MI, usually using drug-eluting intracoronary stents (Antman *et al.*, 2004). Thrombolytic agents are administered at hospitals where emergency PCI is not performed, but outcomes are better with direct PCI than with thrombolytic therapy (Antman *et al.*, 2004) (*see* discussion of thrombolytic and antiplatelet therapies in Chapter 54).

Variant (Prinzmetal) Angina. The large coronary arteries normally contribute little to coronary resistance. However, in variant angina, coronary constriction results in reduced blood flow and ischemic pain. Multiple mechanisms have been proposed to initiate vasospasm, including endothelial cell injury (Friesinger and Robertson, 1986). Whereas long-acting nitrates alone are occasionally efficacious in abolishing episodes of variant angina, additional therapy with Ca^{2+} channel blockers usually is required. Ca^{2+} channel blockers, but not nitrates, have been shown to influence mortality and the incidence of MI favorably in variant angina; they should be included in therapy.

Ca^{2+} CHANNEL ANTAGONISTS

Voltage-sensitive Ca^{2+} channels (L-type or slow channels) mediate the entry of extracellular Ca^{2+} into smooth muscle and cardiac myocytes and sinoatrial (SA) and atrioventricular (AV) nodal cells in response to electrical depolarization. In both smooth muscle and cardiac myocytes, Ca^{2+} is a trigger for contraction, albeit by different mechanisms. Ca^{2+} channel antagonists, also called *Ca²⁺ entry blockers*, inhibit Ca^{2+} channel function. In vascular smooth muscle, this leads to relaxation, especially in arterial beds. These drugs also may produce negative inotropic and chronotropic effects in the heart.

History. The work in the 1960s of Fleckenstein, Godfraind, and their colleagues led to the concept that drugs can alter cardiac and smooth muscle contraction by blocking the entry of Ca^{2+} into myocytes. Godfraind and associates showed that the effect of the diphenylpiperazine analogs *cinnarizine* and *lidoflazine* in preventing agonist-induced vascular smooth muscle contraction could be overcome by raising the concentration of Ca^{2+} in the extracellular medium; they used the term *calcium antagonist* to describe these agents (Godfraind *et al.*, 1986).

Hass and Hartfelder reported in 1962 that *verapamil*, a putative coronary vasodilator, possessed negative inotropic and chronotropic effects that were not seen with other vasodilatory agents, such as nitroglycerin. In 1967, Fleckenstein suggested that the negative inotropic effect resulted from inhibition of excitation–contraction coupling and that the mechanism involved reduced movement of Ca^{2+} into cardiac myocytes. A derivative of verapamil, *gallopamil*, and other compounds, such as

nifedipine, also were shown to block the movement of Ca^{2+} through the cardiac myocyte Ca^{2+} channel, or the slow channel (*see* Chapter 34), and thereby alter the plateau phase of the cardiac action potential. Subsequently, drugs in several chemical classes have been shown to alter cardiac and smooth muscle contraction by blocking or “antagonizing” the entry of Ca^{2+} through channels in the myocyte membrane.

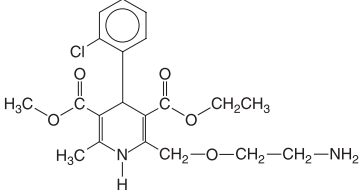

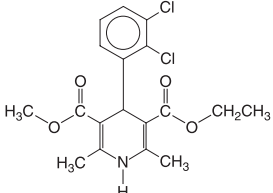

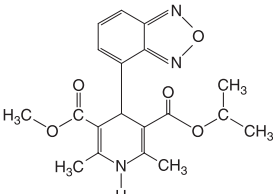

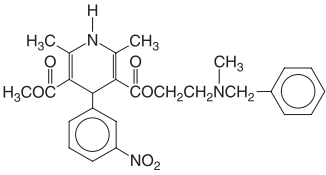

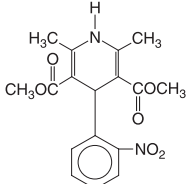

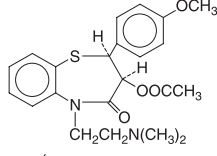

Chemistry. The 10 Ca^{2+} channel antagonists that are approved for clinical use in the United States have diverse chemical structures. Five classes of compounds have been examined: phenylalkylamines, dihydropyridines, benzothiazepines, diphenylpiperazines, and a diarylaminoethylamine. At present, verapamil (a phenylalkylamine); *diltiazem* (a benzothiazepine); nifedipine, *amlodipine*, *felodipine*, *isradipine*, *nicardipine*, *nisoldipine*, and *nimodipine* (dihydropyridines); and *bepridil* (a diarylaminoethylamine ether used only for refractory angina) are approved for clinical use in the United States. Their structures and specificities are shown in Table 31–2. Although these agents are commonly grouped together as “calcium channel blockers,” there are fundamental differences among verapamil, diltiazem, and the dihydropyridines, especially with respect to pharmacologic characteristics, drug interactions, and toxicities.

Mechanisms of Action. An increased concentration of cytosolic Ca^{2+} causes increased contraction in cardiac and vascular smooth muscle cells. The entry of extracellular Ca^{2+} is more important in initiating the contraction of cardiac myocytes (Ca^{2+} -induced Ca^{2+} release). The release of Ca^{2+} from intracellular storage sites also contributes to contraction of vascular smooth muscle, particularly in some vascular beds. Cytosolic Ca^{2+} concentrations may be increased by various contractile stimuli. Thus many hormones and neurohormones increase Ca^{2+} influx through so-called receptor-operated channels, whereas high external concentrations of K^{+} and depolarizing electrical stimuli increase Ca^{2+} influx through voltage-sensitive, or “potential operated,” channels. The Ca^{2+} channel antagonists produce their effects by binding to the α_1 subunit of the L-type Ca^{2+} channels and reducing Ca^{2+} flux through the channel.

Voltage-sensitive channels contain domains of homologous sequence that are arranged in tandem within a single large subunit. In addition to the major channel-forming subunit (termed α_1), Ca^{2+} channels contain several other associated subunits (termed α_2 , β , γ , and δ) (Schwartz, 1992). Voltage-sensitive Ca^{2+} channels have been divided into at least three subtypes based on their conductances and sensitivities to voltage (Schwartz, 1992; Tsien *et al.*, 1988). The channels best characterized to date are the L, N, and T subtypes; P/Q and R channels also have been identified. Only the L-type channel is sensitive to the dihydropyridine Ca^{2+} channel blockers. Large divalent cations such as Cd^{2+} and Mn^{2+} block a wider range of Ca^{2+} channels. All approved Ca^{2+} channel blockers bind to the α_1 subunit of the L-type Ca^{2+} channel, which is the main pore-forming unit of the channel. This 200,000- to 250,000-dalton subunit is associated with a disulfide-linked $\alpha_2\delta$ subunit of approximately 140,000 daltons and an intracellular β subunit of 55,000 to 72,000 daltons. The α_1 subunits share a common topology of four homologous domains (I, II, III, and IV), each of which is composed of six putative transmembrane seg-

ments (S1–S6). The $\alpha_2\delta$ and β subunits modulate the α_1 subunit. The phenylalkylamine Ca²⁺ channel blockers bind to transmembrane segment 6 of domain IV (IVS6), the benzothiazepine Ca²⁺ channel blockers bind to the cytoplasmic bridge between domain III (IIIS) and domain IV (IVS), and the dihydropyridine Ca²⁺ channel blockers bind to transmembrane segment of both domain III (IIIS6) and domain IV (IVS6). These three separate receptor sites are linked allosterically (Hockerman *et al.*, 1997; Abernethy and Schwartz, 1999). The vascular and cardiac effects of some of the Ca²⁺ channel blockers are summarized below and in Table 31-2.

Pharmacological Properties

Cardiovascular Effects. Actions in Vascular Tissue.

Although there is some involvement of Na⁺ currents, depolarization of vascular smooth muscle cells depends primarily on the influx of Ca²⁺. At least three distinct mechanisms may be responsible for contraction of vascular smooth muscle cells. First, voltage-sensitive Ca²⁺ channels open in response to depolarization of the membrane, and extracellular Ca²⁺ moves down its electrochemical gradient (from approximately 1.5 to 120 mM) into the cell. After closure of Ca²⁺ channels, a finite period of time is required before the channels can open again in response to a stimulus. Second, agonist-induced contractions that occur without depolarization of the membrane result from stimulation of the PLC-IP₃ pathway, resulting in the release of intracellular Ca²⁺ from the sarcoplasmic reticulum (Berridge, 1993). This receptor-mediated release of intracellular Ca²⁺ may trigger further influx of extracellular Ca²⁺. Third, receptor-operated Ca²⁺ channels allow the entry of extracellular Ca²⁺ in response to receptor occupancy.

An increase in cytosolic Ca²⁺ results in enhanced binding of Ca²⁺ to calmodulin. The Ca²⁺-calmodulin

complex in turn activates myosin light-chain kinase, with resulting phosphorylation of the myosin light chain. Such phosphorylation promotes interaction between actin and myosin and contraction of smooth muscle. Ca²⁺ channel antagonists inhibit the voltage-dependent Ca²⁺ channels in vascular smooth muscle at significantly lower concentrations than are required to interfere with the release of intracellular Ca²⁺ or to block receptor-operated Ca²⁺ channels. All Ca²⁺ channel blockers relax arterial smooth muscle, but they have little effect on most venous beds and hence do not affect cardiac pre-load significantly.

Actions in Cardiac Cells. The mechanisms involved in excitation-contraction coupling in the cardiac muscle differ from those in vascular smooth muscle in that a portion of the two inward currents is carried by Na⁺ through the fast channel in addition to that carried by Ca²⁺ through the slow channel. Within the cardiac myocyte, Ca²⁺ binds to troponin, relieving the inhibitory effect of troponin on the contractile apparatus and permitting a productive interaction of actin and myosin leading to contraction. Thus Ca²⁺ channel blockers can produce a negative inotropic effect. Although this is true of all classes of Ca²⁺ channel blockers, the greater degree of peripheral vasodilation seen with the dihydropyridines is accompanied by a sufficient baroreflex-mediated increase in sympathetic tone to overcome the negative inotropic effect. Diltiazem also may inhibit mitochondrial Na⁺-Ca²⁺ exchange (Schwartz, 1992).

In the SA and AV nodes, depolarization largely depends on the movement of Ca²⁺ through the slow channel. The effect of a Ca²⁺ channel blocker on AV conduction and on the rate of the sinus node pacemaker

depends on whether or not the agent delays the recovery of the slow channel (Schwarz, 1992). Although nifedipine reduces the slow inward current in a dose-dependent manner, it does not affect the rate of recovery of the slow Ca^{2+} channel. The channel blockade caused by nifedipine and related dihydropyridines also shows little dependence on the frequency of stimulation. At doses used clinically, nifedipine does not affect conduction through the node. In contrast, verapamil not only reduces the magnitude of the Ca^{2+} current through the slow channel but also decreases the rate of recovery of the channel. In addition, channel blockade caused by verapamil (and to a lesser extent by diltiazem) is enhanced as the frequency of stimulation increases, a phenomenon known as *frequency dependence* or *use dependence*. Verapamil and diltiazem depress the rate of the sinus node pacemaker and slow AV conduction; the latter effect is the basis for their use in the treatment of supraventricular tachyarrhythmias (see Chapter 34). Bepridil, like verapamil, inhibits both slow inward Ca^{2+} current and fast inward Na^+ current. It has a direct negative inotropic effect. Its electrophysiological properties lead to slowing of the heart rate, prolongation of the AV nodal effective refractory period, and importantly, prolongation of the QTc interval. Particularly in the setting of hypokalemia, the last effect can be associated with *torsades de pointes*, a potentially lethal ventricular arrhythmia (see Chapter 34).

Hemodynamic Effects. All the Ca^{2+} channel blockers approved for clinical use decrease coronary vascular resistance and increase coronary blood flow. The dihydropyridines are more potent vasodilators *in vivo* and *in vitro* than verapamil, which is more potent than diltiazem. The hemodynamic effects of these agents vary depending on the route of administration and the extent of left ventricular dysfunction.

Nifedipine given intravenously increases forearm blood flow with little effect on venous pooling; this indicates a selective dilation of arterial resistance vessels. The decrease in arterial blood pressure elicits sympathetic reflexes, with resulting tachycardia and positive inotropy. Nifedipine also has direct negative inotropic effects *in vitro*. However, nifedipine relaxes vascular smooth muscle at significantly lower concentrations than those required for prominent direct effects on the heart. Thus arteriolar resistance and blood pressure are lowered, contractility and segmental ventricular function are improved, and heart rate and cardiac output are increased modestly (Serruys *et al.*, 1983). After oral administration of nifedipine, arterial dilation increases peripheral blood flow; venous tone does not change.

The other dihydropyridines—amlodipine, felodipine, isradipine, nicardipine, nisoldipine, and nimodipine—share many of the cardiovascular effects of nifedipine. Amlodipine is a dihydropyridine that has a slow absorption and a prolonged effect. With a plasma half-

life of 35 to 50 hours, plasma levels and effect increase over 7 to 10 days of daily administration of a constant dose. Amlodipine produces both peripheral arterial vasodilation and coronary dilation, with a hemodynamic profile similar to that of nifedipine. However, there is less reflex tachycardia with amlodipine possibly because the long half-life produces minimal peaks and troughs in plasma concentrations (van Zwieten and Pfaffendorf, 1993; Taylor, 1994; Lehmann *et al.*, 1993). Felodipine may have even greater vascular specificity than does nifedipine or amlodipine. At concentrations producing vasodilation, there is no negative inotropic effect. Like nifedipine, felodipine indirectly activates the sympathetic nervous system, leading to an increase in heart rate (Todd and Faulds, 1992). Nicardipine has antianginal properties similar to those of nifedipine and may have selectivity for coronary vessels. Isradipine also produces the typical peripheral vasodilation seen with other dihydropyridines, but because of its inhibitory effect on the SA node, little or no rise in heart rate is seen. This inhibitory effect does not extend to the cardiac myocytes, however, because no cardiodepressant effect is seen. Despite the negative chronotropic effect, isradipine appears to have little effect on the AV node, so it may be used in patients with AV block or combined with a β adrenergic receptor antagonist. In general, because of their lack of myocardial depression and, to a greater or lesser extent, lack of negative chronotropic effect, dihydropyridines are less effective as monotherapy in stable angina than are verapamil, diltiazem, or a β adrenergic receptor antagonist. Nisoldipine is more than 1000 times more potent in preventing contraction of human vascular smooth muscle than in preventing contraction of human cardiac muscle *in vitro*, suggesting a high degree of vascular selectivity (Godfraind *et al.*, 1992). Although nisoldipine has a short elimination half-life, a sustained-release preparation has been developed that is efficacious as an antianginal agent. Nimodipine has high lipid solubility and was developed as an agent to relax the cerebral vasculature. It is effective in inhibiting cerebral vasospasm and has been used primarily to treat patients with neurological defects associated with cerebral vasospasm after subarachnoid hemorrhage.

Bepridil has been demonstrated to reduce blood pressure and heart rate in patients with stable exertional angina. It also produces an increase in left ventricular performance in patients with angina, but its side-effect profile (see below) limits its use to truly refractory patients.

Verapamil is a less potent vasodilator *in vivo* than are the dihydropyridines. Like the latter agents, verapamil causes little effect on venous resistance vessels at concentrations that produce arteriolar dilation. With doses of verapamil sufficient to produce peripheral arterial vasodilation, there are more direct negative chronotropic, dromotropic, and inotropic effects than with the dihydropyridines. Intravenous verapamil causes a decrease in arterial blood pressure owing to a decrease in vascular resistance, but the reflex tachycardia is blunted or abolished by the direct negative chronotropic effect of the drug. This intrinsic negative inotropic effect is partially offset by both a decrease in afterload and the reflex increase in adrenergic tone. Thus, in patients without congestive heart failure, ventricular performance is not impaired and actually may improve, especially if ischemia limits performance. In contrast, in patients with congestive heart failure, intravenous verapamil can cause a marked decrease in contractility and left ventricular function. Oral administration of verapamil reduces peripheral vascular resistance and blood pressure, often with minimal changes in heart rate. The relief of pacing-induced angina seen with verapamil is due primarily to a reduction in myocardial oxygen demand.

Intravenous administration of diltiazem can result initially in a marked decrease in peripheral vascular resistance and arterial blood pressure, which elicits a reflex increase in heart rate and cardiac output. Heart rate then falls below initial levels because of the direct negative chronotropic effect of the agent. Oral administration of diltiazem decreases both heart rate and mean arterial blood pressure. While diltiazem and verapamil produce similar effects on the SA and AV nodes, the negative inotropic effect of diltiazem is more modest.

The effects of Ca^{2+} channel blockers on diastolic ventricular relaxation (the lusitropic state of the ventricle) are complex. The direct effect of several of these agents, especially when given into the coronary arteries, is to impair relaxation (Amende *et al.*, 1983; Serruys *et al.*, 1983; Walsh and O'Rourke, 1985). Although several clinical studies have suggested an improvement in peak left ventricular filling rates when verapamil, nifedipine, nisoldipine, or nicardipine was given systemically (Bonow *et al.*, 1982; Paulus *et al.*, 1983), one must be cautious in extrapolating this change in filling rates to enhancement of relaxation. Because ventricular relaxation is so complex, the effect of even a single agent may be pleiotropic. If reflex stimulation of sympathetic tone increases cyclic AMP levels in myocytes, increased lusitropy will result that may outweigh a direct negative lusitropic effect. Likewise, a reduction in afterload will improve the lusitropic state. In addition, if ischemia is improved, the negative lusitropic effect of asymmetrical left ventricular contraction will be reduced. The sum total of these effects in any given patient cannot be determined *a priori*. Thus caution should be exercised in the use of Ca^{2+} channel blockers for this purpose; the ideal is to determine the end result objectively before committing the patient to therapy.

Absorption, Fate, and Excretion. Although the absorption of these agents is nearly complete after oral administration, their bioavailability is reduced, in some cases markedly, by first-pass hepatic metabolism. The effects of these drugs are evident within 30 to 60 minutes of an oral dose, with the exception of the more slowly absorbed and longer-acting agents amlodipine, isradipine, and felodipine. For comparison, peak effects of verapamil occur within 15 minutes of its intravenous administration. These agents all are bound extensively to plasma proteins (70% to 98%); their elimination half-lives vary widely and range from 1.3 to 64 hours. During repeated oral administration, bioavailability and half-life may increase because of saturation of hepatic metabolism. A major metabolite of diltiazem is desacetyldiltiazem, which has about one-half of diltiazem's potency as a vasodilator. *N*-Demethylation of verapamil results in production of norverapamil, which is biologically active but much less potent than the parent compound. The half-life of norverapamil is about 10 hours. The metabolites of the dihydropyridines are inactive or weakly active. In patients with hepatic cirrhosis, the bioavailabilities and half-lives of the Ca^{2+} channel blockers may be increased, and dosage should be decreased accordingly. The half-lives of these agents also may be longer in older patients. Except for diltiazem and nifedipine, all

the Ca^{2+} channel blockers are administered as racemic mixtures (Abernethy and Schwartz, 1999).

Toxicity and Untoward Responses. The most common side effects caused by the Ca^{2+} channel antagonists, particularly the dihydropyridines, are due to excessive vasodilation. Symptoms include dizziness, hypotension, headache, flushing, digital dysesthesia, and nausea. Patients also may experience constipation, peripheral edema, coughing, wheezing, and pulmonary edema. Nimodipine may produce muscle cramps when given in the large doses required for a beneficial effect in patients with subarachnoid hemorrhage. Less common side effects include rash, somnolence, and occasional minor elevations of liver function tests. These side effects usually are benign and may abate with time or with dose adjustment. Worsened myocardial ischemia has been observed in two studies with the dihydropyridine nifedipine (Schulz *et al.*, 1985; Egstrup and Anderson, 1993). In both these studies, worsening of angina was observed in patients with an angiographically demonstrable coronary collateral circulation. The worsening of angina may have resulted from excessive hypotension and decreased coronary perfusion, selective coronary vasodilation in nonischemic regions of the myocardium in a setting where vessels perfusing ischemic regions were already maximally dilated (*i.e.*, coronary steal), or an increase in oxygen demand owing to increased sympathetic tone and excessive tachycardia. In a study of monotherapy with an immediate-release formulation of nisoldipine, the dihydropyridine was not superior to placebo and was associated with a trend toward an increased incidence of serious adverse events, a process termed *proischemia* (Waters, 1991).

Although bradycardia, transient asystole, and exacerbation of heart failure have been reported with verapamil, these responses usually have occurred after intravenous administration of verapamil in patients with disease of the SA node or AV nodal conduction disturbances or in the presence of β adrenergic receptor blockade. The use of intravenous verapamil with a β adrenergic receptor antagonist is contraindicated because of the increased propensity for AV block and/or severe depression of ventricular function. Patients with ventricular dysfunction, SA or AV nodal conduction disturbances, and systolic blood pressures below 90 mmHg should not be treated with verapamil or diltiazem, particularly intravenously. Some Ca^{2+} channel antagonists can cause an increase in the concentration of digoxin in plasma, although toxicity from the cardiac glycoside rarely develops. The use of verapamil to treat digitalis toxicity

thus is contraindicated; AV nodal conduction disturbances may be exacerbated. Bepridil, because of its antiarrhythmic properties and its ability to prolong the QTc interval, can produce serious arrhythmic side effects. Especially in the setting of hypokalemia and/or bradycardia, polymorphic ventricular tachycardia (*torsades de pointes*), a potentially lethal arrhythmia, can be seen. Agranulocytosis also has been reported. Because of these serious side effects, bepridil should be reserved for patients refractory to all other appropriate medical and surgical therapy.

Several studies have raised concerns about the long-term safety of short-acting nifedipine (Opie *et al.*, 2000). The proposed mechanism for this adverse effect lies in abrupt vasodilation with reflex sympathetic activation. There does not appear to be either significant reflex tachycardia or long-term adverse outcomes from treatment with sustained-release forms of nifedipine or with dihydropyridine Ca²⁺ blockers such as amlodipine or felodipine, which have more favorable (slower) pharmacokinetics.

Therapeutic Uses

Variant Angina. Variant angina results from reduced flow rather than increased oxygen demand. Controlled clinical trials have demonstrated efficacy of the Ca²⁺ channel blocking agents for the treatment of variant angina (Gibbons *et al.*, 2002). These drugs can attenuate *ergonovine*-induced vasospasm in patients with variant angina, which suggests that protection in variant angina is due to coronary dilation rather than to alterations in peripheral hemodynamics.

Exertional Angina. Ca²⁺ channel antagonists also are effective in the treatment of exertional, or exercise-induced, angina. Their utility may result from an increase in blood flow owing to coronary arterial dilation, from a decrease in myocardial oxygen demand (secondary to a decrease in arterial blood pressure, heart rate, or contractility), or both. Numerous double-blind, placebo-controlled studies have shown that these drugs decrease the number of anginal attacks and attenuate exercise-induced ST-segment depression.

The *double product*, calculated as heart rate times systolic blood pressure, is an indirect measure of myocardial O₂ demand. Since these agents reduce the level of the double product at a given external workload, and because the value of the double product at peak exercise is not altered, the beneficial effect of Ca²⁺ channel blockers likely is due primarily to a decrease in O₂ demand rather than to an increase in coronary flow.

As described earlier, Ca²⁺ channel antagonists, particularly the dihydropyridines, may aggravate anginal symptoms in some patients when used without a β adrenergic receptor antagonist. This adverse effect is not prominent with verapamil or diltiazem because of their limited ability to induce marked peripheral vasodilation and reflex tachycardia. Concurrent therapy with nifedipine and the β adrenergic receptor antagonist *propranolol* or with amlodipine and any of several β adrenergic receptor antagonists has proven more effective than either agent given alone in exertional angina, presumably because the β adrenergic receptor antagonist suppresses reflex tachycardia (Gibbons *et al.*, 2002). This concurrent drug therapy is particularly attractive because the dihydropyridines, unlike verapamil and diltiazem, do not delay AV conduction and will not enhance the negative dromotropic effects associated with β adrenergic receptor blockade. Although concurrent administration of verapamil or diltiazem with a β adrenergic receptor antagonist also may reduce angina, the potential for AV block, severe bradycardia, and decreased left ventricular function requires that these combinations be used judiciously, especially if left ventricular function is compromised prior to therapy. Amlodipine produces less reflex tachycardia than does nifedipine probably because of a flatter plasma concentration profile. Isradipine, approximately equivalent to nifedipine in enhancing exercise tolerance, also produces less rise in heart rate, possibly because of its slow onset of action.

Unstable Angina. Medical therapy for unstable angina involves the administration of aspirin, which reduces mortality, nitrates, β adrenergic receptor blocking agents, and heparin, which are effective in controlling ischemic episodes and angina. Since vasospasm occurs in some patients with unstable angina (Yeghiazarians *et al.*, 2000), Ca²⁺ channel blockers offer an additional approach to the treatment of unstable angina. However, there is insufficient evidence to assess whether such treatment decreases mortality except when the underlying mechanism is vasospasm. In a randomized, double-blind clinical trial, the short-acting dihydropyridine nifedipine was found to be less effective than *metoprolol* (Muller *et al.*, 1984), and there are no studies supporting the administration of a dihydropyridine to patients with unstable angina. One small study of 121 patients reported a benefit of intravenous diltiazem compared with nitroglycerin on the end points of refractory angina and event-free survival (Göbel *et al.*, 1995). In contrast, therapy directed toward reduction of platelet function and thrombotic episodes clearly decreases morbidity and mortality in patients with unstable angina (*see* Chapters 26 and 54).

Myocardial Infarction. There is no evidence that Ca²⁺ channel antagonists are of benefit in the early treatment or secondary prevention of acute MI. In several trials, higher doses of the short-acting formulation of the dihydropyridine nifedipine had a detrimental effect on mortality

(Opie *et al.*, 2000; Yusuf, 1995; Furberg *et al.*, 1995). Diltiazem and verapamil may reduce the incidence of reinfarction in patients with a first non-Q-wave infarction who are not candidates for a β adrenergic receptor antagonist (Gibbons *et al.*, 2002), but β adrenergic receptor antagonists remain the drugs of first choice.

Other Uses. The use of Ca^{2+} channel antagonists as antiarrhythmic agents is discussed in Chapter 34; their use for the treatment of hypertension is discussed in Chapter 32; and use of amlodipine in the treatment of heart failure is reviewed in Chapter 33. Clinical trials are under way to evaluate the capacity of Ca^{2+} channel blockers to slow the progression of renal failure and to protect the transplanted kidney. Verapamil has been demonstrated to improve left ventricular outflow obstruction and symptoms in patients with hypertrophic cardiomyopathy. Verapamil also has been used in the prophylaxis of migraine headaches. While several studies suggest that dihydropyridines may suppress the progression of mild atherosclerosis, there is no evidence that this alters mortality or reduces the incidence of ischemic events. Nimodipine has been approved for use in patients with neurological deficits secondary to cerebral vasospasm after the rupture of a congenital intracranial aneurysm. Nifedipine, diltiazem, amlodipine, and felodipine appear to provide symptomatic relief in Raynaud's disease. The Ca^{2+} channel antagonists cause relaxation of the myometrium *in vitro* and may be effective in stopping preterm uterine contractions in preterm labor (*see* Chapter 55).

β ADRENERGIC RECEPTOR ANTAGONISTS

β Adrenergic receptor antagonists are effective in reducing the severity and frequency of attacks of exertional angina and in improving survival in patients who have had an MI. In contrast, these agents are not useful for vasospastic angina and, if used in isolation, may worsen the condition. Most β adrenergic receptor antagonists apparently are equally effective in the treatment of exertional angina (Gibbons *et al.*, 2002). *Timolol*, *metoprolol*, *atenolol*, and *propranolol* have been shown to exert cardioprotective effects. The effectiveness of β adrenergic receptor antagonists in the treatment of exertional angina is attributable primarily to a fall in myocardial oxygen consumption at rest and during exertion, although there also is some tendency for increased flow toward ischemic regions. The decrease in myocardial oxygen consumption is due to a negative chronotropic effect (particularly during exercise), a negative inotropic effect, and a reduction in arterial blood pressure (particularly systolic pressure) during exercise. Not all actions of β adrenergic receptor antagonists are beneficial in all patients. The decreases in heart rate and contractility

cause increases in the systolic ejection period and left ventricular end-diastolic volume; these alterations tend to increase O_2 consumption. However, the net effect of β adrenergic receptor blockade is usually to decrease myocardial O_2 consumption, particularly during exercise. Nevertheless, in patients with limited cardiac reserve who are critically dependent on adrenergic stimulation, β adrenergic receptor blockade can result in profound decreases in left ventricular function. Despite this, several β adrenergic receptor antagonists have been shown to reduce mortality in patients with congestive heart failure (*see* Chapter 33). Numerous β adrenergic receptor antagonists are approved for clinical use in the United States. Their pharmacology and the criteria for choosing a β_1 -selective agent, an agent with intrinsic sympathomimetic activity, or a nonspecific agent are considered in detail in Chapter 10.

Therapeutic Uses

Unstable Angina. β Adrenergic receptor antagonists are effective in reducing recurrent episodes of ischemia and the risk of progression to acute MI (Braunwald *et al.*, 2002). Clinical trials have lacked sufficient statistical power to demonstrate beneficial effects of β adrenergic receptor antagonists on mortality. On the other hand, if the underlying pathophysiology is coronary vasospasm, nitrates and Ca^{2+} channel blockers may be effective, and β adrenergic receptor antagonists should be used with caution. In some patients, there is a combination of severe fixed disease and superimposed vasospasm; if adequate antiplatelet therapy and vasodilation have been provided by other agents and angina continues, the addition of a β adrenergic receptor antagonist may be helpful.

Myocardial Infarction. β Adrenergic receptor antagonists that do not have intrinsic sympathomimetic activity improve mortality in MI. They should be given early and continued indefinitely in patients who can tolerate them (Gibbons *et al.*, 2002).

COMPARISON OF ANTIANGINAL THERAPEUTIC STRATEGIES

In evaluating trials in which different forms of antianginal therapy are compared, careful attention must be paid to the patient population studied and to the pathophysiology and stage of the disease. An important placebo effect may be seen in these trials. The efficacy of antianginal treatment will depend on the severity of angina, the presence of coronary vasospasm, and myocardial O_2 demand. Optimally, the dose of each agent should be titrated to maximum benefit.

Task forces from the American College of Cardiology (ACC) and the American Heart Association (AHA) (Gib-

bons *et al.*, 2002) have published guidelines that are useful in the selection of appropriate initial therapy for patients with chronic stable angina pectoris. Patients with coronary artery disease should be treated with aspirin and a β adrenergic receptor blocking drug (particularly if there is a history of prior MI). The ACC/AHA guidelines also note that solid data support the use of ACE inhibitors in patients with coronary artery disease who also have left ventricular dysfunction and/or diabetes. Therapy of hypercholesterolemia is also indicated. Nitrates, for treatment of angina symptoms, and Ca^{2+} antagonists also may be used (Gibbons *et al.*, 2002). Table 31–3 summarizes the issues that the ACC/AHA task force considered to be relevant in choosing between β adrenergic receptor antagonists and Ca^{2+} channel blockers in patients with angina and other medical conditions. A meta-analysis of publications that compared two or more antianginal therapies has been conducted (Heidenreich *et al.*, 1999). Comparison of β adrenergic receptor antagonists with Ca^{2+} channel blockers showed that β adrenergic receptor antagonists are associated with fewer episodes of angina per week and a lower rate of withdrawal because of adverse events. However, there were no differences in time to ischemia during exercise or in the frequency of adverse events when Ca^{2+} channel blockers other than nifedipine were compared with β adrenergic receptor antagonists. There were no significant differences in outcome between the studies comparing long-acting nitrates and Ca^{2+} channel blockers and the studies comparing long-acting nitrates with β adrenergic receptor antagonists.

Combination Therapy. Since the different categories of antianginal agents have different mechanisms of action, it has been suggested that combinations of these agents would allow the use of lower doses, increasing effectiveness and reducing the incidence of side effects. However, despite the predicted advantages, combination therapy rarely achieves this potential and may be accompanied by serious side effects. Newer antianginal agents have distinct pharmacological mechanisms to reduce myocardial oxygen consumption (*e.g.*, ranolazine); some studies have suggested that these newer compounds may have additional efficacy in combination with other antianginal agents (Chaitman *et al.*, 2004).

Nitrates and β Adrenergic Receptor Antagonists. The concurrent use of organic nitrates and β adrenergic receptor antagonists can be very effective in the treatment of typical exertional angina. The additive efficacy is primarily a result of the blockade by one drug of a reflex effect elicited by the other. β Adrenergic receptor antagonists can block the baroreceptor-mediated reflex tachycardia and positive inotropic effects that are sometimes associated with nitrates, whereas nitrates, by increasing venous capacitance, can attenuate the increase in left ventricular end-diastolic volume associated with β adrenergic receptor blockade. Concurrent administration of nitrates also can alleviate the increase in coronary vascular resistance associated with blockade of β adrenergic receptors.

Ca^{2+} Channel Blockers and β Adrenergic Receptor Antagonists.

Since there is a proven mortality benefit from the use of β adrenergic receptor antagonists in patients with heart disease, this class of drugs represents the first line of therapy. However, when angina is not controlled adequately by a β adrenergic receptor antagonist plus nitrates, additional improvement sometimes can be achieved by the addition of a Ca^{2+} channel blocker, especially if there is a component of coronary vasospasm. The differences among the chemical classes of Ca^{2+} channel blockers can lead to important adverse or salutary drug interactions with β adrenergic receptor antagonists. If the patient already is being treated with maximal doses of verapamil or diltiazem, it is difficult to demonstrate any additional benefit of β adrenergic receptor blockade, and excessive bradycardia, heart block, or heart failure may ensue. However, in patients treated with a dihydropyridine such as nifedipine or with nitrates, substantial reflex tachycardia often limits the effectiveness of these agents. A β adrenergic receptor antagonist may be a helpful addition in this situation, resulting in a lower heart rate and blood pressure with exercise. The efficacy of amlodipine is improved by combination with a β adrenergic receptor antagonist. However, in the Total Ischaemic Burden European Trial (TIBET), which compared the effects of atenolol, a sustained-release form of nifedipine, and their combination on exercise parameters and ambulatory ischemia in patients with mild angina, there were no differences between the agents, either singly or in combination, on any of the measured ischemic parameters (Fox *et al.*, 1996). On the other hand, in two studies of patients with more severe but still stable angina, atenolol and propranolol were shown to be superior to nifedipine, and the combination of propranolol and nifedipine was more effective than a β adrenergic receptor antagonist alone (Fox *et al.*, 1993).

Relative contraindications to the use of β adrenergic receptor antagonists for treatment of angina—bronchospasm, Raynaud's syndrome, or Prinzmetal angina—may lead to a choice to initiate therapy with a Ca^{2+} channel blocker. Fluctuations in coronary tone are important determinants of variant angina. It is likely that episodes of increased tone, such as those precipitated by cold and by emotion, superimposed on fixed disease have a role in the variable anginal threshold seen in some patients with otherwise chronic stable angina. Increased coronary tone also may be important in the anginal episodes occurring early after MI and after coronary angioplasty, and it probably accounts for those patients with unstable angina who respond to dihydropyridines. Atherosclerotic arteries have abnormal vasomotor responses to a number of stimuli (Dudzinski *et al.*, 2005), including exercise, other forms of sympathetic activation, and cholinergic agonists; in such vessels, stenotic segments actually may become more severely stenosed during exertion. This implies that the normal exercise-induced increase in coronary flow is lost in atherosclerosis. Similar exaggerated vascular contractile responses are seen in hyperlipidemia, even before anatomic evidence of atherosclerosis develops. Because of this, coronary vasodilators (nitrates and/or Ca^{2+} channel blockers) are an important part of the therapeutic program in the majority of patients with ischemic heart disease.

Ca^{2+} Channel Blockers and Nitrates. In severe exertional or vasospastic angina, the combination of a nitrate and a Ca^{2+} channel blocker may provide additional relief over that obtained with either type of agent alone. Since nitrates primarily reduce preload, whereas Ca^{2+} channel blockers reduce afterload, the net effect on reduction of oxygen demand should be additive. However, excessive vasodilation and hypotension can occur. The concurrent administration of a nitrate and nifedipine has been advocated in particular for patients

Table 31–3

Recommended Drug Therapy for Angina in Patients with Other Medical Conditions

CONDITION	RECOMMENDED TREATMENT (AND ALTERNATIVES) FOR ANGINA	DRUGS TO AVOID
Medical Conditions		
Systemic hypertension	β Adrenergic receptor antagonists (Ca ²⁺ channel antagonists)	
Migraine or vascular headaches	β Adrenergic receptor antagonists (Ca ²⁺ channel antagonists)	
Asthma or chronic obstructive pulmonary disease with bronchospasm	Verapamil or diltiazem	β Adrenergic receptor antagonists
Hyperthyroidism	β Adrenergic receptor antagonists	
Raynaud's syndrome	Long-acting, slow-release Ca ²⁺ channel antagonists	β Adrenergic receptor antagonists
Insulin-dependent diabetes mellitus	β Adrenergic receptor antagonists (particularly if prior MI) or long-acting, slow-release Ca ²⁺ channel antagonists	
Non-insulin-dependent diabetes mellitus	β Adrenergic receptor antagonists or long-acting, slow-release Ca ²⁺ channel antagonists	
Depression	Long-acting, slow-release Ca ²⁺ channel antagonists	β Adrenergic receptor antagonists
Mild peripheral vascular disease	β Adrenergic receptor antagonists or Ca ²⁺ channel antagonists	
Severe peripheral vascular disease with rest ischemia	Ca ²⁺ channel antagonists	β Adrenergic receptor antagonists
Cardiac Arrhythmias and Conduction Abnormalities		
Sinus bradycardia	Dihydropyridine Ca ²⁺ channel antagonists	β Adrenergic receptor antagonists, diltiazem, verapamil
Sinus tachycardia (not due to heart failure)	β Adrenergic receptor antagonists	
Supraventricular tachycardia	Verapamil, diltiazem, or β adrenergic receptor antagonists	
Atrioventricular block	Dihydropyridine Ca ²⁺ channel antagonists	β Adrenergic receptor antagonists, verapamil, diltiazem
Rapid atrial fibrillation (with digitalis)	Verapamil, diltiazem, or β adrenergic receptor antagonists	
Ventricular arrhythmias	β Adrenergic receptor antagonists	
Left Ventricular Dysfunction		
Congestive heart failure		
Mild (LVEF \geq 40%)	β Adrenergic receptor antagonists	
Moderate to severe (LVEF < 40%)	Amlodipine or felodipine (nitrates)	
Left-sided valvular heart disease		
Mild aortic stenosis	β Adrenergic receptor antagonists	
Aortic insufficiency	Long-acting, slow-release dihydropyridines	
Mitral regurgitation	Long-acting, slow-release dihydropyridines	
Mitral stenosis	β Adrenergic receptor antagonists	
Hypertrophic cardiomyopathy	β Adrenergic receptor antagonists, nondihydropyridine Ca ²⁺ channel antagonists	Nitrates, dihydropyridine Ca ²⁺ channel antagonists

SOURCE: Modified from Gibbons *et al.*, 1999. MI, myocardial infarction; LVEF, left ventricular ejection fraction.

with exertional angina with heart failure, the sick-sinus syndrome, or AV nodal conduction disturbances, but excessive tachycardia may be seen.

Ca²⁺ Channel Blockers, β Adrenergic Receptor Antagonists, and Nitrates. In patients with exertional angina that is not controlled by the administration of two types of antianginal agents, the use of all three may provide improvement, although the incidence of side effects increases significantly. The dihydropyridines and nitrates dilate epicardial coronary arteries; the dihydropyridines decrease afterload; the nitrates decrease preload; and the β adrenergic receptor antagonists decrease heart rate and myocardial contractility. Therefore, there is theoretical, and sometimes real, benefit with their combination, although adverse drug interactions may lead to clinically important events. For example, combining verapamil or diltiazem with a β adrenergic receptor antagonist greatly increases the risk of conduction system and left ventricular dysfunction–related side effects and should be undertaken only with extreme caution and only if no other alternatives exist.

ANTIPLATELET, ANTI-INTEGRIN, AND ANTITHROMBOTIC AGENTS

Aspirin reduces the incidence of MI and death in patients with unstable angina. In addition, low doses of aspirin appear to reduce the incidence of MI in patients with chronic stable angina. Aspirin, given in doses of 160 to 325 mg at the onset of treatment of MI, reduces mortality in patients presenting with unstable angina. The addition of clopidogrel to aspirin therapy reduces mortality in patients with acute coronary syndromes (Lange and Hillis, 2004). Heparin, in its unfractionated form and as low-molecular-weight heparin, also reduces symptoms and prevents infarction in unstable angina (Yeghiazarians *et al.*, 2000). Thrombin inhibitors, such as *hirudin* or *bivalirudin*, are being investigated; these agents directly inhibit even clot-bound thrombin, are not affected by circulating inhibitors, and function independently of antithrombin III. Thrombolytic agents, on the other hand, are of no benefit in unstable angina (Yeghiazarians *et al.*, 2000). Intravenous inhibitors of the platelet GPIIb/IIIa receptor (abciximab, tirofiban, and eptifibatide) are effective in preventing the complications of PCIs and in the treatment of patients presenting with acute coronary syndromes (Bhatt and Topol, 2000; Lange and Hillis, 2004).

TREATMENT OF CLAUDICATION AND PERIPHERAL VASCULAR DISEASE

Most patients with peripheral vascular disease also have coronary artery disease, and the therapeutic approaches

for peripheral and coronary arterial diseases overlap. Mortality in patients with peripheral vascular disease is most commonly due to cardiovascular disease (Regensteiner and Hiatt, 2002), and treatment of coronary disease remains the central focus of therapy. Many patients with advanced peripheral arterial disease are more limited by the consequences of peripheral ischemia than by myocardial ischemia. In the cerebral circulation, arterial disease may be manifest as stroke or transient ischemic attacks. The painful symptoms of peripheral arterial disease in the lower extremities (claudication) typically are provoked by exertion, with increases in skeletal muscle O₂ demand exceeding blood flow impaired by proximal stenoses. When flow to the extremities becomes critically limiting, peripheral ulcers and rest pain from tissue ischemia can become debilitating.

Most of the therapies shown to be efficacious for treatment of coronary artery disease also have a salutary effect on progression of peripheral artery disease. Reductions in cardiovascular morbidity and mortality in patients with peripheral arterial disease have been documented with antiplatelet therapy using aspirin or with ADP antagonists such as clopidogrel or ticlopidine, administration of ACE inhibitors, and treatment of hyperlipidemia (Regensteiner and Hiatt, 2002). Interestingly, neither intensive treatment of diabetes mellitus nor antihypertensive therapy appears to alter the progression of symptoms of claudication. Other risk factor and lifestyle modifications remain cornerstones of therapy for patients with claudication: Physical exercise, rehabilitation, and smoking cessation have proven efficacy. Drugs used specifically in the treatment of lower extremity claudication include *pentoxifylline* and *cilostazol* (Hiatt, 2001). Pentoxifylline is a methylxanthine derivative that has been termed a *rheologic modifier* for its effects on increasing the deformability of red blood cells. However, the effects of pentoxifylline on lower extremity claudication appear to be modest. Cilostazol is an inhibitor of PDE3 and promotes accumulation of intracellular cyclic AMP in many cells, including blood platelets. Cilostazol-mediated increases in cyclic AMP inhibit platelet aggregation and promote vasodilation. The drug is metabolized by CYP3A4 and has important drug interactions with other drugs metabolized *via* this pathway (*see* Chapter 3). Cilostazol treatment improves symptoms of claudication but has no effect on cardiovascular mortality. As a PDE3 inhibitor, cilostazol is placed in the same drug class as *milrinone*, which had been used as an inotropic agent for patients with heart failure. Milrinone therapy was associated with an increase in sudden cardiac death, and the drug was withdrawn from the market. Cilostazol, therefore, is contraindicated in patients with heart failure,

although it is not clear that cilastazol itself leads to increased mortality in such patients. Cilastazol has been reported to increase nonsustained ventricular tachycardia; headache is the most common side effect. Other treatments for claudication, including *naftidrofuryl*, *propionyl levocarnitine*, and *prostaglandins*, have been explored in clinical trials, and there is some evidence that some of these therapies may be efficacious.

MECHANOPHARMACOLOGICAL THERAPY: DRUG-ELUTING ENDOVASCULAR STENTS

Intracoronary stents can ameliorate angina and reduce adverse events in patients with acute coronary syndromes. However, the long-term efficacy of intracoronary stents is limited by subacute luminal restenosis within the stent, which occurs in a substantial minority of patients. The pathways that lead to “in-stent restenosis” are complex, but smooth muscle proliferation within the lumen of the stented artery is a common pathological finding (Schwartz and Henry, 2002). Local antiproliferative therapies at the time of stenting have been explored over many years, and the development of drug-eluting stents has had an important impact on clinical practice (Moses *et al.*, 2003; Stone *et al.*, 2004). Two drugs are currently being used in intravascular stents: *paclitaxel* (TAXOL) and *sirolimus* (RAPAMYCIN). Paclitaxel is a tricyclic diterpene that inhibits cellular proliferation by binding to and stabilizing polymerized microtubules. Sirolimus is a hydrophobic macrolide that binds to the cytosolic immunophilin FKBP12; the FKBP12–sirolimus complex inhibits the mammalian kinase target of RAPAMYCIN (mTOR), thereby inhibiting cell cycle progression (*see* Chapter 53). Paclitaxel and sirolimus differ markedly in their mechanisms of action but share common chemical properties as hydrophobic small molecules. Differences in the intracellular targets of these two drugs are associated with marked differences in their distribution in the vascular wall (Levin *et al.*, 2004). Stent-induced damage to the vascular endothelial cell layer can lead to thrombosis; patients typically are treated with antiplatelet agents, including clopidogrel (for up to 6 months) and aspirin (indefinitely), sometimes in conjunction with intravenously administered GPIIb/IIIa inhibitors. The inhibition of cellular proliferation by paclitaxel and sirolimus not only affects vascular smooth muscle cell proliferation but also attenuates the formation of an intact endothelial layer within the stented artery. Therefore, antiplatelet therapy (typically with clopidogrel)

is continued for several months after intracoronary stenting with drug-eluting stents. The rate of restenosis with drug-eluting stents is reduced markedly compared with “bare metal” stents, and the ongoing development of mechanopharmacological approaches likely will lead to novel approaches in intravascular therapeutics.

THERAPY OF HYPERTENSION

Brian B. Hoffman

Hypertension is the most common cardiovascular disease. The prevalence of hypertension increases with advancing age; for example, about 50% of people between the ages of 60 and 69 years old have hypertension, and the prevalence is further increased beyond age 70 (Chobanian *et al.*, 2003).

Elevated arterial pressure causes pathological changes in the vasculature and hypertrophy of the left ventricle. As a consequence, hypertension is the principal cause of stroke, is a major risk factor for coronary artery disease and its attendant complications myocardial infarction and sudden cardiac death, and is a major contributor to cardiac failure, renal insufficiency, and dissecting aneurysm of the aorta.

Hypertension is defined conventionally as a sustained increase in blood pressure $\geq 140/90$ mm Hg, a criterion that characterizes a group of patients whose risk of hypertension-related cardiovascular disease is high enough to merit medical attention. Actually, the risk of both fatal and nonfatal cardiovascular disease in adults is lowest with systolic blood pressures of less than 120 mm Hg and diastolic BP less than 80 mm Hg; these risks increase progressively with higher systolic and diastolic blood pressures. Recognition of this continuously increasing risk provides a simple definition of hypertension (Chobanian *et al.*, 2003) (Table 32–1). Although many of the clinical trials classify the severity of hypertension by diastolic pressure, progressive elevations of systolic pressure are similarly predictive of adverse cardiovascular events; at every level of diastolic pressure, risks are greater with higher levels of systolic blood pressure. Indeed, beyond age 50 years, systolic blood pressure predicts outcome better than diastolic blood pressure. Systolic blood pressure tends to rise disproportionately greater in the elderly due to decreased compliance in blood vessels associated with

aging and atherosclerosis. Isolated systolic hypertension (sometimes defined as systolic BP >140 to 160 mm Hg with diastolic BP <90 mm Hg) is largely confined to people >60 years of age.

At very high blood pressures (systolic ≥ 210 and/or diastolic ≥ 120 mm Hg), a subset of patients develops fulminant arteriopathy characterized by endothelial injury and a marked proliferation of cells in the intima, leading to intimal thickening and ultimately to arteriolar occlusion. This is the pathological basis of the syndrome of immediately life-threatening hypertension, which is associated with rapidly progressive microvascular occlusive disease in the kidney (with renal failure), brain (hypertensive encephalopathy), congestive heart failure, and pulmonary edema. These patients typically require in-hospital management on an emergency basis for prompt lowering of blood pressure. Interestingly, isolated retinal changes with papilledema in an otherwise asymptomatic patient with very high blood pressure (formerly called “malignant hypertension”) may benefit from a more gradual lowering of blood pressure over days rather than hours.

The presence of pathologic changes in certain target organs heralds a worse prognosis than the same level of blood pressure in a patient lacking these findings. Thus, retinal hemorrhages, exudates, and papilledema indicate a far worse short-term prognosis for a given level of blood pressure. Left ventricular hypertrophy defined by electrocardiogram, or more sensitively by echocardiography, is associated with a substantially worse long-term outcome that includes a higher risk of sudden cardiac death. The risk of cardiovascular disease, disability, and death in hypertensive patients also is increased markedly by concomitant cigarette smoking, diabetes, or elevated low-density lipoprotein; the coexistence of hypertension with these risk factors increases cardiovascular morbidity and mortality to a degree that is compounded by each additional risk factor. Since the purpose of treating hypertension is to decrease cardiovascular risk, other dietary and pharmacological interventions may be required.

Pharmacological treatment of patients with hypertension associated with elevated diastolic pressures reduces morbidity and mortality from cardiovascular disease. Effective antihypertensive therapy markedly reduces the

Table 32–1
Criteria for Hypertension in Adults

CLASSIFICATION	BLOOD PRESSURE (MM HG)	
	Systolic	Diastolic
Normal	<120	and <80
Pre-hypertension	120–139	or 80–89
Hypertension, stage 1	140–159	or 90–99
Hypertension, stage 2	≥160	or ≤100

risk of strokes, cardiac failure, and renal insufficiency due to hypertension. However, reduction in risk of myocardial infarction may be less impressive.

Principles of Antihypertensive Therapy. Nonpharmacological therapy is an important component of treatment of all patients with hypertension. In some stage 1 hypertensives, blood pressure may be adequately controlled by a combination of weight loss (in overweight individuals), restricting sodium intake, increasing aerobic exercise, and moderating consumption of alcohol. These lifestyle changes, though difficult for many to implement, may facilitate pharmacological control of blood pressure in patients whose responses to lifestyle changes alone are insufficient.

Arterial pressure is the product of cardiac output and peripheral vascular resistance. Drugs lower blood pressure by actions on peripheral resistance, cardiac output, or both. Drugs may reduce the cardiac output by inhibiting myocardial contractility or by decreasing ventricular filling pressure. Reduction in ventricular filling pressure may be achieved by actions on the venous tone or on blood volume *via* renal effects. Drugs can reduce peripheral resistance by acting on smooth muscle to cause relaxation of resistance vessels or by interfering with the activity of systems that produce constriction of resistance vessels (*e.g.*, the sympathetic nervous system). In patients with isolated systolic hypertension, complex hemodynamics in a rigid arterial system contribute to increased blood pressure; drug effects may be mediated by changes in peripheral resistance but also *via* effects on large artery stiffness (Franklin, 2000). Antihypertensive drugs can be classified according to their sites or mechanisms of action (Table 32–2).

The hemodynamic consequences of long-term treatment with antihypertensive agents (Table 32–3) provide a rationale for potential complementary effects of concur-

Table 32–2
Classification of Antihypertensive Drugs by Their Primary Site or Mechanism of Action

Diuretics (Chapter 28)

1. Thiazides and related agents (hydrochlorothiazide, chlorthalidone, *etc.*)
2. Loop diuretics (furosemide, bumetanide, torsemide, ethacrynic acid)
3. K⁺-sparing diuretics (amiloride, triamterene, spironolactone)

Sympatholytic drugs (Chapters 9, 10, and 33)

1. β Adrenergic antagonists (metoprolol, atenolol, *etc.*)
2. α Adrenergic antagonists (prazosin, terazosin, doxazosin, phenoxybenzamine, phentolamine)
3. Mixed adrenergic antagonists (labetalol, carvedilol)
4. Centrally acting agents (methyldopa, clonidine, guanabenz, guanfacine)
5. Adrenergic neuron blocking agents (guanadrel, reserpine)

Ca²⁺ channel blockers (Chapters 31 through 34)

(verapamil, diltiazem, nimodipine, felodipine, nicardipine, isradipine, amlodipine)

Angiotensin converting enzyme inhibitors (Chapters 30 and 31),

(captopril, enalapril, lisinopril, quinapril, ramipril, benazepril, fosinopril, moexipril, perindopril, trandolapril)

Angiotensin II–receptor antagonists (Chapters 30 and 33) (losartan, candesartan, irbesartan, valsartan, telmisartan, eprosartan)

Vasodilators (Chapter 33)

1. Arterial (hydralazine, minoxidil, diazoxide, fenoldopam)
2. Arterial and venous (nitroprusside)

rent therapy with two or more drugs. The simultaneous use of drugs with similar mechanisms of action and hemodynamic effects often produces little additional benefit. However, concurrent use of drugs from different classes is a strategy for achieving effective control of blood pressure while minimizing dose-related adverse effects.

It is generally not possible to predict the responses of individuals with hypertension to any specific drug. For example, for some antihypertensive drugs, on average about two-thirds of patients will have a meaningful clinical response, whereas about one-third of patients will not respond to the same drug. There is considerable interest in identifying genetic variation in order to improve selection of antihypertensive drugs in individual patients.

Table 32-3
Hemodynamic Effects of Long-Term Administration of Antihypertensive Agents

	HEART RATE	CARDIAC OUTPUT	TOTAL PERIPHERAL RESISTANCE	PLASMA VOLUME	PLASMA RENIN ACTIVITY
Diuretics	↔	↔	↓	↓	↑
Sympatholytic agents					
Centrally acting	↓	↓	↓	↑	↓
Adrenergic neuron blockers	↓	↓	↓	↑	↑
α Adrenergic antagonists	↑	↑	↓	↑	↔
β Adrenergic antagonists					
No ISA*	↓	↓	↓	↑	↓
ISA	↔	↔	↓	↑	↓
Arteriolar vasodilators	↑	↑	↓	↑	↑
Ca ²⁺ channel blockers	↓ or ↑	↓ or ↑	↓	↑	↑
ACE inhibitors	↔	↔	↓	↔	↑
AT ₁ -receptor antagonists	↔	↔	↓	↔	↑

Changes are indicated as follows: ↑, increased; ↓, decreased; -↑, increased or no change; -↓, decreased or no change; ↔, unchanged. *ISA, intrinsic sympathomimetic activity. ACE, angiotensin converting enzyme; AT₁, the type I receptor for angiotensin II.

Polymorphisms in a number of genes involved in the metabolism of antihypertensive drugs have been identified, for example in the CYP family (phase I metabolism) and in phase II metabolism, such as catechol-O-methyltransferase. While these polymorphisms change the pharmacokinetics of specific drugs, it is not clear that there will be substantial differences in efficacy given the dose range available clinically for these drugs. Consequently, identification of polymorphisms that influence pharmacodynamic responses to antihypertensive drugs are of considerable interest. Polymorphisms influencing the actions of a number of classes of antihypertensive drugs, including angiotensin-converting enzyme inhibitors and diuretics, have been identified; so far, individual genes have not been found to have a major impact on pharmacodynamic responses. Genome-wide scanning may lead to identification of novel genes that are more clinically significant. Likewise, treatment may profit from an understanding of the molecular and genetic bases of hypertension (Garbers and Dubois, 1999).

DIURETICS

An early strategy for the management of hypertension was to alter Na⁺ balance by restriction of salt in the diet. Pharmacological alteration of Na⁺ balance became practical with the development of the orally active thiazide diuretics (see Chapter 28). These and related diuretic agents have antihypertensive effects when used alone, and they enhance the efficacy of virtually all other antihypertensive drugs. On account of these considerations, coupled with the very large favorable experience with

diuretics in randomized trials in patients with hypertension, this class of drugs remains very important in the treatment of hypertension.

The exact mechanism for reduction of arterial blood pressure by diuretics is not certain. Initially, the drugs decrease extracellular volume by interacting with a thiazide-sensitive Na-Cl cotransporter in the kidney, leading to a fall in cardiac output. However, the hypotensive effect is maintained during long-term therapy because of reduced vascular resistance; cardiac output returns to pretreatment values and extracellular volume returns almost to normal due to compensatory responses such as activation of the renin-angiotensin system. How this occurs is unknown; however, thiazides promote vasodilation in isolated vessels from laboratory animals and humans.

Hydrochlorothiazide may open Ca²⁺-activated K⁺ channels, leading to hyperpolarization of vascular smooth muscle cells, which leads in turn to closing of L-type Ca²⁺ channels and lower probability of opening, resulting in decreased Ca²⁺ entry and reduced vasoconstriction (Pickkers and Hughes, 1995). Hydrochlorothiazide also inhibits vascular carbonic anhydrase, which hypothetically may alter smooth-cell systolic pH and thereby cause opening of Ca²⁺-activated K⁺ channels with the consequences noted above (Pickkers *et al.*, 1999). The relevance of this intriguing finding to the observed antihypertensive effects of thiazides is speculative.

Benzothiadiazines and Related Compounds

Benzothiadiazines (“thiazides”) and related diuretics are the most frequently used class of antihypertensive agents in the United States. Following the discovery of *chlorothiazide*, a

number of oral diuretics were developed that have an arylsulfonamide structure and block the $\text{Na}^+\text{-Cl}^-$ cotransporter. Some of these are not benzothiadiazines but have structural features and molecular functions that are similar to the original benzothiadiazine compounds; thus, they are designated as members of the thiazide class of diuretics. For example, *chlorthalidone*, one of the nonbenzothiadiazines, is widely used in the treatment of hypertension. Because members of the thiazide class have the same pharmacological effects, they are generally interchangeable with appropriate adjustment of dosage (see Chapter 28). However, since the pharmacokinetics and pharmacodynamics of these drugs may differ, they may not necessarily have the same clinical efficacy in treating hypertension (Carter *et al.*, 2004).

Regimen for Administration of the Thiazide-Class Diuretics in Hypertension. When a thiazide-class diuretic is utilized as the sole antihypertensive drug (monotherapy), its dose-response curve for lowering blood pressure in patients with hypertension should be kept in mind. Antihypertensive effects can be achieved in many patients with as little as 12.5 mg of chlorthalidone (HYGROTON) or hydrochlorothiazide (HYDRODIURIL) daily. Furthermore, when used as monotherapy, the maximal daily dose of thiazide-class diuretics usually should not exceed 25 mg of hydrochlorothiazide or chlorthalidone (or equivalent). Even though more diuresis can be achieved with higher doses of these diuretics, evidence indicates that doses higher than this are not generally more efficacious in patients with normal renal function. These doses of hydrochlorothiazide are not at the top of the dose-response curve for adverse effects such as K^+ wasting and inhibition of uric acid excretion (see below), emphasizing the importance of knowledge about the dose-response relationships for both beneficial and adverse effects.

A large study comparing 25 and 50 mg of hydrochlorothiazide daily in an elderly population did not show a greater decrease in blood pressure with the larger dose (Medical Research Council Working Party, 1987). In the clinical trials of antihypertensive therapy in the elderly that demonstrated the best outcomes in cardiovascular morbidity and mortality, 25 mg of hydrochlorothiazide or chlorthalidone was the maximum dose given; if this dose did not achieve the target blood pressure reduction, treatment with a second drug was initiated (SHEP Cooperative Research Group, 1991; Dahlöf *et al.*, 1991; Medical Research Council Working Party, 1992). With respect to safety, a case-control study (Siscovick *et al.*, 1994) found a dose-dependent increase in the occurrence of sudden death at doses of hydrochlorothiazide greater than 25 mg daily. This finding supports the hypothesis proposed by the Multiple Risk Factor Intervention Trial Research Group (1982), suggesting that increased cardiovascular mortality is associated with higher diuretic doses. Taken together, clinical studies indicate that if adequate blood pressure reduction is not achieved with the 25-mg daily dose of hydro-

chlorothiazide or chlorthalidone, a second drug should be added rather than increasing the dose of diuretic. There is some concern that thiazide diuretics, especially at higher doses and in the absence of K^+ -sparing diuretics or K^+ supplements, may increase the risk of sudden death. However, their overall therapeutic benefits are well established.

Urinary K^+ loss can be a problem with thiazides. Angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor antagonists will attenuate diuretic-induced loss of potassium to some degree, and this is a consideration if a second drug is required to achieve further blood pressure reduction beyond that attained with the diuretic alone. Because the diuretic and hypotensive effects of these drugs are greatly enhanced when they are given in combination, care should be taken to initiate combination therapy with low doses of each of these drugs. Administration of ACE inhibitors or angiotensin receptor antagonists together with other K^+ -sparing agents or with K^+ supplements requires great caution; combining K^+ -sparing agents with each other or with K^+ supplementation can cause potentially dangerous hyperkalemia in some patients.

In contrast to the limitation on the dose of thiazide-class diuretics used as monotherapy, the treatment of severe hypertension that is unresponsive to three or more drugs may require larger doses of the thiazide-class diuretics. Indeed, hypertensive patients may become refractory to drugs that block the sympathetic nervous system or to vasodilator drugs, because these drugs engender a state in which the blood pressure is very volume-dependent. Therefore, it is appropriate to consider the use of thiazide-class diuretics in doses of 50 mg of daily hydrochlorothiazide equivalent when treatment with appropriate combinations and doses of three or more drugs fails to yield adequate control of the blood pressure. Alternatively, there may be a need to use higher-capacity diuretics such as *furosemide*, especially if renal function is not normal, in some of these patients. Dietary Na^+ restriction is a valuable adjunct to the management of such refractory patients and will minimize the dose of diuretic that is required. This can be achieved by a modest restriction of Na^+ intake to 2 g daily. More stringent Na^+ restriction is not feasible for most patients. Since the degree of K^+ loss relates to the amount of Na^+ delivered to the distal tubule, such restriction of Na^+ can minimize the development of hypokalemia and alkalosis. The effectiveness of thiazides as diuretics or antihypertensive agents is progressively diminished when the glomerular filtration rate falls below 30 ml/min. One exception is *metolazone*, which retains efficacy in patients with this degree of renal insufficiency.

Most patients will respond to thiazide diuretics with a reduction in blood pressure within about 4 weeks, although a minority will not achieve maximum reduction in arterial pressure for up to 12 weeks on a given dose. Therefore, doses should not be increased more often than every 4 to 6 weeks. There is no way to predict the antihypertensive response from the duration or severity of the hypertension in a given patient, although diuretics are unlikely to be effective as sole therapy in patients with stage 2 hypertension. Since the effect of thiazide diuretics is additive with that of other antihypertensive drugs, combination regimens that include these diuretics are common and rational. Diuretics also have the advantage of minimizing the retention of salt and water that is commonly caused by vasodilators and some sympatholytic drugs. Omitting or underutilizing a diuretic is a frequent cause of “resistant hypertension.”

Adverse Effects and Precautions. The adverse effects of diuretics are discussed in Chapter 28. Some of these determine whether patients can tolerate and adhere to diuretic treatment. Erectile dysfunction is a troublesome adverse effect of the thiazide-class diuretics, and physicians should inquire specifically regarding its occurrence in conjunction with treatment with these drugs. Gout may be a consequence of the hyperuricemia induced by these diuretics. The occurrence of either of these adverse effects is a reason for considering alternative approaches to therapy. However, precipitation of acute gout is relatively uncommon with low doses of diuretics. Hydrochlorothiazide may cause rapidly developing, severe hyponatremia in some patients. Thiazides inhibit renal Ca^{2+} excretion, occasionally leading to hypercalcemia; although generally mild, this can be more severe in patients subject to hypercalcemia, such as those with primary hyperparathyroidism. The thiazide-induced decreased Ca^{2+} excretion may be used therapeutically in patients with osteoporosis or hypercalciuria.

Some other effects of thiazide diuretics are laboratory observations that are of concern primarily because they are putative *surrogate markers* for adverse drug effects on morbidity and mortality. See Chapter 5 for a discussion of the utility and problem of surrogate markers.

The effects of diuretic drugs on several surrogate markers for adverse outcomes merit consideration. The K^+ depletion produced by thiazide-class diuretics is dose-dependent and is variable among individuals, such that a subset of patients may become substantially K^+ depleted on diuretic drugs. Given chronically, even small doses lead to some K^+ depletion.

There are two types of ventricular arrhythmias that are thought to be enhanced by K^+ depletion. One of these is polymorphic ventricular tachycardia (*torsades de pointes*), which is induced by a number of drugs, including *quinidine*. Drug-induced polymorphic ventricular tachycardia is initiated by abnormal ventricular repolarization; because K^+

currents normally mediate repolarization, drugs that produce K^+ depletion potentiate polymorphic ventricular tachycardia. Accordingly, thiazide diuretics should not be given together with drugs that can cause polymorphic ventricular tachycardia (see Chapter 34).

The most important concern regarding K^+ depletion is its influence on ischemic ventricular fibrillation, the leading cause of sudden cardiac death and a major contributor to cardiovascular mortality in treated hypertensive patients. Studies in experimental animals have demonstrated that K^+ depletion lowers the threshold for electrically induced ventricular fibrillation in the ischemic myocardium and also increases spontaneous ischemic ventricular fibrillation (Curtis and Hearse, 1989). There is a positive correlation between diuretic dose and sudden cardiac death, and an inverse correlation between the use of adjunctive K^+ -sparing agents and sudden cardiac death (Siscovick *et al.*, 1994). One controlled clinical trial demonstrated a significantly greater occurrence of sudden cardiac death in patients treated with 50 mg of hydrochlorothiazide daily in comparison with the β adrenergic receptor antagonist *metoprolol* (Medical Research Council Working Party, 1992).

Thiazide diuretics have been associated with changes in plasma lipids and glucose tolerance that have led to some concern. The clinical significance of the changes has been disputed. Nonetheless, recent clinical studies continue to demonstrate the efficacy of the thiazide diuretics in reducing cardiovascular risk (ALLHAT Officers, 2002).

All of the thiazide-like drugs cross the placenta, but they have not been shown to have direct adverse effects on the fetus. However, if administration of a thiazide is begun during pregnancy, there is a risk of transient volume depletion that may result in placental hypoperfusion. Since the thiazides appear in breast milk, they should be avoided by nursing mothers.

Other Diuretic Antihypertensive Agents

The thiazide diuretics are more effective antihypertensive agents than are the loop diuretics, such as furosemide and *bumetanide*, in patients who have normal renal function. This differential effect is most likely related to the short duration of action of loop diuretics, such that a single daily dose does not cause a significant net loss of Na^+ for an entire 24-hour period. Indeed, loop diuretics are frequently and inappropriately prescribed as a once-a-day medication in the treatment not only of hypertension, but also of congestive heart failure and ascites. The spectacular efficacy of the loop diuretics in producing a rapid and profound natriuresis can be detrimental for the treatment of hypertension. When a loop diuretic is given twice daily, the acute diuresis can be excessive and lead to more side effects than occur with a slower-acting, milder thiazide diuretic. Loop diuretics may be particularly useful in patients with

azotemia or with severe edema associated with a vasodilator such as *minoxidil*.

Amiloride is a K⁺-sparing diuretic that has some efficacy in lowering blood pressure in patients with hypertension. *Spironolactone* also lowers blood pressure but has some significant adverse effects, especially in men (e.g., impotence, gynecomastia, and benign prostatic hyperplasia). As a result of their capacity to inhibit loss of K⁺ in the urine, these drugs are used in the medical treatment of patients with hyperaldosteronism, a syndrome that can lead to hypokalemia. *Triamterene* is a K⁺-sparing diuretic that decreases the risk of hypokalemia in patients treated with a thiazide diuretic, but does not have efficacy in lowering blood pressure by itself. These agents should be used cautiously with frequent measurements of K⁺ concentrations in plasma in patients predisposed to hyperkalemia. Patients taking spironolactone, amiloride, or triamterene should be cautioned regarding the possibility that concurrent use of K⁺-containing salt substitutes could produce hyperkalemia. Renal insufficiency is a relative contraindication to the use of K⁺-sparing diuretics. *Concomitant use of an ACE inhibitor or an angiotensin-receptor antagonist magnifies the risk of hyperkalemia with these agents.*

Diuretic-Associated Drug Interactions

Since the antihypertensive effects of diuretics are frequently additive with those of other antihypertensive agents, a diuretic commonly is used in combination with other drugs. The K⁺- and Mg²⁺-depleting effects of the thiazides and loop diuretics also can potentiate arrhythmias that arise from *digitalis* toxicity. Corticosteroids can amplify the hypokalemia produced by the diuretics. All diuretics can decrease the clearance of Li⁺, resulting in increased plasma concentrations of Li⁺ and potential toxicity. Nonsteroidal antiinflammatory drugs (see Chapter 26) that inhibit the synthesis of prostaglandins reduce the antihypertensive effects of diuretics. The effects of selective cyclooxygenase-2 (COX-2) inhibitors on renal prostaglandin synthesis and function are similar to those of the traditional nonsteroidal antiinflammatory drugs. Nonsteroidal antiinflammatory drugs, β adrenergic receptor antagonists, and ACE inhibitors reduce plasma concentrations of aldosterone and can potentiate the hyperkalemic effects of a K⁺-sparing diuretic.

SYMPATHOLYTIC AGENTS

With the demonstration in 1940 that bilateral excision of the thoracic sympathetic chain could lower blood pressure, there was a search for effective chemical sympatholytic agents. Many of the early sympathetic drugs were poorly tolerated and had adverse side effects. A number of sympathetic agents are currently in use (Table 32-2). Antagonists of α and β adrenergic receptors are mainstays of antihypertensive therapy.

β Adrenergic Receptor Antagonists

β Adrenergic receptor antagonists were not expected to have antihypertensive effects when they were first investigated in patients with angina, their primary indication. However, *pronethalol*, a drug that was never marketed, was found to reduce arterial blood pressure in hypertensive

patients with angina pectoris. This antihypertensive effect was subsequently demonstrated for *propranolol* and all other β adrenergic receptor antagonists. The pharmacology of these drugs is discussed in Chapter 10; characteristics relevant to their use in hypertension are described here.

Locus and Mechanism of Action. Antagonism of β adrenergic receptors affects the regulation of the circulation through a number of mechanisms, including a reduction in myocardial contractility, heart rate, and cardiac output. An important consequence of using β adrenergic receptors is blockade of the β receptors of the juxtaglomerular complex, reducing renin secretion and thereby diminishing production of circulating angiotensin II. This action likely contributes to the antihypertensive action of this class of drugs, in concert with the cardiac effects. β Adrenergic receptor antagonists may lower blood pressure by other mechanisms, including alteration of the control of the sympathetic nervous system at the level of the CNS, altered baroreceptor sensitivity, altered peripheral adrenergic neuron function, and increased *prostacyclin* biosynthesis. Because all β adrenergic receptor antagonists are effective antihypertensive agents and (+)-propranolol, the inactive isomer that has little β adrenergic receptor blocking activity, has no effect on blood pressure, the antihypertensive therapeutic effect of these agents is undoubtedly related to receptor blockade.

Pharmacological Effects. The β adrenergic blockers vary in their lipid solubility, selectivity for the β_1 adrenergic receptor subtype, presence of partial agonist or intrinsic sympathomimetic activity, and membrane-stabilizing properties. Despite these differences, all of the β adrenergic receptor antagonists are effective as antihypertensive agents. However, these differences do influence the clinical pharmacokinetics and spectrum of adverse effects of the various drugs. Drugs without intrinsic sympathomimetic activity produce an initial reduction in cardiac output and a reflex-induced rise in peripheral resistance, generally with no net change in arterial pressure. In patients who respond with a reduction in blood pressure, peripheral resistance gradually returns to pretreatment values or less. Generally, persistently reduced cardiac output and possibly decreased peripheral resistance accounts for the reduction in arterial pressure. Drugs with intrinsic sympathomimetic activity produce lesser decreases in resting heart rate and cardiac output; the fall in arterial pressure correlates with a fall in vascular resistance below pretreatment levels, possibly because of stimulation of vascular β_2 adrenergic receptors that mediate vasodilation. The clinical significance, if any, of these differences is unknown.

Adverse Effects and Precautions. The adverse effects of β adrenergic blocking agents are discussed in Chapter 10. These drugs should be avoided in patients with reactive airway disease (asthma) or with sinoatrial or atrioventricular (AV) nodal dysfunction or in combination with other drugs that inhibit AV conduction, such as *verapamil*. Patients with insulin-dependent diabetes also are better treated with other drugs.

β Receptor antagonists without intrinsic sympathomimetic activity increase concentrations of triglycerides in plasma and lower those of HDL cholesterol without changing total cholesterol concentrations. β Adrenergic blocking agents with intrinsic sympathomimetic activity have little or no effect on blood lipids or increase HDL cholesterol. The long-term consequences of these effects are unknown.

Sudden discontinuation of some β adrenergic blockers can produce a withdrawal syndrome that is likely due to up-regulation of β receptors during blockade, causing enhanced tissue sensitivity to endogenous catecholamines; this can exacerbate the symptoms of coronary artery disease. The result, especially in active patients, can be rebound hypertension. Thus, β adrenergic blockers should not be discontinued abruptly except under close observation; dosage should be tapered over 10 to 14 days prior to discontinuation.

Nonsteroidal antiinflammatory drugs such as *indomethacin* can blunt the antihypertensive effect of propranolol and probably other β receptor antagonists. This effect may be related to inhibition of vascular synthesis of prostacyclin, as well as to retention of Na^+ (Beckmann *et al.*, 1988).

Epinephrine can produce severe hypertension and bradycardia when a nonselective β receptor antagonist is present. The hypertension is due to the unopposed stimulation of α adrenergic receptors when vascular β_2 receptors are blocked; the bradycardia is the result of reflex vagal stimulation. Such paradoxical hypertensive responses to β adrenergic receptor antagonists have been observed in patients with hypoglycemia or pheochromocytoma, during withdrawal from *clonidine*, following administration of epinephrine as a therapeutic agent, or in association with the illicit use of cocaine.

Therapeutic Uses. The β receptor antagonists provide effective therapy for all grades of hypertension. Despite marked differences in their pharmacokinetic properties, the antihypertensive effect of all the β blockers is of sufficient duration to permit once or twice daily administration. Populations that tend to have a lesser antihypertensive response to β -blocking agents include the

elderly and African-Americans. However, intraindividual differences in antihypertensive efficacy are generally much larger than statistical evidence of differences between racial or age-related groups. Consequently, these observations should not discourage the use of these drugs in individual patients in groups reported to be less responsive.

The β receptor antagonists do not usually cause retention of salt and water, and administration of a diuretic is not necessary to avoid edema or the development of tolerance. However, diuretics do have additive antihypertensive effects when combined with β blockers. The combination of a β receptor antagonist, a diuretic, and a vasodilator is effective for patients who require a third drug. β Adrenergic receptor antagonists are highly preferred drugs for hypertensive patients with conditions such as myocardial infarction, ischemic heart disease, or congestive heart failure.

α_1 Adrenergic Antagonists

The availability of drugs that selectively block α_1 adrenergic receptors without affecting α_2 adrenergic receptors adds another group of antihypertensive agents. The pharmacology of these drugs is discussed in detail in Chapter 10. *Prazosin* (MINIPRESS), *terazosin* (HYTRIN), and *doxazosin* (CARDURA) are the agents that are available for the treatment of hypertension.

Pharmacological Effects. Initially, α_1 adrenergic receptor antagonists reduce arteriolar resistance and increase venous capacitance; this causes a sympathetically mediated reflex increase in heart rate and plasma renin activity. During long-term therapy, vasodilation persists, but cardiac output, heart rate, and plasma renin activity return to normal. Renal blood flow is unchanged during therapy with an α_1 receptor antagonist. The α_1 adrenergic blockers cause a variable amount of postural hypotension, depending on the plasma volume. Retention of salt and water occurs in many patients during continued administration, and this attenuates the postural hypotension. α_1 Receptor antagonists reduce plasma concentrations of triglycerides and total LDL cholesterol and increase HDL cholesterol. These potentially favorable effects on lipids persist when a thiazide-type diuretic is given concurrently. The long-term consequences of these small, drug-induced changes in lipids are unknown.

Adverse Effects. The use of doxazosin as monotherapy for hypertension increased the risk for developing congestive heart failure (ALLHAT Officers, 2002). This

may be a class effect that represents an adverse effect of all of the α_1 adrenergic receptor antagonists. However, this interpretation of the outcome of the ALLHAT study is controversial.

A major precaution regarding the use of the α_1 receptor antagonists for hypertension is the so-called first-dose phenomenon, in which symptomatic orthostatic hypotension occurs within 90 minutes of the initial dose of the drug or after a dosage increase. This effect may occur in up to 50% of patients, especially in patients who are already receiving a diuretic or an α receptor antagonist. After the first few doses, patients develop a tolerance to this marked hypotensive response.

Therapeutic Uses. α_1 Receptor antagonists are not recommended as monotherapy for hypertensive patients. Thus, they are used primarily in conjunction with diuretics, β blockers, and other antihypertensive agents. β Receptor antagonists enhance the efficacy of the α_1 blockers. α_1 Receptor antagonists are not the drugs of choice in patients with pheochromocytoma, because a vasoconstrictor response to epinephrine can still result from activation of unblocked vascular α_2 adrenergic receptors. α_1 Receptor antagonists are attractive drugs for hypertensive patients with benign prostatic hyperplasia, since they also improve urinary symptoms.

Combined α_1 and β Adrenergic Receptor Antagonists

Labetalol (NORMODYNE, TRANDATE) (see Chapter 10) is an equimolar mixture of four stereoisomers. One isomer is an α_1 antagonist (like prazosin), another is a nonselective β antagonist with partial agonist activity (like *pindolol*), and the other two isomers are inactive. Because of its capacity to block α_1 adrenergic receptors, labetalol given intravenously can reduce pressure sufficiently rapidly to be useful for the treatment of hypertensive emergencies. Labetalol has efficacy and side effects that would be expected with any combination of β and α_1 receptor antagonists; it also has the disadvantages that are inherent in fixed-dose combination products: the extent of α receptor antagonism compared to β receptor antagonism is somewhat unpredictable and varies from patient to patient.

Carvedilol (COREG) (see Chapters 10 and 33) is a β receptor antagonist with α_1 receptor antagonist activity. The drug has been approved for the treatment of hypertension and symptomatic heart failure. The ratio of α_1 to β receptor antagonist potency for carvedilol is approximately 1:10. Carvedilol undergoes oxidative metabolism and glucuronidation in the liver; the oxidative metabolism occurs via CYP2D6. Carvedilol reduces mortality in patients with systolic dysfunction and heart failure when used as an adjunct to therapy with diuretics and ACE inhibitors. It should not be given to those patients with decompensated heart failure who are dependent on sympathetic stimulation. As with labetalol, the long-term efficacy and side effects of carvedilol in hypertension are predictable based on its properties as a β and α_1 adrenergic receptor antagonist.

Figure 32–1. The metabolism of methyl dopa in adrenergic neurons. α -Methylnorepinephrine replaces norepinephrine in neurosecretory vesicles.

Methyldopa

Methyldopa (ALDOMET) is a centrally acting antihypertensive agent. It is a prodrug that exerts its antihypertensive action *via* an active metabolite. Although used frequently as an antihypertensive agent in the past, methyl dopa's significant adverse effects limit its current use in the United States to treatment of hypertension in pregnancy, where it has a record for safety.

Methyldopa (α -methyl-3,4-dihydroxy-L-phenylalanine), an analog of 3,4-dihydroxyphenylalanine (DOPA), is metabolized by the L-aromatic amino acid decarboxylase in adrenergic neurons to α -methyldopamine, which then is converted to α -methylnorepinephrine (Figure 32–1). α -Methylnorepinephrine is stored in the secretory vesicles of adrenergic neurons, substituting for norepinephrine (NE) itself. Thus, when the adrenergic neuron discharges its neurotransmitter, α -methylnorepinephrine is released instead of norepinephrine.

Because α -methylnorepinephrine is as potent as norepinephrine as a vasoconstrictor, its substitution for norepinephrine in peripheral adrenergic neurosecretory vesicles does not alter the vasoconstrictor response to peripheral adrenergic neurotransmission. Rather, α -methylnorepinephrine acts in the CNS to inhibit adrenergic neuronal outflow from the brainstem. Methylnorepinephrine probably acts as an agonist at presynaptic α_2 adrenergic receptors in the brainstem, attenuating NE release and thereby reducing the output of vasoconstrictor adrenergic signals to the peripheral sympathetic nervous system.

A body of evidence supports the conclusion that methyl dopa acts in the brain *via* an active metabolite to lower blood pressure (Bobik *et al.*, 1988; Granata *et al.*, 1986; Reid, 1986). In experimental animals, the hypotensive effect of methyl dopa is blocked by DOPA

decarboxylase inhibitors that have access to the brain, but not by inhibitors that are excluded from the CNS. The hypotensive effect also is abolished by inhibitors of dopamine β -hydroxylase and by centrally acting α adrenergic receptor antagonists. Small doses of methyldopa that do not lower blood pressure when injected systemically elicit a hypotensive effect when injected into the vertebral artery. Selective microinjection of α -methylnorepinephrine into the C-1 area of the rostral ventrolateral medulla of the rat elicits a hypotensive response that is prevented by nonselective α receptor blockade and by α_2 receptor blockade. Presumably, methylnorepinephrine inhibits neurons in this area that are responsible for maintaining tonic discharge of peripheral sympathetic nerves and for transmission of baroreflex-initiated tone. The excess α adrenergic inhibition of sympathetic output may reflect the accumulation of methylnorepinephrine in quantities larger than the norepinephrine that it displaces. This model is feasible because methylnorepinephrine is not a substrate for monoamine oxidase, the enzyme principally responsible for norepinephrine degradation in the brain. In addition to inhibiting sympathetic output in the C-1 area of the rostral ventrolateral medulla, methylnorepinephrine may also exert inhibitory effects at other sites such as the solitary tract nucleus.

Pharmacological Effects. Methyldopa reduces vascular resistance without causing much change in cardiac output or heart rate in younger patients with uncomplicated essential hypertension. In older patients, however, cardiac output may be decreased as a result of decreased heart rate and stroke volume; this is secondary to relaxation of veins and a reduction in preload. The fall in arterial pressure is maximal 6 to 8 hours after an oral or intravenous dose. Although the decrease in supine blood pressure is less than that in the upright position, symptomatic orthostatic hypotension is less common with methyldopa than with drugs that act exclusively on peripheral adrenergic neurons or autonomic ganglia; this is because methyldopa attenuates but does not completely block baroreceptor-mediated vasoconstriction. For this reason, it is well tolerated during surgical anesthesia. Any severe hypotension is reversible with volume expansion. Renal blood flow is maintained and renal function is unchanged during treatment with methyldopa.

Plasma concentrations of norepinephrine fall in association with the reduction in arterial pressure, and this reflects the decrease in sympathetic tone. Renin secretion also is reduced by methyldopa, but this is not a major effect of the drug and is not necessary for its hypotensive effects. Salt and water often are gradually retained with prolonged use of methyldopa, and this tends to blunt the antihypertensive effect. This has been termed “pseudo-tolerance,” and can be overcome with concurrent use of a diuretic.

Absorption, Metabolism, and Excretion. Since methyldopa is a prodrug that is metabolized in the brain to the

active form, its concentration in plasma has less relevance for its effects than that for many other drugs. When administered orally, methyldopa is absorbed by an active amino acid transporter. Peak concentrations in plasma occur after 2 to 3 hours. The drug is distributed in a relatively small apparent volume (0.4 liter/kg) and is eliminated with a half-life of about 2 hours. The transport of methyldopa into the CNS is apparently also an active process. Methyldopa is excreted in the urine primarily as the sulfate conjugate (50% to 70%) and as the parent drug (25%). The remaining fraction is excreted as other metabolites, including methyldopamine, methylnorepinephrine, and *O*-methylated products of these catecholamines. The half-life of methyldopa is prolonged to 4 to 6 hours in patients with renal failure.

In spite of its rapid absorption and short half-life, the peak effect of methyldopa is delayed for 6 to 8 hours, even after intravenous administration, and the duration of action of a single dose is usually about 24 hours; this permits once- or twice-daily dosing. The discrepancy between the effects of methyldopa and the measured concentrations of the drug in plasma is most likely related to the time required for transport into the CNS, conversion to the active metabolite storage of α -methyl norepinephrine and its subsequent release in the vicinity of relevant α_2 receptors in the CNS. This is a good example of the potential for a complex relationship between a drug's pharmacokinetics and its pharmacodynamics. Patients with renal failure are more sensitive to the antihypertensive effect of methyldopa, but it is not known if this is due to alteration in excretion of the drug or to an increase in transport into the CNS.

Adverse Effects and Precautions. In addition to lowering blood pressure, the active metabolite of methyldopa acts on α_2 adrenergic receptors in the brainstem to inhibit the centers that are responsible for wakefulness and alertness. Thus, methyldopa produces sedation that is largely transient. A diminution in psychic energy may persist in some patients, and depression occurs occasionally. Medullary centers that control salivation also are inhibited by α adrenergic receptors, and methyldopa may produce dryness of the mouth. Other side effects that are related to the pharmacological effects in the CNS include a reduction in libido, parkinsonian signs, and hyperprolactinemia that may become sufficiently pronounced to cause gynecomastia and galactorrhea. It seems possible that accumulation of α -methyldopamine in dopaminergic neurons could account for some central effects. In individuals who have sinoatrial node dysfunction, methyldopa may precipitate severe bradycardia and

sinus arrest, including that which occurs with carotid sinus hypersensitivity.

Methyldopa also produces some adverse effects that are not related to its pharmacological action. Hepatotoxicity, sometimes associated with fever, is an uncommon but potentially serious toxic effect of methyldopa. Prompt diagnosis of hepatotoxicity requires a low threshold for considering the drug as a cause for hepatitis-like symptoms (*e.g.*, nausea, anorexia) and screening for hepatotoxicity (*e.g.*, with determination of hepatic transaminases) after 3 weeks and again 3 months after initiation of treatment. The incidence of methyldopa-induced hepatitis is unknown, but about 5% of patients will have transient increases in hepatic transaminases in plasma. Hepatic dysfunction usually is reversible with prompt discontinuation of the drug, but will recur if methyldopa is given again; a few cases of fatal hepatic necrosis have been reported. It is advisable to avoid the use of methyldopa in patients with hepatic disease.

Methyldopa can cause hemolytic anemia. At least 20% of patients who receive methyldopa for a year develop a positive Coombs test (antiglobulin test) that is due to autoantibodies directed against the Rh antigen on erythrocytes. The development of a positive Coombs test is not necessarily an indication to stop treatment with methyldopa; 1% to 5% of these patients will develop a hemolytic anemia that requires prompt discontinuation of the drug. The Coombs test may remain positive for as long as a year after discontinuation of methyldopa, but the hemolytic anemia usually resolves within a matter of weeks. Severe hemolysis may be attenuated by treatment with glucocorticoids. Adverse effects that are even more rare include leukopenia, thrombocytopenia, red cell aplasia, lupus erythematosus–like syndrome, lichenoid and granulomatous skin eruptions, myocarditis, retroperitoneal fibrosis, pancreatitis, diarrhea, and malabsorption.

Therapeutic Uses. Methyldopa is an effective antihypertensive agent that has been replaced by other drugs in many parts of the world. Methyldopa is a preferred drug for treatment of hypertension during pregnancy based on its effectiveness and safety for both mother and fetus.

The usual initial dose of methyldopa is 250 mg twice daily, and there is little additional effect with doses above 2 g per day. Administration of a single daily dose of methyldopa at bedtime minimizes sedative effects, but administration twice daily is required for some patients.

Clonidine, Guanabenz, and Guanfacine

The detailed pharmacology of the α_2 adrenergic agonists clonidine (CATAPRES), *guanabenz* (WYTENSIN), and *guanfacine* (TENEX) is discussed in Chapter 10. These drugs stimulate the α_{2A} subtype of α_2 adrenergic receptors in the brainstem, resulting in a reduction in sympathetic outflow from the CNS (Macmillan *et al.*, 1996). The decrease in plasma concentrations of norepinephrine

is correlated directly with the hypotensive effect (Goldstein *et al.*, 1985; Sorkin and Heel, 1986). Patients who have had a spinal cord transection above the level of the sympathetic outflow tracts do not display a hypotensive response to clonidine. At doses higher than those required to stimulate central α_{2A} receptors, these drugs can activate α_2 receptors of the α_{2B} subtype on vascular smooth muscle cells (Link *et al.*, 1996; MacMillan *et al.*, 1996). This effect accounts for the initial vasoconstriction that is seen when overdoses of these drugs are taken, and it has been postulated to be responsible for the loss of therapeutic effect that is observed with high doses (Frisk-Holmberg *et al.*, 1984; Frisk-Holmberg and Wibell, 1986). A major limitation in the use of these drugs is the paucity of information about their efficacy in reducing the risk of cardiovascular consequences of hypertension.

Pharmacological Effects. The α_2 adrenergic agonists lower arterial pressure by an effect on both cardiac output and peripheral resistance. In the supine position, when the sympathetic tone to the vasculature is low, the major effect is to reduce both heart rate and stroke volume; however, in the upright position, when sympathetic outflow to the vasculature is normally increased, these drugs reduce vascular resistance. This action may lead to postural hypotension. The decrease in cardiac sympathetic tone leads to a reduction in myocardial contractility and heart rate; this could promote congestive heart failure in susceptible patients.

Adverse Effects and Precautions. Many patients experience annoying and sometimes intolerable adverse effects with these drugs. Sedation and xerostomia are prominent adverse effects. The xerostomia may be accompanied by dry nasal mucosa, dry eyes, and parotid gland swelling and pain. Postural hypotension and erectile dysfunction may be prominent in some patients. Clonidine may produce a lower incidence of dry mouth and sedation when given transdermally, perhaps because high peak concentrations are avoided. Less common CNS side effects include sleep disturbances with vivid dreams or nightmares, restlessness, and depression. Cardiac effects related to the sympatholytic action of these drugs include symptomatic bradycardia and sinus arrest in patients with dysfunction of the sinoatrial node and AV block in patients with AV nodal disease or in patients taking other drugs that depress AV conduction. Some 15% to 20% of patients who receive transdermal clonidine may develop contact dermatitis.

Sudden discontinuation of clonidine and related α_2 adrenergic agonists may cause a withdrawal syndrome consisting of headache, apprehension, tremors, abdominal pain, sweating, and tachycardia. The arterial blood pressure may rise to levels above those that were present prior to treatment, but the syndrome may occur in the absence of an overshoot in pressure. Symptoms typically occur 18 to 36 hours after the drug is stopped and are associated with increased sympathetic discharge, as evidenced by elevated plasma and urine concentrations of catecholamines. The exact incidence of the withdrawal syndrome is not known, but it is likely dose related and more dangerous in patients with poorly controlled hypertension. Rebound hypertension also has been seen after discontinuation of transdermal administration of clonidine (Metz *et al.*, 1987).

Treatment of the withdrawal syndrome depends on the urgency of reducing the arterial blood pressure. In the absence of life-threatening target organ damage, patients can be treated by restoring the use of clonidine. If a more rapid effect is required, *sodium nitroprusside* or a combination of an α and β adrenergic blocker is appropriate. β Adrenergic blocking agents should not be used alone in this setting, since they may accentuate the hypertension by allowing unopposed α adrenergic vasoconstriction caused by activation of the sympathetic nervous system and elevated circulating catecholamines.

Because perioperative hypertension has been described in patients in whom clonidine was withdrawn the night before surgery, surgical patients who are being treated with an α_2 adrenergic agonist either should be switched to another drug prior to elective surgery or should receive their morning dose and/or transdermal clonidine prior to the procedure. All patients who receive one of these drugs should be warned of the potential danger of discontinuing the drug abruptly, and patients suspected of being nonadherent with medications should not be given α_2 adrenergic agonists for hypertension.

Adverse drug interactions with α_2 adrenergic agonists are rare. Diuretics predictably potentiate the hypotensive effect of these drugs. Tricyclic antidepressants may inhibit the antihypertensive effect of clonidine, but the mechanism of this interaction is not known.

Therapeutic Uses. The CNS effects are such that this class of drugs is not a leading option for monotherapy of hypertension. Indeed, there is no fixed place for these drugs in the treatment of hypertension. They effectively lower blood pressure in some patients who have not responded adequately to combinations of other agents. Enthusiasm for these drugs is diminished by the relative absence of evidence demonstrating reduction in risk of adverse cardiovascular events.

Clonidine has been used in hypertensive patients for the diagnosis of pheochromocytoma. The lack of suppression of the plasma concentration of norepinephrine to less than 500 pg/ml 3 hours after an oral dose of 0.3 mg of clonidine suggests the presence of such a tumor. A modification of this test, wherein overnight urinary excretion of norepinephrine and epinephrine is measured

after administration of a 0.3-mg dose of clonidine at bedtime, may be useful when results based on plasma norepinephrine concentrations are equivocal. Other uses for α_2 adrenergic agonists are discussed in Chapters 10, 13, and 23.

Guanadrel

Guanadrel (HYLOREL) specifically inhibits the function of peripheral postganglionic adrenergic neurons. The structure of guanadrel, which contains the strongly basic guanidine group, is:

Locus and Mechanism of Action. Guanadrel is an exogenous false neurotransmitter that is accumulated, stored, and released like norepinephrine but is inactive at adrenergic receptors. The drug reaches its site of action by active transport into the neuron by the same transporter that is responsible for the reuptake of norepinephrine (*see* Chapter 6). In the neuron, guanadrel is concentrated within the adrenergic storage vesicle, where it replaces norepinephrine. During chronic administration, guanadrel acts as a "false neurotransmitter": it is present in storage vesicles, depletes the normal transmitter, can be released by stimuli that normally release norepinephrine but is inactive at adrenergic receptors. This replacement of norepinephrine with an inactive transmitter is probably the principal mechanism of action of guanadrel.

When given intravenously, guanadrel initially releases norepinephrine in an amount sufficient to increase arterial blood pressure. This is not noticeable with oral administration, since norepinephrine is released only slowly from the vesicles under this circumstance and is degraded within the neuron by monoamine oxidase. Nonetheless, because of the potential for norepinephrine release, guanadrel is contraindicated in patients with pheochromocytoma.

During adrenergic neuron blockade with guanadrel, effector cells become supersensitive to norepinephrine. The supersensitivity is similar to that produced by postganglionic sympathetic denervation.

Pharmacological Effects. Essentially all of the therapeutic and adverse effects of guanadrel result from functional sympathetic blockade. The antihypertensive effect is achieved by a reduction in peripheral vascular resistance that results from inhibition of α receptor-mediated vasoconstriction. Consequently, arterial pressure is reduced modestly in the supine position when sympathetic activity is usually low, but the pressure can fall to a greater extent during situations in which reflex sympathetic activation is a mechanism for maintaining arterial pressure, such as assumption of the upright posture, exercise, and depletion of plasma volume. Plasma volume often expands, which may diminish the antihypertensive efficacy of

guanadrel and require administration of diuretic to restore the anti-hypertensive effect.

Absorption, Distribution, Metabolism, and Excretion. Guanadrel is rapidly absorbed, leading to maximal levels in plasma at 1 to 2 hours. Because guanadrel must be transported into and accumulate in adrenergic neurons, the maximum effect on blood pressure is not seen until 4 to 5 hours. Although the β phase of its elimination has an estimated half-life of 5 to 10 hours, this almost certainly does not reflect the longer half-life of drug stored at its site of action in the secretory vesicles of adrenergic neurons. The half-life of the pharmacological effect of guanadrel is determined by the drug's persistence in this neuronal pool and is probably at least 10 hours. Guanadrel is administered in a regimen of twice-daily doses.

Guanadrel is cleared from the body by both renal and nonrenal disposition. Its elimination is impaired in patients with renal insufficiency; total-body clearance was reduced by four- to fivefold in a group of patients with a creatinine clearance averaging 13 ml per minute.

Adverse Effects. Guanadrel produces undesirable effects that are related entirely to sympathetic blockade. Symptomatic hypotension during standing, exercise, ingestion of alcohol, or hot weather is the result of the lack of sympathetic compensation for these stresses. A general feeling of fatigue and lassitude is partially, but not entirely, related to postural hypotension. Sexual dysfunction usually presents as delayed or retrograde ejaculation. Diarrhea also may occur.

Because guanadrel is actively transported to its site of action, drugs that block or compete for the catecholamine transporter on the presynaptic membrane will inhibit the effect of guanadrel. Such drugs include the tricyclic antidepressants, *cocaine*, *chlorpromazine*, *ephedrine*, *phenylpropanolamine*, and *amphetamine* (see Chapter 6).

Therapeutic Uses. Because of the availability of a number of drugs that lower blood pressure without producing this degree of orthostatic hypotension, guanadrel is not employed in the monotherapy of hypertension and is used chiefly as an additional agent in patients who have not achieved a satisfactory antihypertensive effect on multiple other agents. The need to use this drug arises very rarely. The usual starting dose is 10 mg daily, and side effects can be minimized by not exceeding 20 mg daily.

Reserpine

Reserpine was the first drug that was found to interfere with the function of the sympathetic nervous system in human beings, and its use began the modern era of effective pharmacotherapy of hypertension.

Reserpine is an alkaloid extracted from the root of *Rauwolfia serpentina*, a climbing shrub indigenous to India. Ancient Hindu Ayurvedic writings describe medicinal uses of the plant; Sen and Bose described its use in the Indian biomedical literature. However, rauwolfia alkaloids were not used in western medicine until the mid-1950s. The structure of reserpine is:

Locus and Mechanism of Action. Reserpine binds tightly to adrenergic storage vesicles in central and peripheral adrenergic neurons and remains bound for prolonged periods of time. The interaction inhibits the vesicular catecholamine transporter that facilitates vesicular storage. Thus, nerve endings lose their capacity to concentrate and store norepinephrine and dopamine. Catecholamines leak into the cytoplasm, where they are metabolized by intraneuronal monoamine oxidase, and little or no active transmitter is discharged from nerve endings when they are depolarized. The overall result is a pharmacological sympathectomy. A similar process occurs at storage sites for 5-hydroxytryptamine. Reserpine-induced depletion of biogenic amines correlates with evidence of sympathetic dysfunction and antihypertensive effects. Recovery of sympathetic function requires synthesis of new storage vesicles, which takes days to weeks after discontinuation of the drug. Since reserpine depletes amines in the CNS as well as in the peripheral adrenergic neuron, it is probable that its antihypertensive effects are related to both central and peripheral actions.

Pharmacological Effects. Both cardiac output and peripheral vascular resistance are reduced during long-term therapy with reserpine. Orthostatic hypotension may occur but does not usually cause symptoms. Heart rate and renin secretion fall. Salt and water are retained, which commonly results in "pseudotolerance."

Absorption, Metabolism, and Excretion. Few data are available on the pharmacokinetic properties of reserpine because of the lack of an assay capable of detecting low concentrations of the drug or its metabolites. Reserpine that is bound to isolated storage vesicles cannot be removed by dialysis, indicating that the binding is not in equilibrium with the surrounding medium. Because of the irreversible nature of reserpine binding, the amount of drug in plasma is unlikely to bear any consistent relationship to drug concentration at the site of action. Free reserpine is entirely metabolized; none of the parent drug is excreted unchanged.

Toxicity and Precautions. Most adverse effects of reserpine are due to its effect on the CNS. Sedation and inability to concentrate or perform complex tasks are the most common adverse effects. More serious is the occasional psychotic depression that can lead to suicide. Depression usually appears insidiously over many weeks or months and may not be attributed to the drug because of the delayed and gradual onset of symptoms. Reserpine must be discontinued at the first sign of depression; reserpine-induced depression may last several months after the drug is discontinued. The risk of depression is likely dose related. Depression appears to be uncommon, but not unknown, with doses of 0.25 mg per day or less. The drug should never be given to patients with a history of depression. Other

adverse effects include nasal stuffiness and exacerbation of peptic ulcer disease, which is uncommon with small oral doses.

Therapeutic Uses. With the availability of newer drugs that are both effective and well tolerated, the use of reserpine has diminished because of its CNS side effects. Nonetheless, there has been some recent interest in using reserpine at low doses, in combination with diuretics, in the treatment of hypertension, especially in the elderly. Reserpine is used once daily with a diuretic, and several weeks are necessary to achieve a maximum effect. The daily dose should be limited to 0.25 mg or less, and as little as 0.05 mg per day may be efficacious when a diuretic is also used. One advantage of reserpine is that it is considerably less expensive than other antihypertensive drugs; thus, it is still used in developing nations.

Metyrosine

Metyrosine (DEMSEK) is (–)- α -methyl-L-tyrosine. It has the structure shown below. Metyrosine inhibits tyrosine hydroxylase, the enzyme that catalyzes the conversion of tyrosine to DOPA and the rate-limiting step in catecholamine biosynthesis (see Chapter 6). At a dose of 1 to 4 g per day, metyrosine decreases catecholamine biosynthesis by 35% to 80% in patients with pheochromocytoma. The maximal decrease in synthesis occurs only after several days and may be assessed by measurements of urinary catecholamines and their metabolites.

Metyrosine is used as an adjuvant to *phenoxybenzamine* and other α adrenergic blocking agents for the management of malignant pheochromocytoma and in the preoperative preparation of patients for resection of pheochromocytoma. Metyrosine carries a risk of crystalluria, which can be minimized by maintaining a daily urine volume of more than 2 liters. Other adverse effects include orthostatic hypotension, sedation, extrapyramidal signs, diarrhea, anxiety, and psychic disturbances. Doses must be titrated carefully to achieve significant inhibition of catecholamine biosynthesis and yet minimize these substantive side effects.

Ca²⁺ CHANNEL ANTAGONISTS

Ca²⁺ channel blocking agents are an important group of drugs for the treatment of hypertension. The general pharmacology of these drugs is presented in Chapter 31; their use in heart failure is discussed in Chapter 33; and their use in cardiac arrhythmias is covered in Chapter 34. Verapamil was the first clinically available calcium-channel blocker; it is a congener of *papaverine*. Many other calcium entry blockers with a wide range of structures are now available. The largest group, including *amlodipine*, *felodipine*, *isradipine*, and *nifedipine*, are termed dihydropyridines. *Diltiazem* is, with verapamil, the other

non-dihydropyridine available clinically. Interestingly, these different structures lead to differences in their sites and modes of action on calcium entry for reasons that are not well understood. Intracellular calcium flux is a final common path for a spectrum of cellular responses to a wide variety of stimuli. Given that the molecular basis of calcium channels is quite heterogeneous, coupled with the chemical heterogeneity of available calcium-channel blockers, the pharmacologic similarities of presently available dihydropyridines may mask differences in action that could be significant in terms of efficacy or adverse effects. The basis for their use in hypertension comes from the understanding that hypertension is generally the result of increased peripheral vascular resistance. Since contraction of vascular smooth muscle is dependent on the free intracellular concentration of Ca²⁺, inhibition of transmembrane movement of Ca²⁺ through voltage-sensitive Ca²⁺ channels can decrease the total amount of Ca²⁺ that reaches intracellular sites. Ca²⁺-calmodulin-dependent activation of myosin light chain kinase, resulting in phosphorylation of myosin light chains, causes an increase in actin-myosin ATPase activity and contraction (see Chapter 1). Indeed, all of the Ca²⁺ channel blockers lower blood pressure by relaxing arteriolar smooth muscle and decreasing peripheral vascular resistance (Weber, 2002). As a consequence of a decrease in peripheral vascular resistance, the Ca²⁺ channel blockers evoke a baroreceptor-mediated sympathetic discharge. In the case of the dihydropyridines, tachycardia may occur from the adrenergic stimulation of the sinoatrial node; this response is generally quite modest except when the drug is administered rapidly. Tachycardia is typically minimal to absent with verapamil and diltiazem because of the direct negative chronotropic effect of these two drugs. Indeed, the concurrent use of a β receptor antagonist drug may magnify negative chronotropic effects of these drugs or cause heart block in susceptible patients. Consequently, the concurrent use of β receptor antagonists with either verapamil or diltiazem may be problematic.

All Ca²⁺ channel blockers are effective when used alone for the treatment of mild to moderate hypertension; however, this class of drug is not currently viewed as appropriate for monotherapy of hypertension (Chobanian *et al.*, 2003). Patients with isolated systolic hypertension are an exception (see below).

The profile of adverse reactions to the Ca²⁺ channel blockers varies among the drugs in this class. Patients receiving immediate-release capsules of nifedipine develop headache, flushing, dizziness, and peripheral edema. However, short-acting formulations of nifedipine are not appropriate in the long-term treatment of hypertension.

Dizziness and flushing are much less of a problem with the sustained-release formulations and with the dihydropyridines having a long half-life and relatively constant concentrations of drug in plasma. The peripheral edema is not the result of generalized fluid retention; it most likely results from increased hydrostatic pressure in the lower extremities owing to precapillary dilation and reflex postcapillary constriction. Some other adverse effects of these drugs are due to actions in nonvascular smooth muscle. Contraction of the lower esophageal sphincter is inhibited by the Ca^{2+} channel blockers. For example, Ca^{2+} channel blockers can cause or aggravate gastroesophageal reflux. Constipation is a common side effect of verapamil, but it occurs less frequently with other Ca^{2+} channel blockers. Urinary retention is a rare adverse effect. Inhibition of sinoatrial node function by diltiazem and verapamil can lead to bradycardia and even sinoatrial node arrest, particularly in patients with sinoatrial node dysfunction; this effect is exaggerated by concurrent use of β adrenergic receptor antagonists.

Oral administration of nifedipine as an approach to urgent reduction of blood pressure has been abandoned. Sublingual administration does not achieve the maximum plasma concentration any more quickly than does oral administration. Moreover, in the absence of deleterious consequences of high arterial pressure, data do not support the rapid lowering of blood pressure. There is no place in the treatment of hypertension for the use of nifedipine or other dihydropyridine Ca^{2+} channel blockers with short half-lives when administered in a standard (immediate-release) formulation, because of the oscillation in blood pressure and concurrent surges in sympathetic reflex activity within each dosage interval.

Compared with other classes of antihypertensive agents, there is a greater frequency of achieving blood pressure control with Ca^{2+} channel blockers as monotherapy in elderly subjects and in African-Americans, population groups in which the low renin status is more prevalent. However, intrasubject variability is more important than relatively small differences between population groups. Ca^{2+} channel blockers are effective in lowering blood pressure and decreasing cardiovascular events in the elderly with isolated systolic hypertension (Staessen *et al.*, 1997). Indeed, these drugs may be a preferred treatment in these patients.

Significant drug-drug interactions may be encountered when Ca^{2+} channel blockers are used to treat hypertension. Verapamil blocks the P-glycoprotein drug transporter. Both the renal and hepatic disposition of *digoxin* occurs *via* this transporter. Accordingly, verapamil inhibits the elimination of digoxin and other drugs that are

cleared from the body by the P-glycoprotein (*see* Chapter 2). When used with quinidine, Ca^{2+} channel blockers may cause excessive hypotension, particularly in patients with idiopathic hypertrophic subaortic stenosis.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin II is an important regulator of cardiovascular function (*see* Chapter 30). The ability to reduce levels of angiotensin II with orally effective inhibitors of angiotensin-converting enzyme (ACE) represents an important advance in the treatment of hypertension. *Captopril* (CAPOTEN) was the first such agent to be developed for the treatment of hypertension. Since then, *enalapril* (VASOTEC), *lisinopril* (PRINIVIL), *quinapril* (ACCUPRIL), *ramipril* (ALTACE), *benazepril* (LOTENSIN), *moexipril* (UNIVASC), *fosinopril* (MONOPRIL), *trandolapril* (MAVIK), and *perindopril* (ACEON) also have become available. These drugs have proven to be very useful for the treatment of hypertension because of their efficacy and their very favorable profile of adverse effects, which enhances patient adherence. Chapter 30 presents the pharmacology of ACE inhibitors in detail.

The ACE inhibitors appear to confer a special advantage in the treatment of patients with diabetes, slowing the development and progression of diabetic glomerulopathy. They also are effective in slowing the progression of other forms of chronic renal disease, such as glomerulosclerosis, and many of these patients also have hypertension. An ACE inhibitor is the preferred initial agent in these patients. Patients with hypertension and ischemic heart disease are candidates for treatment with ACE inhibitors; administration of ACE inhibitors in the immediate postmyocardial infarction period has been shown to improve ventricular function and reduce morbidity and mortality (*see* Chapter 33).

The endocrine consequences of inhibiting the biosynthesis of angiotensin II are of importance in a number of facets of hypertension treatment. Because ACE inhibitors blunt the rise in aldosterone concentrations in response to Na^+ loss, the normal role of aldosterone to oppose diuretic-induced natriuresis is diminished. Consequently, ACE inhibitors tend to enhance the efficacy of diuretic drugs. This means that even very small doses of diuretics may substantially improve the antihypertensive efficacy of ACE inhibitors; conversely, the use of high doses of diuretics together with ACE inhibitors may lead to excessive reduction in blood pressure and to Na^+ loss in some patients.

The attenuation of aldosterone production by ACE inhibitors also influences K^+ homeostasis. There is only a very small and clinically unimportant rise in serum K^+ when these agents are used alone in patients with normal renal function. However, substantial retention of K^+ can occur in some patients with renal insufficiency. Furthermore, the potential for developing hyperkalemia should be considered when ACE inhibitors are used with other drugs that can cause K^+ retention, including the K^+ -sparing diuretics (amiloride, triamterene, and spironolactone), nonsteroidal antiinflammatory drugs, K^+ supplements, and β receptor antagonists. Some patients with diabetic nephropathy may be at greater risk of hyperkalemia.

There are several cautions in the use of ACE inhibitors in patients with hypertension. Angioedema is a rare but serious and potentially fatal adverse effect of the ACE inhibitors. Patients starting treatment with these drugs should be explicitly warned to discontinue their use with the advent of any signs of angioedema. Due to the risk of severe fetal adverse effects, ACE inhibitors are contraindicated during pregnancy, a fact that should be communicated to women of childbearing age.

In most patients there is no appreciable change in glomerular filtration rate following the administration of ACE inhibitors. However, in renovascular hypertension, the glomerular filtration rate is generally maintained as the result of increased resistance in the postglomerular arteriole caused by angiotensin II. Accordingly, in patients with bilateral renal artery stenosis or stenosis in a sole kidney, the administration of an ACE inhibitor will reduce the filtration fraction and cause a substantial reduction in glomerular filtration rate. In some patients with preexisting renal disease, the glomerular filtration may decrease with an ACE inhibitor. More information is needed on how to balance the potential risk of reversible drug-induced impairment of glomerular filtration rate *versus* inhibition of the progression of kidney disease.

ACE inhibitors lower the blood pressure to some extent in most patients with hypertension. Following the initial dose of an ACE inhibitor, there may be a considerable fall in blood pressure in some patients; this response to the initial dose is a function of plasma renin activity prior to treatment. The potential for a large initial drop in blood pressure is the reason for using a low dose to initiate therapy, especially in patients who may have a very active renin-angiotensin system supporting blood pressure, such as patients with diuretic-induced volume contraction or congestive heart failure. With continuing treatment, there usually is a progressive fall in blood pressure that in most patients does not reach a maximum for several weeks. The blood pressure seen during chronic treat-

ment is not strongly correlated with the pretreatment plasma renin activity. Young and middle-aged Caucasian patients have a higher probability of responding to ACE inhibitors; elderly African-American patients as a group are more resistant to the hypotensive effect of these drugs. While most ACE inhibitors are approved for once-daily dosing for hypertension, a significant fraction of patients have a response that lasts for less than 24 hours. These patients may require twice-daily dosing for adequate control of blood pressure. These drugs are discussed in detail in Chapter 30.

AT₁ ANGIOTENSIN II RECEPTOR ANTAGONISTS

The importance of angiotensin II in regulating cardiovascular function has led to the development of nonpeptide antagonists of the AT₁ angiotensin II receptor for clinical use. *Losartan* (COZAAR), *candesartan* (ATACAND), *irbesartan* (AVAPRO), *valsartan* (DIOVAN), *telmisartan* (MICARDIS), and *eprosartan* (TEVETEN) have been approved for the treatment of hypertension. The pharmacology of AT₁ receptor antagonists is presented in detail in Chapter 30. By antagonizing the effects of angiotensin II, these agents relax smooth muscle and thereby promote vasodilation, increase renal salt and water excretion, reduce plasma volume, and decrease cellular hypertrophy. Angiotensin II receptor antagonists also theoretically overcome some of the disadvantages of ACE inhibitors, which not only prevent conversion of angiotensin I to angiotensin II but also prevent ACE-mediated degradation of bradykinin and substance P.

There are two distinct subtypes of angiotensin II receptors, designated as type 1 (AT₁) and type 2 (AT₂). The AT₁ angiotensin II-receptor subtype is located predominantly in vascular and myocardial tissue and also in brain, kidney, and adrenal glomerulosa cells, which secrete aldosterone (*see* Chapter 30). The AT₂ subtype of angiotensin II receptor is found in the adrenal medulla, kidney, and in the CNS, and may play a role in vascular development (Horiuchi *et al.*, 1999). Because the AT₁ receptor mediates feedback inhibition of renin release, renin and angiotensin II concentrations are increased during AT₁-receptor antagonism. The clinical consequences of increased angiotensin II effects on an uninhibited AT₂ receptor are unknown; however, emerging data suggest that the AT₂ receptor may elicit antigrowth and antiproliferative responses.

Adverse Effects and Precautions. The adverse effects of AT₁ receptor antagonists may be considered in the con-

text of those known to be associated with the ACE inhibitors. ACE inhibitors cause problems of two major types, those related to diminished concentrations of angiotensin II and those due to molecular actions independent of abrogating the function of angiotensin II.

Adverse effects of ACE inhibitors that result from inhibiting angiotensin II–related functions (*see above*) also occur with AT₁ receptor antagonists. These include hypotension, hyperkalemia, and reduced renal function, including that associated with bilateral renal artery stenosis and stenosis in the artery of a solitary kidney. Hypotension is most likely to occur in patients in whom the blood pressure is highly dependent on angiotensin II, including those with volume depletion (*e.g.*, with diuretics), renovascular hypertension, cardiac failure, and cirrhosis; in such patients initiation of treatment with low doses and attention to blood volume is essential. Hyperkalemia may occur in conjunction with other factors that alter K⁺ homeostasis, such as renal insufficiency, ingestion of excess K⁺, and the use of drugs that promote K⁺ retention. Cough, an adverse effect of ACE inhibitors, is less frequent with angiotensin II receptor antagonists. Angioedema occurs very rarely.

AT₁ receptor antagonists should not be administered during pregnancy and should be discontinued as soon as pregnancy is detected.

Therapeutic Uses. When given in adequate doses, the AT₁ receptor antagonists appear to be as effective as ACE inhibitors in the treatment of hypertension. As with ACE inhibitors, these drugs may be less effective in African-American and low-renin patients.

The full effect of AT₁ receptor antagonists on blood pressure typically is not observed until about 4 weeks after the initiation of therapy. If blood pressure is not controlled by an AT₁ receptor antagonist alone, a low dose of a hydrochlorothiazide or other diuretic may be added. In several randomized, double-blind studies of patients with mild-to-severe hypertension, the addition of hydrochlorothiazide to an AT₁ receptor antagonist produced significant additional reductions in blood pressure in patients who demonstrated an insufficient response to hydrochlorothiazide alone. A smaller initial dosage is preferred for patients who have already received diuretics and therefore have an intravascular volume depletion, and for other patients whose blood pressure is highly dependent on angiotensin II. Given the different mechanisms by which they act, there is no assurance that the effects of ACE inhibitors and antagonists of the AT₁ receptor will be equivalent in preventing target organ damage in patients with hypertension.

VASODILATORS

Hydralazine

Hydralazine (APRESOLINE) was one of the first orally active antihypertensive drugs to be marketed in the United States; however, the drug initially was used infrequently because of tachycardia and tachyphylaxis. With a better understanding of the compensatory cardiovascular responses that accompany use of arteriolar vasodilators, hydralazine was combined with sympatholytic agents and diuretics with greater therapeutic success. Nonetheless, its role in the treatment of hypertension has markedly diminished on account of the subsequent introduction of new classes of antihypertensive drugs.

Numerous phthalazines have been synthesized in the hope of producing vasoactive agents, but only those with hydrazine moieties in the 1 or 4 position of the ring have vasodilatory activity. None of the analogs has any advantage over hydralazine. The structural formula of hydralazine (1-hydrazinophthalazine) is:

Locus and Mechanism of Action. Hydralazine causes direct relaxation of arteriolar smooth muscle. The molecular mechanisms mediating this action are not clear, but may ultimately involve a fall in intracellular calcium concentrations. While a variety of changes in cellular signaling pathways are influenced by hydralazine, precise molecular targets that explain its capacity to dilate arteries remain uncertain. The drug does not dilate epicardial coronary arteries or relax venous smooth muscle. Hydralazine-induced vasodilation is associated with powerful stimulation of the sympathetic nervous system, likely due to baroreceptor-mediated reflexes, which results in increased heart rate and contractility, increased plasma renin activity, and fluid retention; all of these effects counteract the antihypertensive effect of hydralazine. Although most of the sympathetic activity is due to a baroreceptor-mediated reflex, hydralazine may stimulate the release of norepinephrine from sympathetic nerve terminals and augment myocardial contractility directly.

Pharmacological Effects. Most of the effects of hydralazine are confined to the cardiovascular system. The decrease in blood pressure after administration of hydralazine is associated with a selective decrease in vascular resistance in the coronary, cerebral, and renal circulations, with a smaller effect in skin and muscle. Because of preferential dilation of arterioles over veins,

postural hypotension is not a common problem; hydralazine lowers blood pressure equally in the supine and upright positions.

Absorption, Metabolism, and Excretion. Hydralazine is well absorbed through the gastrointestinal tract, but the systemic bioavailability is low (16% in fast acetylators and 35% in slow acetylators). Hydralazine is *N*-acetylated in the bowel and/or the liver. The half-life of hydralazine is 1 hour, and systemic clearance of the drug is about 50 ml/kg per minute.

The rate of acetylation is genetically determined; about half of the U.S. population acetylates rapidly and half do so slowly. The acetylated compound is inactive; thus, the dose necessary to produce a systemic effect is larger in fast acetylators. Since the systemic clearance exceeds hepatic blood flow, extrahepatic metabolism must occur. Indeed, hydralazine rapidly combines with circulating α -keto acids to form hydrazones, and the major metabolite recovered from the plasma is hydralazine pyruvic acid hydrazone. This metabolite has a longer half-life than hydralazine, but it does not appear to be very active. Although the rate of acetylation is an important determinant of the bioavailability of hydralazine, it does not play a role in the systemic elimination of the drug, probably because the hepatic clearance is so high that systemic elimination is principally a function of hepatic blood flow.

The peak concentration of hydralazine in plasma and the peak hypotensive effect of the drug occur within 30 to 120 minutes of ingestion. Although its half-life in plasma is about an hour, the duration of the hypotensive effect of hydralazine can last as long as 12 hours. There is no clear explanation for this discrepancy.

Toxicity and Precautions. Two types of adverse effects occur after the use of hydralazine. The first, which are extensions of the pharmacological effects of the drug, include headache, nausea, flushing, hypotension, palpitations, tachycardia, dizziness, and angina pectoris. Myocardial ischemia occurs because of the increased O_2 demand induced by the baroreceptor reflex-induced stimulation of the sympathetic nervous system and also because hydralazine does not dilate the epicardial coronary arteries; thus, the arteriolar dilation it produces may cause a “steal” of blood flow away from the ischemic region. Following parenteral administration to patients with coronary artery disease, the myocardial ischemia may be sufficiently severe and protracted to cause frank myocardial infarction. For this reason, parenteral administration of hydralazine is not advisable in hypertensive patients with coronary artery disease, hypertensive patients with multiple cardiovascular risk factors, or in older patients. In addition, if the drug is used alone, there may be salt retention with development of high-output congestive heart failure. When combined with a β adrenergic receptor blocker and a diuretic, hydralazine is better toler-

ated, although adverse effects such as headache are still commonly described and may necessitate discontinuation of the drug.

The second type of adverse effect is caused by immunological reactions, of which the drug-induced lupus syndrome is the most common. Administration of hydralazine also can result in an illness that resembles serum sickness, hemolytic anemia, vasculitis, and rapidly progressive glomerulonephritis. The mechanism of these autoimmune reactions is unknown.

The drug-induced lupus syndrome usually occurs after at least 6 months of continuous treatment with hydralazine, and its incidence is related to dose, sex, acetylator phenotype, and race. In one study, after 3 years of treatment with hydralazine, drug-induced lupus occurred in 10% of patients who received 200 mg daily, 5% who received 100 mg daily, and none who received 50 mg daily (Cameron and Ramsay, 1984). The incidence is four times higher in women than in men, and the syndrome is seen more commonly in Caucasians than in African-Americans. The rate of conversion to a positive antinuclear antibody test is faster in slow acetylators than in rapid acetylators, suggesting that the native drug or a nonacetylated metabolite is responsible. However, since the majority of patients with positive antinuclear antibody tests do not develop the drug-induced lupus syndrome, hydralazine need not be discontinued unless clinical features of the syndrome appear. These features are similar to those of other drug-induced lupus syndromes and consist mainly of arthralgia, arthritis, and fever. Pleuritis and pericarditis may be present, and pericardial effusion can occasionally cause cardiac tamponade. Discontinuation of the drug is all that is necessary for most patients with the hydralazine-induced lupus syndrome, but symptoms may persist in a few patients and administration of corticosteroids may be necessary.

Hydralazine also can produce a pyridoxine-responsive polyneuropathy. The mechanism appears to be related to the ability of hydralazine to combine with pyridoxine to form a hydrazone. This side effect is very unusual with doses ≤ 200 mg per day.

Therapeutic Uses. Hydralazine is no longer a first-line drug in the treatment of hypertension on account of its relatively unfavorable adverse-effect profile. It may have utility in the treatment of some patients with severe hypertension, can be part of evidence-based therapy in patients with congestive heart failure (in combination with nitrates for patients who cannot tolerate ACE inhibitors or AT_1 receptor antagonists), and in the treatment of hypertensive emergencies in pregnant women (especially preeclampsia) on account of extensive experience with the drug in that setting. Hydralazine should be used with the greatest of caution in elderly patients and in hypertensive patients with coronary artery disease because of the possibility of precipitation of myocardial ischemia due to reflex tachycardia. The usual oral dosage of hydralazine is 25 to 100 mg twice daily. Twice-daily administration is as effective as administration four

times a day for control of blood pressure, regardless of acetylator phenotype. The maximum recommended dose of hydralazine is 200 mg per day to minimize the risk of drug-induced lupus syndrome.

K⁺_{ATP} Channel Openers: Minoxidil

The discovery in 1965 of the hypotensive action of minoxidil (LONITEN) was a significant advance in the treatment of hypertension, since the drug has proven to be efficacious in patients with the most severe and drug-resistant forms of hypertension. The chemical structure of minoxidil is:

Locus and Mechanism of Action. Minoxidil is not active *in vitro* but must be metabolized by hepatic sulfotransferase to the active molecule, minoxidil *N-O* sulfate; the formation of this active metabolite is a minor pathway in the metabolic disposition of minoxidil. Minoxidil sulfate relaxes vascular smooth muscle in isolated systems where the parent drug is inactive. Minoxidil sulfate activates the ATP-modulated K⁺ channel. By opening K⁺ channels in smooth muscle and thereby permitting K⁺ efflux, it causes hyperpolarization and relaxation of smooth muscle (Leblanc *et al.*, 1989).

Pharmacological Effects. Minoxidil produces arteriolar vasodilation with essentially no effect on the capacitance vessels; the drug resembles hydralazine and *diazoxide* in this regard. Minoxidil increases blood flow to skin, skeletal muscle, the gastrointestinal tract, and the heart more than to the CNS. The disproportionate increase in blood flow to the heart may have a metabolic basis, in that administration of minoxidil is associated with a reflex increase in myocardial contractility and in cardiac output. The cardiac output can increase markedly, as much as three- to fourfold. The principal determinant of the elevation in cardiac output is the action of minoxidil on peripheral vascular resistance to enhance venous return to the heart; by inference from studies with other drugs, the increased venous return probably results from enhancement of flow in the regional vascular beds with a fast time constant for venous return to the heart (Ogilvie, 1985). The adrenergically mediated

increase in myocardial contractility contributes to the increased cardiac output, but is not the predominant causal factor.

The effects of minoxidil on the kidney are complex. Minoxidil is a renal artery vasodilator, but systemic hypotension produced by the drug occasionally can decrease renal blood flow. Renal function usually improves in patients who take minoxidil for the treatment of hypertension, especially if renal dysfunction is secondary to hypertension (Mitchell *et al.*, 1980). Minoxidil is a very potent stimulator of renin secretion; this effect is mediated by a combination of renal sympathetic stimulation and activation of the intrinsic renal mechanisms for regulation of renin release.

Discovery of K⁺_{ATP} channels in a variety of cell types and in mitochondria is prompting consideration of K⁺_{ATP} channel modulators as therapeutic agents in myriad cardiovascular diseases (Pollesello and Mebazaa, 2004) and may provide explanations for some of the effects of minoxidil noted in the previous section. Various K⁺_{ATP} channels possess different regulatory sulfonylurea receptor subunits and thus exhibit tissue-specific responses. Recent studies suggest that certain actions of K⁺_{ATP} channel openers can be influenced by hypercholesterolemia and by concurrent administration of sulfonylurea hypoglycemic agents (Miura and Miki, 2003).

Absorption, Metabolism, and Excretion. Minoxidil is well absorbed from the gastrointestinal tract. Although peak concentrations of minoxidil in blood occur 1 hour after oral administration, the maximal hypotensive effect of the drug occurs later, possibly because formation of the active metabolite is delayed.

Only about 20% of the absorbed drug is excreted unchanged in the urine, and the main route of elimination is by hepatic metabolism. The major metabolite of minoxidil is the glucuronide conjugate at the *N-oxide* position in the pyrimidine ring. This metabolite is less active than minoxidil, but it persists longer in the body. The extent of biotransformation of minoxidil to its active metabolite, minoxidil *N-O* sulfate, has not been evaluated in human beings. Minoxidil has a half-life in plasma of 3 to 4 hours, but its duration of action is 24 hours or occasionally even longer. It has been proposed that persistence of minoxidil in vascular smooth muscle is responsible for this discrepancy. However, without knowledge of the pharmacokinetic properties of the active metabolite, an explanation for the prolonged duration of action cannot be given.

Adverse Effects and Precautions. The adverse effects of minoxidil can be severe and are divided into three major categories: fluid and salt retention, cardiovascular effects, and hypertrichosis.

Retention of salt and water results from increased proximal renal tubular reabsorption, which is in turn secondary to reduced renal perfusion pressure and to reflex stimulation of renal tubular α adrenergic receptors. Similar antinatriuretic effects can be observed with the other arteriolar dilators (*e.g.*, diazoxide and

hydralazine). Although administration of minoxidil causes increased secretion of renin and aldosterone, this is not an important mechanism for retention of salt and water in this case. Fluid retention usually can be controlled by the administration of a diuretic. However, thiazides may not be sufficiently efficacious, and it may be necessary to use a loop diuretic, especially if the patient has any degree of renal dysfunction. Retention of salt and water in patients taking minoxidil may be profound, requiring large doses of loop diuretics to prevent edema formation.

The cardiac consequences of the baroreceptor-mediated activation of the sympathetic nervous system during minoxidil therapy are similar to those seen with hydralazine; there is an increase in heart rate, myocardial contractility, and myocardial O₂ consumption. Thus, myocardial ischemia can be induced by minoxidil in patients with coronary artery disease. The cardiac sympathetic responses are attenuated by concurrent administration of a β adrenergic blocker. The adrenergically induced increase in renin secretion also can be ameliorated by a β receptor antagonist or an ACE inhibitor, with enhancement of blood pressure control.

The increased cardiac output evoked by minoxidil has particularly adverse consequences in those hypertensive patients who have left ventricular hypertrophy and diastolic dysfunction. Such poorly compliant ventricles respond suboptimally to increased volume loads, with a resulting increase in left ventricular filling pressure. This is probably a major contributor to the increased pulmonary artery pressure seen with minoxidil (and hydralazine) therapy in hypertensive patients, and is compounded by the retention of salt and water caused by minoxidil. Cardiac failure can result from minoxidil therapy in such patients; the potential for this complication can be reduced but not prevented by effective diuretic therapy. Pericardial effusion is an uncommon but serious complication of minoxidil. Although more commonly described in patients with cardiac failure and renal failure, pericardial effusion can occur in patients with normal cardiovascular and renal function. Mild and asymptomatic pericardial effusion is not an indication for discontinuing minoxidil, but the situation should be monitored closely to avoid progression to tamponade. Effusions usually clear when the drug is discontinued but can recur if treatment with minoxidil is resumed.

Flattened and inverted T waves frequently are observed in the electrocardiogram following the initiation of minoxidil treatment. These are not ischemic in origin and are seen with other drugs that activate K⁺ channels. These drugs accelerate myocardial repolarization, shorten the refractory period, and one of them, *pinacidil*, lowers the ventricular fibrillation threshold and increases spontaneous ventricular fibrillation in the setting of myocardial ischemia (Chi *et al.*, 1990). The effect of minoxidil on the refractory period and ischemic ventricular fibrillation has not been investigated; whether or not such findings enhance the risk of ventricular fibrillation in human myocardial ischemia is unknown.

Hypertrichosis occurs in patients who receive minoxidil for an extended period and is probably a consequence of K⁺ channel activation. Growth of hair occurs on the face, back, arms, and legs, and is particularly offensive to women. Frequent shaving or depilatory agents can be used to manage this problem. Topical minoxidil (ROGAINE) is marketed for the treatment of male pattern baldness. The topical use of minoxidil can cause measurable cardiovascular effects in some individuals (Leenen *et al.*, 1988).

Other side effects of the drug are rare and include rashes, Stevens-Johnson syndrome, glucose intolerance, serosanguineous bullae, formation of antinuclear antibodies, and thrombocytopenia.

Therapeutic Uses. Minoxidil is best reserved for the treatment of severe hypertension that responds poorly to other antihypertensive medications, especially in male patients with renal insufficiency (Campese, 1981). It has been used successfully in the treatment of hypertension in both adults and children. Minoxidil should never be used alone; it must be given concurrently with a diuretic to avoid fluid retention and with a sympatholytic drug (usually a β receptor antagonist) to control reflex cardiovascular effects. The drug usually is administered either once or twice a day, but some patients may require more frequent dosing for adequate control of blood pressure. The initial daily dose of minoxidil may be as little as 1.25 mg, which can be increased gradually to 40 mg in one or two daily doses.

Sodium Nitroprusside

Although sodium nitroprusside has been known since 1850 and its hypotensive effect in human beings was described in 1929, its safety and usefulness for the short-term control of severe hypertension were not demonstrated until the mid-1950s. Several investigators subsequently demonstrated that sodium nitroprusside also was effective in improving cardiac function in patients with left ventricular failure (*see* Chapter 34). The structural formula of sodium nitroprusside is:

Locus and Mechanism of Action. Nitroprusside is a nitrovasodilator that acts by releasing nitric oxide (NO). NO activates the guanylyl cyclase–cyclic GMP–PKG pathway, leading to vasodilation (Murad, 1986; Linder *et al.*, 2005), mimicking the production of NO by vascular endothelial cells, which is impaired in many hypertensive patients (Ramchandra *et al.*, 2005). The mecha-

nism of release of NO is not clear and likely involves both enzymatic and nonenzymatic pathways (Feelisch, 1998). Tolerance develops to *nitroglycerin* but not to nitroprusside (Fung, 2004). The pharmacology of the organic nitrates, including nitroglycerin, is presented in Chapter 31.

Pharmacological Effects. Nitroprusside dilates both arterioles and venules, and the hemodynamic response to its administration results from a combination of venous pooling and reduced arterial impedance. In subjects with normal left ventricular function, venous pooling affects cardiac output more than does the reduction of afterload; cardiac output tends to fall. In contrast, in patients with severely impaired left ventricular function and diastolic ventricular distention, the reduction of arterial impedance is the predominant effect, leading to a rise in cardiac output (*see* Chapter 33).

Sodium nitroprusside is a nonselective vasodilator, and regional distribution of blood flow is little affected by the drug. In general, renal blood flow and glomerular filtration are maintained, and plasma renin activity increases. Unlike minoxidil, hydralazine, diazoxide, and other arteriolar vasodilators, sodium nitroprusside usually causes only a modest increase in heart rate and an overall reduction in myocardial demand for oxygen.

Absorption, Metabolism, and Excretion. Sodium nitroprusside is an unstable molecule that decomposes under strongly alkaline conditions or when exposed to light. The drug must be given by continuous intravenous infusion to be effective. Its onset of action is within 30 seconds; the peak hypotensive effect occurs within 2 minutes, and when the infusion of the drug is stopped, the effect disappears within 3 minutes.

The metabolism of nitroprusside by smooth muscle is initiated by its reduction, which is followed by the release of cyanide and then nitric oxide (Bates *et al.*, 1991; Ivankovich *et al.*, 1978). Cyanide is further metabolized by liver rhodanase to thiocyanate, which is eliminated almost entirely in the urine. The mean elimination half-time for thiocyanate is 3 days in patients with normal renal function, and it can be much longer in patients with renal insufficiency.

Toxicity and Precautions. The short-term adverse effects of nitroprusside are due to excessive vasodilation, with hypotension and the consequences thereof. Close monitoring of blood pressure and the use of a continuous variable-rate infusion pump will prevent an excessive hemodynamic response to the drug in the majority of cases.

Less commonly, toxicity may result from conversion of nitroprusside to cyanide and thiocyanate. Toxic accumulation of cyanide leading to severe lactic acidosis usually occurs when sodium nitroprusside is infused at a rate greater than 5 $\mu\text{g}/\text{kg}$ per minute, but also can occur in some patients receiving doses about 2 $\mu\text{g}/\text{kg}$ per minute for a prolonged period. The limiting factor in the metabolism of cyanide appears to be the availability of sulfur-containing substrates in the body (mainly thiosulfate). The concomitant administration of *sodium thiosulfate* can prevent accumulation of cyanide in patients who are receiving higher-than-usual doses of sodium nitroprusside; the efficacy of the drug is unchanged (Schulz, 1984). The risk of thiocyanate toxicity increases when sodium nitroprusside is infused for more than 24 to 48 hours, especially if renal function is impaired. Signs and symptoms of thiocyanate toxicity include anorexia, nausea, fatigue, disorientation, and toxic psychosis. The plasma concentration of thiocyanate should be monitored during prolonged infusions of nitroprusside and should not be allowed to exceed 0.1 mg/ml. Rarely, excessive concentrations of thiocyanate may cause hypothyroidism by inhibiting iodine uptake by the thyroid gland. In patients with renal failure, thiocyanate can be removed readily by hemodialysis.

Nitroprusside can worsen arterial hypoxemia in patients with chronic obstructive pulmonary disease because the drug interferes with hypoxic pulmonary vasoconstriction and therefore promotes mismatching of ventilation with perfusion.

Therapeutic Uses. Sodium nitroprusside is used primarily to treat hypertensive emergencies, but can also be used in many situations when short-term reduction of cardiac preload and/or afterload is desired. Nitroprusside has been used to lower blood pressure during acute aortic dissection, to improve cardiac output in congestive heart failure, especially in hypertensive patients with pulmonary edema that does not respond to other treatment (*see* Chapter 33), and to decrease myocardial oxygen demand after acute myocardial infarction. In addition, nitroprusside is used to induce controlled hypotension during anesthesia in order to reduce bleeding in surgical procedures. In the treatment of acute aortic dissection, it is important to administer a β adrenergic receptor antagonist with nitroprusside, since reduction of blood pressure with nitroprusside alone can increase the rate of rise in pressure in the aorta as a result of increased myocardial contractility, thereby enhancing propagation of the dissection.

Sodium nitroprusside is available in vials that contain 50 mg. The contents of the vial should be dissolved in 2 to 3 ml of 5% dextrose in water. Addition of this solution to 250 to 1000 ml of 5% dextrose in water produces a concentration of 50 to 200 $\mu\text{g}/\text{ml}$. Because the compound decomposes in light, only fresh solutions should be used, and the bottle should be covered with an opaque wrapping. The drug must be administered as a controlled continuous infusion, and the patient must be closely observed. The majority of hypertensive patients respond to an infusion of 0.25 to 1.5 $\mu\text{g}/\text{kg}$ per minute. Higher rates of infusion are necessary to produce controlled hypotension in normotensive patients under surgical anesthesia. Infusion of nitroprusside at rates exceeding 5 $\mu\text{g}/\text{kg}$

per minute over a prolonged period can cause cyanide and/or thiocyanate poisoning. Patients who are receiving other antihypertensive medications usually require less nitroprusside to lower blood pressure. If infusion rates of 10 $\mu\text{g}/\text{kg}$ per minute do not produce adequate reduction of blood pressure within 10 minutes, the rate of administration of nitroprusside should be reduced to minimize potential toxicity.

Diazoxide

Diazoxide (HYPERSTAT IV) is used in the treatment of hypertensive emergencies. Sodium nitroprusside is the drug of choice for this indication, but diazoxide may rarely be used if accurate infusion pumps are not available and/or close monitoring of blood pressure is not feasible. It also is administered orally (PROGLYCEM) to treat patients with various forms of hypoglycemia (*see* Chapter 60).

NONPHARMACOLOGICAL THERAPY OF HYPERTENSION

Nonpharmacological approaches to the reduction of blood pressure generally are advisable as the initial approach to treatment of patients with diastolic blood pressures in the range of 90 to 95 mm Hg. Furthermore, these approaches will augment the effectiveness of pharmacological therapy in patients with higher levels of blood pressure. Also, for patients with diastolic blood pressures in the range of 85 to 90 mm Hg, the epidemiological data on cardiovascular risks support the institution of nonpharmacological therapy. The indications and efficacy of various lifestyle modifications in hypertension are reviewed in a summary statement from the Joint National Committee (Chobanian *et al.*, 2003).

To maintain compliance with a therapeutic regimen, the intervention should not lessen the quality of life. All drugs have side effects. If minor alterations of normal activity or diet can reduce blood pressure to a satisfactory level, the complications of drug therapy can be avoided. In addition, nonpharmacological methods to lower blood pressure allow patients to participate actively in the management of their disease. Reduction of weight, restriction of salt, and moderation in the use of alcohol may reduce blood pressure and improve the efficacy of drug treatment. In addition, regular isotonic exercise also lowers blood pressure in hypertensive patients.

Reduction of Body Weight. Obesity and hypertension are closely associated, and the degree of obesity is positively correlated with the incidence of hypertension. Obese hypertensives may lower their blood pressure by losing weight regardless of a change in salt consumption (Maxwell *et al.*, 1984). The mechanism by which obesity causes hypertension is unclear, but increased secre-

tion of insulin in obesity could result in insulin-mediated enhancement of renal tubular reabsorption of Na^+ and an expansion of extracellular volume. Obesity also is associated with increased activity of the sympathetic nervous system; this is reversed by weight loss. Maintenance of weight loss is difficult for many. A combination of aerobic physical exercise and dietary counseling may enhance compliance.

Sodium Restriction. Severe restriction of salt will lower the blood pressure in most hospitalized hypertensive patients. However, severe salt restriction is not practical from a standpoint of compliance. Several studies have shown that moderate restriction of salt intake to approximately 5 g per day (2 g Na^+) will, on average, lower blood pressure by 12 mm Hg systolic and 6 mm Hg diastolic. The higher the initial blood pressure, the greater the response. In addition, subjects over 40 years of age are more responsive to the hypotensive effect of moderate restriction of salt (Grobbee and Hoffman, 1986). Even though not all hypertensive patients respond to restriction of salt, this intervention is likely benign and can easily be advised as an initial approach in all patients with mild hypertension. An additional benefit of salt restriction is improved responsiveness to some antihypertensive drugs.

Alcohol Restriction. Consumption of alcohol can raise blood pressure, but it is unclear how much alcohol must be consumed to observe this effect. Heavy consumption of alcohol increases the risk of cerebrovascular accidents but not coronary heart disease (Kagan *et al.*, 1985). In fact, small amounts of ethanol have been found to protect against the development of coronary artery disease. Hypertensive patients should be advised to restrict consumption of ethanol to no more than 30 ml per day (*see* Chapter 22).

Physical Exercise. Increased physical activity lowers rates of cardiovascular disease in men (Paffenbarger *et al.*, 1986). It is not known if this beneficial effect is secondary to an antihypertensive response to exercise. Lack of physical activity is associated with a higher incidence of hypertension (Blair *et al.*, 1984). Although consistent changes in blood pressure are not always observed, meticulously controlled studies have demonstrated that regular isotonic exercise reduces both systolic and diastolic blood pressures by approximately 10 mm Hg (Nelson *et al.*, 1986). The mechanism by which exercise can lower blood pressure is not clear. Regular isotonic exercise reduces blood volume and plasma catecholamines and elevates plasma concentrations of atrial natriuretic peptide. The beneficial effect of exercise can occur in subjects who demonstrate no change in body weight or salt intake during the training period.

Relaxation and Biofeedback Therapy. The fact that long-term stressful stimuli can cause sustained hypertension in animals has given credence to the possibility that relaxation therapy will lower blood pressure in some hypertensive patients. A few studies have generated positive results, but in general, relaxation therapy has inconsistent and modest effects on blood pressure (Jacob *et al.*, 1986). In addition, the long-term efficacy of such treatment has been difficult to demonstrate, presumably in part because patients must be highly motivated to respond to relaxation and biofeedback therapy. Only those few patients with mild hypertension who wish to use this method should be encouraged to try, and these patients should be closely followed and receive pharmacological treatment if necessary.

Potassium Therapy. There is a positive correlation between total body Na^+ and blood pressure and a negative correlation between total body K^+ and blood pressure in hypertensive patients (Lever *et al.*, 1981). In addition, dietary intake, plasma concentrations, and urinary excretion of K^+ are reduced in various populations of hypertensive subjects. Increased intake of K^+ might reduce blood pressure by increasing excretion of Na^+ , suppressing renin secretion, causing arteriolar dilation (possibly by stimulating Na^+, K^+ -ATPase activity, and decreasing intracellular concentrations of Ca^{2+}), and impairing responsiveness to endogenous vasoconstrictors. In hypertensive rats, supplementation with K^+ decreases blood pressure and reduces the incidence of stroke, regardless of blood pressure (Tobian, 1986). In mildly hypertensive patients, oral K^+ supplements of 48 mmol per day reduce both systolic and diastolic blood pressure (Siani *et al.*, 1987). Supplementation with K^+ also may protect against ventricular ectopy and stroke (Khaw and Barrett-Connor, 1987). Based on all of these data, it seems prudent to use a high- K^+ diet in conjunction with moderate restriction of Na^+ in the nonpharmacological treatment of hypertension. *However, a high- K^+ diet should not be recommended for patients on ACE inhibitors.*

Tobacco, Coffee, and Other Factors. Smoking *per se* does not cause hypertension, although cigarette smoking acutely raises blood pressure due to actions of nicotine. Smoking is a major risk factor for coronary heart disease. Hypertensive patients should have a great incentive to stop smoking. While clonidine has some efficacy in facilitating withdrawal from smoking, there is no evidence that preferential use of this drug in hypertensive smokers is desirable (*see* Chapter 23). Consumption of caffeine can raise blood pressure and elevate plasma concentrations of norepinephrine, but long-term consumption of caffeine causes tolerance to these effects and has not been associated with the development of hypertension. An increased intake of Ca^{2+} has been reported by some investigators to lower blood pressure. The mechanism of this effect is not understood, but suppression of the secretion of parathyroid hormone apparently is involved. However, supplemental Ca^{2+} does not lower blood pressure when populations of hypertensive subjects are studied. Although it is possible that there are some hypertensive patients who have a hypotensive response to Ca^{2+} , there is no easy way to identify such individuals. Supplemental use of Ca^{2+} for this purpose cannot be recommended at the present time (Kaplan, 1988).

SELECTION OF ANTIHYPERTENSIVE DRUGS IN INDIVIDUAL PATIENTS

Choice of antihypertensive drugs for individual patients may be complex; there are many sources of influence that modify therapeutic decisions. While results derived from randomized controlled clinical trials are the optimal foundation for rational therapeutics, it may be difficult to sort through the multiplicity of results and address how they apply to an individual patient. While therapeutic guidelines can be useful in reaching appropriate therapeutic decisions, it is often difficult for clini-

cians to apply guidelines at the point of care, and guidelines often do not provide enough information about recommended drugs. In addition, intense marketing of specific drugs to both clinicians and patients may confound optimal decision making. Moreover, persuading patients to continue taking sometimes expensive drugs for an asymptomatic disease is a challenge. Clinicians may be reluctant to prescribe and patients reluctant to consume the number of drugs that may be necessary to adequately control blood pressure. For these and other reasons, perhaps one-half of patients being treated for hypertension have not achieved therapeutic goals in blood pressure lowering.

Choice of an antihypertensive drug should be driven by likely benefit in an individual patient, taking into account concomitant diseases such as diabetes mellitus, problematic adverse effects of specific drugs, and cost.

Recent guidelines recommend diuretics as preferred initial therapy for most patients with uncomplicated stage 1 hypertension who are unresponsive to nonpharmacological measures. Patients are also commonly treated with other drugs: β receptor antagonists, ACE inhibitors/ AT_1 -receptor antagonists, and Ca^{2+} channel blockers. Patients with uncomplicated stage 2 hypertension will likely require the early introduction of a diuretic and another drug from a different class. Subsequently, doses can be titrated upward and additional drugs added in order to achieve goal blood pressures (blood pressure $<140/90$ mm Hg in uncomplicated patients). Some of these patients may require four different drugs to reach their goal.

A most important and high-risk group of patients with hypertension are those with compelling indications for specific drugs on account of other underlying serious cardiovascular disease (heart failure, post-myocardial infarction, or with high risk for coronary artery disease), chronic kidney disease, or diabetes (Chobanian *et al.*, 2003). For example, a hypertensive patient with congestive heart failure ideally should be treated with a diuretic, β receptor antagonist, ACE inhibitor/ AT_1 receptor antagonist, and spironolactone because of the benefit of these drugs in congestive heart failure, even in the absence of hypertension. Similarly, ACE inhibitors/ AT_1 receptor antagonists should be first-line drugs in the treatment of diabetics with hypertension in view of their well-established benefits in diabetic nephropathy.

Other patients may have less serious underlying diseases that could influence choice of antihypertensive drugs. For example, a hypertensive patient with symptomatic benign prostatic hyperplasia might benefit from having an α_1 receptor antagonist as part of his therapeutic program,

since α_1 antagonists are efficacious in both diseases. Similarly, a patient with recurrent migraine attacks might particularly benefit from use of a β receptor antagonist since a number of drugs in this class are efficacious in preventing migraine attacks.

Patients with isolated systolic hypertension (systolic blood pressure >160 mm Hg and diastolic blood pressure <90 mm Hg) benefit particularly from diuretics and also from Ca^{2+} channel blockers. These should be first-line drugs in these patients in terms of efficacy, but compelling indications as above need to be taken into account.

These considerations have been addressed with regard to patients with hypertension that need treatment to reduce long-term risk, not patients in immediately life-threatening settings due to hypertension. While there are very limited clinical trial data, clinical judgment favors rapidly lowering blood pressure in patients with life-threatening complications of hypertension, such as patients with hypertensive encephalopathy or pulmonary edema due to severe hypertension. Rapid reduction in blood pressure has considerable risks for the patients; if blood pressure is decreased too quickly or extensively, cerebral blood flow may diminish due to adaptations in the cerebral circulation that protect the brain from the sequelae of very high blood pressures. The temptation to rapidly treat patients merely on the basis of increased blood pressure should be resisted. Appropriate therapeutic decisions need to encompass how well the patients' major organs are reacting to the very high blood pressures.

PHARMACOTHERAPY OF CONGESTIVE HEART FAILURE

Thomas P. Rocco and James C. Fang

Congestive heart failure (CHF) is a major contributor to morbidity and mortality worldwide. There are approximately 5 million established cases of heart failure in the United States alone; a similar number of patients have asymptomatic left ventricular dysfunction and are therefore at risk to develop CHF. Heart failure accounts for more than half a million deaths annually in the United States; mortality in patients with advanced heart failure exceeds 50% at 1 year (American Heart Association, 2003). Fortunately, substantive advances in the understanding of CHF at the organ systems and cellular-molecular levels have driven important advances in the pharmacotherapy of heart failure that have revolutionized clinical practice. While palliation of symptoms and improvement in the quality of life remain important goals, it now is possible to approach therapy with the expectation that disease progression can be attenuated, and, in many instances, survival prolonged.

Historically, drug therapies have focused on the endpoint components of this syndrome, volume overload (congestion) and myocardial dysfunction (heart failure). Treatment strategies have typically emphasized the use of diuretics and cardiac glycosides, with investigative efforts directed at the development of new agents that improved contractile performance. While effective in providing relief of symptoms and in stabilizing patients with hemodynamic decompensation, such therapies have not been proven to improve survival. More recent work has provided greater insight into the induction and propagation of CHF, providing a conceptual framework in which heart failure is viewed as a consequence of disordered circulatory dynamics and pathologic cardiac remodeling. These developments have had a major positive impact on the treatment of CHF. Before discussing the clinical pharma-

cotherapy of heart failure, it is useful to establish a pathophysiologic framework through which its treatment can be approached.

Pathophysiology of Congestive Heart Failure

The principal function of the circulatory system is to deliver oxygenated blood to the periphery in response to aggregate local demand. Circulatory homeostasis therefore requires defense of both forward cardiac output and mean arterial pressure (MAP). The importance of the MAP derives from the fact that the systemic circulation consists of a number of parallel regional circulatory beds, each of which offers an intrinsic resistance to flow. Perfusion of these regional beds is determined by the inflow pressure (MAP) and is inversely proportional to the vascular resistance in the given subsegment of the circulation. This intrinsic resistance can be modulated to increase or decrease perfusion based on local and/or whole body demand for oxygen. The net effect is that the cardiac output delivered by the left ventricle is distributed, as required, to sites of demand *via* modulation of resistors in the peripheral circulatory beds. This local modulation of resistance is the mechanism by which blood flow is coupled to oxygen demand.

While local autoregulation determines the peripheral distribution of the cardiac output under physiologic circumstances, the circulation must also have the capacity to supersede local autoregulation when aggregate demand exceeds the delivery capacity of the cardiac output. The classic such example is hypovolemic shock, a situation in which forward cardiac output is reduced as a consequence of decreased intravascular volume. In this setting, both the sympathetic branch of the autonomic nervous system (*see*

Chapter 6) and the renin–angiotensin system (*see* Chapter 30) are activated; the vasoconstrictive effects of these systems substantially increase peripheral vascular resistance, leading to reduced flow to noncritical vascular beds. This redistribution of the cardiac output maintains perfusion to critical circulatory beds such as the CNS, the left ventricular myocardium, and the kidney. Concomitant with the redistribution of cardiac output, these neurohumoral systems also initiate a host of biological responses that increase the reabsorption of Na^+ and water. These compensatory mechanisms typically operate in the context of normal myocardial contractility and normal myocardial compliance, conditions that generally do not hold in the setting of heart failure and are best suited to the provision of short-term circulatory support to overcome transient, dynamic cardiovascular stress.

It is difficult to provide a comprehensive definition of CHF, since the term describes a final common pathway for the expression of myocardial dysfunction of diverse etiologies. While some emphasize the clinical distinction between systolic and diastolic heart failure, many patients exhibit abnormalities of both contractile performance and ventricular relaxation/filling. This is well illustrated by the fact that the rate and temporal partitioning of left ventricular diastolic filling are directly affected by impaired systolic contractile performance.

Despite the difficulties inherent in creating a unifying description to encompass these distinct clinical states, definitions of CHF have emerged that have been used in consensus guidelines developed to guide the evaluation and management of heart failure.

Congestive heart failure is the pathophysiologic state in which the heart is unable to pump blood at a rate commensurate with the requirements of metabolizing tissues, or can do so only from an elevated filling pressure (Braunwald and Bristow, 2000).

Heart failure is a complex of symptoms—fatigue, shortness of breath, and congestion—that are related to the inadequate perfusion of tissue during exertion and often to the retention of fluid. Its primary cause is an impairment of the heart's ability to fill or empty the left ventricle properly (Cohn, 1996).

Although inevitably incomplete, such definitions can provide a point of departure from which a pathophysiologic framework can be constructed. Integrating the above, one can define heart failure as a condition in which the heart fails to provide adequate forward output at normal filling pressures; this condition is typically associated with a clinical syndrome of reduced functional capacity and pulmonary and systemic venous congestion. It is important to reemphasize the fact that the failing heart

functions in the context of a systemic circulation that requires mechanisms by which both cardiac output and vascular resistance can be modulated.

The primary mechanism by which forward cardiac output is maintained is recruitment of preload reserve, a dynamic reduction of venous capacitance that results in “centralization” of peripheral blood volume and enhanced venous return, thereby increasing left ventricular end-diastolic volume (EDV). This increased left ventricular volume in turn leads to an increase in the length of left ventricular (LV) muscle fibers, thereby enhancing actin-myosin interaction and producing greater contractile force and increased LV stroke volume (SV); this fundamental relationship between left ventricular filling and stroke volume is the *Frank-Starling relationship* (the “normal” curve in Figure 33–1). This preload recruitment represents the primary mechanism intrinsic to the cardiovascular system by which cardiac output can be augmented. If preload recruitment does not provide sufficient forward cardiac output, the compensatory responses that

Figure 33–1. Hemodynamic responses to pharmacological interventions in heart failure. The relationships between diastolic filling pressure (or preload) and stroke volume (or ventricular performance) are illustrated for a normal heart (*black line*; the Frank-Starling relationship) and for a patient with heart failure due to predominant systolic dysfunction (*blue line*). Note that positive inotropic agents (I), such as cardiac glycosides or dobutamine, move patients to a higher ventricular function curve (*lower dashed line*), resulting in greater cardiac work for a given level of ventricular filling pressure. Vasodilators (V), such as ACE inhibitors or nitroprusside, also move patients to improved ventricular function curves while reducing cardiac filling pressures. Diuretics (D) improve symptoms of congestive heart failure by moving patients to lower cardiac filling pressures along the same ventricular function curve. Combinations of drugs often will yield additive effects on hemodynamics.

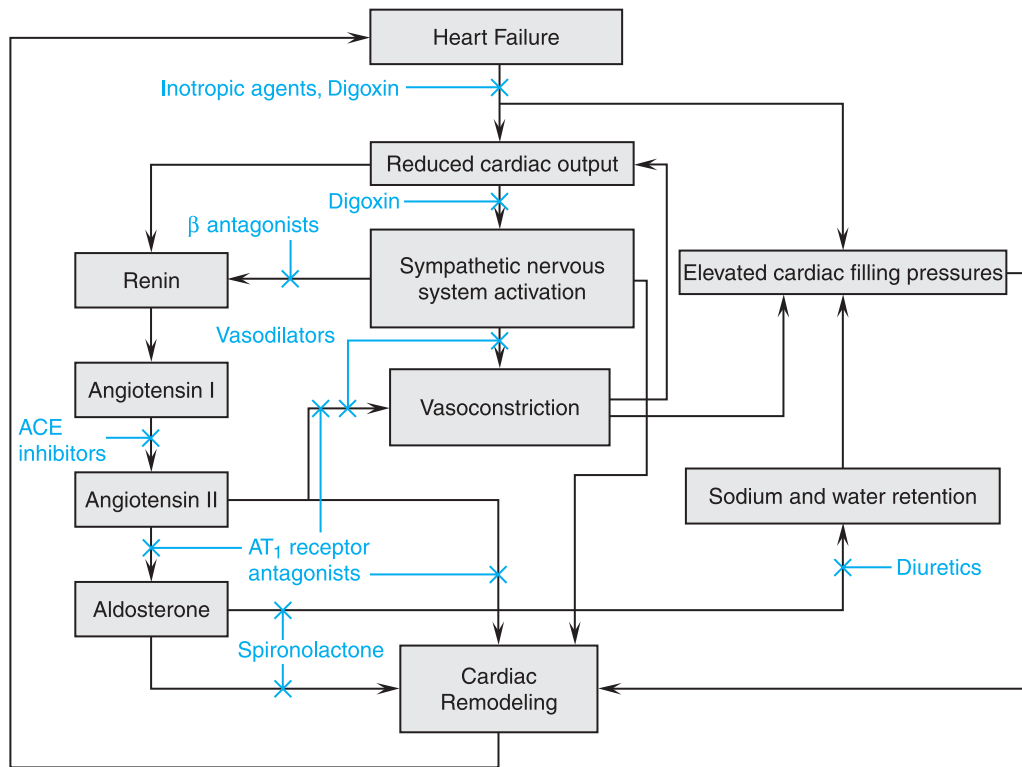

Figure 33–2. Pathophysiological mechanisms of heart failure and major sites of drug action. Heart failure is accompanied by compensatory neurohormonal responses including activation of the sympathetic nervous and renin–angiotensin systems. Although these responses initially help to maintain cardiovascular function by increasing ventricular preload and systemic vascular tone, with time they contribute to the progression of myocardial failure. Increased ventricular afterload, due to systemic vasoconstriction and chamber dilation, causes a depression in systolic function. In addition, increased afterload and the direct effects of angiotensin and norepinephrine on the ventricular myocardium cause pathological remodeling characterized by progressive chamber dilation and loss of contractile function. The figure illustrates several mechanisms that appear to play important roles in the pathophysiology of heart failure, and the sites of action of pharmacological therapies that have been shown to be of clinical value.

follow reflect the severity and duration of the hemodynamic stress.

In the case of acute circulatory stress (e.g., myocardial infarction), neurohumoral systems are activated that support the circulation; principal among these are the sympathetic branch of the autonomic nervous system and the renin–angiotensin system. The net effect of activation of the sympathetic nervous system is increased myocardial contractility, enhanced myocardial relaxation, and increased heart rate (β adrenergic effects); activation of the sympathetic efferents also results in increases in systemic vascular resistance and MAP (α adrenergic effects). The renin–angiotensin system also supports cardiac output and mean arterial pressure. The system is activated by reduction of renal perfusion pressure, which increases renin secretion; renin cleaves circulating angiotensinogen to produce angiotensin I (Ang I); Ang I is converted to angiotensin II (Ang II) by the action of angiotensin-converting enzyme (ACE).

Ang II, a potent vasoconstrictor, thereby helps to maintain MAP; Ang II also leads to increased adrenal production of aldosterone, a mineralocorticoid that causes Na^+ and fluid retention, thereby expanding intravascular volume and increasing venous return. Thus, the sympathetic nervous system and renin–angiotensin system collaborate to maintain the MAP and cardiac output. Under physiologic conditions, these compensatory mechanisms operate in the context of normal myocardial contractility, normal myocardial compliance, and temporally constrained hemodynamic stress. In patients with CHF, these compensatory systems must operate under circumstances in which left ventricular performance is impaired and the hemodynamic stress is chronic. The intersections of compensatory mechanisms with pathophysiologic mechanisms, as well as sites of drug action, are shown in Figure 33–2.

In the setting of contractile dysfunction, the normal relationship between EDV and SV is shifted downward

(Figure 33–1), such that left ventricular SV may be reduced even if EDV is markedly increased. This increase in EDV results in higher diastolic and systolic wall stress and eventually leads to increases in left ventricular end-diastolic pressure and left atrial pressure; this in turn alters Starling forces in the pulmonary capillaries to favor transudation of fluid into the extravascular spaces of the pulmonary interstitium, producing interstitial and alveolar edema. In addition, the vasoconstrictive effectors of the sympathetic nervous system and the renin–angiotensin system lead to an increase in systemic vascular resistance, which contributes to an increased impedance to left ventricular ejection (increased afterload). The left ventricle becomes increasingly sensitive to the effects of afterload in the setting of contractile dysfunction; such increases in afterload ultimately produce substantial reductions in left ventricular stroke volume. The consequent reduction of cardiac output serves as an iterative stimulus to continued activation of the neurohumoral systems that stimulate the heart and constrict the vessels.

Hypertrophic Remodeling. It has long been presumed that the adult heart cannot respond to sustained hemodynamic stress by hyperplasia. In the face of such stress, however, signal transduction systems do exist that initiate the synthesis and spatial organization of new contractile proteins, a process known as *hypertrophic remodeling*.

In cases of chronic pressure overload, such as systemic arterial hypertension or valvular aortic stenosis, contractile proteins and new sarcomeres are added to existing cardiac myocytes in parallel to existing myofilaments. This leads to increased wall thickness and decreased chamber radius, resulting in reduction of systolic wall stress. Because LV ejection fraction is inversely proportional to systolic wall stress, this compensatory mechanism contributes to the maintenance of normal LV stroke volume. The disadvantage of concentric remodeling derives from the decrease in LV compliance that occurs as a consequence of this pattern of hypertrophy: LV diastolic pressure is increased at any given LV volume, predisposing to congestive symptoms.

In contrast, sustained increases of volume, such as left-sided valvular regurgitation, result in eccentric pattern hypertrophy. In this pattern of remodeling, new contractile proteins are added to existing myofilaments in series, leading to increased myocardial compliance and thereby attenuating diastolic wall stress. At the whole-organ level, this allows continued preload recruitment without significant elevation of LV diastolic pressure. As a result, total LV stroke volume is increased and forward cardiac output is maintained at normal filling pressures. This compensatory response does carry

some consequence: progressive LV dilation ultimately produces a secondary increase in systolic wall stress.

In circumstances of sustained pressure or volume loading, cardiomyocyte injury and whole-organ pump dysfunction supervene if the abnormal loading conditions are not corrected. This transition from compensated hypertrophy to contractile dysfunction has been referred to as the cardiomyopathy of chronic overload, the end result of maladaptive proliferative signaling (Katz, 1994; Villarreal, 2005).

Cellular Pathophysiology. At the cellular level, changes associated with the transition to contractile dysfunction include dysregulation of Ca^{2+} homeostasis, changes in the regulation and expression of the contractile proteins, and alterations in adrenergic signal transduction pathways.

Altered calcium homeostasis results in prolongation of the action potential and the Ca^{2+} transient. Mechanisms that increase the cytosolic concentration of Ca^{2+} include reduction of Ca^{2+} sequestration by the sarcoplasmic reticulum and increased Ca^{2+} uptake *via* the Na^+ - Ca^{2+} exchanger. The derivative abnormalities of calcium handling can result in impairment of both myocardial contraction and relaxation.

Dysfunctional contractile proteins are produced by changes in the transcription of a number of genes in the cardiac myocyte. Available data indicate that myocytes enter a maladaptive proliferative phase in which fetal isoforms are expressed. Alterations of the contractile proteins associated with heart failure range from abnormalities of tropinin and myosin that interfere with the rate of cross-bridge cycling to activation of collagenase/matrix metalloproteinases that disrupt the extracellular matrix that couples cellular elements.

Desensitization of the β receptor- G_s -adenylyl cyclase-cyclic AMP pathway is another major abnormality that has been described in the failing cardiac myocyte (Mann, 1999). The number of β receptors expressed at the cell surface is down-regulated, resulting in reduction of cyclic AMP production in response to β adrenergic stimulation. This reduction in β adrenergic signaling may reflect increased expression of both β adrenergic receptor kinase (which phosphorylates and thereby inhibits β receptors) and G_i , the inhibitory G protein. The expression of inducible nitric oxide (NO) synthase is increased in CHF; NO can have negative inotropic effects and can reduce cyclic AMP signaling. The net result of these alterations at the level of signaling *via* cyclic AMP-PKA is decreased phosphorylation of phospholamban, resulting in impaired Ca^{2+} uptake by the sarcoplasmic reticulum and consequent impairment of both contraction and relaxation.

Clinical Heart Failure

From the above discussion, one can delineate the following pathophysiologic sequence in response to myocardial failure. Initially, myocardial dysfunction and the attendant reduction of forward cardiac output lead to expansion of intravascular volume and activation of neurohumoral systems, particularly the sympathetic nervous system and the renin–angiotensin system. These compensatory responses maintain perfusion to vital organs by increasing left ventricular preload, stimulating myocardial contractility, and increasing arterial tone. While physiologic in the context of volume contraction, in the context of congestive failure, avid retention of Na^+ and water and vasoconstriction are pathologic (Weber, 2001). Acutely, these mechanisms help to sustain cardiac output by allowing the heart to

operate at higher end-diastolic volumes, leading to increased stroke volume; concomitant peripheral vasoconstriction allows for regional redistribution of the cardiac output to critical perfusion beds. Unfortunately, each of these compensatory responses will also promote disease progression. Expansion of the intravascular volume and elevated ventricular chamber volumes will lead to increased diastolic and systolic wall stress; these changes in turn will lead to impaired myocardial energetics and will induce hypertrophic remodeling. Neurohumoral activation will lead to arterial and venous constriction; the former will increase left ventricular afterload (thereby compromising left ventricular stroke volume) and the latter will increase preload, thereby exacerbating both diastolic and systolic wall stress. In addition, the neurohumoral effectors (such as norepinephrine and Ang II) may act directly on the myocardium to promote unfavorable remodeling by causing myocyte apoptosis, abnormal gene expression, and alterations in the extracellular matrix (Colucci and Braunwald, 2000; Villarreal, 2005).

PHARMACOLOGICAL TREATMENT OF HEART FAILURE

The abnormalities of myocardial structure and function that underlie heart failure are often irreversible. As noted above, these abnormalities can serve as stimuli to the activation of biological responses that drive disease progression. It is perhaps not surprising that the syndrome of CHF is typically a chronic illness during which episodic, acute decompensation may occur. Drugs that reduce ventricular wall stress or inhibit the renin-angiotensin system (*e.g.*, selected vasodilators, ACE inhibitors, and aldosterone antagonists) or the sympathetic nervous system (*e.g.*, β adrenergic antagonists) can decrease pathological ventricular remodeling, attenuate disease progression, and decrease mortality in patients with heart failure due to systolic dysfunction. As a result, these drugs have become mainstays in the long-term treatment of heart failure. Some of the drugs that slow progression afford an immediate beneficial impact on hemodynamic function and symptoms (*e.g.*, vasodilators and ACE inhibitors). Other agents that attenuate disease progression can have an adverse effect on hemodynamic function and worsen symptoms in the short term and must therefore be used with caution (*e.g.*, β receptor antagonists). Figure 33–2 provides an overview of the pathophysiological mechanisms of heart failure and the sites of action of the major drug classes used in treatment.

The pharmacological treatment of heart failure for many years was limited to the use of digitalis glycosides and diuretics. Although *digitalis* has been supplanted by therapies that provide a mortality benefit (*e.g.*, ACE inhibitors), the clinical and investigative uses of the cardiac

glycosides have informed approaches to therapy and drug design and development. Similarly, while diuretics do not offer a mortality benefit, volume overload clearly remains a central component of the clinical syndrome and is often the factor that leads to initial diagnosis or to hospitalization for treatment of acute exacerbations.

The current approach to therapy for CHF involves preload reduction, afterload reduction, and enhancement of inotropic state (Figure 33–1). A variety of vasodilators will reduce preload and afterload (Table 33–1). Although a vasodilator's more prominent effect may be the reduction of either preload or afterload, most agents affect both, to differing extents.

Diuretics

Diuretics retain a central role in the pharmacological management of the “congestive” symptoms in patients with heart failure. The pharmacological properties of these agents are presented in detail in Chapter 28. Their importance in heart failure management reflects the central role of the kidney in the hemodynamic, hormonal, and autonomic responses to myocardial failure. The net effect of these responses is the retention of Na^+ and water and expansion of the extracellular fluid volume, allowing the heart to operate at higher end-diastolic volumes, and thereby to maintain LV stroke volume. However, this increase in end-diastolic volume results in higher end-diastolic filling pressures, increased ventricular chamber dimensions, and elevated wall stress. In turn, these changes result in pulmonary venous congestion and peripheral edema, ultimately limiting further augmentation of cardiac output. Elevated filling pressures are associated with enhanced activation of neurohumoral systems that can drive the progression of CHF (Hillege *et al.*, 2000).

Diuretics reduce extracellular fluid volume and ventricular filling pressure (or “preload”). Because patients with heart failure often operate on a “plateau” phase of the Starling curve (Figure 33–1), preload reduction can occur without concomitant reduction in cardiac output. Note that reduction in cardiac output can occur in patients who have had either sustained natriuresis and/or a rapid decline in intravascular volume. In this circumstance, diuretic therapy may augment neurohormonal activation due to volume depletion, with potentially deleterious effects on the progression of heart failure (McCurley *et al.*, 2004). For this reason, it is preferable to avoid the use of diuretics in the subset of patients with asymptomatic LV dysfunction and to use the minimal dose necessary to maintain euvolemia in patients with symptoms related to volume retention. Despite the efficacy

Table 33-1

Vasodilator Drugs Used to Treat Heart Failure

DRUG CLASS	EXAMPLES	MECHANISM OF VASODILATING ACTION	PRELOAD REDUCTION	AFTERLOAD REDUCTION
Organic nitrates	Nitroglycerin, isosorbide dinitrate	NO-mediated vasodilation	+++	+
Nitric oxide donors	Nitroprusside	NO-mediated vasodilation	+++	+++
Angiotensin-converting enzyme inhibitors	Captopril, enalapril, lisinopril	Inhibition of Ang II generation, decreased bradykinin degradation	++	++
Angiotensin receptor blockers	Losartan, candesartan	Blockade of AT ₁ receptors	++	++
Phosphodiesterase inhibitors	Milrinone, inamrinone	Inhibition of cyclic AMP degradation	++	++
Direct-acting K ⁺ -channel agonist	Hydralazine Minoxidil	Unknown Hyperpolarization of vascular smooth muscle cells	+ +	+++ +++
α ₁ Adrenergic antagonists	Doxazosin, prazosin	Selective α ₁ adrenergic receptor blockade	+++	++
Nonselective α adrenergic antagonists	Phentolamine	Nonselective α adrenergic receptor blockade	+++	+++
Vasodilating β/α ₁ adrenergic antagonists	Carvedilol, labetalol	Selective α ₁ adrenergic receptor blockade	++	++
Ca ²⁺ channel blockers	Amlodipine, nifedipine, felodipine	Inhibition of L-type Ca ²⁺ channels	+	+++
β adrenergic agonists	Isoproterenol	Stimulation of vascular β ₂ adrenergic receptors	+	++

ABBREVIATIONS: Ang II, angiotensin II; AT₁, type 1 Ang II receptor; NO, nitric oxide.

of diuretics in controlling congestive symptoms and improving exercise capacity, the use of diuretics, with the exception of aldosterone antagonists, does not reduce mortality in heart failure.

Dietary Sodium Restriction. All patients with clinically significant ventricular dysfunction, regardless of symptom status, should be advised to limit dietary intake of NaCl. Most patients will tolerate moderate reductions in salt intake (2 to 3 g/day total intake). More stringent salt restriction is seldom necessary and may be counterproductive, as it can lead to hyponatremia, hypokalemia, and hypochloremic metabolic alkalosis when combined with administration of loop diuretics.

Loop Diuretics. Of the loop diuretics currently available, *furosemide* (LASIX), *bumetanide* (BUMEX), and *toremide* (DEMADEX) are widely used in the treatment of heart failure. Due to the increased risk of ototoxicity, *ethacrynic acid* (EDECRIN) should be reserved for patients who are

allergic to sulfonamides or who have developed interstitial nephritis on alternative drugs.

Loop diuretics inhibit a specific ion transport protein, the Na⁺-K⁺-2Cl⁻ symporter on the apical membrane of renal epithelial cells in the ascending limb of the loop of Henle (*see* Chapter 28). Their efficacy is dependent upon sufficient renal plasma flow and proximal tubular secretion to deliver the diuretics to their site of action. These drugs also reduce the tonicity of the medullary interstitium by preventing the resorption of solute in excess of water in the thick ascending limb of the loop of Henle. The increased delivery of Na⁺ and fluid to distal nephron segments also markedly enhances K⁺ secretion, particularly in the presence of elevated aldosterone levels, as is typically the case in heart failure.

The bioavailability of orally administered furosemide ranges from 40% to 70%. Higher doses of drug often are required to initiate diuresis in patients who present with worsening symptoms (Gottlieb, 2004); thus upward titration of dosage is required before furosemide is deemed ineffective. In contrast, the oral bioavailabilities of bumetanide and toremide exceed 80%; as a result these agents provide more consistent absorption, albeit at a considerably greater cost. The pharmacologic actions of the loop diuretics are similar; thus, the use of the more expensive agents rarely is warranted (Brater, 1998).

Furosemide and bumetanide are short-acting drugs. The resultant postdose decline in renal tubular diuretic levels leads to avid renal Na^+ retention by all nephron segments. This can limit or prevent negative Na^+ balance and it is a common practice in CHF patients to administer two or more doses daily. This is an acceptable strategy for outpatient management of heart failure, provided there is adequate monitoring of daily weight and blood electrolyte levels.

Thiazide Diuretics. The thiazide diuretics (DIURIL, HYDRO-DIURIL, others) are most frequently used in the treatment of systemic hypertension; these drugs have a more restricted role in the treatment of CHF.

The principal site of action of the thiazide diuretics is the Na^+ - Cl^- cotransporter of the epithelial cells in the distal convoluted tubule (see Chapter 28). This distal site of action permits rapid adjustment of water and solute absorption by more proximal nephron segments, limiting the utility of thiazide monotherapy in patients with more advanced disease. Thiazide diuretics are ineffective at glomerular filtration rates below 30 ml/min and are therefore not used in patients with significant impairment of renal function.

While thiazides have a limited role as single agents in the treatment of heart failure, they exhibit true synergism with loop diuretics: the natriuresis that follows coadministration exceeds the summed effects of the drugs administered individually. This synergism is the rationale for combination therapy in patients who appear refractory to loop diuretics. In general, thiazides are associated with a greater degree of potassium wasting for comparable volume reduction when compared to loop diuretics (Gottlieb, 2004).

K^+ -Sparing Diuretics. K^+ -sparing diuretics (see Chapter 28) act principally in the collecting duct of the nephron and either inhibit apical membrane Na^+ conductance channels in epithelial cells (e.g., *amiloride*, *triamterene*) or act as aldosterone antagonists (e.g., *canrenone* [not commercially available in the United States], *spironolactone*, and *eplerenone*). These agents are relatively weak diuretics and therefore are not effective for volume reduction. Historically, these agents have been used to limit renal K^+ and Mg^{2+} wasting and/or to augment the diuretic response to other agents. There is now evidence that aldosterone antagonists improve survival in patients with advanced heart failure via a mechanism that is independent of diuresis (Pitt *et al.*, 1999; Pitt *et al.*, 2003).

Use of Diuretics in Clinical Practice. The majority of patients with heart failure will require chronic administration of a loop diuretic to maintain euvolemia. In patients with clinically evident fluid retention, furosemide typically is started at a dose of 40 mg once or twice per day, and the dosage is increased until an adequate diuresis is achieved. A larger initial dose may be required in patients with more

advanced heart failure or with concurrent azotemia. Serum electrolytes and renal function should be monitored frequently in patients with preexisting renal insufficiency or those in whom a rapid diuresis is desirable. Once fluid retention has resolved, the diuretic dose should be reduced to the minimal level necessary to maintain euvolemia. Electrolyte abnormalities and/or worsening azotemia may supervene before euvolemia is achieved. Hypokalemia may be corrected by potassium supplementation or addition of a potassium-sparing diuretic.

Aldosterone Antagonists

One of the principal features of CHF is marked activation of the renin–angiotensin–aldosterone system. In heart failure patients, plasma aldosterone concentrations may increase to as high as 20 times the normal level. Aldosterone has a range of biological effects beyond salt retention (Table 33–2), and antagonism of aldosterone’s actions may be beneficial in patients with heart failure (Weber, 2001).

Clinical Use of Spironolactone in Heart Failure. The RALES Trial (Randomized Aldactone Evaluation Study) randomized patients with moderate-to-severe heart failure (New York Heart Association [NYHA] Class III to IV) to treatment with ≥ 25 mg daily of spirono-

Table 33–2
Potential Roles of Aldosterone in the Pathophysiology of Heart Failure

MECHANISM	PATHOPHYSIOLOGICAL EFFECT
Increased Na^+ and water retention K^+ and Mg^{2+} loss	Edema, elevated cardiac filling pressures Arrhythmogenesis and risk of sudden cardiac death
Reduced myocardial norepinephrine uptake	Potential of norepinephrine effects: myocardial remodeling and arrhythmogenesis
Reduced baroreceptor sensitivity	Reduced parasympathetic activity and risk of sudden cardiac death
Myocardial fibrosis, fibroblast proliferation	Remodeling and ventricular dysfunction
Alterations in Na^+ channel expression	Increased excitability and contractility of cardiac myocytes

lactone or placebo as an addition to conventional therapy; the large majority of patients were receiving concomitant ACE inhibitor therapy (Pitt *et al.*, 1999). Patients with serum creatinine concentrations >2.5 mg/dl ($221 \mu\text{M}$) were excluded from the study; a very small number of patients received 50 mg of spironolactone daily. Patients randomized to spironolactone had a significant ($\sim 30\%$) reduction in mortality and hospitalization for heart failure. The decrease in the risk of death was due to reductions in both progressive heart failure and sudden cardiac death. This risk reduction was achieved in the absence of a demonstrable diuretic effect, lending support to the hypothesis that aldosterone antagonists attenuate or reverse the pathologic remodeling that occurs in heart failure (Weber, 2001; Redfield *et al.*, 2003). Treatment generally was well tolerated; although 10% of men in the spironolactone group developed gynecomastia, withdrawal of treatment was necessary in less than 2%. Severe hyperkalemia occurred in only 2% of patients on spironolactone, and there were no clinically significant effects on renal function.

The RALES trial suggests that the beneficial effects of spironolactone are additive to those of ACE inhibitors; the use of spironolactone should be considered in patients with NYHA Class III and IV heart failure. Caution should be exercised when significant renal impairment is present. Treatment should be initiated at a dose of 12.5 or 25 mg daily. Higher doses should be avoided, as they may lead to hyperkalemia, particularly in patients receiving an ACE inhibitor (Juurlink *et al.*, 2004). Serum K^+ levels and electrolytes should be checked after initiation of treatment, and vigilance is warranted for potential drug interactions and medical disorders that may cause elevations in serum K^+ concentration (*e.g.*, potassium supplements, ACE inhibitors, and worsening renal function).

The findings of the RALES Trial were recently corroborated in the EPHEMUS (Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival) study (Pitt *et al.*, 2003). The EPHEMUS data suggest that treatment with aldosterone antagonists is associated with mortality benefit in patients with heart failure due to left ventricular systolic dysfunction. The observations support the use of aldosterone antagonists in conjunction with inhibitors of the renin-angiotensin system and β receptor antagonists in patients with symptomatic heart failure. The role of aldosterone antagonists in patients with asymptomatic left ventricular dysfunction has not been established.

Diuretics in the Decompensated Patient. As discussed for the treatment of heart failure in the ambulatory patient, diuretics are important for the alleviation of intravascular and extravascular fluid overload. In patients with decompensated heart failure of a severity that warrants hospital admission, it is generally desirable to initiate diuresis by intravenous administration of a loop diuretic. This typically provides a more rapid and predictable diuresis than does enteral therapy. The loop diuretic may be administered as repetitive boluses titrated to achieve the desired response, or by constant infusion. An advantage of infusion is that the same total daily dose of diuretic, given as a continuous infusion, results in a more sustained natriuresis due to maintenance of high drug levels within the lumen of renal tubules (Dormans *et al.*, 1996). In addition, the risk of ototoxicity is reduced by continuous infusion when compared to repetitive, intermittent intravenous dosing (Lahav *et al.*, 1992). A typical continuous furosemide infusion is initiated with a 40-mg bolus injection followed by a constant infusion of 10 mg/hour, with upward titration of the infusion as necessary. When there is a poor response to monotherapy, coadministration of a thiazide agent is

warranted. If the poor response is due to reduced renal perfusion, short-term administration of sympathomimetic drugs or phosphodiesterase inhibitors to increase cardiac output may be required.

Diuretic Resistance in Heart Failure. The response to diuretics is often impaired in patients with CHF. This impaired response may itself be a manifestation of the Na^+ avidity and the volume retention that characterize advanced heart failure. While there may initially be a brisk response to once-daily dosing, a compensatory increase in Na^+ reabsorption during the remainder of the day may prevent effective diuresis; as a result, reduction of the dosing interval may be warranted. In advanced heart failure, edema, decreased motility of the bowel wall, and reduced splanchnic blood flow can result in delay or attenuation of peak diuretic effect. Patients who have impaired renal function typically require higher doses of diuretic to ensure adequate delivery of the drug to its site of action.

Following prolonged administration of a loop diuretic, a process of adaptation can occur in which there is a compensatory increase in Na^+ reabsorption in the distal nephron and blunting of net Na^+ and water loss. The more common causes of diuretic resistance are listed in Table 33–3. An increasing diuretic requirement may also be due to intravascular volume depletion following aggressive diuresis or to concurrent administration of vasoactive drugs; the possibility that diuretic resistance may be a manifestation of progressive heart failure must be considered. Invasive assessment of intracardiac filling pressures and cardiac output may be required to make these distinctions.

Vasodilators commonly employed as “unloading” agents in heart failure may reduce renal blood flow despite an increase in cardiac output; this occurs as a result of reduction in mean arterial pressure and redistribution of cardiac output to extrarenal circulatory beds. The net effect may be reduction of diuretic effectiveness. In addition, the presence of atherosclerotic renal artery stenosis in

Table 33–3

Causes of Diuretic Resistance in Heart Failure

- Noncompliance with medical regimen; excess dietary Na^+ intake
- Decreased renal perfusion and glomerular filtration rate due to:
 - Excessive intravascular volume depletion and hypotension due to aggressive diuretic or vasodilator therapy*
 - Decline in cardiac output due to worsening heart failure, arrhythmias, or other primary cardiac causes*
 - Selective reduction in glomerular perfusion pressure following initiation (or dose increase) of ACE inhibitor therapy*
- Nonsteroidal antiinflammatory drugs
- Primary renal pathology (*e.g.*, cholesterol emboli, renal artery stenosis, drug-induced interstitial nephritis, obstructive uropathy)
- Reduced or impaired diuretic absorption due to gut wall edema and reduced splanchnic blood flow

patients who receive vasodilator drugs may reduce renal perfusion pressure to levels below that necessary to maintain normal autoregulation and glomerular filtration.

The caveats about concomitant therapy merit particular emphasis when considering coadministration of diuretics and ACE inhibitors or AT₁ receptor antagonists. These inhibitors of the renin-angiotensin system can either augment or reduce the effectiveness of diuretics. A reduced response is observed most commonly in patients with decreased renal arterial perfusion pressure, due either to renal artery stenosis or to reduction of forward cardiac output. In such patients, a high level of Ang II–mediated glomerular efferent arteriolar tone is necessary to maintain glomerular filtration pressure. Pharmacologic antagonism of this intrarenal autoregulation may be accompanied by a decline in creatinine clearance and a derivative rise in the serum creatinine. In general, this is readily distinguished from the modest and limited rise in serum creatinine levels that commonly accompany administration of ACE inhibitors. Diuretic resistance that reflects poor forward cardiac output may require the use of positive inotropic agents (*e.g.*, *dobutamine*) as vasodilator therapy is initiated.

Decreased responsiveness to loop diuretics in patients with known chronic heart failure should prompt an increase in the dose administered or the dosing frequency. If this is ineffective, a thiazide diuretic (*e.g.*, *hydrochlorothiazide* or *metolazone*) administered with the loop diuretic is often effective (Ellison, 1991). However, this combination can result in an unpredictable and sometimes excessive diuresis, leading to intravascular volume depletion and renal K⁺ wasting; the combination therefore should be used cautiously. Spironolactone also may be effective in these patients when combined with a loop diuretic. For a detailed discussion on the subject of diuretic resistance, see the review by Ellison (1999).

Metabolic Consequences of Diuretic Therapy. The side effects of diuretics are discussed in Chapter 28 (Gottlieb, 2004). With regard to diuretic use in heart failure, the most important adverse sequelae of diuretics are electrolyte abnormalities, including hyponatremia, hypokalemia, and hypochloremic metabolic alkalosis. The clinical importance, or even the existence, of significant Mg²⁺ deficiency with chronic diuretic use remains controversial (Bigger, 1994; Davies and Fraser, 1993). Both hypokalemia and renal Mg²⁺ wasting can be limited by administration of oral KCl supplements or a K⁺-sparing diuretic.

Vasodilators

The rationale for the use of oral vasodilator drugs in the pharmacotherapy of CHF derived from the experience with the parenteral agents *phentolamine* and *nitroprusside* in patients with severe heart failure and elevated systemic vascular resistance (Cohn and Franciosa, 1977). Although a number of vasodilators may improve symptoms in heart failure, only the *hydralazine–isosorbide dinitrate* combination and antagonists of the renin-angiotensin system (ACE inhibitors and AT₁ receptor blockers) have been shown to improve survival in prospective randomized trials. The pharmacology of the vasodilators discussed in this chapter is considered in

more detail in Chapters 10, 30, and 32. Table 33–1 summarizes some properties of vasodilators used to treat heart failure.

A randomized, prospective trial verified the effectiveness of the isosorbide dinitrate–hydralazine combination in reducing mortality in patients with heart failure due to systolic dysfunction (Veterans Administration Cooperative Vasodilator-Heart Failure Trial I; V-HeFT I) (Cohn *et al.*, 1986). V-HeFT I also demonstrated that the mortality impact was agent-specific: the α receptor agonist *prazosin* was no better than placebo when compared to isosorbide plus hydralazine. In another trial, treatment with the ACE inhibitor *enalapril* was associated with reduction of mortality in patients with NYHA Class IV heart failure (CONSENSUS Trial Study Group, 1987). V-HeFT II, a trial that compared the isosorbide dinitrate–hydralazine combination to enalapril, indicated that vasodilators that antagonize the effects of angiotensin provide incremental survival benefit (Cohn *et al.*, 1991). Subsequent trials with ACE inhibitors and AT₁ receptor antagonists corroborated these early data and provided evidence supporting the use of ACE inhibitors and AT₁ receptor antagonists in patients with less advanced CHF and in those with asymptomatic left ventricular dysfunction.

Inhibitors of the Renin–Angiotensin System: ACE Inhibitors and AT₁ Receptor Antagonists

Renin–Angiotensin System Antagonists. The renin-angiotensin system (Figure 33–3) plays a central role in the pathophysiology of heart failure. Angiotensinogen is cleaved by kidney-derived renin to form the decapeptide angiotensin I (Ang I); ACE converts Ang I to the octapeptide Ang II. Ang II is a potent arterial vasoconstrictor and an important mediator of Na⁺ and water retention through its effects on glomerular filtration pressure and aldosterone secretion. In addition, Ang II potentiates neural catecholamine release, is a secretagogue for catecholamine release from the adrenal medulla, is arrhythmogenic, promotes vascular hyperplasia and pathologic myocardial hypertrophy, and stimulates myocyte death. Consequently, the antagonism of Ang II forms one of the cornerstones of heart failure management (Weber, 2001).

ACE inhibitors suppress Ang II and aldosterone production, decrease sympathetic nervous system activity, and potentiate the effects of diuretics in heart failure. However, Ang II levels frequently return to baseline values following chronic treatment with ACE inhibitors (Juillerat *et al.*, 1990), due in part to production of Ang II through ACE-independent enzymes such as chymase, a tissue protease. The sustained clinical effectiveness of ACE inhibitors despite Ang II “escape” suggests that there are alternate mechanisms that contribute to the clinical effects of ACE inhibitors in heart failure. ACE is iden-

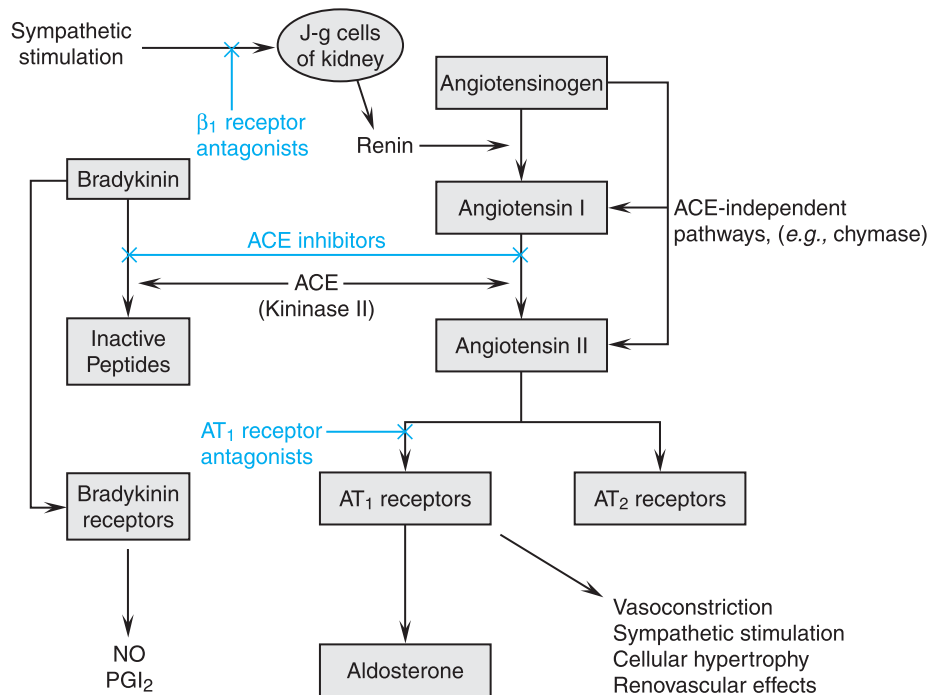

Figure 33-3. The renin-angiotensin-aldosterone system. Renin, excreted in response to β adrenergic stimulation of the juxtaglomerular (J-g) cells of the kidney, cleaves plasma angiotensinogen to produce angiotensin I (Ang I). Angiotensin II (Ang II) is formed through the cleavage of Ang I by angiotensin-converting enzyme (ACE). Most of the known biological effects of Ang II are mediated by the type 1 angiotensin receptor (AT₁). In general, the AT₂ receptor appears to counteract the effects of Ang II mediated by activation of the AT₁ pathway. Ang II also may be formed through ACE-independent pathways. These pathways, and possibly incomplete inhibition of tissue ACE, may account for persistence of angiotensin in patients treated with ACE inhibitors. AT₁ receptor antagonists have been postulated to provide more complete blockade of the renin-angiotensin-aldosterone system than ACE inhibition alone. ACE inhibition reduces bradykinin degradation, thus enhancing its levels and biological effects, including the production of nitric oxide (NO) and prostaglandin I₂ (PGI₂). Bradykinin may mediate some of the biological effects of ACE inhibitors.

tical to kininase II, which degrades bradykinin and other kinins that stimulate production of NO, cyclic GMP, and vasoactive eicosanoids; these vasodilator substances seem to oppose the effects of Ang II on the growth of vascular smooth muscle and cardiac fibroblasts and on production of extracellular matrix. Thus, the increased levels of bradykinin that result from ACE inhibition may play a role in the hemodynamic and anti-remodeling effects of ACE inhibitors.

ACE inhibitors are more potent arterial than venous dilators. In response to ACE inhibition, mean arterial pressure (MAP) may decrease or be unchanged; the change in MAP will be determined by the stroke volume response to afterload reduction. Heart rate typically is unchanged, even when there is a decrease in systemic arterial pressure, a response that likely reflects a decrease in sympathetic nervous system activity in response to ACE inhibition. The decrease in left ventricular afterload results in increased stroke volume and cardiac output.

Venodilation results in decreases in right and left heart filling pressures and end-diastolic volumes.

An alternative means of attenuating the hemodynamic and vascular impact of the renin-angiotensin system is through inhibition of angiotensin receptors. Most of the known clinical actions of angiotensin II, including its deleterious effects in heart failure, are mediated through the AT₁ angiotensin receptor. AT₂ angiotensin receptors, also present throughout the cardiovascular system, seem to mediate responses that counterbalance the biological effects of AT₁ receptor stimulation.

Due to their more distal site of action, AT₁ receptor antagonists may provide more potent reduction of the effects of angiotensin II than do ACE inhibitors. Furthermore, AT₁ receptor blockade may result in greater AT₂ receptor activation, as Ang II levels rise as a consequence of AT₁ receptor blockade. Note that blockade of AT₁ receptors does not alter bradykinin metabolism, which ACE inhibitors reduce.

Angiotensin-Converting Enzyme Inhibitors. The first orally active ACE inhibitor, *captopril* (CAPOTEN), was introduced in 1977, and five other ACE inhibitors—*enalapril* (VASOTEC), *ramipril* (ALTACE), *lisinopril* (PRINIVIL, ZESTRIL), *quinapril* (ACCUPRIL), and *fosinopril* (MONOPRIL)—are currently approved by the FDA for the treatment of heart failure. Data from numerous clinical trials involving well over 100,000 patients support the use of ACE inhibitors for the treatment of patients with heart failure of any severity, including the patient cohort with asymptomatic left ventricular dysfunction.

ACE-inhibitor therapy should be initiated at a low dose (*e.g.*, 6.25 mg of captopril or 5 mg of lisinopril), as some patients may experience an abrupt drop in blood pressure, particularly in the setting of volume contraction. Hypotension following drug administration can usually be reversed by intravascular volume expansion, although this may be counterproductive in patients with symptomatic heart failure. It is therefore reasonable to consider initiation of these drugs while congestive symptoms are present. ACE-inhibitor doses are customarily increased over several days in hospitalized patients or a few weeks in ambulatory patients, with careful observation of blood pressure, serum electrolytes, and serum creatinine levels.

There is no precisely defined relationship between dose and long-term clinical effectiveness of these drugs. However, it has been suggested that the target dose should in general be the doses used in clinical trials that have established drug efficacy in patients with heart failure. On this basis, target doses of these drugs would be 50 mg three times per day for captopril (Pfeffer *et al.*, 1992); 10 mg twice daily for enalapril (SOLVD Investigators, 1991; Cohn *et al.*, 1991); 10 mg once daily for lisinopril (GISSI-3, 1994); or 5 mg twice daily for ramipril (AIRE Study Investigators, 1993). In patients who have not achieved an adequate clinical response at these doses, further increases, as tolerated, may be of value. For instance, high-dose lisinopril (32.5 or 35 mg) reduced the combined endpoint of mortality and hospitalization when compared to lower doses of this agent in the ATLAS (Assessment of Treatment with Lisinopril and Survival) study (Packer *et al.*, 1999).

In patients with heart failure and reduced renal blood flow, ACE inhibitors, unlike other vasodilators, limit the kidney's ability to autoregulate glomerular perfusion pressure due to their selective effects on efferent arteriolar tone. If this occurs, the dose of ACE inhibitor should be reduced or another class of vasodilator added or substituted. Rarely, worsening of renal function following initiation of therapy with an ACE inhibitor will be due to the presence of bilateral renal artery stenosis. Preferably, the renal artery stenosis should be treated; if this is not technically or logistically feasible, another class of vasodilator should be substituted. Similarly, angioedema secondary to ACE inhibition should prompt immediate cessation of therapy. A small rise in serum K⁺ levels occurs frequently with ACE inhibitors; this rise can be substantial in patients with renal impairment or in diabetic patients with type IV renal tubular acidosis (hyporeninemic hypoaldosteronism). Mild hyperkalemia is best managed by institution of a low-potassium diet, but may require adjustment of dosage. A troublesome cough may occur that is likely related to the effects of bradykinin. Substitution of an AT₁ receptor antagonist often alleviates this problem. The inability to use ACE inhibitors as a consequence of cardiorenal side effects (*e.g.*, excessive hypotension, progressive renal insufficiency, or

hyperkalemia) is itself a marker of poor prognosis in the CHF patient (Kittleson *et al.*, 2003).

Effect of ACE Inhibitors on Survival in Heart Failure. A number of placebo-controlled trials have demonstrated that ACE inhibitors improve survival in patients with overt heart failure due to systolic ventricular dysfunction, independent of the etiology. The CONSENSUS Study (Cooperative North Scandinavian Enalapril Survival Study, 1987) demonstrated a 40% reduction in mortality after 6 months in patients with severe heart failure randomized to enalapril rather than placebo. These results were extended to patients with mild-to-moderate heart failure in the treatment arm of the Studies On Left Ventricular Dysfunction (SOLVD Investigators, 1991) Trial, which reported a 16% reduction in mortality with enalapril treatment. ACE inhibitors are also more effective than other vasodilators. The second Veterans Administration Cooperative Vasodilator-Heart Failure Trial (V-HeFT II) (Cohn *et al.*, 1991) showed a small but clear incremental survival benefit in patients with mild-to-moderate heart failure with enalapril *vs.* the isosorbide dinitrate-hydralazine combination. A smaller randomized trial comparing captopril to hydralazine and isosorbide dinitrate in patients with moderate to severe heart failure also demonstrated a significant survival advantage in patients receiving the ACE inhibitor (Fonarow *et al.*, 1992).

These data have convinced many clinicians that ACE inhibitors improve survival of patients with symptomatic heart failure. Data from the prevention arm of the SOLVD Trial subsequently examined the impact of ACE inhibitors in asymptomatic patients with left ventricular systolic dysfunction (SOLVD Investigators, 1992). Although this study failed to demonstrate reduction in mortality among enalapril-treated patients, there was a statistically significant (29%) reduction in the combined endpoint of all-causes mortality/development of symptomatic heart failure.

Myocardial infarction is the leading cause of heart failure due to systolic dysfunction in industrialized countries. ACE inhibitors also prevent the development of clinically significant ventricular dysfunction and mortality following acute infarction. The Survival And Ventricular Enlargement trial (SAVE) (Pfeffer *et al.*, 1992) examined patients with recent, acute anterior myocardial infarction and ejection fractions of $\leq 40\%$; this study reported a 20% reduction in mortality and a 36% reduction in the rate of progression to severe heart failure at 12 months follow-up in the captopril-treated group. Two similar trials—AIRE Investigators (1993), and TRACE investigators (1995)—used two different ACE inhibitors in the post-myocardial infarct setting and found that both drugs improved mortality when compared to placebo. Both the SOLVD trials (Konstam *et al.*, 1992) and the SAVE trial (St. John Sutton *et al.*, 1994) demonstrated that enalapril and captopril, respectively, attenuated or prevented the increase in left ventricular end-diastolic/end-systolic volumes and the decline in LV ejection fraction that was observed in patients randomized to placebo. These benefits appear to accrue from all drugs in this class. ACE inhibitors appear to prevent the progression of heart failure after myocardial infarction by preventing adverse ventricular remodeling.

ACE inhibitors have been shown to be effective in specific patient subgroups, including women, African-Americans, and the elderly. Despite early reports to the contrary, analyses from the SOLVD database indicate that ACE inhibitors delay the progression of heart failure and improve mortality in African-Americans (Dries *et al.*, 2002).

AT₁ Receptor Antagonists. Activation of the AT₁ receptor mediates most of the deleterious effects of Ang II that have been described above. The receptor blockade pro-

vided by AT₁ antagonists provides a pharmacologic means by which to reduce the phenomenon of Ang II “escape” that occurs with ACE inhibitors. AT₁ receptor antagonism might also be expected to avoid the bradykinin-mediated side effects of ACE inhibition, principally cough and angioedema. These side effects, which occur in >10% of patients, represent an important limitation to the use of ACE inhibitors in clinical practice. It merits emphasis that angioedema has also been reported with AT₁ receptor antagonists and caution is therefore warranted when prescribing these agents to patients with a history of ACE inhibitor–associated angioedema.

The initial clinical application of AT₁ receptor antagonists was in the treatment of systemic hypertension, for which these agents are both effective and well-tolerated. Trial data also demonstrated that AT₁ antagonists provided additive antihypertensive effect when used in combination with ACE inhibitors. Several trials, including ELITE (Evaluation of Losartan in the Elderly) (Pitt *et al.*, 1997), SPICE (Study of Patients Intolerant of Converting Enzyme Inhibitors) (Bart, *et al.*, 1999) and CHARM (Candesartan in Heart Failure Assessment of Reduction in Morbidity and Mortality) (Doggrell, 2005), established that angiotensin-receptor blockers were well tolerated by patients with CHF. In ELITE, the effects of *losartan* (50 mg per day) and captopril (50 mg three times daily) were compared in elderly CHF patients (Pitt *et al.*, 1997). The drugs had similar effect on renal function; 10.5% of patients in both groups experienced ≥ 0.3 -mg/dl increase in serum creatinine following initiation of therapy. Losartan was well tolerated; fewer patients in the losartan group discontinued therapy for side effects (12.5% vs. 20.8% in the captopril group). The principal side effect leading to discontinuation of ACE inhibitor therapy was cough. The SPICE Registry confirmed that AT₁ receptor antagonism is well tolerated in CHF patients; 83% of patients who were intolerant of an ACE inhibitor were able to tolerate treatment with *candesartan*.

The impact of AT₁ receptor antagonists with respect to mortality in heart failure patients was addressed in one arm of the CHARM study, a program of three separate studies of *candesartan* in heart failure. In the CHARM-Alternative trial, patients who were intolerant of ACE inhibitors were randomized to *candesartan* or placebo. Cardiovascular death and heart failure hospitalizations were significantly decreased in the active treatment arm (33% vs. 40%). These data support the use of AT₁ blockers as an alternative to ACE inhibitors in heart failure patients who do not tolerate ACE inhibition; furthermore, the data suggest that AT₁ antagonists provide a mortality benefit that is similar in magnitude to that achieved with ACE inhibitors.

Subsequent clinical trials have compared mortality in patients treated with ACE inhibitors or AT₁ receptor antagonists. The available data support the contention that AT₁ receptor antagonists provide an alternative to ACE inhibitors in the treatment of heart failure and provide comparable mortality benefits (Pitt *et al.*, 2000).

The combined use of ACE inhibitors and ARBs in the treatment of heart failure offers the intriguing possibility of additive therapeutic benefit by virtue of distinctive modes of angiotensin antagonism. Preliminary studies suggested that combined therapy with *candesartan* and *enalapril* had more favorable effects on hemodynamics, ventricular remodeling, and neurohormonal profile compared to therapy with either agent alone (McKelvie *et al.*, 1999). Two subsequent trials, Val-HeFT (Valsartan Heart Failure Trial) and

CHARM-Added, assessed combination therapy in chronic heart failure. Neither trial demonstrated an incremental mortality benefit with combination therapy, but each reported that combination therapy significantly reduced hospitalizations for heart failure.

The efficacy of AT₁ receptor antagonists (*candesartan* 32 mg once daily vs. placebo) has been studied in patients with diastolic heart failure in a clinical trial in patients with CHF who have preserved LV systolic function (the CHARM-Preserved Trial) (Yusuf, 2003). Although there was no significant difference in the primary endpoint of cardiovascular death or heart failure hospitalization, there were again fewer heart failure hospitalizations in the active treatment arm.

Thus, AT₁ receptor antagonists are well tolerated and effective in the treatment of hypertension and CHF. In patients with heart failure, AT₁ antagonists provide a mortality benefit that is similar to that provided by ACE inhibitors. AT₁ receptor antagonists should at present be viewed as the preferred alternative when ACE inhibitors cannot be tolerated. Current American Heart Association/American College of Cardiology guidelines suggest that the addition of an AT₁ blocker to a regimen that includes an ACE inhibitor can be considered in an effort to reduce hospitalizations, but conflicting evidence and divergence of opinion remain. Finally, AT₁ antagonists do appear to reduce hospitalization in patients with diastolic heart failure.

Nitrovasodilators. Nitrovasodilators have long been used in the treatment of heart failure and remain among the most widely used vasoactive medications in clinical practice. These drugs relax vascular smooth muscle by supplying NO and thereby activating soluble guanylyl cyclase. Thus, the drugs mimic the actions of endogenous NO, an intracellular and paracrine autocoid formed by the conversion of arginine to citrulline by a family of enzymes termed *NO synthases*. These enzymes are widely distributed and are found in endothelial and smooth muscle cells throughout the vasculature.

The basis for the differential sensitivity of selected regions of the vasculature to specific nitrovasodilators (*e.g.*, the sensitivity of the epicardial coronary arteries to *nitroglycerin*) remains controversial. Unlike nitroprusside, which is spontaneously converted to NO by reducing agents such as glutathione, nitroglycerin and other organic nitrates undergo a more complex enzymatic biotransformation to NO or bioactive *S*-nitrosothiols. The activities of specific enzyme(s) and cofactor(s) required for this biotransformation appear to differ among organs and at different levels of the vasculature within an organ (Napoli and Ignarro, 2003; Fung, 2004; Fukuto, *et al.*, 2005). The basic pharmacology of the organic nitrates is discussed in Chapter 31.

Organic Nitrates. Organic nitrates are available in a number of formulations that include rapid-acting nitroglycerin tablets or spray for sublingual administration, short-acting oral agents such as isosorbide dinitrate (ISORDIL, SORBITRATE, others), long-acting oral agents such as *isosorbide mononitrate* (IMDUR), topical preparations such as nitroglycerin ointment and transdermal patches, and intravenous nitroglycerin. The nitrate preparations are rel-

actively safe and effective agents whose principal action in the treatment of congestive heart failure is reduction of left ventricular filling pressures. This preload reduction is due to an increase in peripheral venous capacitance. Nitrates will cause a decline in pulmonary and systemic vascular resistance, particularly at higher doses, although this response is less marked and less predictable than with nitroprusside. These drugs do have a selective vasodilator effect on the epicardial coronary vasculature and may enhance both systolic and diastolic ventricular function by increasing coronary flow; the clinical relevance of this coronary vasodilator effect in patients with epicardial coronary obstruction remains controversial.

Isosorbide dinitrate is more effective than placebo in improving exercise capacity and in reducing symptoms when administered to patients with chronic heart failure. However, the limited effects of these agents on the systemic vascular resistance and the problem of pharmacological tolerance limit the utility of organic nitrates as monotherapy in the treatment of CHF. In a number of small trials, isosorbide dinitrate has been shown to increase the clinical effectiveness of other vasodilators such as hydralazine, resulting in a sustained improvement in hemodynamics that exceeded that of either drug given alone. As noted previously, the combination of isosorbide dinitrate and hydralazine reduced overall mortality compared to placebo or the α_1 receptor antagonist prazosin in patients with mild-to-moderate heart failure concurrently treated with *digoxin* and diuretics (Cohn *et al.*, 1986). The mononitrate formulation has not been studied in chronic heart failure; the transdermal formulations are infrequently used in the treatment of CHF, reflecting concerns related to perfusion-dependent drug absorption in such patients.

Nitrate tolerance can limit the long-term effectiveness of these drugs in the treatment of CHF. Blood levels of these drugs should be permitted to fall to negligible levels for at least 6 to 8 hours each day. The timing of nitrate withdrawal can be adjusted to the patient's symptoms. Patients with recurrent orthopnea or paroxysmal nocturnal dyspnea, for example, would likely benefit most by using nitrates at night. *N-acetylcysteine* (MUCOMYST) may diminish tolerance to the hemodynamic effects of nitrates in heart failure (Mehra *et al.*, 1994). Likewise, hydralazine may decrease nitrate tolerance by an antioxidant effect that attenuates superoxide formation, thereby increasing the bioavailability of NO (Gogia *et al.*, 1995).

Hydralazine. The mechanism that underlies the vasodilator activity of hydralazine (APRESOLINE) remains poorly understood. The effects of this agent are not mediated through recognized neurohumoral systems and its mechanism of action at the cellular level in vascular smooth muscle is uncertain. Hydralazine is an effective antihypertensive drug (*see* Chapter 32), particularly when combined with agents that blunt compensatory increases in sympathetic tone and salt and water retention. In heart failure, hydralazine reduces right and left ventricular afterload by reducing pulmonary and systemic vascular resistance. This results in an augmentation of forward stroke volume and a reduction in ventricular systolic wall stress. Hydralazine

also appears to have moderate “direct” positive inotropic activity in cardiac muscle unrelated to afterload reduction. Hydralazine is effective in reducing renal vascular resistance and in increasing renal blood flow to a greater degree than are most other vasodilators, with the exception of ACE inhibitors. Reflecting these aggregate effects, hydralazine may be useful in heart-failure patients with renal dysfunction who cannot tolerate an ACE inhibitor. Hydralazine has minimal effects on venous capacitance and therefore is most effective when combined with agents with venodilating activity (*e.g.*, organic nitrates).

The combination of hydralazine (300 mg/day) and isosorbide dinitrate increased survival when compared to placebo or to the α_1 adrenergic antagonist prazosin in the landmark V-HeFT I Trial (Cohn *et al.*, 1986). Hydralazine, with or without nitrates, may provide additional hemodynamic improvement for patients with advanced heart failure who already are being treated with conventional doses of an ACE inhibitor, *digoxin*, and diuretics (Cohn, 1994). The combination preparation isosorbide dinitrate–hydralazine (BIDL) was most recently investigated in the African-American Heart Failure Trial (A-HeFT). In this study of 1050 patients with NYHA Class III or IV heart failure, the isosorbide dinitrate–hydralazine combination (when added to standard therapy that included neurohumoral blockade) was associated with a significant (43%) reduction in all-cause mortality when compared to placebo.

There are several important limitations that constrain the use of hydralazine in the treatment of CHF. Although hydralazine therapy was associated with a greater increase in ejection fraction and exercise duration when compared to the ACE inhibitor enalapril, the latter drug was superior with respect to reduction of mortality (V-HeFT II, mortality 25% with hydralazine vs. 18% with enalapril). Side effects that may necessitate dose adjustment or withdrawal of hydralazine are common. In V-HeFT I, only 55% of patients were taking full doses of both hydralazine and isosorbide at 6 months. The lupus-like side effects associated with hydralazine are relatively uncommon (3.2% in V-HeFT I) and may be more likely to occur in patients with the “slow-acetylator” phenotype (*see* Chapter 3). Finally, compliance with the multidosing regimen may be difficult in CHF patients who are often taking multiple concurrent medications.

The oral bioavailability and pharmacokinetics of hydralazine are not altered significantly by heart failure unless there is severe hepatic congestion or hypoperfusion. Intravenous hydralazine is available but provides little practical advantage over oral formulations except for urgent use during pregnancy, a state in which relative or absolute contraindications exist for most other vasodilators. Hydralazine is typically started at a dose of 10 to 25 mg three or four times per day and the dosage up-titrated to 75 to 100 mg three or four times daily, as tolerated.

β Adrenergic Receptor Antagonists

Heart failure is characterized by sympathetic hyperactivation, a neurohumoral state that reflects biological responses that can be both compensatory and maladaptive. As detailed above, the sympathetic branch of the autonomic nervous system is activated as a physiological short-term compensatory response to hemodynamic stress. Sympa-

thetic activation supports circulatory function by enhancing contractility (inotropy), augmenting ventricular relaxation and filling (lusitropy), and increasing heart rate (chronotropy). For many years, pharmacological approaches to the treatment of heart failure involved the use of drugs that would further stimulate sympathetic responses. These approaches reflected the viewpoint that the fundamental abnormality in CHF is the reduction of stroke volume/cardiac output that occurs as a consequence of myocardial dysfunction. Under this model, the use of β adrenergic receptor antagonists was judged to be contraindicated in patients with heart failure, and there was widespread use of drugs that further stimulate cardiac sympathetic pathways. Paradoxically, many of these sympathomimetics increased mortality in CHF patients, while an unexpected mortality benefit was seen with the administration of β adrenergic blocking drugs.

The use of sympathomimetic drugs such as dobutamine and dopamine was found to provide short-term relief of heart failure symptoms in patients with advanced ventricular dysfunction. It was presumed that the development of oral congeners of these sympathomimetic agents would represent a major advance in the pharmacotherapy of heart failure. This mechanistic hypothesis has been discredited by the results of a number of trials that have addressed the longer-term use of positive inotropic agents. These trials have been concordant in demonstrating increased mortality in CHF patients treated with drugs that amplify the β receptor/cyclic AMP–modulated Ca^{2+} signaling that underlies myocardial contraction and relaxation. These unexpected results underscore the critical observation that the salutary effects of a drug on hemodynamic function need not correlate with improved clinical outcomes. The recognition that sustained activation of sympathetic nerves in the context of myocardial injury contributes to the progression of contractile dysfunction is now well established and derives support from the demonstrable adverse consequences of long-term sympathetic stimulation (such as maladaptive proliferative signaling in the myocardium, direct cardiomyocyte toxicity, and myocyte apoptosis). The initial phase of the clinical investigation of β receptor antagonists in the treatment of heart failure encountered both skepticism regarding the underlying hypothesis and reluctance in clinical execution; the approach found support from empirical evidence in patients with heart failure and from the large database acquired in clinical trials of β blockers in patients with coronary artery disease and antecedent myocardial infarction (Gottlieb *et al.*, 1998).

Despite clinical and experimental evidence that β blockers can impair the inotropic performance of the ventricle, Waagstein and associates (1993) reported that β receptor antagonists (most commonly the β_1 -selective agent metoprolol) improved symptoms, exercise tolerance, and measures of ventricular function over a period of several months in patients with heart failure due to idiopathic dilated cardiomyopathy (Swedberg, 1993). With few exceptions, clinical trials over the next decade reinforced these initial observations (Bristow, 2000). Although none of these studies was sufficiently powered to define the impact of β receptor antagonists on mortality in patients with heart failure, all demonstrated a consistent increase in left ventricular ejection fraction (Figure 33–4). Serial measurements indicate that a decrease in

Figure 33–4. Time-dependent effects of metoprolol on left ventricular ejection fraction in patients with heart failure.

In patients with severe left ventricular dysfunction, the initial administration of a low dose of metoprolol caused an immediate depression in ejection fraction (day 1). However, over time and despite up-titration of metoprolol to full therapeutic levels, ejection fraction returned to baseline (1 month), and by 3 months was significantly higher than at baseline. In the group given standard therapy, ejection fraction did not change significantly. An increase in left ventricular systolic function between 2 and 4 months after initiation of therapy is seen consistently with β receptor antagonists used in patients with heart failure. This observation confirms that the direct hemodynamic effect of a β adrenergic antagonist in patients with heart failure is to depress contractile function. Thus, the improvement in function with chronic therapy cannot be attributed to a direct hemodynamic effect, and likely reflects a beneficial effect of treatment on the biology of the myocardium. (Adapted with permission from Hall *et al.*, 1995.)

systolic function does occur immediately after initiation of a β antagonist in the CHF patient cohort, but systolic function recovers and improves beyond baseline levels over the ensuing 2 to 4 months (Hall *et al.*, 1995). It has been suggested that improved ventricular function with chronic β receptor antagonist therapy is due to attenuation or prevention of the β adrenergic receptor-mediated adverse effects of catecholamines on the myocardium (Eichhorn and Bristow, 1996).

Metoprolol. Metoprolol (LOPRESSOR, TOPROL XL, OTHERS) is a β_1 -selective antagonist. The 25-mg extended-release tablet formulation is FDA approved for the management of mild-to-moderate heart failure.

A number of clinical trials have demonstrated the beneficial effects of β antagonist therapy in heart failure. In the Metoprolol in Dilated Cardiomyopathy Trial (Waagstein *et al.*, 1993), enrolled patients were receiving “optimal” medical management, including ACE inhibitors, and the mean dose of metoprolol was approximately 100 mg/day (achieved over a 6-week period of gradual upward titration that began at 10 mg/day). Although there was no difference in

mortality between the treatment groups at 12 month follow-up, fewer patients in the β blocker arm required cardiac transplantation and there were significant improvements in ejection fraction, exercise tolerance, and quality of life (Waagstein *et al.*, 1993; Andersson *et al.*, 1994). In the MERIT-HF Trial (Metoprolol Randomized Intervention Trial in Congestive Heart Failure), patients (NYHA functional Class II to IV symptoms and an ejection fraction <40%) received metoprolol succinate (target dose, 200 mg per day) or placebo (MERIT-HF Study Group, 1999). β Blocker therapy decreased all-cause mortality by 34%, with this difference attributable to both reductions in sudden death and death from worsening heart failure. These beneficial effects on mortality were independent of age, sex, etiology of heart failure, or ejection fraction. Despite the relatively large target dose of metoprolol succinate (200 mg once daily), 64% of patients who received the β blocker achieved this goal (mean dose, ~160 mg per day).

Carvedilol. Carvedilol (COREG) is a nonselective β receptor antagonist and α_1 -selective antagonist that is FDA approved for the management of mild-to-severe heart failure.

The U.S. Carvedilol Trial randomized patients with symptomatic heart failure (NYHA Classes II, III, and IV) and ejection fraction <35% to carvedilol or placebo (Packer *et al.*, 1996). All patients received concomitant ACE inhibitor therapy and were clinically and hemodynamically stable. Carvedilol (25 mg twice per day) was associated with significant (65%) reduction in all-cause mortality, an effect that was independent of age, sex, etiology of heart failure, or ejection fraction. The mortality benefit was due primarily to a decrease in deaths due to refractory pump failure, and to a lesser reduction in sudden cardiac death. There was a concomitant 27% reduction in hospitalization for heart failure exacerbations. The improvements in mortality and ejection fraction were dose related (Figure 33–5) (Bristow *et al.*, 1996). Exercise capacity (assessed by a 6-minute walk test) did not improve with carvedilol, but carvedilol did appear to slow the progression of heart failure in a subgroup of patients with good exercise capacity and mild symptoms at baseline (Colucci *et al.*, 1996). The Australia/New Zealand Carvedilol Trial, which studied patients with mild heart failure due to coronary artery disease, also reported a significant reduction (26%) in the combined endpoint of all-cause mortality and hospitalization (Australia/New Zealand Heart Failure Research Collaborative Group, 1997).

In the CAPRICORN Trial (Carvedilol Post Infarct Survival Control in LV Dysfunction Trial) (Dargie, 2001), patients with recent myocardial infarction (3 to 21 days prior to enrollment) and impaired systolic function (ejection fraction of <40%) were randomized to carvedilol (25 mg twice daily) or placebo. Patients with symptomatic heart failure and those with asymptomatic left ventricular dysfunction were included. Although there was no difference in the primary endpoint of all-cause mortality, carvedilol therapy was associated with a significant reduction in the combined endpoint of all-cause mortality and nonfatal myocardial infarction. At the opposite end of the spectrum, patients with symptomatic heart failure (at rest or with minimal exertion) and impaired systolic function (ejection fraction <25%) were randomized to carvedilol vs. placebo in the COPERNICUS Trial (Carvedilol Prospective Randomized Cumulative Survival Study) (Packer *et al.*, 2002a). Consistent with previous trials, there was a 35% decrease in all-cause mortality. Although the patients included in the trial had established heart failure, it merits emphasis that the placebo group mortality at 1 year

Figure 33–5. Dose-dependent effect of carvedilol on left ventricular ejection fraction. In the U.S. Carvedilol Trials Program, a subgroup of patients were randomized to placebo or carvedilol in the standard dose (25 mg twice per day bid), or in a reduced dose of 12.5 or 6.25 mg twice per day. After 6 months of treatment, left ventricular ejection fraction (Δ LVEF) increased with all three doses of carvedilol, but not with placebo. The increase in ejection fraction was strongly related to the dose of carvedilol. These data emphasize the importance of titrating doses of β receptor antagonists to the target or the highest tolerated dose. (Adapted with permission from Bristow *et al.*, 1996.)

was 18.5%, a finding that suggests that the cohort as a whole was not representative of patients with advanced heart failure.

Bisoprolol. Bisoprolol (ZEBETA) is also a β_1 -selective antagonist. The CIBIS-II trial reported a 34% reduction in all-cause mortality in bisoprolol-treated patients that was due primarily to a decrease in sudden deaths (44% reduction) and to a lesser extent, a decrease in pump failure (26% reduction). The mortality benefit of bisoprolol was independent of the etiology of heart failure; β blocker therapy resulted in a significant (36%) decrease in hospitalizations for heart failure (CIBIS-II Investigators and Committee, 1999). In the United States, heart failure currently represents an off-label use for bisoprolol.

Mechanism of Action. The mechanisms by which β receptor antagonists affect clinical outcomes in patients with congestive heart failure have not been fully delineated. A consistent finding is a reduction in the incidence of sudden death, presumably reflecting a decrease in malignant ventricular arrhythmias. Thus, an antiarrhythmic benefit seems likely, possibly reflecting a reduced propensity to develop hypokalemia in the face of systemic β adrenergic blockade, or perhaps a direct consequence of the anti-ischemic effects of these drugs. Another consistent finding with β adrenergic blockade is an improvement in left ventricular structure and function with a decrease in chamber size and an increase in ejection fraction. This

favorable remodeling is likely mediated by attenuating the molecular and cellular events that underlie pathological remodeling. Several lines of experimental evidence support this speculation. β adrenergic stimulation can cause apoptosis of cardiac myocytes (Communal *et al.*, 1998). In a mouse model of dilated cardiomyopathy, overexpression of the β_1 receptor in the myocardium is associated with myocyte apoptosis (Bisognano *et al.*, 2000). β Receptors may affect remodeling and turnover of extracellular matrix through their effects on myocardial gene expression. β Receptor antagonists could improve myocardial energetics (Eichhorn *et al.*, 1994) or reduce oxidative stress in the myocardium (Sawyer and Colucci, 2000). More recent data indicate that β antagonist therapy may attenuate the hyperphosphorylation of the ryanodine (RyR) receptor that has been linked to abnormal intracellular Ca^{2+} handling in experimental models of heart failure (Reiken *et al.*, 2001).

Clinical Use of β Adrenergic Receptor Antagonists in Heart Failure

The extensive body of data regarding the use of β receptor antagonists in chronic heart failure, reflecting more than 15,000 patients enrolled in controlled trials, provides compelling evidence that β antagonists improve symptoms, reduce hospitalization, and decrease mortality in patients with mild and moderate heart failure. Accordingly, β receptor antagonists are now recommended for routine use in patients with an ejection fraction $<35\%$ and NYHA Class II or III symptoms in conjunction with ACE inhibitor or angiotensin-receptor antagonist, and diuretics as required to palliate symptoms.

This general recommendation should be tempered by certain limitations in the experimental database. First, the large majority of the data that underlie this recommendation were obtained in relatively stable patients with mild-to-moderate symptoms. Therefore, the role of β receptor antagonists in patients with more severe symptoms, or with recent decompensation, is not yet clear. Likewise, the utility of β receptor blockade in patients with asymptomatic left ventricular dysfunction has not been studied. Finally, although it appears likely that the beneficial effects of these drugs are related to β receptor blockade, it cannot be assumed that all β receptor antagonists will exert similar effects. Thus, as discussed in Chapter 10, there is marked heterogeneity in pharmacological characteristics within this general class (*e.g.*, β adrenergic receptor selectivity, pharmacokinetics, direct or receptor-mediated vasodilation, and other non-receptor-mediated actions such as antioxidant effects). These properties may play a role determining the overall efficacy of a given β receptor antagonist. Since β antagonists have the potential to worsen both ventricular function and symptoms in patients with heart failure, several caveats should be considered:

1. β Adrenergic receptor antagonists should be initiated at very low doses, generally less than one-tenth of the final target dose.
2. These drugs should be increased slowly, over the course of weeks, and under careful supervision. The rapid institution of the usual β adrenergic receptor-blocking doses used for hypertension or coronary artery disease may cause decompensation in many patients who otherwise would be able to tolerate a slower titration of dose. Even when therapy is initiated with low doses of a β antagonist,

there may be an increased tendency to retain fluid that will require adjustments in the diuretic regimen.

3. Although limited experience with NYHA Class IIIB and IV patients suggests that they may tolerate β blockers and benefit from their use, this group of patients should be approached with a high level of caution.
4. There is almost no experience in patients with new-onset, recently decompensated heart failure. There are theoretical reasons for caution in such patients, and at present they should not be treated with β blockers until after they have stabilized for several days to weeks.

Parenteral Vasodilators

The failing left ventricle is characterized by depression of myocardial contractility and increased sensitivity to alterations of left ventricular afterload. This latter attribute of the failing ventricle is manifest by a greater proportional reduction of stroke volume as the impedance to ejection is increased. Conversely, reduction in afterload in this setting can be associated with substantial increases in stroke volume. This increased afterload dependence underlies the beneficial effects of load reduction therapy in patients with heart failure due to systolic dysfunction (Figure 33–6).

Figure 33–6. Relationship between ventricular outflow resistance and stroke volume in patients with systolic ventricular dysfunction. An increase in ventricular outflow resistance, a principal determinant of afterload, has little effect on stroke volume in normal hearts, as illustrated by the relatively flat curve. In contrast, in patients with systolic ventricular dysfunction, an increase in outflow resistance often is accompanied by a sharp decline in stroke volume. With more severe ventricular dysfunction, this curve becomes steeper. Because of this relationship, a reduction in systemic vascular resistance (one component of outflow resistance) in response to an arterial vasodilator may markedly increase stroke volume in patients with severe myocardial dysfunction. The resultant increase in stroke volume may be sufficient to offset the decrease in systemic vascular resistance, thereby preventing a fall in systemic arterial pressure. (Adapted with permission from Cohn and Franciosa, 1977.)

Sodium Nitroprusside. *Sodium nitroprusside* (NITRO-PRESS) is a prodrug and potent vasodilator that is effective in reducing both ventricular filling pressures and systemic vascular resistance. It has a rapid onset (2 to 5 minutes) and offset (quickly metabolized to cyanide and NO, the active vasodilator) of action and its dose can be titrated expeditiously to achieve the desired hemodynamic effect. For these reasons, nitroprusside is commonly used in intensive-care settings for rapid control of severe hypertension and for the management of decompensated heart failure. The basic pharmacologic properties of this drug are described in Chapter 32.

Several mechanisms contribute to the reduction of ventricular filling pressures after treatment with nitroprusside. This agent directly increases venous capacitance, resulting in a redistribution of blood volume from the central to the peripheral venous circulation. Nitroprusside also causes a fall in peripheral vascular resistance as well as an increase in aortic wall compliance and improves ventricular–vascular coupling; left ventricular afterload is decreased and cardiac output is thereby increased. This combination of preload and afterload reduction improves myocardial energetics by reducing wall stress. This improvement in myocardial energetics is contingent upon maintenance of a mean arterial pressure sufficient to drive coronary perfusion during diastole. Following the rapid withdrawal of nitroprusside, a transient deterioration in ventricular function associated with a rebound increase in systemic vascular resistance occurs.

Nitroprusside is particularly effective in patients with CHF due to elevations of systemic vascular resistance and/or mechanical complications that follow acute myocardial infarction (such as mitral regurgitation or left-to-right shunts through a ventricular septal defect). Thus, this drug is commonly used in cardiac care units.

As with most vasodilators, the most common adverse effect of nitroprusside is hypotension. In general, nitroprusside initiation in patients with severe heart failure results in increased cardiac output and a parallel increase in renal blood flow, improving both glomerular filtration and diuretic effectiveness. However, excessive reduction of systemic arterial pressure may limit or prevent an increase in renal blood flow in patients with more severe contractile dysfunction.

Cyanide produced during the biotransformation of nitroprusside is rapidly metabolized by the liver to thiocyanate, which is cleared by the kidney. Thiocyanate and/or cyanide toxicity is uncommon but may occur in the setting of hepatic or renal failure, or following prolonged high-dose infusion of the drug. Typical symptoms include unexplained abdominal pain, mental status changes, convulsions, or lactic acidosis. Methemoglobinemia is another unusual complication of prolonged, high-dose nitroprusside infusion and is due to the oxidation of hemoglobin by NO.

Intravenous Nitroglycerin. Intravenous nitroglycerin, like nitroprusside, is a vasoactive NO source that is commonly used in cardiac care units. Its structure and basic pharmacology are described in Chapter 31. Unlike nitroprusside, nitroglycerin is relatively selective for venous capacitance vessels, particularly at low infusion rates. Intravenous nitroglycerin is most often used in the treatment of acute coro-

nary syndromes. In patients with CHF, intravenous nitroglycerin is most clearly indicated in the treatment of left heart failure due to acute myocardial ischemia. Parenteral nitroglycerin also is used in the treatment of nonischemic left heart failure when expeditious reduction of ventricular filling pressures is desired; nitroglycerin can be particularly useful in patients with symptomatic volume overload in whom effective diuresis has not been established. At higher infusion rates, this drug can also reduce systemic arterial resistance, although this effect is less predictable. Nitroglycerin therapy may be limited by headache and the development of nitrate tolerance, although the latter is generally overcome by uptitration of the infusion rate to maintain the desired response. Since nitroglycerin is administered in ethanol, high infusion rates can be associated with significant elevation of blood alcohol levels.

Nesiritide. *Nesiritide* (NATRECOR), a recombinant form of human brain natriuretic peptide (BNP), has been approved by the FDA for treatment of dyspnea due to congestive heart failure. The natriuretic peptides—atrial natriuretic peptide (ANP), BNP, and C-type natriuretic peptide—are a family of endogenous neurohormones that possess potent natriuretic, diuretic, and vasodilator properties. BNP is the agent that has found broad clinical application. It is secreted by ventricular cardiac myocytes in response to stretch; circulating levels of BNP correlate with the severity of heart failure. In the setting of heart failure, the effects of BNP counteract the effects of angiotensin and norepinephrine by producing vasodilation, natriuresis, and diuresis.

The BNP receptor is the extracellular domain of type A guanylyl cyclase, GC-A. GC-A is a monospanning membrane protein resembling the growth factor receptors, with guanylyl cyclase activity on the cytoplasmic tail. The active receptor–cyclase complex is a homodimer. Activation of GC-A by nesiritide (BNP) increases cyclic GMP content in target tissues, including vascular, endothelial, and smooth muscle cells. As with activation of the soluble guanylyl cyclase by NO derived from nitrovasodilators, elevated cyclic GMP leads to relaxation of vascular smooth muscle and vasodilation in both the venous and arterial systems. BNP is metabolized by specific clearance receptors, which facilitate its internalization and enzymatic degradation. It is also inactivated by neutral endopeptidases (NEP). The contribution of renal elimination of the drug is minor, and dose adjustment is not required in patients with renal dysfunction.

Nesiritide lowers right and left side cardiac filling pressures without a direct chronotropic or inotropic action. The hemodynamic response to nesiritide is characterized by decreased right atrial, pulmonary arterial, and pulmonary capillary wedge pressures; systemic vascular resistance is reduced and cardiac index is increased. Improvement in global clinical status, attenuation of dyspnea and fatigue, and enhanced diuretic responsiveness have been reported and corroborated. The 2002 VAMC Trial (Vasodilation in the Acute Management of CHF), compared nesiritide to intravenous nitroglycerin and placebo in the treatment of decompensated heart failure. Nesiritide was associated with greater

reductions in pulmonary capillary wedge pressure at 3 and 24 hours. Improvements in dyspnea were comparable to nitroglycerin and better than placebo. In contrast to the effects of parenteral inotropic agents, nesiritide is not associated with increased ventricular or atrial arrhythmias. Thus, nesiritide may be preferable to inotropic drugs when treating refractory heart failure in patients at risk for arrhythmia.

Nesiritide therapy is initiated with a loading dose of 2 $\mu\text{g}/\text{kg}$ followed by an infusion rate of 0.01 $\mu\text{g}/\text{kg}$ per minute that can be increased in increments of 0.005 $\mu\text{g}/\text{kg}$ per minute to a maximum of 0.03 $\mu\text{g}/\text{kg}$ per minute. The primary side effect is hypotension that is reversible upon discontinuation of the drug. The half-life of the drug is 18 minutes; however, hypotensive effects may persist for a longer period than would be predicted on the basis of the elimination half-life. Although there is no specific systolic blood pressure below which nesiritide therapy is contraindicated, studies have typically excluded patients with systolic blood pressure ≤ 90 mm Hg; inotropic support may be preferred in such patients.

Vasopeptidase Inhibitors and BNP. Vasopeptidase inhibitors are a novel group of drugs that simultaneously inhibit ACE and neutral endopeptidases (NEP) and are effective antihypertensive agents. NEP is responsible for the enzymatic degradation of atrial and brain natriuretic peptides. Inhibitors of NEP therefore are expected to increase circulating levels of these natriuretic hormones and on this basis have been investigated as therapeutic agents in heart failure. Early studies suggest that vasopeptidase inhibitors are comparable to ACE inhibitors with respect to improving exercise capacity and decreasing symptoms. In the OVERTURE Trial (Omapatrilat Versus Enalapril Randomized Trial of Utility in Reducing Events), the vasopeptidase inhibitor omapatrilat did reduce the risk of death and hospitalization in chronic heart failure; the effect of omapatrilat was comparable to that of the ACE inhibitor, but was more frequently associated with symptomatic hypotension (Packer *et al.*, 2002b).

Cardiac Glycosides

The beneficial effects of cardiac glycosides in the treatment of heart failure have been attributed to a positive inotropic effect on failing myocardium and efficacy in controlling the ventricular rate response to atrial fibrillation. The cardiac glycosides also modulate autonomic nervous system activity, and it is likely that this mechanism contributes substantially to their efficacy in the management of heart failure. The cardiac glycosides possess a common molecular structure, a steroid nucleus containing an unsaturated lactone at the C17 position, and one or more glycosidic residues at C3 (Figure 33–7). However, the advent of alternative therapies that both palliate symptoms and improve survival has led to a more limited role for the cardiac glycosides in the pharmacotherapy of congestive heart failure. Only digoxin (LANOXIN, LANOXI-CAPS) is in widespread clinical use today.

Mechanisms of Action. Inhibition of $\text{Na}^+, \text{K}^+ \text{-ATPase}$. All cardiac glycosides are potent and highly selective inhibitors of the active transport of Na^+ and K^+ across cell membranes. This biological effect is accomplished by binding to a specific site on the α subunit

Figure 33–7. Structure of digoxin.

of $\text{Na}^+, \text{K}^+ \text{-ATPase}$, the cellular Na^+ pump. The binding of cardiac glycosides to $\text{Na}^+, \text{K}^+ \text{-ATPase}$ and inhibition of the cellular ion pump is reversible and entropically driven. The regulation of $\text{Na}^+, \text{K}^+ \text{-ATPase}$ by cardiac glycosides has been reviewed in detail (Eichhorn and Gheorghide, 2002).

Mechanism of the Positive Inotropic Effect. Both Na^+ and Ca^{2+} ions enter cardiac muscle cells during each depolarization (Figure 33–8). Ca^{2+} that enters the cell *via* the L-type Ca^{2+} channel during depolarization triggers the release of stored intracellular Ca^{2+} into the cytosol from the sarcoplasmic reticulum *via* the ryanodine receptor (RyR). This Ca^{2+} -induced Ca^{2+} release increases the level of cytosolic Ca^{2+} available to interact with the contractile proteins, thereby increasing the force of contraction. During myocyte repolarization and relaxation, cellular Ca^{2+} is re-sequestered by the sarcoplasmic reticular Ca^{2+} -ATPase (SERCA2), and also is removed from the cell by the $\text{Na}^+ \text{-Ca}^{2+}$ exchanger (NCX) and by a sarcolemmal Ca^{2+} -ATPase.

The capacity of the exchanger to extrude Ca^{2+} from the cell depends on the intracellular Na^+ concentration. Binding of cardiac glycosides to the sarcolemmal $\text{Na}^+, \text{K}^+ \text{-ATPase}$ and inhibition of cellular Na^+ pump activity results in a reduction in the rate of active Na^+ extrusion and a rise in cytosolic Na^+ . This increase in intracellular Na^+ reduces the transmembrane Na^+ gradient that drives the extrusion of intracellular Ca^{2+} during myocyte repolarization. With reduced Ca^{2+} efflux and repeated entry of Ca^{2+} with each action potential, Ca^{2+} accumulates in the myocyte: Ca^{2+} uptake into the SR is increased; this increased Ca^{2+} becomes available for release from the SR onto troponin C and other Ca^{2+} -sensitive proteins of the contractile apparatus during the next cycle of excitation-contraction coupling, thereby augmenting myocyte contractility (Figure 33–8). This increase in releasable Ca^{2+} from the sarcoplasmic reticulum is the biological substrate through which cardiac glycosides enhance myocardial contractility. The cardiac glycoside binds preferentially to the phosphorylated form of the α subunit of the $\text{Na}^+, \text{K}^+ \text{-ATPase}$. Extracellular K^+ promotes dephosphorylation of the enzyme as an initial step in this cation's active translocation into the cytosol, and also thereby decreases the affinity of the enzyme for cardiac glycosides. This explains in part the observation that increased extracellular K^+ reverses some of the toxic effects of the cardiac glycosides.

Figure 33–8. Sarcolemmal exchange of Na^+ and Ca^{2+} during cell depolarization and repolarization. Na^+ and Ca^{2+} enter the cardiac myocyte via the Na^+ channel and the L-type Ca^{2+} channel during each cycle of membrane depolarization, triggering the release, through the ryanodine receptor (RyR), of larger amounts of Ca^{2+} from internal stores in the sarcoplasmic reticulum (SR). The resulting increase in intracellular Ca^{2+} interacts with troponin C and activates interactions between actin and myosin that result in sarcomere shortening. The electrochemical gradient for Na^+ across the sarcolemma is maintained by active transport of Na^+ out of the cell by the sarcolemmal Na^+, K^+ -ATPase. The bulk of cytosolic Ca^{2+} is pumped back into the SR by a Ca^{2+} -ATPase, SERCA2. The remainder is removed from the cell by either a sarcolemmal Ca^{2+} -ATPase or a high capacity Na^+ - Ca^{2+} exchange protein, NCX. NCX exchanges three Na^+ for every Ca^{2+} , using the electrochemical potential of Na^+ to drive Ca^{2+} extrusion. The direction of Na^+ - Ca^{2+} exchange may reverse briefly during depolarization, when the electrical gradient across the sarcolemma is transiently reversed. β Receptor agonists and phosphodiesterase inhibitors, by increasing intracellular cyclic AMP levels, activate PKA, which phosphorylates target proteins, including phospholamban, the α subunit of the L-type Ca^{2+} channel and regulatory components of the RyR, as well as TnI, the inhibitory subunit of troponin (not shown). The effect of these phosphorylations is a positive inotropic effect: a faster rate of tension development to a higher level of tension, followed by a faster rate of relaxation. \blacktriangle indicates site of cardiac glycoside binding. See text for mechanism of positive inotropic effect of cardiac glycosides.

Electrophysiological Actions. Atrial and ventricular myocytes, sinoatrial and atrioventricular (AV) nodal cells, and conduction fibers exhibit different responses to cardiac glycosides that are summations of direct responses and neurally-mediated reflex responses. At therapeutic serum or plasma concentrations (*i.e.*, 1 to 2 ng/ml), digoxin decreases automaticity and increases maximal diastolic resting membrane potential in atrial and AV nodal tissues, due to an increase in vagal tone and a decrease in sympathetic nervous system activity. In addition, there is prolongation of the effective refractory period and decreased conduction velocity in AV nodal tissue. These aggregate effects may cause sinus bradycardia or arrest and/or prolongation of AV conduction or higher-grade AV block. At higher concentrations, cardiac glycosides can increase sympathetic nervous system activity and directly affect automaticity in cardi-

ac tissue, actions that contribute to the genesis of atrial and ventricular arrhythmias. Increased intracellular Ca^{2+} loading and increased sympathetic tone increase the spontaneous (phase 4) rate of diastolic depolarization as well as delayed afterdepolarizations that may reach the threshold for generation of a propagated action potential. This simultaneous nonuniform increase in automaticity and depression of conduction in His-Purkinje and ventricular muscle fibers produces an electrophysiologic substrate that predisposes to serious ventricular arrhythmias, including ventricular tachycardia and ventricular fibrillation (*see* Chapter 34).

Regulation of Sympathetic Nervous System Activity. When cardiac output declines to a level that is inadequate to meet the demands of body tissues, increased sympathetic nervous system activity occurs as a compensatory

response. This is due in part to a reduction in the sensitivity of the arterial baroreflex response to blood pressure, resulting in a decline in baroreflex-mediated tonic suppression of CNS-directed sympathetic activity (Ferguson *et al.*, 1989). This desensitization of the normal baroreflex arc also contributes to the sustained elevation in plasma norepinephrine, renin, vasopressin, and other indices of systemic neurohumoral activation that are present in heart failure.

A direct effect of cardiac glycosides on carotid baroreflex responsiveness to changes in carotid sinus pressure has been demonstrated in isolated preparations from animals with experimental heart failure (Wang *et al.*, 1990). In patients with moderate-to-advanced heart failure, infusion of a cardiac glycoside increased forearm blood flow and cardiac index and decreased heart rate; skeletal muscle sympathetic nerve activity, an indicator of the central sympathetic nervous system tone, was markedly reduced (Ferguson *et al.*, 1989). It is unlikely that these effects can be attributed to a direct inotropic effect of the drug, since dobutamine infusion did not suppress muscle sympathetic nerve activity in these patients despite comparable increases in cardiac output. Thus, the effects of digoxin in heart failure apparently include a reduction in neurohumoral activation that could represent an important contribution to the efficacy of cardiac glycosides in the treatment of heart failure.

Pharmacokinetics. The elimination half-life for digoxin is 36 to 48 hours in patients with normal or near-normal renal function. This permits once-a-day dosing; near steady-state blood levels are achieved one week after initiation of maintenance therapy. Digoxin is excreted by the kidney with a clearance rate that is proportional to the glomerular filtration rate. In patients with congestive heart failure and marginal cardiac reserve, an increase in cardiac output and renal blood flow with vasodilator therapy or sympathomimetic agents may increase renal digoxin clearance, necessitating adjustment of daily maintenance doses. Conversely, the half-life of the drug is increased substantially in patients with advanced renal insufficiency (to approximately 3.5 to 5 days); both the volume of distribution and the clearance rate of the drug are decreased in the elderly. As a result, the drug must be used with caution in patients with renal insufficiency and in the elderly.

Despite renal clearance, digoxin is not removed effectively by hemodialysis due to the drug's large (4 to 7 liters/kg) volume of distribution. The principal tissue reservoir is skeletal muscle and not adipose tissue, and thus dosing should be based on estimated lean body mass. Most digoxin tablets average 70% to 80% oral bioavailability; however, approximately 10% of the general population harbors the enteric bacterium *Eubacterium lentum*, which can convert digoxin into inactive metabolites, and this may account for some cases of apparent resistance to stan-

dard doses of oral digoxin. Liquid-filled capsules of digoxin (LANOXICAPS) have a higher bioavailability than do tablets (LANOXIN) and require dosage adjustment if a patient is switched from one dosage form to the other. Digoxin is available for intravenous administration, and maintenance doses can be given intravenously when oral dosing is impractical. Digoxin administered intramuscularly is erratically absorbed, causes local discomfort, and is not recommended. A number of drug interactions and clinical conditions can alter the pharmacokinetics of digoxin or alter patient susceptibility to the toxic manifestations of this drug. For example, chronic renal failure decreases the volume of distribution of digoxin, and therefore requires a decrease in maintenance dosage of the drug. Electrolyte disturbances, especially hypokalemia, acid-base imbalances, and the type of underlying heart disease also may alter a patient's susceptibility to toxic manifestations of digoxin.

Clinical Use of Digoxin in Heart Failure. The cardiac glycosides have long been used in the treatment of CHF. For a century, however, there has been controversy surrounding the efficacy of cardiac glycosides in the treatment of patients with heart failure who are in sinus rhythm. Despite widespread use of digoxin, objective data from randomized, controlled trials on the safety and efficacy of digoxin were lacking until the past decade.

The PROVED (Prospective Randomized study Of Ventricular failure and Efficacy of Digoxin) (Uretsky *et al.*, 1993) and RADIANCE (Randomized Assessment of Digoxin on Inhibition of Angiotensin Converting Enzyme) (Packer *et al.*, 1993) trials examined the effects of withdrawal of digoxin in stable patients with mild-to-moderate heart failure (*i.e.*, NYHA Class II and III) and systolic ventricular dysfunction (left ventricular ejection fraction <0.35%). All patients studied were in normal sinus rhythm. Withdrawal of digoxin resulted in a significant worsening of heart failure symptoms in patients who received placebo compared with patients who continued to receive active drug. Maximal treadmill exercise tolerance also declined significantly in patients withdrawn from digoxin in both trials, despite continuation of other medical therapies for heart failure.

The much larger Digoxin Investigation Group (DIG) trial studied the effect of digoxin therapy on survival in patients with heart failure (The Digitalis Investigation Group, 1997). Overall, there was no difference in mortality (from all causes) between the treatment groups. Over the 48 months of the study, fewer patients in the digoxin group died from or were hospitalized due to worsening heart failure; this benefit was seen at all levels of ejection fraction, but was greatest in patients with more severe degrees of heart failure. In a predefined substudy of patients with normal ejection fraction (*i.e.*, presumed to have diastolic heart failure), a similar pattern of benefit was seen with digoxin. Retrospective subgroup analyses suggest that the benefits of digoxin are optimized when serum concentrations are <1 ng/ml.

Use of Digoxin in Clinical Practice and Monitoring of Serum Levels. It is now recommended that digoxin be reserved for patients with heart failure who are in atrial fibrillation, or for patients in

sinus rhythm who remain symptomatic despite maximal therapy with ACE inhibitors and β adrenergic receptor antagonists. The latter agents are viewed as first-line therapies on the basis of the proven mortality benefit. Most studies suggest that the maximal increase in contractility is apparent at serum levels of digoxin around 1.4 ng/ml or 1.8 nmol (Kelly and Smith, 1992a). The neurohormonal benefits of digoxin may occur at lower serum levels, between 0.5 and 1 ng/ml; higher serum concentrations are not associated with further decreases in neurohormonal activation or with increased clinical benefit. A retrospective subgroup analysis of the DIG trial suggested that the risk of death was greater with increasing serum concentrations, even at values that were within the traditional therapeutic range. Many authorities therefore advocate maintaining digoxin levels below 1 ng/ml (Gheorghiadu *et al.*, 2004).

In summary, digoxin is no longer viewed as a first-line agent in the treatment of congestive heart failure. Despite this fact, it should be emphasized that digoxin, unlike virtually all other inotropic agents studied to date, does not have an adverse impact on mortality in CHF. Thus, digoxin is a therapeutic option in patients who remain symptomatic despite treatment with agents that improve survival. Digoxin may be unique among inotropic drugs by virtue of its neurohumoral effects, which include attenuation of sympathetic activation and reduction of renin release.

Digoxin Toxicity. The incidence and severity of digoxin toxicity have declined substantially in the past two decades, due in part to the development of alternative drugs for the treatment of supraventricular arrhythmias and heart failure, to the increased understanding of digoxin pharmacokinetics, to the monitoring of serum digoxin levels, and to the identification of important interactions between digoxin and other concomitantly administered drugs. Nevertheless, the recognition of digoxin toxicity remains an important consideration in the differential diagnosis of arrhythmias and neurological and gastrointestinal symptoms in patients receiving cardiac glycosides.

Vigilance for and early recognition of disturbances of impulse formation, conduction, or both are critically important. Among the more common electrophysiological manifestations are ectopic beats of AV junctional or ventricular origin, first-degree AV block, an excessively slow ventricular rate response to atrial fibrillation, or an accelerated AV junctional pacemaker. These often require only a dosage adjustment and appropriate monitoring. Sinus bradycardia, sinoatrial arrest or exit block, and second- or third-degree AV conduction delay usually respond to *atropine*, although temporary ventricular pacing may be necessary. Potassium administration should be considered for patients with evidence of increased AV junctional or ventricular automaticity, even when the serum K^+ is in the normal range, unless high-grade AV block also is present. *Lidocaine* or *phenytoin*, which have minimal effects on AV conduction, may be used for the treatment of worsening ventricular arrhythmias that threaten hemodynamic compromise (*see* Chapter 34). Electrical cardioversion carries an increased risk of inducing severe rhythm disturbances in patients with overt digitalis toxicity and should be used with particular caution. Note, too, that inhibition of the Na^+,K^+ -ATPase activity of skeletal muscle can cause hyperkalemia.

Antidigoxin Immunotherapy. An effective antidote for life-threatening digoxin or *digitoxin* toxicity is available in the form of antidigoxin immunotherapy with purified Fab fragments from ovine antidigoxin antisera (DIGIBIND). A full neutralizing dose of Fab based on either the estimated total dose of drug ingested or the total body digoxin burden can be administered intravenously in saline solution over 30 to 60 minutes. For a more comprehensive review of the treatment of digitalis toxicity, see Kelly and Smith (1992b).

Parenteral Inotropic Agents

General Considerations. As noted earlier, patients with heart failure are most commonly hospitalized because of fluid retention that results in dyspnea and peripheral edema. Accordingly, relief of congestion through the use of diuretics and venodilators remains a therapeutic priority. A subset of these patients may present with clinical evidence of reduced forward cardiac output; the symptoms and signs associated with low output can range from fatigue, a common complaint, to azotemia and alterations in mental status. Patients who present with more severe decompensation typically require intensive therapy that may include parenteral inotropic agents; in extreme circumstances assisted ventilation and mechanical circulatory support may be required. Right heart catheterization and placement of a pulmonary artery catheter for continuous monitoring of intracardiac pressures can be helpful, particularly when volume status is unclear. In the setting of severe decompensation, the principal focus of initial therapy is to increase cardiac output by administration of agents that increase myocardial contractility.

β Adrenergic and Dopaminergic Agonists

Dopamine and dobutamine are the positive inotropic agents most often used for the short-term support of the circulation in advanced heart failure. These drugs act *via* stimulation of the cardiac myocyte dopamine D_1 receptor and β adrenergic receptor, leading to stimulation of the G_s -adenylyl cyclase-cyclic AMP-PKA pathway. The catalytic subunit of PKA phosphorylates a number of substrates that enhance Ca^{2+} -dependent contraction and speed relaxation (Figure 33-8). *Isoproterenol*, *epinephrine*, and *norepinephrine*, although useful in specific circumstances, have little role in the treatment of heart failure. The basic pharmacology of these and other adrenergic agonists is discussed in Chapter 10.

Dopamine. Dopamine, an endogenous catecholamine, has limited utility in the treatment of most patients with cardiogenic circulatory failure.

The pharmacological and hemodynamic effects of dopamine are dose dependent. At *low doses* ($\leq 2 \mu\text{g}/\text{kg}$ per minute, based on esti-

mated lean body mass), dopamine causes vasodilation by stimulating dopaminergic receptors on smooth muscle (causing cyclic AMP-dependent relaxation) and by stimulating presynaptic D₂ receptors on sympathetic nerves in the peripheral circulation (inhibiting norepinephrine release and reducing α adrenergic stimulation of vascular smooth muscle); these receptors are prominent in splanchnic and renal arterial beds. Dopamine infusion at this rate may increase renal blood flow and thereby help to maintain the glomerular filtration rate in patients who are refractory to diuretics; the clinical efficacy of this practice remains controversial. Dopamine also has direct effects on renal tubular epithelial cells that promote diuresis.

At *intermediate* infusion rates (2 to 5 $\mu\text{g}/\text{kg}$ per minute), dopamine directly stimulates β receptors on the heart and vascular sympathetic neurons (enhancing cardiac contractility and neural norepinephrine release). At *higher* infusion rates (5 to 15 $\mu\text{g}/\text{kg}$ per minute), peripheral arterial and venous constriction occur, mediated by α adrenergic receptor stimulation (*see above*). This effect may be desirable for support of a critically reduced arterial pressure in selected patients in whom circulatory failure is the result of vasodilation (*e.g.*, sepsis or anaphylaxis). However, high-dose dopamine infusion has little role in the treatment of patients with primary contractile dysfunction; in this setting, increased vasoconstriction will lead to increased afterload, further compromising left ventricular stroke volume, and forward cardiac output. Tachycardia, which is more pronounced with dopamine than with dobutamine, may provoke ischemia in patients with coronary artery disease.

Dobutamine. Dobutamine (DOBUTREX) is the β agonist of choice for the management of patients with systolic dysfunction and CHF. In the formulation available for clinical use, dobutamine is a racemic mixture that stimulates both β_1 and β_2 receptor subtypes. In addition, the (–) enantiomer is an agonist for α adrenergic receptors, whereas the (+) enantiomer is a very weak partial agonist. At infusion rates that result in a positive inotropic effect in humans, the β_1 adrenergic effect in the myocardium predominates. In the vasculature, the α adrenergic agonist effect of the (–) enantiomer appears to be negated by the partial agonism of the (+) enantiomer and the vasodilator effects of β_2 receptor stimulation. Thus, the principal hemodynamic effect of dobutamine is an increase in stroke volume due to its positive inotropic action. At doses that increase cardiac output, there is relatively little increase in heart rate. Dobutamine infusion generally causes a modest decrease in systemic resistance and intracardiac filling pressures (Figure 33–9). Dobutamine does not activate dopaminergic receptors. As such, the increase in renal blood flow that occurs in association with dobutamine is proportional to the increase in cardiac output.

Continuous infusion of dobutamine for up to several days in patients with severe clinical decompensation has been a common practice; pharmacological tolerance may limit efficacy during longer-term administration. Infusions are typically initiated at 2 to 3 $\mu\text{g}/\text{kg}$ per minute, without a loading dose, and increased until the

desired hemodynamic response is achieved. The blood pressure response to dobutamine is variable and is dependent on the relative effects of this agent on vascular tone and cardiac output. If cardiac output is significantly increased, heart rate may decline secondary to reflex withdrawal of sympathetic tone. The major side effects of dobutamine are excessive tachycardia and arrhythmias, which may require a reduction in dosage. Tolerance may occur after prolonged use, requiring substitution of an alternative drug such as a class III phosphodiesterase inhibitor. In patients who have been receiving a β receptor antagonist, the initial response to dobutamine may be attenuated.

Phosphodiesterase Inhibitors. The cyclic AMP–phosphodiesterase (PDE) inhibitors reduce the degradation of cellular cyclic AMP; the consequences are generally those of elevated cyclic AMP, much as would occur in response to a stimulator of adenylyl cyclase activity. In the heart, the result is positive inotropism. In the peripheral vasculature, the result is dilation of both resistance and capacitance vessels, leading to reduction of both afterload and preload. These combined effects on the myocardium and in the periphery underlie the classification of these drugs as “ino-dilators.” The clinical use of older PDE inhibitors such as *theophylline* and *caffeine* is limited by their lack of isoform specificity and concomitant side effects. *Amrinone*, *milrinone*, and other PDE inhibitors with isoenzyme selectivity largely alleviate these side effects.

Inamrinone and Milrinone. Parenteral formulations of *inamrinone* (previous name *amrinone*) and *milrinone* have been approved for short-term support of the circulation in advanced heart failure. Both drugs are bipyridine derivatives and relatively selective inhibitors of PDE3, the cyclic GMP–inhibited cyclic AMP PDE. These drugs cause direct stimulation of myocardial contractility and acceleration of myocardial relaxation. In addition, they cause balanced arterial and venous dilation with a consequent fall in systemic and pulmonary vascular resistances, and left and right heart filling pressures. Cardiac output increases due to the stimulation of myocardial contractility and the decrease in left ventricular afterload. As a result of this dual mechanism of action, the increase in cardiac output with *milrinone* is greater than that seen with nitroprusside at doses that produce comparable reductions of systemic resistance. Conversely, the arterial and venous dilator effects of *milrinone* are greater than those of dobutamine at doses that produce comparable increases in cardiac output (Figure 33–10).

Both *inamrinone* and *milrinone* are effective for short-term treatment of patients with severe heart failure due to systolic dysfunction. Intravenous infusions of either drug should be initiated with a loading dose followed by a continuous infusion. For *inamrinone*, a 0.75-mg/kg bolus injection administered over 2 to 3 minutes is followed by a 2- to 20- $\mu\text{g}/\text{kg}$ per minute infusion. The loading dose of *milrinone* is usually 50 $\mu\text{g}/\text{kg}$, and the continuous infusion rate ranges from 0.25 to 1 $\mu\text{g}/\text{kg}$ per minute. The elimination half-lives of

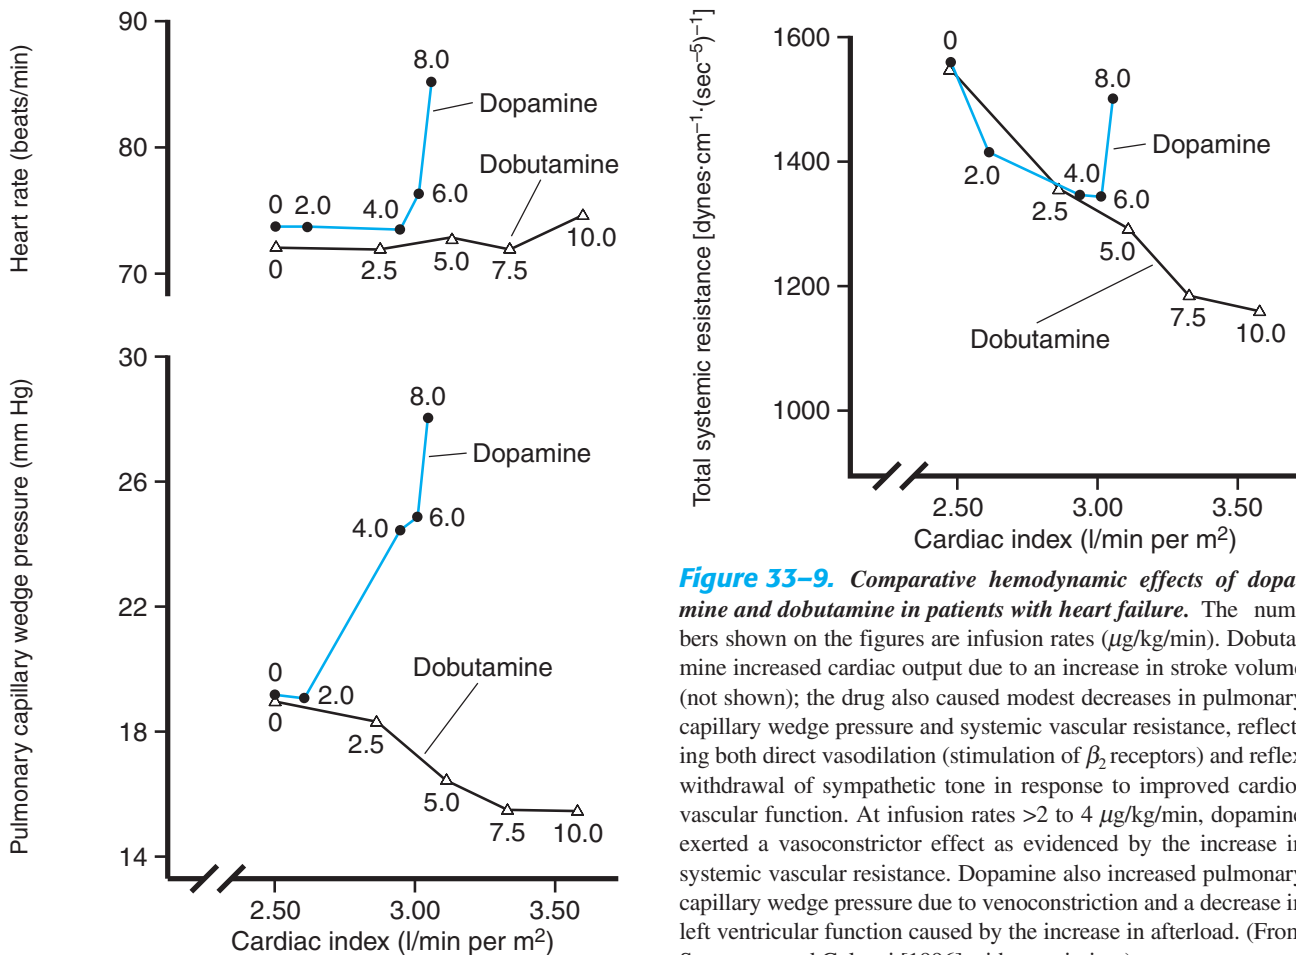

Figure 33-9. Comparative hemodynamic effects of dopamine and dobutamine in patients with heart failure. The numbers shown on the figures are infusion rates ($\mu\text{g}/\text{kg}/\text{min}$). Dobutamine increased cardiac output due to an increase in stroke volume (not shown); the drug also caused modest decreases in pulmonary capillary wedge pressure and systemic vascular resistance, reflecting both direct vasodilation (stimulation of β_2 receptors) and reflex withdrawal of sympathetic tone in response to improved cardiovascular function. At infusion rates >2 to $4 \mu\text{g}/\text{kg}/\text{min}$, dopamine exerted a vasoconstrictor effect as evidenced by the increase in systemic vascular resistance. Dopamine also increased pulmonary capillary wedge pressure due to venoconstriction and a decrease in left ventricular function caused by the increase in afterload. (From Stevenson and Colucci [1996] with permission.)

inamrinone and milrinone in healthy subjects are 2 to 3 hours and 0.5 to 1 hour, respectively, and are approximately doubled in patients with severe heart failure. Clinically significant thrombocytopenia occurs in 10% of patients receiving inamrinone but is rare with milrinone. Because of its greater selectivity for PDE3 isoenzymes, shorter half-life, and more favorable side-effect profile, milrinone is the agent of choice among currently available PDE inhibitors for *short-term*, parenteral inotropic support. The vasodilating effects of the drug and its relatively protracted half-life limit use in patients with low systemic arterial pressure.

Chronic Positive Inotropic Therapy

Several oral inotropic agents have been developed and subsequently investigated in clinical trials. Some of these agents, particularly those of the PDE inhibitor class, have vasodilator actions in addition to their inotropic effects. While improvement in symptoms, functional status, and hemodynamic profile have been reported, the impact of these drugs on mortality during longer-term therapy has been disappointing. The dopaminergic agonist *ibopamine*, PDE inhibitors milrinone, inamrinone, and *vesnarinone*, and the benzimidazole PDE inhibitor with calcium-sensitizing properties,

pimobendan, have been associated with increased mortality (Hampton *et al.*, 1997; Packer *et al.*, 1991; Cohn *et al.*, 1998). These observations underscore the conclusion stated earlier: *salutary effects on hemodynamic function do not translate into improved survival*. At present, digoxin is the only oral inotropic agent that is available for use in patients with CHF.

Continuous or intermittent outpatient therapy with dobutamine or milrinone, administered by a portable or home-based infusion pump through a central venous catheter, has been evaluated in patients with end-stage heart failure and symptoms refractory to other classes of drugs. There is as yet no convincing evidence that *chronic* parenteral inotropic therapy improves the quality or length of life. Furthermore, there are concerns that this form of therapy may actually hasten death (Gheorghiad *et al.*, 2000).

Diastolic Heart Failure

Epidemiologic studies of CHF indicate that approximately 30% to 40% of cases occur in patients with normal or preserved left ventricular systolic function.

Figure 33–10. Comparative effects of dobutamine, milrinone, and nitroprusside on left ventricular contractility and systemic vascular resistance. Dobutamine, milrinone, and nitroprusside are parenteral agents used in the management of patients with severe heart failure. Shown are the effects of these drugs on left ventricular contractility, as reflected by left ventricular peak contractility (+dP/dt), and systemic vascular resistance (SVR) in patients with heart failure. Dobutamine and milrinone both increase left ventricular contractility due to their positive inotropic actions on the myocardium. Milrinone and dobutamine (to a lesser extent) also decrease SVR, indicating that they also exert a vasodilatory action. However, for a comparable increase in contractility, milrinone causes a greater decrease in SVR. Nitroprusside, a pure vasodilator, decreases SVR but had no effect on contractility. (Adapted with permission from Colucci *et al.*, 1986.)

Despite intact systolic function, such patients will present with typical signs and symptoms of heart failure, including dyspnea, impaired functional capacity, and pulmonary/systemic venous congestion. The pathogenesis of diastolic heart failure includes structural and functional abnormalities of the ventricle that are associated with impaired ventricular relaxation and impaired left ventricular distensibility (*i.e.*, abnormal LV compliance with increased chamber stiffness). These abnormalities in patients with diastolic heart failure are reflected in the LV pressure–volume relationship during diastole, which is shifted upward and to the left relative to normal subjects (Figure 33–11). Consonant with the definition of heart failure outlined above, the diagnosis of diastolic heart failure is made when the left ventricle is unable to fill to a volume that is sufficient to maintain normal cardiac output without exceeding the upper range of normal

diastolic pressure. In effect, the underlying problem in diastolic heart failure is the inability to fill (rather than to empty) the ventricle.

Over the last two decades, there has been a resurgence of interest in the diastolic phase of the cardiac cycle. In patients with primary diastolic dysfunction, the myocardial abnormality that accounts for abnormal filling is intrinsic; this is perhaps best illustrated by infiltrative disorders (restrictive cardiomyopathies) such as cardiac amyloidosis, hemochromatosis, sarcoidosis, and rare conditions such as endomyocardial fibrosis and Fabry’s disease. It is also common to include familial hypertrophic cardiomyopathy among the disorders that are associated with clinical heart failure and intact systolic function.

Diastolic heart failure occurs more commonly as a secondary condition. This can occur as a consequence of excessive preload (*e.g.*, renal failure), excessive afterload (systemic hypertension), or changes in ventricular size, shape, and function that occur as a response to abnormal loading conditions. Diastolic heart failure can also occur in patients as a consequence of extramyocardial cardiac disease such as epicardial coronary artery disease or pericardial disease. With respect to secondary diastolic dysfunction, the disorder is more prevalent in women than men and increases in prevalence with advancing age. Systemic hypertension and diabetes are more common in such patients. The consensus view is that mortality in diastolic heart failure is less than that reported for age-matched patients with systolic dysfunction and CHF (5% to 8% vs. 10% to 15% annual mortality, respectively), although this remains controversial (Jones *et al.*, 2004).

Historically, hemodynamic findings obtained at cardiac catheterization were considered the gold standard for the diagnosis of diastolic heart failure: elevated intracardiac filling pressures; confirmation of preserved ejection fraction; and reduction of cardiac output at rest or subnormal increase in output during exercise. However, in the absence of invasive confirmation, the diagnosis should not be made until other conditions that can cause exertional dyspnea and exercise intolerance have been excluded. This caveat is particularly relevant in the era of widespread noninvasive evaluation of diastolic function. In one study, diastolic abnormalities (defined by echocardiographic criteria) were present in 28% of the study group, less than one-half of whom had clinical evidence of heart failure (American Heart Association, 2003).

Figure 33–11. Diastolic dysfunction. EDPVR, end-diastolic pressure–volume relationship; ESPVR, end-systolic pressure–volume relationship. (Courtesy of Michael Parker, M.D.)

In contrast to the pharmacotherapy of patients with heart failure due to systolic dysfunction, there are few objective data upon which to base treatment decisions in patients with diastolic heart failure. There are no randomized, placebo-controlled trials to guide therapy in such patients, and one is therefore unable to initiate treatment in anticipation of attenuating disease progression or reducing mortality. It is, however, possible to make some general comments regarding mechanistic considerations in selecting treatment.

Patients with diastolic heart failure are typically dependent upon preload to maintain adequate cardiac output. While patients with symptomatic volume overload will benefit from careful modulation of intravascular volume, volume reduction should be accomplished gradually and treatment goals reassessed frequently. In addition to cautious volume management, it is important to maintain synchronous atrial contraction in such patients; this helps to maintain adequate left ventricular filling during the latter phase of diastole. As one might predict, cardiac function is often severely impaired if such patients develop atrial fibrillation; patients with diastolic heart failure will frequently experience clinical exacerbations coincident with conversion to atrial fibrillation, particularly in the context of suboptimal ventricular rate control. Meticulous control of the ventricular rate with drugs that slow AV conduction is mandatory (*see* Chapter 34) and restoration of sinus rhythm should be considered. It is also important to consider evaluation for and treatment of conditions that are associated with dynamic abnormalities of diastolic function, such as myocardial ischemia and poorly controlled systemic hypertension.

CLINICAL SUMMARY

Heart failure is a chronic illness that begins with a primary myocardial insult (that leads to loss of cardiomyocyte number or function) and that is progressive (through a course that is characterized by a variety of functional and structural compensations). In fact, this temporal progression of disease provides the basis for a revised classification system that is replacing the standard New York Heart Association categories that are based on patient functional status. Under this new construct (Figure 33–12), patients progress from a stage in which they are at risk to develop heart failure (Stage A) to a phase in which structural heart disease is established and demonstrable (Stage B). From this point of asymptomatic ventricular dysfunction, patients progress to a stage in which symptoms of the heart failure syndrome are present (Stage C); a subset of Stage C patients will progress to end-stage status (Stage D) in which symptoms refractory to medical therapy are present. Given that the syndrome of heart failure begins with a primary insult to the myocardium (such as infarction, excessive hemodynamic load, or inflammation), treatment should begin with prevention *via* the identification and remediation of risk factors that predispose to the development of

structural heart disease. For example, since coronary artery disease is the most common etiologic basis for systolic dysfunction and CHF, the prevention of myocardial infarction through risk factor modification (*e.g.*, lipid lowering, control of hypertension, and smoking cessation) is a critical therapeutic strategy with substantial public health implications.

Once structural heart disease is established (Stage B), compensatory mechanisms are activated that support cardiovascular function, but that also set the stage for disease progression. Symptoms are not present and this phase can therefore be referred to as the stage of asymptomatic ventricular dysfunction. Treatment in Stage B is directed at attenuation of sustained neurohormonal activation. With respect to therapy, it is advised that target doses of β blockers, ACE inhibitors, or AT₁ receptor antagonists be selected using the treatment guidelines applied in the clinical trials that established the morbidity and mortality benefits of these agents; it is axiomatic that the specific agent selected and the dosing regimen must be individualized.

After an asymptomatic period of variable duration, heart failure usually progresses to a symptomatic stage, with clinical manifestations reflecting specific hemodynamic profiles. Once symptoms ensue (Stage C), the goals of treatment include both relief of symptoms and prevention of disease progression. Drugs are selected that target the hemodynamic derangements that are thought to be responsible for symptoms. In addition to the use of diuretics and load-reducing therapies for relief of congestive symptoms, antagonism of the renin–angiotensin system and the sympathetic branch of the autonomic nervous system are indicated to prevent further myocardial injury, thereby attenuating disease progression. In the ambulatory patient in a compensated hemodynamic state, diuretics and organic nitrates are used to establish and maintain euvolemia; vasodilators are used to reduce the systemic vascular resistance in order to optimize forward cardiac output. While maintenance of forward cardiac output will help to attenuate neurohormonal activation, agents that antagonize the effects of Ang II and sympathetic stimulation are indicated; ACE inhibitors and AT₁ receptor antagonists are the agents of choice. If neither of these agents is tolerated, treatment with the hydralazine–isosorbide dinitrate combination should be initiated. Treatment with β blockers should be undertaken when hemodynamic stability is established and treatment with aldosterone antagonists considered in patients with preserved renal function. Digoxin is now primarily used for persistent symptoms in the ambulatory patient; this drug does have positive inotropic effects

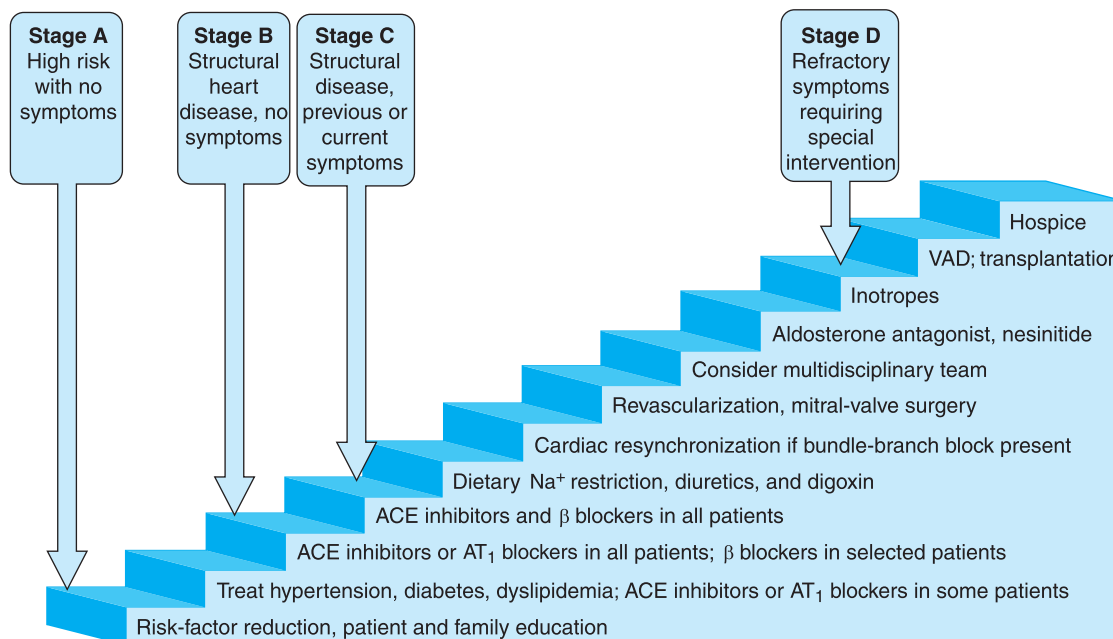

Figure 33–12. Stages of heart failure. (Reproduced with permission from Jessup and Brozena [2003].)

and independent effects that are mediated *via* neurohormonal antagonism. However, there are no data that cardiac glycosides decrease mortality.

In the symptomatic patient with hemodynamic decompensation, hospitalization may be required, since oral diuretic and vasodilator therapy alone may be inadequate to reestablish euvolemia and adequate peripheral perfusion. In such patients, parenteral vasodilators and inotropic agents may be required to restore forward cardiac output; such parenteral support may be required to reverse the avid retention of Na^+ and water that characterizes the decompensated state. Cardiac output can be increased by a number of distinctive therapeutic agents. In designing a treatment regimen, the clinician must consider the hemodynamic status of the individual patient. It is frequently possible to do so by qualitative assessment of the forward cardiac output (normal *versus* low), systemic vascular resistance (normal *versus* high), and intracardiac filling pressures (normal *versus* high); if assessment by physical examination is inconclusive, hemodynamic monitoring *via* bedside pulmonary artery catheterization can provide a more objective, quantitative assessment of these critical parameters of cardiac performance (Nohria *et al.*, 2003).

In patients with elevated systemic vascular resistance and normal-to-elevated systemic blood pressure, afterload reduction with nitroprusside is a logical treatment; it should be emphasized that nitroprusside will also increase venous

capacitance, thereby decreasing preload as well. In the context of myocardial dysfunction, reduction of afterload will typically lead to improved forward cardiac output, based on the inverse relationship between impedance to ejection and stroke volume in the failing ventricle. Nitroprusside may also be effective when the systemic vascular resistance is elevated and systemic blood pressure is reduced; the caveat in this more complex hemodynamic setting is that the load reduction produced by nitroprusside must be counterbalanced by an increase in stroke volume. This derivative increase in stroke volume may not occur in the patient with advanced heart failure; rather, the result will be a further reduction in mean arterial pressure and the potential risk of peripheral organ hypoperfusion. An alternative approach would be the use of an inotropic-dilator drug such as milrinone; this drug will provide both preload and afterload reduction, and its concurrent positive inotropic effect may offset the reduction in mean arterial pressure that can occur from vasodilation alone.

In the decompensated patient who presents with heart failure and normal systemic vascular resistance, afterload reduction may be contraindicated in the short term. In such patients, treatment with a parenteral agent such as dobutamine may be preferable. The risk attendant to treatment with sympathomimetic drugs is related to the increase in myocardial O_2 consumption that may occur; this is of particular concern in patients with left heart failure that occurs as a direct consequence of myocardial

ischemia. This clinical quandary has become less common in the era of aggressive myocardial revascularization; when it is encountered, coadministration of dobutamine with parenteral nitroglycerin should be considered.

In general, therapy in the patient with symptomatic pulmonary congestion should include diuresis to alleviate pulmonary and systemic vascular congestion. The administration of an oral or intravenous nitrate preparation may provide rapid symptomatic relief of pulmonary congestion by increasing venous capacitance. This treatment goal is desirable to reduce patient discomfort; an important ancillary impact of such treatment is the attenuation of the neurohumoral activation that accompanies elevation of intracardiac filling pressures and the attendant dyspnea. As previously noted, excessive preload reduction should be avoided given the dependence on preload that accompanies advanced myocardial dysfunction.

When advanced heart failure is unresponsive to these standard therapies, invasive hemodynamic monitoring may be required. Effective treatment of these patients is often complicated by concurrent renal insufficiency and hypotension, despite evidence of persistent elevation of intracardiac filling pressures. In this setting, selection of parenteral agents is guided by the data regarding systemic vascular resistance and filling pressures provided by the indwelling pulmonary artery catheter.

In patients who remain symptomatic and/or hemodynamically unstable (Stage D), referral to a specialized tertiary center with expertise in the evaluation and management of heart failure should be considered. At this advanced stage of disease, resource-intensive treatment (such as cardiac resynchronization therapy, mechanical assist devices, high-risk surgical interventions, or cardiac transplantation) or investigational therapies can be considered.

ANTIARRHYTHMIC DRUGS

Dan M. Roden

Cardiac cells undergo depolarization and repolarization to form cardiac action potentials about sixty times per minute. The shape and duration of each action potential are determined by the activity of ion channel protein complexes in the membranes of individual cells, and the genes encoding most of these proteins now have been identified. Thus each heartbeat results from the highly integrated electrophysiological behavior of multiple proteins on multiple cardiac cells. Ion channel function can be perturbed by acute ischemia, sympathetic stimulation, or myocardial scarring to create abnormalities of cardiac rhythm, or arrhythmias. Available antiarrhythmic drugs suppress arrhythmias by blocking flow through specific ion channels or by altering autonomic function. An increasingly sophisticated understanding of the molecular basis of normal and abnormal cardiac rhythm may lead to identification of new targets for antiarrhythmic drugs and perhaps improved therapies.

Arrhythmias can range from incidental, asymptomatic clinical findings to life-threatening abnormalities. Mechanisms underlying cardiac arrhythmias have been identified in cellular and animal experiments. In some human arrhythmias, precise mechanisms are known, and treatment can be targeted specifically against those mechanisms. In other cases, mechanisms can be only inferred, and the choice of drugs is based largely on results of prior experience. Antiarrhythmic drug therapy can have two goals: termination of an ongoing arrhythmia or prevention of an arrhythmia. Unfortunately, antiarrhythmic drugs not only help to control arrhythmias but also can cause them, especially during long-term therapy. Thus, prescribing antiarrhythmic drugs requires that precipitating factors be excluded or minimized, that a precise diagnosis of the type of arrhythmia (and its possible mechanisms) be made, that the prescriber has reason to believe that drug therapy will be beneficial, and that the risks of drug therapy can be minimized.

PRINCIPLES OF CARDIAC ELECTROPHYSIOLOGY

The flow of ions across cell membranes generates the currents that make up cardiac action potentials. The factors that determine the magnitude of individual currents and their modulation by drugs can be explained at the cellular and molecular levels (Fozzard and Arnsdorf, 1991; Snyders *et al.*, 1991; Priori *et al.*, 1999). However, the action potential is a highly integrated entity: Changes in one current almost inevitably produce secondary changes in other currents. Most antiarrhythmic drugs affect more than one ion current, and many exert ancillary effects such as modification of cardiac contractility or autonomic nervous system function. Thus antiarrhythmic drugs usually exert multiple actions and can be beneficial or harmful in individual patients (Roden, 1994; Priori *et al.*, 1999).

The Cardiac Cell at Rest: A K⁺-Permeable Membrane

Ions move across cell membranes in response to electrical and concentration gradients, not through the lipid bilayer but through specific ion channels or transporters. The normal cardiac cell at rest maintains a transmembrane potential approximately 80 to 90 mV negative to the exterior; this gradient is established by pumps, especially the Na⁺,K⁺-ATPase, and fixed anionic charges within cells. There are both an electrical and a concentration gradient that would move Na⁺ ions into resting cells (Figure 34–1). However, Na⁺ channels, which allow Na⁺ to move along this gradient, are closed at negative transmembrane potentials, so Na⁺ does not enter normal resting cardiac cells. In contrast, a specific type of K⁺ channel protein (the inward rectifier channel) is in an open conformation at negative potentials. Hence K⁺ can move through these channels across the cell membrane at negative potentials in response to either electrical or concentration gradients (Figure 34–1). For each individual ion, there is an equilibrium potential E_x at which there is no net driving force for the ion to move across the membrane. E_x can be calculated using the Nernst equation:

$$E_x = -61 \log([x]_i/[x]_o) \quad (34-1)$$

where $[x]_o$ is the extracellular concentration of the ion and $[x]_i$ is the intracellular concentration. For typical values for K⁺, $[K]_o = 4$ mM and $[K]_i = 140$ mM, the calculated K⁺ equilibrium potential E_K is -94 mV. There is thus no net force driving K⁺ ions into or out of a cell when the transmembrane potential is -94 mV, which is close to the resting

Figure 34-1. Electrical and chemical gradients for K^+ and for Na^+ in a resting cardiac cell. Inward rectifier K^+ channels are open (left), allowing K^+ ions to move across the membrane and the transmembrane potential to approach E_K . In contrast, Na^+ does not enter the cell despite a large net driving force because Na^+ channel proteins are in the closed conformation (right) in resting cells.

potential. If $[K^+]_o$ is elevated to 10 mM, as might occur in diseases such as renal failure or myocardial ischemia, the calculated E_K rises to -70 mV. In this situation, there is excellent agreement between changes in theoretical E_K owing to changes in $[K^+]_o$ and the actual measured transmembrane potential (Figure 34-2), indicating that the normal cardiac cell at rest is permeable to K^+ (because inward rectifier channels are open) and that $[K^+]_o$ is the major determinant of resting potential.

Na^+ Channel Opening Initiates the Action Potential

If an atrial or ventricular cell at rest is depolarized above a threshold potential, Na^+ channel proteins change conformation from the “closed” (resting) state to the “open” (conducting) state, allowing up to 10^7 Na^+ ions per second to enter each cell and moving the transmembrane potential toward E_{Na} ($+65$ mV). This surge of Na^+ ion movement lasts only about a millisecond, after which the Na^+ channel protein rapidly changes conformation from the “open” state to an “inactivated,” nonconducting state. Measuring Na^+ current directly is technically demanding; the maximum upstroke slope of phase 0 (dV/dt_{max} , or V_{max}) of the action potential (Figure 34-3), which is proportional to Na^+ current, is a convenient surrogate in some experimental settings. The traditional view is that Na^+ channels, once inactivated, cannot reopen until they reassume the closed conformation. Electrophysiological techniques capable of measuring the behavior of individual ion channel proteins now are revealing some of the detailed mechanisms of these state transitions, and the findings obtained are changing some traditional views. For example, a small population of Na^+ channels may continue to open during the action potential plateau in some cells (Figure 34-3). In fact, a defect in the structural region of the Na^+ channel protein that has been implicated in control of channel inactivation causes one form of the congenital long QT syndrome, a disease associated with

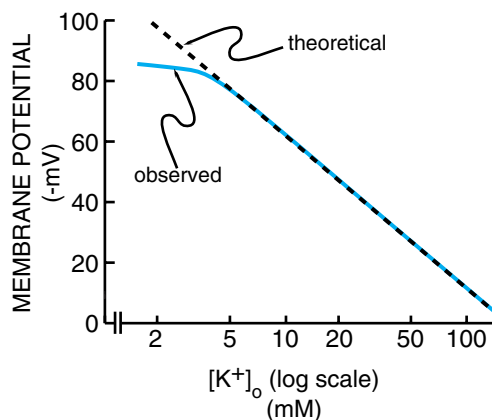

Figure 34-2. The influence of extracellular K^+ on theoretical E_K (dotted line) and on measured transmembrane potential (solid line). At values of extracellular K^+ of more than 4 mM, the two lines are identical, indicating that extracellular K^+ is the major factor influencing resting potential.

abnormally long repolarization and serious arrhythmias (Roden and Spooner, 1999; Keating and Sanguinetti, 2001). In general, however, as the cell membrane repolarizes, the negative membrane potential moves Na^+ channel proteins from inactivated to “closed” conformations. The relationship between Na^+ channel availability and transmembrane potential is an important determinant of conduction and refractoriness in many cells, as discussed below.

The changes in transmembrane potential generated by the inward Na^+ current produce, in turn, a series of openings (and in some cases subsequent inactivation) of other channels (Figure 34-3). For example, when a cell from the epicardium or the His–Purkinje conducting system is depolarized by the Na^+ current, “transient outward” K^+ channels change conformation to enter an open, or conducting, state; since the transmembrane potential at the end of phase 0 is positive to E_K , the opening of transient outward channels results in an outward, or repolarizing, K^+ current (termed I_{TO}), which contributes to the phase 1 “notch” seen in action potentials from these tissues. Transient outward K^+ channels, like Na^+ channels, inactivate rapidly. During the phase 2 plateau of a normal cardiac action potential, inward, depolarizing currents, primarily through Ca^{2+} channels, are balanced by outward, repolarizing currents primarily through K^+ (“delayed rectifier”) channels. Delayed rectifier currents (collectively termed I_K) increase with time, whereas Ca^{2+} currents inactivate (and so decrease with time); as a result, cardiac cells repolarize (phase 3) several hundred milliseconds after the initial Na^+ channel opening. Mutations in the genes encoding repolarizing K^+ channels are responsible for the most common forms of the congenital long QT syndrome (Roden and Spooner, 1999; Keating and Sanguinetti, 2001). Identification of these specific channels has allowed more precise characterization of the pharmacological effects of antiarrhythmic drugs. A common mechanism whereby drugs prolong cardiac action potentials and provoke arrhythmias is inhibition of a specific delayed rectifier current, I_{Kr} , generated by expression of the *human ether-a-go-go related gene* (*HERG*). The ion channel protein generated by *HERG* expression differs from other ion channels in important structural features that make it much more susceptible to drug block; understanding these structural constraints is an important first step to designing drugs lacking I_{Kr} -

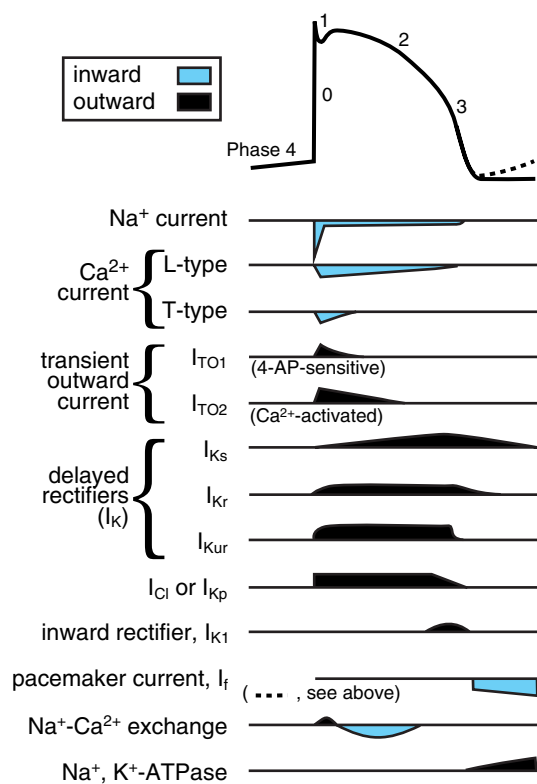

Figure 34–3. The relationship between a hypothetical action potential from the conducting system and the time course of the currents that generate it. The current magnitudes are not to scale; the Na^+ current is ordinarily 50 times larger than any other current, although the portion that persists into the plateau (phase 2) is small. Multiple types of Ca^{2+} current, transient outward current (I_{TO}), and delayed rectifier (I_{K}) have been identified. Each represents a different channel protein, usually associated with ancillary (function-modifying) subunits. 4-AP (4-aminopyridine) is a widely used *in vitro* blocker of K^+ channels. I_{TO2} may be a Cl^- current in some species. Components of I_{K} have been separated on the basis of how rapidly they activate: slowly (I_{Ks}), rapidly (I_{Kr}), or ultrarapidly (I_{Kur}). The voltage-activated, time-independent current may be carried by Cl^- (I_{Cl}) or K^+ (I_{Kp} , p for plateau). For all currents shown here (with the possible exception of I_{TO2}), the genes encoding the major pore-forming proteins have been cloned. (Adapted from Task Force of the Working Group on Arrhythmias of the European Society of Cardiology, 1991, with permission.)

blocking properties (Mitcheson *et al.*, 2000). Avoiding I_{Kr} /HERG channel block has become a major issue in the development of new antiarrhythmic drugs (Roden, 2004).

Differing Action Potential Behaviors Among Cardiac Cells

This general description of the action potential and the currents that underlie it must be modified for certain cell types (Figure 34–4) pre-

sumably because of variability in the ion channel proteins expressed in individual cells. Endocardial ventricular cells lack a prominent transient outward current, whereas cells from the subendocardial His–Purkinje conducting system (and in some species from the midmyocardium) have very long action potentials (Antzelevitch *et al.*, 1991). Atrial cells have very short action potentials probably because I_{TO} is larger, and an additional repolarizing K^+ current, activated by the neurotransmitter acetylcholine, is present. As a result, vagal stimulation further shortens atrial action potentials. Cells of the sinus and atrioventricular (AV) nodes lack substantial Na^+ currents. In addition, these cells, as well as cells from the conducting system, normally display the phenomenon of spontaneous diastolic, or phase 4, depolarization and thus spontaneously reach threshold for regeneration of action potentials. The rate of spontaneous firing usually is fastest in sinus node cells, which therefore serve as the natural pacemaker of the heart. Specialized K^+ channels underlie the pacemaker current in the heart.

Modern molecular biological and electrophysiological techniques, by which the behavior of single ion channel proteins in an isolated patch of membrane can be studied, have refined the description of ion channels important for the normal functioning of cardiac cells and have identified channels that may be particularly important under pathological conditions. For example, we now know that transient outward and delayed rectifier currents actually result from multiple ion channel subtypes (Tseng and Hoffman, 1989; Sanguinetti and Jurkiewicz, 1990) (Figure 34–3) and that acetylcholine-evoked hyperpolarization results from activation of a K^+ channel formed by hetero-oligomerization of multiple, distinct channel proteins (Krapivinsky *et al.*, 1995).

The understanding that molecularly diverse entities subserve regulation of the cardiac action potential is important because drugs may target one channel subtype selectively. Furthermore, ancillary function-modifying proteins (the products of diverse genes) have been identified for most ion channels. In addition to the usual (L-type) Ca^{2+} channels, a second type of Ca^{2+} channel that is most prominent at relatively negative potentials, the T-type, has been identified in some cardiac cells (Bean, 1985). The T-type Ca^{2+} channel may be important in diseases such as hypertension and may play a role in pacemaker activity in some cells. A T-type-selective anti-hypertensive agent, *mibefradil*, was available briefly in the late 1990s but was withdrawn because it was involved in many serious, undesirable drug–drug interactions. Molecular cloning also has identified multiple isoforms, derived from separate genes, that underlie the L-type calcium channel. Specific channels that transport Cl^- ions and result in repolarizing currents (I_{Cl}) have been identified in many species (Hume and Harvey, 1991); some of these are observed only under pathophysiological conditions. Some K^+ channels are quiescent when intracellular adenosine triphosphate (ATP) stores are normal and become active when these stores are depleted. Such ATP-inhibited K^+ channels may become particularly important in repolarizing cells during states of metabolic stress such as myocardial ischemia (Weiss *et al.*, 1991).

Maintenance of Intracellular Homeostasis

With each action potential, the cell interior gains Na^+ ions and loses K^+ ions. An ATP-requiring Na^+ – K^+ exchange mechanism, or pump, is activated in most cells to maintain intracellular homeostasis. This Na^+ – K^+ –ATPase extrudes three Na^+ ions for every two K^+ ions shuttled from the exterior of the cell to the interior; as a result, the act of pumping itself generates a net outward (repolarizing) current.

Normally, intracellular Ca^{2+} is maintained at very low levels (<100 nM). In cardiac myocytes, the entry of Ca^{2+} during each

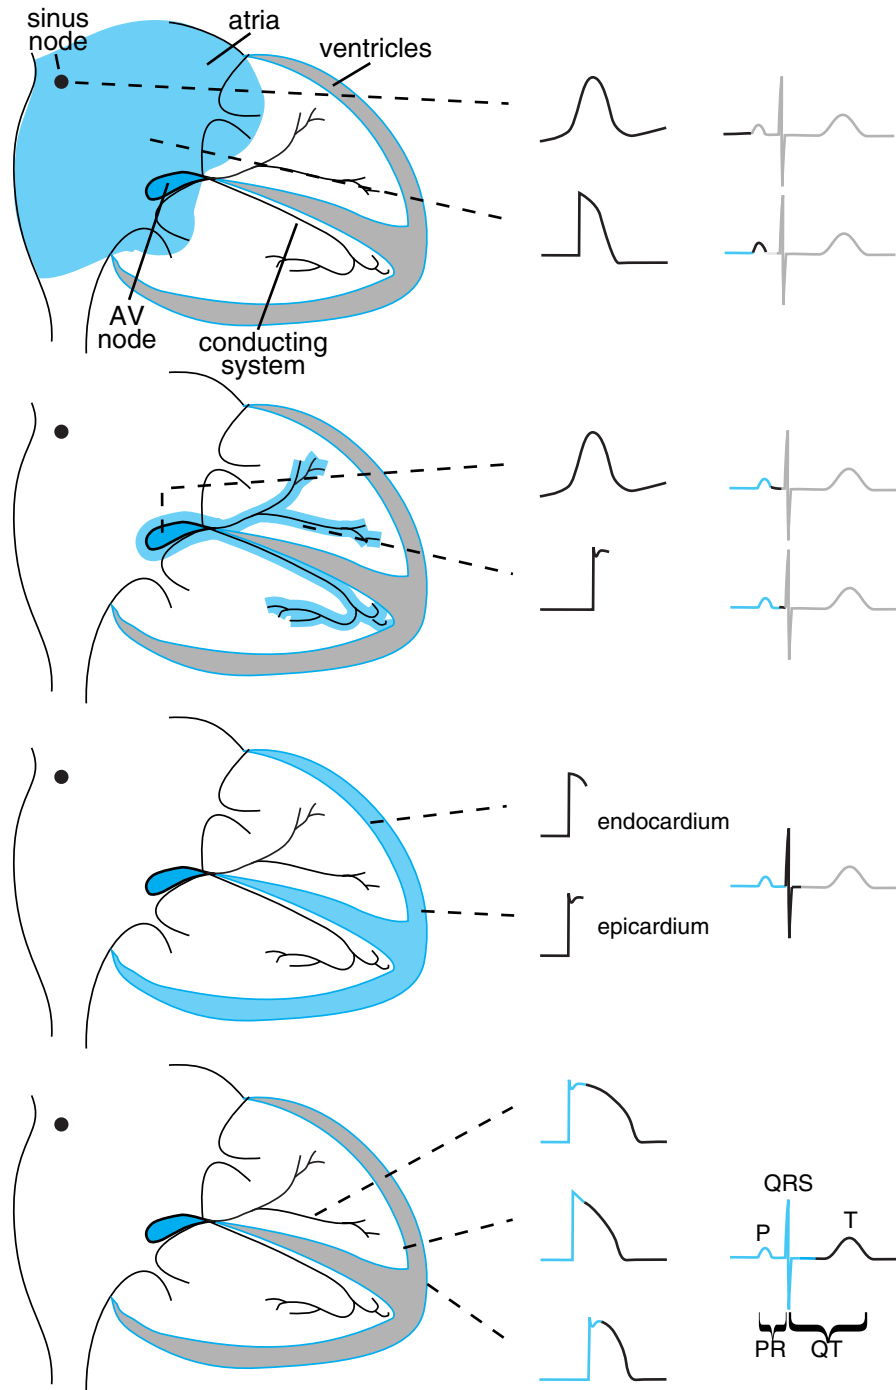

Figure 34-4. Normal impulse propagation. Action potentials from different regions of the heart are shown. In each panel, tissue that is depolarized is shown in light blue, and the portion of the electrocardiogram to which it contributes is shown in black.

action potential is a signal to the sarcoplasmic reticulum to release its Ca^{2+} stores. The resulting increase in intracellular Ca^{2+} then triggers Ca^{2+} -dependent contractile processes. Removal of intracellular Ca^{2+} occurs by both an ATP-dependent Ca^{2+} pump (which moves Ca^{2+} ions back to storage sites in the sarcoplasmic reticulum) and an

electrogenic $\text{Na}^+-\text{Ca}^{2+}$ exchange mechanism on the cell surface, which exchanges three Na^+ ions from the exterior for each Ca^{2+} ion extruded. Abnormal regulation of intracellular calcium, characterized by contractile dysfunction, is increasingly well described in heart failure and also may contribute to arrhythmias in this setting

(Pogwizd and Bers, 2004). The initial rise in Ca^{2+} , which serves as the trigger for Ca^{2+} release from intracellular stores, results from the opening of Ca^{2+} channels in the cell membrane or from Ca^{2+} entry through Na^+ - Ca^{2+} exchange; *i.e.*, in response to phase 0 entry of Na^+ , the Na^+ - Ca^{2+} exchange protein may transiently extrude Na^+ ions in exchange for Ca^{2+} ions (Figure 34-3).

Impulse Propagation and the Electrocardiogram

Normal cardiac impulses originate in the sinus node. Impulse propagation in the heart depends on two factors: the magnitude of the depolarizing current (usually Na^+ current) and the geometry of cell-cell electrical connections. Cardiac cells are relatively long and thin and well coupled through specialized gap junction proteins at their ends, whereas lateral (“transverse”) gap junctions are sparser. As a result, impulses spread along cells two to three times faster than across cells. This “anisotropic” (direction-dependent) conduction may be a factor in the genesis of certain arrhythmias described below (Priori *et al.*, 1999). Once impulses leave the sinus node, they propagate rapidly throughout the atria, resulting in atrial systole and the P wave of the surface electrocardiogram (ECG; Figure 34-4). Propagation slows markedly through the AV node, where the inward current (through Ca^{2+} channels) is much smaller than the Na^+ current in atria, ventricles, or the subendocardial conducting system. This conduction delay allows the atrial contraction to propel blood into the ventricle, thereby optimizing cardiac output. Once impulses exit the AV node, they enter the conducting system, where Na^+ currents are larger than in any other tissue. Hence propagation is correspondingly faster, up to 0.75 m/s longitudinally, and manifests as the QRS complex on the ECG as impulses spread from the endocardium to the epicardium, stimulating coordinated ventricular contraction. Ventricular repolarization results in the T wave of the ECG.

The ECG can be used as a rough guide to some cellular properties of cardiac tissue (Figure 34-4): (1) Heart rate reflects sinus node automaticity, (2) PR-interval duration reflects AV nodal conduction time, (3) QRS duration reflects conduction time in the ventricle, and (4) the QT interval is a measure of ventricular action potential duration.

Refractoriness: Fast-Response versus Slow-Response Tissue

If a single action potential, such as that shown in Figure 34-3, is restimulated very early during the plateau, no Na^+ channels are available to open, so no inward current results, and no action potential is generated: The cell is refractory. On the other hand, if a stimulus occurs after the cell has repolarized completely, Na^+ channels have recovered from inactivation, and a normal Na^+ channel-dependent upstroke results (Figure 34-5A). When a stimulus occurs during phase 3 of the action potential, the magnitude of the resultant Na^+ current depends on the number of Na^+ channels that have recovered from inactivation (Figure 34-5A), which, in turn, depends on the voltage at which the extra stimulus was applied. Thus, in atrial, ventricular, and His-Purkinje cells (“fast-response cells”), refractoriness is determined by the voltage-dependent recovery of Na^+ channels from inactivation. Refractoriness frequently is measured by assessing whether premature stimuli applied to tissue preparations (or the whole heart) result in propagated impulses. While the magnitude of the Na^+ current is one major determinant of such propagation, cellular geometry also is important in multicellular preparations. Ordinarily, each cell is connected to many neighbors so that impulses spread rapidly, and the heart acts like a single large cell, *i.e.*, a syncytium. However, if the

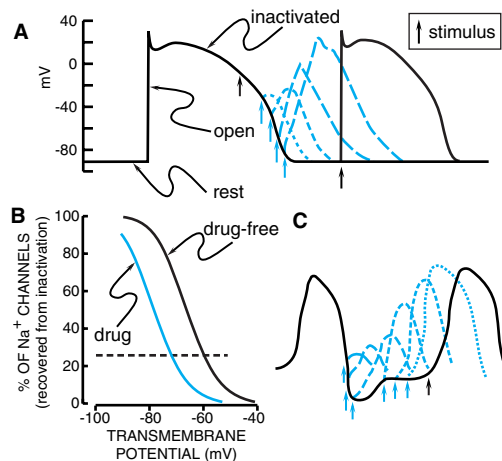

Figure 34-5. Qualitative differences in responses of fast- and slow-response tissues to premature stimuli. **A.** With a very early premature stimulus (black arrow) in fast-response tissue, all Na^+ channels still are in the inactivated state, and no upstroke results. As the action potential repolarizes, Na^+ channels recover from the inactivated to the resting state, from which opening can occur. The phase 0 upstroke slope of the premature action potentials (blue) are greater with later stimuli because recovery from inactivation is voltage-dependent. **B.** The relationship between transmembrane potential and degree of recovery of Na^+ channels from inactivation. The dotted line indicates 25% recovery. Most Na^+ channel-blocking drugs shift this relationship to the left. **C.** In slow-response tissues, premature stimuli delivered even after full repolarization of the action potential are depressed; recovery from inactivation is time-dependent.

geometric arrangement is such that a single cell must supply depolarizing current to many neighbors, conduction can fail. The *effective refractory period* (ERP) is the shortest interval at which a premature stimulus results in a propagated response and often is used to describe drug effects in intact tissue.

The situation is different in Ca^{2+} channel-dependent (“slow-response”) tissue such as the AV node. The major factor controlling recovery from inactivation of Ca^{2+} channels is time (Figure 34-5C). Thus, even after a Ca^{2+} channel-dependent action potential has repolarized to its initial resting potential, not all Ca^{2+} channels are available for re-excitation. Therefore, an extra stimulus applied shortly after repolarization is complete generates a reduced Ca^{2+} current, which may propagate slowly to adjacent cells prior to extinction. An extra stimulus applied later will result in a larger Ca^{2+} current and faster propagation. Thus, in Ca^{2+} channel-dependent tissues, which include not only the AV node but also tissues whose underlying characteristics have been altered by factors such as myocardial ischemia, refractoriness is time-dependent, and propagation occurs slowly. Conduction that exhibits such dependence on the timing of premature stimuli is termed *decremental*. By contrast, conduction velocity in fast-response tissues is independent of prematurity until a stimulus shorter than the effective refractory period is applied, when it fails completely (“all-or-none response”). Slow conduction in the heart, a critical factor in the genesis of re-entrant arrhythmias (*see below*), also can occur when Na^+ currents are

depressed by disease or membrane depolarization (e.g., elevated $[K]_o$), resulting in decreased steady-state Na^+ channel availability (Figure 34–5B).

MECHANISMS OF CARDIAC ARRHYTHMIAS

When the normal sequence of impulse initiation and propagation is perturbed, an arrhythmia occurs. Failure of impulse initiation may result in slow heart rates (bradyarrhythmias), whereas failure of impulses to propagate normally from atrium to ventricle results in dropped beats or “heart block” that usually reflects an abnormality in either the AV node or the His–Purkinje system. These abnormalities may be caused by drugs (Table 34–1) or by structural heart disease; in the latter case, permanent cardiac pacing may be required.

Abnormally rapid heart rhythms (tachyarrhythmias) are common clinical problems that may be treated with antiarrhythmic drugs. Three major underlying mechanisms have been identified: enhanced automaticity, triggered automaticity, and re-entry.

Enhanced Automaticity

Enhanced automaticity may occur in cells that normally display spontaneous diastolic depolarization—the sinus and AV nodes and the His–Purkinje system. β Adrenergic stimulation, hypokalemia, and mechanical stretch of cardiac muscle cells increase phase 4 slope and so accelerate pacemaker rate, whereas *acetylcholine* reduces pacemaker rate both by decreasing phase 4 slope and by hyperpolarization (making the maximum diastolic potential more negative). In addition, automatic behavior may occur in sites that ordinarily lack spontaneous pacemaker activity; e.g., depolarization of ventricular cells (e.g., by ischemia) may produce such “abnormal” automaticity. When impulses propagate from a region of enhanced normal or abnormal automaticity to excite the rest of the heart, arrhythmias result.

Afterdepolarizations and Triggered Automaticity

Under some pathophysiological conditions, a normal cardiac action potential may be interrupted or followed by an abnormal depolarization (Figure 34–6). If this abnormal depolarization reaches threshold, it may, in turn, give rise to secondary upstrokes that can propagate and create abnormal rhythms. These abnormal secondary upstrokes occur only after an initial normal, or “triggering,” upstroke and so are termed *triggered rhythms*.

Two major forms of triggered rhythms are recognized. In the first case, under conditions of intracellular Ca^{2+} overload (e.g., myocardial ischemia, adrenergic stress, digitalis intoxication, or heart failure), a normal action potential may be followed by a *delayed afterdepolarization* (DAD; Figure 34–6A). If this afterdepolarization reaches threshold, a secondary triggered beat or beats may occur. DAD amplitude is increased *in vitro* by rapid pacing, and clinical arrhythmias thought to correspond to DAD-mediated triggered beats are more frequent when the underlying cardiac rate is rapid (Priori *et al.*, 1999). In the second type of triggered activity, the key abnormality is marked prolongation of the cardiac action potential. When this occurs, phase 3 repolarization may be interrupted by an *early afterdepolarization* (EAD; Figure 34–6B). EAD-mediated triggering *in vitro* and clinical arrhythmias are most common when the underlying heart rate is slow, extracellular K^+ is low, and certain drugs that prolong action potential duration (antiarrhythmics and others) are present. EAD-related triggered upstrokes probably reflect inward current through Na^+ or Ca^{2+} channels. EADs are

induced much more readily in Purkinje cells and in midmyocardial (or M) cells than in epicardial or endocardial cells. When cardiac repolarization is markedly prolonged, polymorphic ventricular tachycardia with a long QT interval, known as the *torsades de pointes* syndrome, may occur. This arrhythmia is thought to be caused by EADs, which trigger functional re-entry (discussed below) owing to heterogeneity of action potential durations across the ventricular wall (Priori *et al.*, 1999). Congenital long QT syndrome, a disease in which *torsades de pointes* is common, can be caused by mutations in the genes encoding the Na^+ channels or the channels underlying the repolarizing currents I_{Kr} and I_{Ks} (Roden and Spooner, 1999).

Re-entry

Anatomically Defined Re-entry. Re-entry can occur when impulses propagate by more than one pathway between two points in the heart, and those pathways have heterogeneous electrophysiological properties. Patients with Wolff–Parkinson–White (WPW) syndrome have accessory connections between the atrium and ventricle (Figure 34–7). With each sinus node depolarization, impulses can excite the ventricle *via* the normal structures (AV node) or the accessory pathway. However, the electrophysiological properties of the AV node and accessory pathways are different: Accessory pathways usually consist of fast-response tissue, whereas the AV node is composed of slow-response tissue. Thus, with a premature atrial beat, conduction may fail in the accessory pathway but continue, albeit slowly, in the AV node and then through the His–Purkinje system; the propagating impulse may encounter the ventricular end of the accessory pathway when it is no longer refractory. The likelihood that the accessory pathway is no longer refractory increases as AV nodal conduction slows. When the impulse re-enters the atrium, it then can re-enter the ventricle *via* the AV node, re-enter the atrium *via* the accessory pathway, and so on (Figure 34–7). Re-entry of this type, referred to as *AV re-entrant tachycardia*, is determined by (1) the presence of an anatomically defined circuit, (2) heterogeneity in refractoriness among regions in the circuit, and (3) slow conduction in one part of the circuit. Similar “anatomically defined” re-entry commonly occurs in the region of the AV node (*AV nodal re-entrant tachycardia*) and in the atrium (*atrial flutter*). The term *paroxysmal supraventricular tachycardia* (PSVT) includes both AV re-entry and AV nodal re-entry, which share many clinical features. In some cases, it now is possible to identify and ablate critical portions of re-entrant pathways (or automatic foci), thus curing the patient and obviating the need for long-term drug therapy. Radiofrequency ablation is carried out through a catheter advanced to the interior of the heart and requires minimal convalescence.

Functionally Defined Re-entry. Re-entry also may occur in the absence of a distinct, anatomically defined pathway (Figure 34–8). For example, alterations in cell–cell coupling following acute myocardial infarction in dogs result in re-entrant ventricular tachycardia (VT) whose circuit depends not only on postinfarction scarring but also on the rapid longitudinal and slow transverse conduction properties of cardiac tissue (Wit *et al.*, 1990). If ischemia or other electrophysiological perturbations result in an area of sufficiently slow conduction in the ventricle, impulses exiting from that area may find the rest of the myocardium re-excitable, in which case fibrillation may ensue. Atrial or ventricular fibrillation is an extreme example of “functionally defined” (or “leading circle”) re-entry: Cells are re-excited as soon as they are repolarized sufficiently to allow enough Na^+ channels to recover from inactivation. In this

Table 34-1

Drug-Induced Cardiac Arrhythmias

ARRHYTHMIA	DRUG	LIKELY MECHANISM	TREATMENT*	CLINICAL FEATURES
Sinus bradycardia	Digoxin	↑Vagal tone	Antidigoxin antibodies	Atrial tachycardia may also be present
AV block			Temporary pacing	
Sinus bradycardia	Verapamil	Ca ²⁺ channel block	Ca ²⁺	
AV block	Diltiazem		Temporary pacing	
Sinus bradycardia	β-Blockers	Sympatholytic	Isoproterenol	
AV block	Clonidine		Temporary pacing	
	Methyldopa			
Sinus tachycardia	β-Blocker	Upregulation of β-receptors with chronic therapy; more receptors available for agonist after withdrawal of blocker	β-Blockade	Hypertension, angina also possible
Any other tachycardia	withdrawal			
↑ Ventricular rate in atrial flutter	Quinidine Flecainide Propafenone	Conduction slowing in atrium, with enhanced (quinidine) or unaltered AV conduction	AV nodal blockers	QRS complexes often widened at fast rates
↑ Ventricular rate in atrial fibrillation in patients with WPW syndrome	Digoxin Verapamil	↓ accessory pathway refractoriness	IV procainamide DC cardioversion	Ventricular rate can exceed 300/min
Multifocal atrial tachycardia	Theophylline	?↑ Intracellular Ca ²⁺ and DADs	Withdraw theophylline ?Verapamil	Often in advanced lung disease
Polymorphic VT with ↑ QT interval (<i>torsades de pointes</i>)	Quinidine Sotalol Procainamide Disopyramide Dofetilide Ibutilide “Noncardioactive” drugs (<i>see text</i>) Amiodarone (rare)	EAD-related triggered activity	Cardiac pacing Isoproterenol Magnesium	Hypokalemia, bradycardia frequent Related to ↑ plasma concentrations, except for quinidine
Frequent or difficult to terminate VT (“incessant” VT)	Flecainide Propafenone Quinidine (rarer)	Conduction slowing in reentrant circuits	Na ⁺ bolus reported effective in some cases	Most often in patients with advanced myocardial scarring
Atrial tachycardia with AV block; ventricular bigeminy and others	Digoxin	DAD-related triggered activity (±↑ vagal tone)	Antidigoxin antibodies	Coexistence of abnormal impulses with abnormal sinus or AV nodal function
Ventricular fibrillation	Inappropriate use of IV verapamil	Severe hypotension and/or myocardial ischemia	Cardiac resuscitation (DC cardioversion)	Misdiagnosis of VT as PSVT → inappropriate use of verapamil

*In each of these cases, recognition and withdrawal of the offending drug(s) are mandatory.

ABBREVIATIONS: AV, atrioventricular; DAD, delayed afterdepolarization; DC, direct current; EAD, early afterdepolarization; WPW, Wolff–Parkinson–supraventricular tachycardia; IV, intravenous; ↑, increase; ↓, decrease; ?, unclear.

Figure 34-6. Afterdepolarizations and triggered activity. **A.** Delayed afterdepolarization (DAD) arising after full repolarization. A DAD that reaches threshold results in a triggered upstroke (black arrow, right). **B.** Early afterdepolarization (EAD) interrupting phase 3 repolarization. Under some conditions, triggered beat(s) can arise from an EAD (black arrow, right).

Figure 34-7. Atrioventricular re-entrant tachycardia in the Wolff-Parkinson-White syndrome. In these patients, an accessory atrioventricular connection is present (light blue). A premature atrial impulse blocks in the accessory pathway (1) and propagates slowly through the AV node and conducting system. On reaching the accessory pathway (by now no longer refractory), the impulse re-enters the atrium (2), where it then can re-enter the ventricle *via* the AV node and become self-sustaining (see Figure 34-9C). AV nodal blocking drugs readily terminate this tachycardia. Recurrences can be prevented by drugs that prevent atrial premature beats, by drugs that alter the electrophysiological characteristics of tissue in the circuit (e.g., they prolong AV nodal refractoriness), and by nonpharmacological techniques that section the accessory pathway.

setting, neither organized activation patterns nor coordinated contractile activity is present.

Common Arrhythmias and Their Mechanisms

The primary tool for diagnosis of arrhythmias is the ECG, although more sophisticated approaches sometimes are used, such as recording from specific regions of the heart during artificial induction of arrhythmias by specialized pacing techniques. Table 34-2 lists common

Figure 34-8. Two types of re-entry. The border of a propagating wavefront is denoted by a heavy black arrowhead. In anatomically defined re-entry (top), a fixed pathway is present (e.g., Figure 34-7). The black area denotes tissue in the re-entrant circuit that is completely refractory because of the recent passage of the propagating wavefront; the gray area denotes tissue in which depressed upstrokes can be elicited (see Figure 34-5A), and the dark blue area represents tissue in which restimulation would result in action potentials with normal upstrokes. The dark blue area is termed an *excitable gap*. In functionally defined, or “leading circle,” re-entry (bottom), there is no anatomic pathway and no excitable gap. Rather, the circulating wavefront creates an area of inexcitable tissue at its core. In this type of re-entry, the circuit does not necessarily remain in the same anatomic position during consecutive beats, and multiple such “rotors” may be present.

arrhythmias, their likely mechanisms, and approaches that should be considered for their acute termination and for long-term therapy to prevent recurrence. Examples of some arrhythmias discussed here are shown in Figure 34-9. Some arrhythmias, notably ventricular fibrillation (VF), are best treated not with drugs but with direct current (dc) cardioversion—the application of a large electric current across the chest. This technique also can be used to immediately restore normal rhythm in less serious cases; if the patient is conscious, a brief period of general anesthesia is required. Implantable cardioverter-defibrilla-

Table 34–2

A Mechanistic Approach to Antiarrhythmic Therapy

ARRHYTHMIA	COMMON MECHANISM	ACUTE THERAPY ^a	CHRONIC THERAPY ^a
Premature atrial, nodal, or ventricular depolarizations	Unknown	None indicated	None indicated
Atrial fibrillation	Disorganized “functional” reentry Continual AV node stimulation → irregular, often rapid, ventricular rate	1. Control ventricular response: AV nodal block ^b 2. Restore sinus rhythm: DC cardioversion	1. Control ventricular response: AV nodal block ^b 2. Maintain normal rhythm: K ⁺ channel block Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ second
Atrial flutter	Stable reentrant circuit in the right atrium Ventricular rate often rapid and irregular	Same as atrial fibrillation	Same as atrial fibrillation AV nodal blocking drugs especially desirable to avoid ↑ ventricular rate Ablation in selected cases ^c
Atrial tachycardia	Enhanced automaticity, DAD-related automaticity, or reentry within the atrium	Same as atrial fibrillation	Same as atrial fibrillation Ablation of tachycardia “focus” ^c
AV nodal reentrant tachycardia (PSVT)	Reentrant circuit within or near AV node	*Adenosine AV nodal block Less commonly: ↑ vagal tone (digitalis, edrophonium, phenylephrine)	*AV nodal block Flecainide Propafenone *Ablation ^c
Arrhythmias associated with WPW syndrome:			
1. AV reentry (PSVT)	Reentry (Figure 34–7)	Same as AV nodal reentry	K ⁺ channel block Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ second Ablation ^c
2. Atrial fibrillation with atrioventricular conduction <i>via</i> accessory pathway	Very rapid rate due to nondecremental properties of accessory pathway	*DC cardioversion *Procainamide	Ablation ^c K ⁺ channel block Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ second (AV nodal blockers can be harmful)
VT in patients with remote myocardial infarction	Reentry near the rim of the healed myocardial infarction	Lidocaine Amiodarone Procainamide DC cardioversion	*ICD ^d *Amiodarone K ⁺ channel block Na ⁺ channel block
VT in patients without structural heart disease	DADs triggered by ↑ sympathetic tone	Adenosine ^e Verapamil ^e β-Blockers ^e DC cardioversion	Verapamil ^e β-Blockers ^e

(Continued)

Table 34–2

A Mechanistic Approach to Antiarrhythmic Therapy (Continued)

ARRHYTHMIA	COMMON MECHANISM	ACUTE THERAPY ^a	CHRONIC THERAPY ^a
VF	Disorganized reentry	*DC cardioversion Lidocaine Amiodarone Procainamide	*ICD ^d *Amiodarone K ⁺ channel block Na ⁺ channel block
<i>Torsades de pointes</i> , congenital or acquired; (often drug-related)	EAD-related triggered activity	Pacing Magnesium Isoproterenol	β -Blockade Pacing

*Indicates treatment of choice. ^aAcute drug therapy is administered intravenously; chronic therapy implies long-term oral use. ^bAV nodal block can be achieved clinically by adenosine, Ca²⁺ channel block, β adrenergic receptor blockade, or increased vagal tone (a major antiarrhythmic effect of digitalis glycosides). ^cAblation is a procedure in which tissue responsible for the maintenance of a tachycardia is identified by specialized recording techniques and then selectively destroyed, usually by high-frequency radio waves delivered through a catheter placed in the heart. ^dICD, implanted cardioverter/defibrillator. A device that can sense VT or VF and deliver pacing and/or cardioverting shocks to restore normal rhythm. ^eThese may be harmful in reentrant VT and so should be used for acute therapy only if the diagnosis is secure.

ABBREVIATIONS: DAD, delayed afterdepolarization; EAD, early afterdepolarization; WPW, Wolff–Parkinson–White; PSVT, paroxysmal supraventricular tachycardia; VT, ventricular tachycardia; VF, ventricular fibrillation.

tors (ICDs), devices that are capable of detecting VF and automatically delivering a defibrillating shock, are used increasingly in patients judged to be at high risk for VF. Often drugs are used with these devices if defibrillating shocks, which are painful, occur frequently.

MECHANISMS OF ANTIARRHYTHMIC DRUG ACTION

Drug effects that may be antiarrhythmic can be demonstrated *in vitro* or in animal models, but the relationship between the multiple effects that drugs produce in patients and their effects on arrhythmias can be complex. A single arrhythmia may result from multiple mechanisms. Drugs may be antiarrhythmic by suppressing the initiating mechanism or by altering the re-entrant circuit. In some cases, drugs may suppress the initiator but nonetheless promote re-entry (*see below*).

Drugs may slow automatic rhythms by altering any of the four determinants of spontaneous pacemaker discharge (Figure 34–10): increase maximum diastolic potential, decrease phase 4 slope, threshold potential, or increase action potential duration. *Adenosine* and acetylcholine may increase maximum diastolic potential, and β adrenergic receptor antagonists (β -blockers; *see Chapter 10*) may decrease phase 4 slope. Block of Na⁺ or Ca²⁺ channels usually results in altered threshold, and block of cardiac K⁺ channels prolongs the action potential.

Antiarrhythmic drugs may block arrhythmias owing to DADs or EADs by two major mechanisms: (1) inhibition of the development of afterdepolarizations, and (2) interference with the inward current (usually through Na⁺ or Ca²⁺ channels), which is responsible for the upstroke. Thus arrhythmias owing to *digitalis*-induced DADs may be inhibited by *verapamil* (which blocks the development of DAD) or by *quinidine* (which blocks Na⁺ channels, thereby elevating the threshold required to produce the abnormal upstroke). Similarly, two approaches are used in arrhythmias related to EAD-induced triggered beats (Tables 34–1 and 34–2). EADs can be inhibited by shortening action potential duration; in practice, heart rate is accelerated by *isoproterenol* infusion or by pacing. Triggered beats arising from EADs can be inhibited by Mg²⁺, without normalizing repolarization *in vitro* or QT interval, through mechanisms that are not well understood. In patients with a congenitally prolonged QT interval, *torsades de pointes* often occurs with adrenergic stress; therapy includes β adrenergic blockade (which does not shorten the QT interval) as well as pacing.

In anatomically determined re-entry, drugs may terminate the arrhythmia by blocking propagation of the action potential. Conduction usually fails in a “weak link” in the circuit. In the example of the WPW-related arrhythmia described earlier, the weak link is the AV node, and drugs that prolong AV nodal refractoriness and slow AV nodal conduction, such as Ca²⁺ channel blockers, β adrenergic

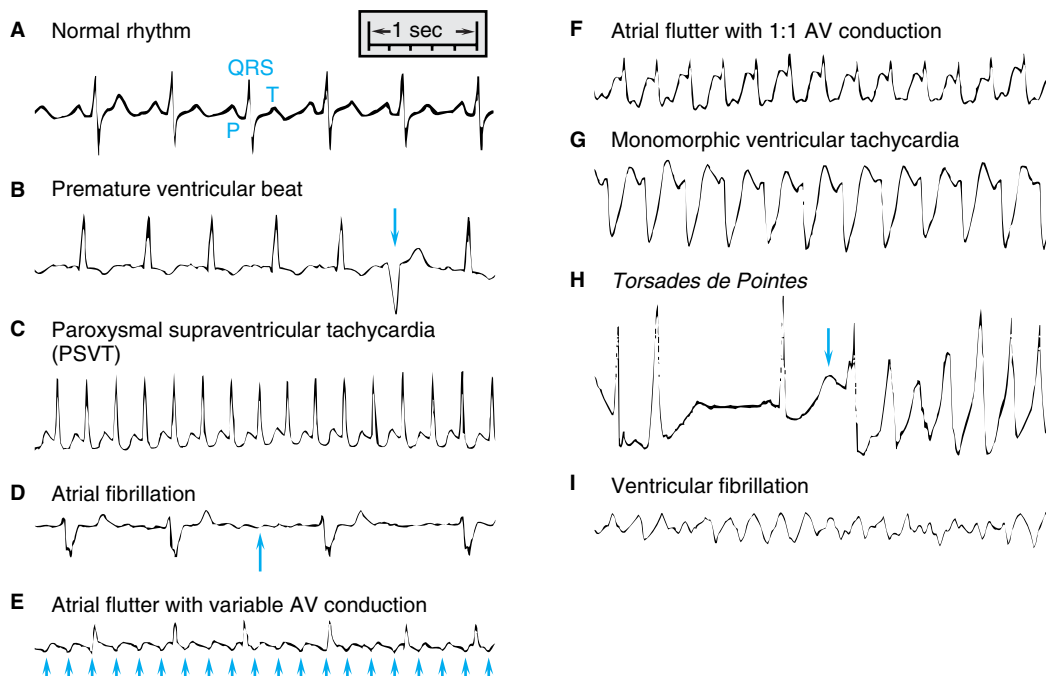

Figure 34-9. ECGs showing normal and abnormal cardiac rhythms. The P, QRS, and T waves in normal sinus rhythm are shown in panel A. Panel B shows a premature beat arising in the ventricle (*arrow*). Paroxysmal supraventricular tachycardia (PSVT) is shown in panel C; this is most likely re-entry using an accessory pathway (*see* Figure 34-7) or re-entry within or near the AV node. In atrial fibrillation (panel D), there are no P waves, and the QRS complexes occur irregularly (and at a slow rate in this example); electrical activity between QRS complexes shows small undulations (*arrow*) corresponding to fibrillatory activity in the atria. In atrial flutter (panel E), the atria beat rapidly, approximately 250 beats per minute (*arrows*) in this example, and the ventricular rate is variable. If a drug that slows the rate of atrial flutter is administered, 1:1 atrioventricular conduction (panel F) can occur. In monomorphic ventricular tachycardia (VT, panel G), identical wide QRS complexes occur at a regular rate, 180 beats per minute. The electrocardiographic features of the *torsades de pointes* syndrome (panel H) include a very long QT interval (>600 ms in this example, *arrow*), and ventricular tachycardia in which each successive beat has a different morphology (polymorphic VT). Panel I shows the disorganized electrical activity characteristic of ventricular fibrillation.

receptor antagonists, or digitalis glycosides, are likely to be effective. On the other hand, slowing conduction in functionally determined re-entrant circuits may change the pathway without extinguishing the circuit. In fact, slow conduction generally promotes the development of re-entrant arrhythmias, whereas the most likely approach for terminating functionally determined re-entry is prolongation of refractoriness (Task Force, 1991). In fast-response tissues, refractoriness is prolonged by delaying the recovery of Na^+ channels from inactivation. Drugs that act by blocking Na^+ channels generally shift the voltage dependence of recovery from block (Figure 34-5B) and so prolong refractoriness (Figure 34-11).

Drugs that increase action potential duration without direct action on Na^+ channels (*e.g.*, by blocking delayed rectifier currents) also will prolong refractoriness (Singh,

1993) (Figure 34-11). In slow-response tissues, Ca^{2+} channel block prolongs refractoriness. Drugs that interfere with cell-cell coupling also theoretically should increase refractoriness in multicellular preparations; *amiodarone* may exert this effect in diseased tissue (Levine *et al.*, 1988). Acceleration of conduction in an area of slow conduction also could inhibit re-entry; *lidocaine* may exert such an effect, and peptides that suppress experimental arrhythmias by increasing gap junction conductance have been described.

State-Dependent Ion Channel Block

Mathematical models describing drug-channel interactions have been useful in understanding conditions under which drugs do or do not suppress arrhythmias. A

Figure 34-10. Four ways to reduce the rate of spontaneous discharge in automatic tissues. The thin horizontal line represents threshold potential.

more recent advance has been the elucidation of molecular and structural determinants of ion channel permeation and drug block. This information likely will play an increasing role in analyzing the actions of available and new antiarrhythmic compounds (MacKinnon, 2003).

A key concept is that ion channel–blocking drugs bind to specific sites on the ion channel proteins to modify function (*e.g.*, decrease current) and that the affinity of the ion channel protein for the drug on its target site will vary as the ion channel protein shuttles among functional con-

Figure 34-11. Two ways to increase refractoriness in fast-response cells. In this figure, the black dot indicates the point at which a sufficient number of Na^+ channels (an arbitrary 25%; see Figure 34-5B) have recovered from inactivation to allow a premature stimulus to produce a propagated response in the absence of a drug. Block of Na^+ channels (A) shifts voltage dependence of recovery (see Figure 34-5B) and so delays the point at which 25% of channels have recovered (blue diamond), prolonging refractoriness. Note that if the drug also dissociates slowly from the channel (see Figure 34-12), refractoriness in fast-response tissues actually can extend beyond full repolarization (“postrepolarization refractoriness”). Drugs that prolong the action potential (B) also will extend the point at which an arbitrary percentage of Na^+ channels have recovered from inactivation, even without directly interacting with Na^+ channels.

formations (or ion channel “states”) (Snyders *et al.*, 1991). Physicochemical characteristics, such as molecular weight and lipid solubility, are important determinants of state-dependent binding. State-dependent binding has been studied most extensively in the case of Na^+ channel–blocking drugs. Most useful agents of this type block open and/or inactivated Na^+ channels and have very little affinity for channels in the resting state. Thus, with each action potential, drugs bind to Na^+ channels and block them, and with each diastolic interval, drugs dissociate, and the block is released. Block may be due to a drug

Figure 34–12. Recovery from block of Na^+ channels during diastole. This recovery is the critical factor determining extent of steady-state Na^+ channel block. Na^+ channel blockers bind to (and block) Na^+ channels in the open and/or inactivated states, resulting in phasic changes in the extent of block during the action potential. As shown in the middle panel, a decrease in the rate of recovery from block increases the extent of block. Different drugs have different rates of recovery, and depolarization reduces the rate of recovery. The right panel shows that increasing heart rate, which results in relatively less time spent in the rest state and also increases the extent of block. (Modified from Roden *et al.*, 1993, with permission.)

binding within the conduction pore or binding at a remote site that then induces allosteric changes in the ability of the channel protein to form a pore. As illustrated in Figure 34–12, the dissociation rate is a key determinant of steady-state block of Na^+ channels. When heart rate increases, the time available for dissociation decreases, and steady-state Na^+ channel block increases. The rate of recovery from block also slows as cells are depolarized, as in ischemia (Snyders *et al.*, 1991). This explains the finding that Na^+ channel blockers depress Na^+ current, and hence conduction, to a greater extent in ischemic tissues than in normal tissues. Open versus inactivated-state block also may be important in determining the effects of some drugs. Increased action potential duration, which results in a relative increase in time spent in the inactivated state, may increase block by drugs that bind to inactivated channels, such as lidocaine or amiodarone (Snyders *et al.*, 1991).

The rate of recovery from block often is expressed as a time constant (τ_{recovery} , the time required to complete approximately 63% of an exponentially determined process to be complete; Courtney, 1987). In the case of drugs such as lidocaine, τ_{recovery} is so short ($\ll 1$ s) that recovery from block is very rapid, and substantial Na^+ channel block occurs only in rapidly driven tissues, particularly in ischemia. Conversely, drugs such as *flecainide* have such long τ_{recovery} values (>10 s) that roughly the same number of Na^+ channels is blocked during systole and diastole. As a result, marked slowing of conduction occurs even in normal tissues at normal rates.

Classifying Antiarrhythmic Drugs

Classifying drugs by common electrophysiological properties emphasizes the connection between basic electrophysiological actions and antiarrhythmic effects (Vaughan Williams, 1992). To the extent that the clinical actions of drugs can be predicted from their basic electrophysiological properties, such classification schemes have merit. However, as each compound is better characterized in a range of *in vitro* and *in vivo* test systems, it becomes apparent that differences in pharmacological effects occur even among drugs that share the same classification, some of which may be responsible for the observed clinical differences in responses to drugs of the same broad “class” (Table 34–3). An alternative way of approaching antiarrhythmic therapy is to attempt to classify arrhythmia mechanisms and then to target drug therapy to the electrophysiological mechanism most likely to terminate or prevent the arrhythmia (Task Force, 1991) (Table 34–2).

Na⁺ Channel Block. The extent of Na^+ channel block depends critically on heart rate and membrane potential, as well as on drug-specific physicochemical characteristics that determine τ_{recovery} (Figure 34–12). The following description applies when Na^+ channels are blocked, *i.e.*, at rapid heart rates in diseased tissue with a rapid-recovery drug such as lidocaine or even at normal rates in normal tissues with a slow-recovery drug such as *flecainide*. When Na^+ channels are blocked, threshold for excitability is decreased; *i.e.*, greater membrane depolarization is required

Table 34-3

Major Electrophysiological Actions of Antiarrhythmic Drugs

DRUG	NA ⁺ CHANNEL BLOCK		↑APD	Ca ²⁺ CHANNEL BLOCK	AUTONOMIC EFFECTS	OTHER EFFECTS
	$\tau_{RECOVERY}^1$, SECONDS	STATE DEPENDENCE ¹				
Lidocaine	0.1	I > O				
Phenytoin	0.2	I				
Mexiletine*	0.3					
Tocainide*	0.4	O > I				
Procainamide	1.8	O	✓		Ganglionic blockade (especially intravenous)	✓: Metabolite prolongs APD
Quinidine	3	O	✓	(x)	α -Blockade, vagolytic	
Disopyramide [†]	9	O	✓		Anticholinergic	
Moricizine	~10	O \approx I				
Propafenone [†]	11	O \approx I	✓		β -Blockade (variable clinical effect)	
Flecainide*	11	O	(x)	(x)		
β -Blockers: Propranolol [†]					β -Blockade	Na ⁺ channel block <i>in vitro</i>
Sotalol [†]			✓		β -Blockade	
Amiodarone	1.6	I	✓	(x)	Noncompetitive β -blockade	Antithyroid action
Dofetilide			✓			
Ibutilide			✓			
Verapamil*				✓		
Diltiazem*				✓		
Digoxin					✓: Vagal stimulation	✓: Inhibition of Na ⁺ , K ⁺ -ATPase
Adenosine				✓	✓: Adenosine receptor activation	✓: Activation of out- ward K ⁺ current
Magnesium				?✓		Mechanism not well understood

✓ indicates an effect that is important in mediating the clinical action of a drug. (x) indicates a demonstrable effect whose relationship to drug action in patients is less well established. * indicates drugs prescribed as racemates, and the enantiomers are thought to exert similar electrophysiological effects. [†] indicates racemates for which clinically relevant differences in the electrophysiological properties of individual enantiomers have been reported (see text). One approach to classifying drugs is:

Class	Major action
I	Na ⁺ channel block
II	β -blockade
III	action potential prolongation (usually by K ⁺ channel block)
IV	Ca ²⁺ channel block

Drugs are listed here according to this scheme. It is important to bear in mind, however, that many drugs exert multiple effects that contribute to their clinical actions. It is occasionally clinically useful to subclassify Na⁺ channel blockers by their rates of recovery from drug-induced block ($\tau_{recovery}$) under physiological conditions. Since this is a continuous variable and can be modulated by factors such as depolarization of the resting potential, these distinctions can become blurred: class Ib, $\tau_{recovery} < 1$ s; class Ia, $\tau_{recovery} 1-10$ s; class Ic, $\tau_{recovery} > 10$ s. These class and subclass effects are associated with distinctive ECG changes, characteristic "class" toxicities, and efficacy in specific arrhythmia syndromes (see text). ¹These data are dependent on experimental conditions, including species and temperature. The $\tau_{recovery}$ values cited here are from Courtney (1987), with the exception of moricizine, which was found by Lee and Rosen (1991) to have a value slightly less than that for flecainide. The state-dependence is from Snyder *et al.*, (1991).

ABBREVIATIONS: O, Open state blocker; I, inactivated state blocker; APD, action potential duration.

to bring Na⁺ channels from the rest to open states. This change in threshold probably contributes to the clinical findings that Na⁺ channel blockers tend to increase both pacing threshold and the energy required to defibrillate the fibrillating heart (Echt *et al.*, 1989). These deleterious effects may be important if antiarrhythmic drugs are used in patients with pacemakers or implanted defibrillators. Na⁺ channel block decreases conduction velocity in fast-response tissue and increases QRS duration. Usual doses of flecainide prolong QRS intervals by 25% or more during normal rhythm, whereas lidocaine increases QRS intervals only at very fast heart rates. Drugs with τ_{recovery} values greater than 10 s (*e.g.*, flecainide) also tend to prolong the PR interval; it is not known whether this represents additional Ca²⁺ channel block (*see* below) or block of fast-response tissue in the region of the AV node. Drug effects on the PR interval also are highly modified by autonomic effects. For example, quinidine actually tends to shorten the PR interval largely as a result of its vagolytic properties. Action potential duration is either unaffected or shortened by Na⁺ channel block; some Na⁺ channel-blocking drugs do prolong cardiac action potentials but by other mechanisms, usually K⁺ channel block (Table 34–3).

By increasing threshold, Na⁺ channel block decreases automaticity (Figure 34–10B) and can inhibit triggered activity arising from DADs or EADs. Many Na⁺ channel blockers also decrease phase 4 slope (Figure 34–10A). In anatomically defined re-entry, Na⁺ channel blockers may decrease conduction sufficiently to extinguish the propagating re-entrant wavefront. However, as described earlier, conduction slowing owing to Na⁺ channel block may exacerbate re-entry. Block of Na⁺ channels also shifts the voltage dependence of recovery from inactivation (Figure 34–5B) to more negative potentials, thereby tending to increase refractoriness. Thus, whether a given drug exacerbates or suppresses re-entrant arrhythmias depends on the balance between its effects on refractoriness and on conduction in a particular re-entrant circuit. Lidocaine and *mexiletine* have short τ_{recovery} values and are not useful in atrial fibrillation or flutter, whereas quinidine, flecainide, *propafenone*, and similar agents are effective in some patients. Many of these agents owe part of their antiarrhythmic activity to blockade of K⁺ channels.

Na⁺ Channel-Blocker Toxicity. Conduction slowing in potential re-entrant circuits can account for toxicity to drugs that block the Na⁺ channel (Table 34–1). For example, Na⁺ channel block decreases conduction velocity and hence slows atrial flutter rate. Normal AV nodal function permits a greater number of impulses to penetrate the ventricle, and heart rate actually may increase (Figure 34–9). Thus atrial flutter rate may drop from 300 per minute, with

2:1 or 4:1 AV conduction (*i.e.*, a heart rate of 150 or 75 beats per minute), to 220 per minute, but with 1:1 transmission to the ventricle (*i.e.*, a heart rate of 220 beats per minute), with potentially disastrous consequences. This form of drug-induced arrhythmia is especially common during treatment with quinidine because the drug also increases AV nodal conduction through its vagolytic properties; flecainide and propafenone also have been implicated. Therapy with Na⁺ channel blockers in patients with re-entrant ventricular tachycardia after a myocardial infarction can increase the frequency and severity of arrhythmic episodes. Although the mechanism is unclear, slowed conduction allows the re-entrant wavefront to persist within the tachycardia circuit. Such drug-exacerbated arrhythmia can be very difficult to manage, and deaths owing to intractable drug-induced ventricular tachycardia have been reported. In this setting, Na⁺ infusion may be beneficial. Several Na⁺ channel blockers (*e.g.*, *procainamide* and quinidine) have been reported to exacerbate neuromuscular paralysis by D-tubocurarine (*see* Chapter 9).

Action Potential Prolongation. Most drugs that prolong the action potential do so by blocking K⁺ channels, although enhanced inward Na⁺ current also can cause prolongation. Enhanced inward current may underlie QT prolongation (and arrhythmia suppression) by *ibutilide*. Block of cardiac K⁺ channels increases action potential duration and reduces normal automaticity (Figure 34–10D). Increased action potential duration, seen as an increase in QT interval, increases refractoriness (Figure 34–11) and therefore should be an effective way of treating re-entry (Task Force, 1991; Singh, 1993). Experimentally, K⁺ channel block produces a series of desirable effects: reduced defibrillation energy requirement, inhibition of ventricular fibrillation owing to acute ischemia, and increased contractility (Echt *et al.*, 1989; Roden, 1993). As shown in Table 34–3, most K⁺ channel blocking drugs also interact with β adrenergic receptors (*sotalol*) or other channels (*e.g.*, amiodarone and quinidine). Amiodarone and sotalol appear to be at least as effective as drugs with predominant Na⁺ channel-blocking properties in both atrial and ventricular arrhythmias. “Pure” action potential-prolonging drugs (*e.g.*, *dofetilide* and *ibutilide*) also are available (Murray, 1998; Torp-Pedersen *et al.*, 1999).

Toxicity of Drugs That Prolong QT Interval. Most of these agents disproportionately prolong cardiac action potentials when underlying heart rate is slow and can cause *torsades de pointes* (Table 34–1, Figure 34–9). While this effect usually is seen with QT-prolonging antiarrhythmic drugs, it can occur more rarely with drugs that are used for noncardiac indications. For such agents, the

risk of *torsades de pointes* may become apparent only after widespread use postmarketing, and recognition of this risk has been a common cause for drug withdrawal (Roden, 2004). For unknown reasons, drug-induced *torsades de pointes* associated with antiarrhythmic drugs is significantly more common in women (Makkar *et al.*, 1993).

Ca²⁺ Channel Block. The major electrophysiological effects resulting from block of cardiac Ca²⁺ channels are in slow-response tissues, the sinus and AV nodes. Dihydropyridines, such as *nifedipine*, which are used commonly in angina and hypertension (*see* Chapters 31 and 32), preferentially block Ca²⁺ channels in vascular smooth muscle; their cardiac electrophysiological effects, such as heart rate acceleration, result principally from reflex sympathetic activation secondary to peripheral vasodilation. Only verapamil, *diltiazem*, and *bepridil* block Ca²⁺ channels in cardiac cells at clinically used doses. These drugs generally slow heart rate (Figure 34–10A), although hypotension, if marked, can cause reflex sympathetic activation and tachycardia. The velocity of AV nodal conduction decreases, so the PR interval increases. AV nodal block occurs as a result of decremental conduction, as well as increased AV nodal refractoriness. These latter effects form the basis of the antiarrhythmic actions of Ca²⁺ channel blockers in re-entrant arrhythmias whose circuit involves the AV node, such as AV re-entrant tachycardia (Figure 34–7).

Another important indication for antiarrhythmic therapy is to reduce ventricular rate in atrial flutter or fibrillation. Rare forms of ventricular tachycardia appear to be DAD-mediated and respond to verapamil (Sung *et al.*, 1983). Parenteral verapamil and diltiazem are approved for rapid conversion of PSVTs to sinus rhythm and for temporary control of rapid ventricular rate in atrial flutter or fibrillation. Oral verapamil may be used in conjunction with digoxin to control ventricular rate in chronic atrial flutter or fibrillation and for prophylaxis of repetitive PSVT. Unlike β adrenergic receptor antagonists, Ca²⁺ channel blockers have not been shown to reduce mortality after myocardial infarction (Singh, 1990). In contrast to other Ca²⁺ channel blockers, bepridil increases action potential duration in many tissues and can exert an antiarrhythmic effect in atria and ventricles. However, because bepridil can cause *torsades de pointes*, it is not prescribed widely and has been discontinued in the United States.

Verapamil and Diltiazem. The major adverse effect of intravenous verapamil or diltiazem is hypotension, particularly with bolus administration. This is a particular problem if the drugs are used mistakenly in patients with ventricular tachycardia (in which Ca²⁺ channel blockers

usually are not effective) misdiagnosed as AV nodal re-entrant tachycardia (Stewart *et al.*, 1986). Hypotension also is frequent in patients receiving other vasodilators, including quinidine, and in patients with underlying left ventricular dysfunction, which the drugs can exacerbate. Severe sinus bradycardia or AV block also occurs, especially in susceptible patients, such as those also receiving β -blockers. With oral therapy, these adverse effects tend to be less severe. Constipation can occur with oral verapamil.

Verapamil (CALAN, ISOPTIN, VERELAN, COVERA-HS) is prescribed as a racemate. L-Verapamil is a more potent calcium channel blocker than is D-verapamil. However, with oral therapy, the L-enantiomer undergoes more extensive first-pass hepatic metabolism. For this reason, a given concentration of verapamil prolongs the PR interval to a greater extent when administered intravenously (where concentrations of the L- and D-enantiomers are equivalent) than when administered orally (Echizen *et al.*, 1985). *Diltiazem* (CARDIZEM, TIAZAC, DILACOR XR, and others) also undergoes extensive first-pass hepatic metabolism, and both drugs have metabolites that exert Ca²⁺ channel-blocking actions. In clinical practice, adverse effects during therapy with verapamil or diltiazem are determined largely by underlying heart disease and concomitant therapy; plasma concentrations of these agents are not measured routinely. Both drugs can increase serum digoxin concentration, although the magnitude of this effect is variable; excess slowing of ventricular response may occur in patients with atrial fibrillation.

Block of β Adrenergic Receptors. β Adrenergic stimulation increases the magnitude of the Ca²⁺ current and slows its inactivation, increases the magnitude of repolarizing K⁺ and Cl⁻ currents (Sanguinetti *et al.*, 1991; Hume and Harvey, 1991), increases pacemaker current (thereby increasing sinus rate; DiFrancesco, 1993), and under pathophysiological conditions, can increase both DAD- and EAD-mediated arrhythmias. The increases in plasma epinephrine associated with severe stress (*e.g.*, acute myocardial infarction or resuscitation from cardiac arrest) lower serum K⁺, especially in patients receiving chronic diuretic therapy (Brown *et al.*, 1983). β Adrenergic receptor antagonists inhibit these effects and can be antiarrhythmic by reducing heart rate, decreasing intracellular Ca²⁺ overload, and inhibiting afterdepolarization-mediated automaticity. Epinephrine-induced hypokalemia appears to be mediated by β_2 adrenergic receptors and is blocked by “noncardioselective” antagonists such as *propranolol* (*see* Chapter 10). In acutely ischemic tissue, β -blockers increase the energy required to fibrillate the heart, an antiarrhythmic action (Anderson *et al.*, 1983). Although the

precise mechanisms have not been established, these effects may contribute to the reduced mortality observed in trials of chronic therapy with β -blockers—including propranolol, *timolol*, and *metoprolol*—after myocardial infarction (Singh, 1990). *Atenolol* and metoprolol have been shown to decrease mortality in the first week following myocardial infarction.

As with Ca^{2+} channel blockers and digitalis, β -blockers increase AV nodal conduction time (increased PR interval) and prolong AV nodal refractoriness; hence they are useful in terminating re-entrant arrhythmias that involve the AV node and in controlling ventricular response in atrial fibrillation or flutter. In many (but not all) patients with the congenital long QT syndrome, as well as in many other patients, arrhythmias are triggered by physical or emotional stress; β -blockers may be useful in these cases (Schwartz *et al.*, 2000; Roden and Spooner, 1999). β Adrenergic receptor antagonists also reportedly are effective in controlling arrhythmias owing to Na^+ channel blockers; this effect may be due in part to slowing of the heart rate, which then decreases the extent of rate-dependent conduction slowing by Na^+ channel block (Myerburg *et al.*, 1989). As described further in Chapter 10, adverse effects of β -blockade include fatigue, bronchospasm, hypotension, impotence, depression, aggravation of heart failure, worsening of symptoms owing to peripheral vascular disease, and masking of the symptoms of hypoglycemia in diabetic patients (*see* Chapters 10 and 32). In patients with arrhythmias owing to excess sympathetic stimulation (*e.g.*, pheochromocytoma or *clonidine* withdrawal), β -blockers can result in unopposed α adrenergic stimulation, with resulting severe hypertension and/or α adrenergic-mediated arrhythmias. In such patients, arrhythmias should be treated with both α and β adrenergic antagonists or with a drug such as labetalol that combines α - and β -blocking properties. Abrupt discontinuation of chronic β -blocker therapy can lead to “rebound” symptoms, including hypertension, increased angina, and arrhythmias; thus β -receptor antagonists are tapered over 2 weeks (*see* Chapters 10 and 31 to 33).

Selected β Adrenergic Receptor Blockers. It is likely that most β adrenergic antagonists share antiarrhythmic properties. Some, such as propranolol, also exert Na^+ channel–blocking (“membrane stabilizing”) effects at high concentrations *in vitro*, but the clinical significance of this effect is uncertain. Similarly, drugs with intrinsic sympathomimetic activity may be less useful as antiarrhythmics, at least in theory (Singh, 1990). *Acebutolol* is as effective as quinidine in suppressing ventricular ectopic beats, an arrhythmia that many clinicians no longer treat. Sotalol (*see* below) is more effective for many

arrhythmias than are other β -blockers probably because of its K^+ channel–blocking actions. *Esmolol* (Frishman *et al.*, 1988) is a β_1 -selective agent that is metabolized by erythrocyte esterases and so has a very short elimination half-life (9 minutes). Intravenous esmolol is useful in clinical situations in which immediate β adrenergic blockade is desired (*e.g.*, for rate control of rapidly conducted atrial fibrillation). Because of esmolol’s very rapid elimination, adverse effects due to β adrenergic blockade—should they occur—dissipate rapidly when the drug is stopped. Although methanol is a metabolite of esmolol, methanol intoxication has not been a clinical problem.

PRINCIPLES IN THE CLINICAL USE OF ANTIARRHYTHMIC DRUGS

Drugs that modify cardiac electrophysiology often have a very narrow margin between the doses required to produce a desired effect and those associated with adverse effects. Moreover, antiarrhythmic drugs can induce new arrhythmias with possibly fatal consequences. Nonpharmacological treatments, such as cardiac pacing, electrical defibrillation, or ablation of targeted regions (Morady, 1999), are indicated for some arrhythmias; in other cases, no therapy is required, even though an arrhythmia is detected. Therefore, the fundamental principles of therapeutics described here must be applied to optimize antiarrhythmic therapy.

1. Identify and Remove Precipitating Factors

Factors that commonly precipitate cardiac arrhythmias include hypoxia, electrolyte disturbances (especially hypokalemia), myocardial ischemia, and certain drugs. Antiarrhythmics, including cardiac glycosides, are not the only drugs that can precipitate arrhythmias (Table 34–1). For example, *theophylline* can cause multifocal atrial tachycardia, which sometimes can be managed simply by reducing the dose of theophylline. *Torsades de pointes* can arise not only during therapy with action potential–prolonging antiarrhythmics but also with other drugs not ordinarily classified as having effects on ion channels. These include the antibiotic *erythromycin* (*see* Chapter 46); the antiprotozoal *pentamidine* (*see* Chapter 40); some antipsychotics, notably *thioridazine* (*see* Chapter 18); and certain tricyclic antidepressants (*see* Chapter 17).

2. Establish the Goals of Treatment

Some Arrhythmias Should Not Be Treated: The CAST Example. Abnormalities of cardiac rhythm are readily detectable by a variety of recording methods. However, the mere detection of an abnormality does not equate with the need for therapy. This was illustrated in the Cardiac Arrhythmias Suppression Trial (CAST). The presence of asymptomatic ventricular ectopic beats is a known marker for increased risk of sudden death owing to ventricular fibrillation in

patients convalescing from myocardial infarction. In the CAST, patients whose ventricular ectopic beats were suppressed by the potent Na⁺ channel blockers *encainide* (no longer marketed) or *flecainide* were randomly assigned to receive those drugs or placebo. Unexpectedly, the mortality rate was two- to threefold higher among patients treated with the drugs than those treated with placebo (CAST Investigators, 1989). While the explanation for this effect is not known, several lines of evidence suggest that in the presence of these drugs, transient episodes of myocardial ischemia and/or sinus tachycardia can cause marked conduction slowing (because these drugs have a very long τ_{recovery}), resulting in fatal re-entrant ventricular tachyarrhythmias (Ruskin, 1989; Ranger *et al.*, 1989; Akiyama *et al.*, 1991). One consequence of this pivotal clinical trial was to re-emphasize the concept that therapy should be initiated only when a clear benefit to the patient can be identified. When symptoms are obviously attributable to an ongoing arrhythmia, there usually is little doubt that termination of the arrhythmia will be beneficial; when chronic therapy is used to prevent recurrence of an arrhythmia, the risks may be greater (Roden, 1994). *Among the antiarrhythmic drugs discussed here, only β adrenergic blockers and, to a lesser extent, amiodarone (Connolly, 1999) have been shown to reduce mortality during long-term therapy.*

Symptoms Due to Arrhythmias. Some patients with an arrhythmia may be asymptomatic; in this case, establishing any benefit for treatment will be very difficult. Some patients may present with presyncope, syncope, or even cardiac arrest, which may be due to brady- or tachyarrhythmias. Other patients may present with a sensation of irregular heartbeats (*i.e.*, palpitations) that can be minimally symptomatic in some individuals and incapacitating in others. The irregular heartbeats may be due to intermittent premature contractions or to sustained arrhythmias such as atrial fibrillation (which results in an irregular ventricular rate) (Figure 34–9). Finally, patients may present with symptoms owing to decreased cardiac output attributable to arrhythmias. The most common symptom is breathlessness either at rest or on exertion. Rarely, sustained tachycardias may produce no “arrhythmia” symptoms (such as palpitations) but will depress contractile function; these patients may present with congestive heart failure that can be controlled by treating the arrhythmia.

Choosing Among Therapeutic Approaches. In choosing among available therapeutic options, it is important to establish clear therapeutic goals. For example, three options are available in patients with atrial fibrillation: (1) Reduce the ventricular response using AV nodal blocking agents such as digitalis, verapamil, diltiazem, or β adrenergic antagonists (Table 34–1); (2) restore and maintain normal rhythm using drugs such as quinidine, flecainide, or amiodarone; or (3) decide not to implement antiarrhythmic therapy, especially if the patient truly is asymptomatic. Most patients with atrial fibrillation also benefit from anticoagulation to reduce stroke incidence regardless of symptoms (Singer, 1996) (*see Chapter 54*).

Factors that contribute to choice of therapy include not only symptoms but also the type and extent of structural heart disease, the QT interval prior to drug therapy, the coexistence of conduction system disease, and the presence of noncardiac diseases (Table 34–4). In the rare patient with the WPW syndrome and atrial fibrillation, the ventricular response can be extremely rapid and can be accelerated paradoxically by AV nodal blocking drugs such as digitalis or Ca²⁺ channel blockers; deaths owing to drug therapy have been reported under these circumstances.

Table 34–4
Patient-Specific Antiarrhythmic Drug Contraindications

CONDITION	EXCLUDE/USE WITH CAUTION
Cardiac	
Heart failure	Disopyramide, flecainide
Sinus or AV node dysfunction	Digoxin, verapamil, diltiazem, β adrenergic receptor antagonists, amiodarone
Wolff–Parkinson–White syndrome (risk of extremely rapid rate if atrial fibrillation develops)	Digoxin, verapamil, diltiazem
Infranodal conduction disease	Na ⁺ channel blockers, amiodarone
Aortic/subaortic stenosis	Bretylium
History of myocardial infarction	Flecainide
Prolonged QT interval	Quinidine, procainamide, disopyramide, sotalol, dofetilide, ibutilide, amiodarone
Cardiac transplant	Adenosine
Noncardiac	
Diarrhea	Quinidine
Prostatism, glaucoma	Disopyramide
Arthritis	Chronic procainamide
Lung disease	Amiodarone
Tremor	Mexiletine, tocainide (use discontinued in U.S.)
Constipation	Verapamil
Asthma, peripheral vascular disease, hypoglycemia	β Adrenergic blockers, propafenone

The frequency and reproducibility of arrhythmia should be established prior to initiating therapy because inherent variability in the occurrence of arrhythmias can be confused with a beneficial or adverse drug effect. Techniques for this assessment include recording cardiac rhythm for prolonged periods or evaluating the response of the heart to artificially induced premature beats. It is important to recognize that drug therapy may be only partially effective: A marked decrease in the duration of paroxysms of atrial fibrillation may be sufficient to render a patient asymptomatic even if an occasional episode still can be detected.

3. Minimize Risks

Antiarrhythmic Drugs Can Cause Arrhythmias. One well-recognized risk of antiarrhythmic therapy is the possibility of provoking new

arrhythmias, with potentially life-threatening consequences. Antiarrhythmic drugs can provoke arrhythmias by different mechanisms (Table 34–1). These drug-provoked arrhythmias must be recognized because further treatment with antiarrhythmic drugs often exacerbates the problem, whereas withdrawal of the causative agent often is curative. Thus, establishing a precise diagnosis is critical, and targeting therapies at underlying mechanisms of the arrhythmias may be required. For example, treating a ventricular tachycardia with verapamil not only may be ineffective but also can cause catastrophic cardiovascular collapse (Stewart *et al.*, 1986).

Monitoring of Plasma Concentration. Some adverse effects of antiarrhythmic drugs result from excessive plasma drug concentrations. Measuring plasma concentration and adjusting the dose to maintain the concentration within a prescribed therapeutic range may minimize some adverse effects. In many patients, serious adverse reactions relate to interactions involving antiarrhythmic drugs (often at usual plasma concentrations), transient factors such as electrolyte disturbances or myocardial ischemia, and the type and extent of the underlying heart disease (Ruskin, 1989; Roden, 1994). Factors such as generation of unmeasured active metabolites, variability in elimination of enantiomers (which may exert differing pharmacological effects), and disease- or enantiomer-specific abnormalities in drug binding to plasma proteins can complicate the interpretation of plasma drug concentrations.

Patient-Specific Contraindications. Another way to minimize the adverse effects of antiarrhythmic drugs is to avoid certain drugs in certain patient subsets altogether. For example, patients with a history of congestive heart failure are particularly prone to develop heart failure during *disopyramide* therapy. In other cases, adverse effects of drugs may be difficult to distinguish from exacerbations of underlying disease. Amiodarone may cause interstitial lung disease; its use therefore is undesirable in a patient with advanced pulmonary disease in whom the development of this potentially fatal adverse effect would be difficult to detect. Specific diseases that constitute relative or absolute contraindications to specific drugs are listed in Table 34–4.

4. The Electrophysiology of the Heart as a “Moving Target”

Cardiac electrophysiology varies dynamically in response to external influences such as changing autonomic tone, myocardial ischemia, and myocardial stretch (Priori *et al.*, 1999). For example, myocardial ischemia results in changes in extracellular K^+ that make the resting potential less negative, inactivate Na^+ channels, decrease Na^+ current, and slow conduction (Weiss *et al.*, 1991). In addition, myocardial ischemia can result in the formation and release of metabolites such as lysophosphatidylcholine, which can alter ion channel function; ischemia also may activate channels that otherwise are quiescent, such as the ATP-inhibited K^+ channels. Thus, in response to myocardial ischemia, a normal heart may display changes in resting potential, conduction velocity, intracellular Ca^{2+} concentrations, and repolarization, any one of which then may create arrhythmias or alter response to antiarrhythmic therapy.

ANTIARRHYTHMIC DRUGS

Summaries of important electrophysiological and pharmacokinetic features of the drugs considered here are pre-

sented in Tables 34–3 and 34–5. Ca^{2+} channel blockers and β adrenergic antagonists were considered earlier and in Chapters 1 and 31 to 33. The drugs are presented in alphabetical order.

Adenosine. Adenosine (ADENOCARD) is a naturally occurring nucleoside that is administered as a rapid intravenous bolus for the acute termination of re-entrant supraventricular arrhythmias (Lerman and Belardinelli, 1991). Rare cases of ventricular tachycardia in patients with otherwise normal hearts are thought to be DAD-mediated and can be terminated by adenosine. Adenosine also has been used to produce controlled hypotension during some surgical procedures and in the diagnosis of coronary artery disease. Intravenous ATP appears to produce effects similar to those of adenosine.

Pharmacological Effects. The effects of adenosine are mediated by its interaction with specific G protein-coupled adenosine receptors (*see* Chapter 11). Adenosine activates acetylcholine-sensitive K^+ current in the atrium and sinus and AV nodes, resulting in shortening of action potential duration, hyperpolarization, and slowing of normal automaticity (Figure 34–10C). Adenosine also inhibits the electrophysiological effects of increased intracellular cyclic AMP that occur with sympathetic stimulation. Because adenosine thereby reduces Ca^{2+} currents, it can be antiarrhythmic by increasing AV nodal refractoriness and by inhibiting DADs elicited by sympathetic stimulation.

Administration of an intravenous bolus of adenosine to humans transiently slows sinus rate and AV nodal conduction velocity and increases AV nodal refractoriness. A bolus of adenosine can produce transient sympathetic activation by interacting with carotid baroreceptors (Biaggioni *et al.*, 1991); a continuous infusion can cause hypotension.

Adverse Effects. A major advantage of adenosine therapy is that adverse effects are short-lived because the drug is transported into cells and deaminated so rapidly. Transient asystole (lack of any cardiac rhythm whatsoever) is common but usually lasts less than 5 seconds and is

(x): metabolite or route of elimination probably of minor clinical importance. *The elimination half-life is one, but not the only, determinant of how frequently a drug must be administered to maintain a therapeutic effect and avoid toxicity (Chapter 5: Principles of Therapeutics). For some drugs with short elimination half-lives, infrequent dosing is nevertheless possible, *e.g.*, propranolol or verapamil. Formulations that allow slow release into the gastrointestinal tract of a rapidly eliminated compound (available for many drugs including procainamide, disopyramide, verapamil, diltiazem, and propranolol) also allow infrequent dosing. †The therapeutic range is bounded by a plasma concentration below which no therapeutic effect is likely, and an upper concentration above which the risk of adverse effects increases. As discussed in the text, many serious adverse reactions to antiarrhythmic drugs can occur at “therapeutic” concentrations in susceptible individuals. When only an upper limit is cited, a lower limit has not been well defined. Variable generation of active metabolites may further complicate the interpretation of plasma concentration data (Chapters 1: Pharmacokinetics: The Dynamics of Drug Absorption, Distribution, and Elimination and 5: Principles of Therapeutics). ‡Oral doses are presented unless otherwise indicated. Doses are presented as suggested ranges in adults of average build; lower doses are less likely to produce toxicity. Lower maintenance dosages may be required in patients with renal or hepatic disease. Loading doses are only indicated when a therapeutic effect is desired before maintenance therapy would bring drug concentrations into a therapeutic range, *i.e.*, for acute therapy (*e.g.*, lidocaine, verapamil, adenosine) or when the elimination half-life is extremely long (amiodarone). §Bioavailability reduced by incomplete absorption. ¶Indicates suggested dosage using slow-release formulation. ¶¶This drug is available only in a restricted distribution system (*see* text).

ABBREVIATIONS: IV, intravenous; q, every.

in fact the therapeutic goal. Most patients feel a sense of chest fullness and dyspnea when therapeutic doses (6 to 12 mg) of adenosine are administered. Rarely, an adenosine bolus can precipitate bronchospasm or atrial fibrillation presumably by heterogeneously shortening atrial action potentials.

Clinical Pharmacokinetics. Adenosine is eliminated with a half-life of seconds by carrier-mediated uptake, which occurs in most cell types, including the endothelium, and subsequent metabolism by adenosine deaminase. Adenosine probably is the only drug whose efficacy requires a rapid bolus dose, preferably through a large central intravenous line; slow administration results in elimination of the drug prior to its arrival at the heart.

The effects of adenosine are potentiated in patients receiving *dipyridamole*, an adenosine-uptake inhibitor, and in patients with cardiac transplants owing to denervation hypersensitivity. Methylxanthines (*see* Chapter 27) such as theophylline and caffeine block adenosine receptors; therefore, larger than usual doses are required to produce an antiarrhythmic effect in patients who have consumed these agents in beverages or as therapy.

Amiodarone. *Amiodarone* (CORDARONE, PACERONE) exerts a multiplicity of pharmacological effects, none of which is clearly linked to its arrhythmia-suppressing properties (Mason, 1987). Amiodarone is a structural analog of thyroid hormone, and some of its antiarrhythmic actions and its toxicity may be attributable to interaction with nuclear thyroid hormone receptors. Amiodarone is highly lipophilic, is concentrated in many tissues, and is eliminated extremely slowly; consequently, adverse effects may resolve very slowly. In the United States, the drug is indicated for oral therapy in patients with recurrent ventricular tachycardia or fibrillation resistant to other drugs. Oral amiodarone also is effective in maintaining sinus rhythm in patients with atrial fibrillation (Connolly, 1999). An intravenous form is indicated for acute termination of ventricular tachycardia or fibrillation (Kowey *et al.*, 1995) and is supplanting lidocaine as first-line therapy for out-of-hospital cardiac arrest (Dorian *et al.*, 2002). Trials of oral amiodarone have shown a modest beneficial effect on mortality after acute myocardial infarction (Amiodarone Trials Meta-Analysis Investigators, 1997). Despite uncertainties about its mechanisms of action and the potential for serious toxicity, amiodarone now is used very widely in the treatment of common arrhythmias such as atrial fibrillation (Roy *et al.*, 2000).

Pharmacological Effects. Studies of the acute effects of amiodarone in *in vitro* systems are complicated by its insolubility in water, necessitating the use of solvents such as dimethyl sulfoxide. Amiodarone's effects may be mediated by perturbation of the lipid environment of the ion channels (Herbette *et al.*, 1988). Amiodarone blocks inactivated Na⁺ channels and has a relatively rapid rate of recovery (time constant \approx 1.6 s) from block. It also decreases Ca²⁺ current and transient outward delayed rectifier and inward rectifier K⁺ currents and exerts a non-competitive adrenergic blocking effect. Amiodarone potently inhibits abnormal automaticity and, in most tissues, prolongs action potential duration. Amiodarone decreases conduction velocity by Na⁺ channel block and by a poorly understood effect on cell-cell coupling that may be especially important in diseased tissue (Levine *et al.*, 1988). Prolongations of the PR, QRS, and QT intervals and sinus bradycardia are frequent during chronic therapy. Amiodarone prolongs refractoriness in all cardiac tissues; Na⁺ channel block, delayed repolarization owing to K⁺ channel block, and inhibition of cell-cell coupling all may contribute to this effect.

Adverse Effects. Hypotension owing to vasodilation and depressed myocardial performance are frequent with the intravenous form of amiodarone and may be due in part to the solvent. While depressed contractility can occur during long-term oral therapy, it is unusual. Despite administration of high doses that would cause serious toxicity if continued long-term, adverse effects are unusual during oral drug-loading regimens, which typically require several weeks. Occasional patients develop nausea during the loading phase, which responds to a decrease in daily dose.

Adverse effects during long-term therapy reflect both the size of daily maintenance doses and the cumulative dose (*i.e.*, to duration of therapy), suggesting that tissue accumulation may be responsible. The most serious adverse effect during chronic amiodarone therapy is pulmonary fibrosis, which can be rapidly progressive and fatal. Underlying lung disease, doses of 400 mg/day or more, and recent pulmonary insults such as pneumonia appear to be risk factors (Dusman *et al.*, 1990). Serial chest X-rays or pulmonary function studies may detect early amiodarone toxicity, but monitoring plasma concentrations has not been useful. With low doses, such as 200 mg/day or less used in

atrial fibrillation, pulmonary toxicity is unusual. Other adverse effects during long-term therapy include corneal microdeposits (which often are asymptomatic), hepatic dysfunction, neuromuscular symptoms (most commonly peripheral neuropathy or proximal muscle weakness), photosensitivity, and hypo- or hyperthyroidism. The multiple effects of amiodarone on thyroid function are discussed further in Chapter 56. Treatment consists of withdrawal of the drug and supportive measures, including corticosteroids, for life-threatening pulmonary toxicity; reduction of dosage may be sufficient if the drug is deemed necessary and the adverse effect is not life-threatening. Despite the marked QT prolongation and bradycardia typical of chronic amiodarone therapy, *torsades de pointes* and other drug-induced tachyarrhythmias are unusual.

Clinical Pharmacokinetics. Amiodarone's oral bioavailability is approximately 30% presumably because of poor absorption. This incomplete bioavailability is important in calculating equivalent dosing regimens when converting from intravenous to oral therapy. The drug is distributed in lipid; *e.g.*, heart-tissue-to-plasma concentration ratios of greater than 20:1 and lipid-to-plasma ratios of greater than 300:1 have been reported. After the initiation of amiodarone therapy, increases in refractoriness, a marker of pharmacological effect, require several weeks to develop. Amiodarone undergoes hepatic metabolism by CYP3A4 to desethyl-amiodarone, a metabolite with pharmacological effects similar to those of the parent drug. When amiodarone therapy is withdrawn from a patient who has been receiving therapy for several years, plasma concentrations decline with a half-life of weeks to months. The mechanism whereby amiodarone and desethyl-amiodarone are eliminated is not well established.

A therapeutic plasma amiodarone concentration range of 0.5 to 2 $\mu\text{g/ml}$ has been proposed. However, efficacy apparently depends as much on duration of therapy as on plasma concentration, and elevated plasma concentrations do not predict toxicity (Dusman *et al.*, 1990). Because of amiodarone's slow accumulation in tissue, a high-dose oral loading regimen (*e.g.*, 800 to 1600 mg/day) usually is administered for several weeks before maintenance therapy is started. Maintenance dose is adjusted based on adverse effects and the arrhythmias being treated. If the presenting arrhythmia is life-threatening, dosages of more than 300 mg/day normally are used unless unequivocal toxicity occurs. On the other hand, maintenance doses of 200 mg/day or less are used if recurrence of an arrhythmia would be tolerated, as in patients with atrial fibrillation. Because of its very slow elimination, amiodarone is administered once daily, and omission of one or two doses during chronic therapy rarely results in recurrence of arrhythmia.

Dosage adjustments are not required in hepatic, renal, or cardiac dysfunction. Amiodarone potentially inhibits the hepatic metabolism or renal elimination of many compounds. Mechanisms identified to date include inhibition of CYP3A4 and CYP2C9 and P-glycoprotein (*see* Chapter 3). Dosages of warfarin, other antiarrhythmics (*e.g.*, flecainide, procainamide, and quinidine), or digoxin usually require reduction during amiodarone therapy.

Bretylum. *Bretylum* is a quaternary ammonium compound that prolongs cardiac action potentials and interferes with reuptake of norepinephrine by sympathetic neurons. In the past, *bretylum* was used to treat ventricular fibrillation and prevent its recurrence; the drug no longer is available.

Cardiac Glycosides. Pharmacological Effects. Digitalis glycosides exert positive inotropic effects and are used widely in heart failure (*see* Chapter 33). Their inotropic action results from increased intracellular Ca^{2+} (Smith, 1988), which also forms the basis for arrhythmias related to cardiac glycoside intoxication. Cardiac glycosides increase phase 4 slope (*i.e.*, increase the rate of automaticity), especially if $[\text{K}]_o$ is low. These drugs (*e.g.*, digoxin) also exert prominent vagotonic actions, resulting in inhibition of Ca^{2+} currents in the AV node and activation of acetylcholine-mediated K^+ currents in the atrium. Thus the major "indirect" electrophysiological effects of cardiac glycosides are hyperpolarization, shortening of atrial action potentials, and increases in AV nodal refractoriness. The latter action accounts for the utility of digitalis in terminating re-entrant arrhythmias involving the AV node and in controlling ventricular response in patients with atrial fibrillation. Cardiac glycosides may be especially useful in the latter situation because many such patients have heart failure, which can be exacerbated by other AV nodal blocking drugs such as Ca^{2+} channel blockers or β adrenergic receptor antagonists. However, sympathetic drive is increased markedly in many patients with advanced heart failure, so digitalis is not very effective in decreasing the rate; on the other hand, even a modest decrease in rate can ameliorate heart failure. Similarly, in other conditions in which high sympathetic tone drives rapid atrioventricular conduction (*e.g.*, chronic lung disease and thyrotoxicosis), digitalis therapy may be only marginally effective in slowing the rate. In heart transplant patients, in whom innervation has been ablated, cardiac glycosides are ineffective for rate control. Increased sympathetic activity and hypoxia can potentiate digitalis-induced changes in automaticity and DADs, thus increasing the risk of digitalis toxicity. A further complicating feature in thyrotoxicosis is increased digoxin clearance. The major ECG effects of cardiac glycosides are PR prolongation and a nonspecific alteration in ventricular repolarization

(manifested by depression of the ST segment), whose underlying mechanism is not well understood.

Adverse Effects. Because of the low therapeutic index of cardiac glycosides, their toxicity is a common clinical problem (*see* Chapter 33). Arrhythmias, nausea, disturbances of cognitive function, and blurred or yellow vision are the usual manifestations. Elevated serum concentrations of digitalis, hypoxia (*e.g.*, owing to chronic lung disease), and electrolyte abnormalities (*e.g.*, hypokalemia, hypomagnesemia, and hypercalcemia) predispose patients to digitalis-induced arrhythmias. While digitalis intoxication can cause virtually any arrhythmia, certain types of arrhythmias are characteristic. Arrhythmias that should raise a strong suspicion of digitalis intoxication are those in which DAD-related tachycardias occur along with impairment of sinus node or AV nodal function. Atrial tachycardia with AV block is classic, but ventricular bigeminy (sinus beats alternating with beats of ventricular origin), “bidirectional” ventricular tachycardia (a very rare entity), AV junctional tachycardias, and various degrees of AV block also can occur. With severe intoxication (*e.g.*, with suicidal ingestion), severe hyperkalemia owing to poisoning of Na^+, K^+ -ATPase and profound bradyarrhythmias, which may be unresponsive to pacing therapy, are seen. In patients with elevated serum digitalis levels, the risk of precipitating ventricular fibrillation by DC cardioversion probably is increased; in those with therapeutic blood levels, DC cardioversion can be used safely.

Minor forms of cardiac glycoside intoxication may require no specific therapy beyond monitoring cardiac rhythm until symptoms and signs of toxicity resolve. Sinus bradycardia and AV block often respond to intravenous atropine, but the effect is transient. Mg^{2+} has been used successfully in some cases of digitalis-induced tachycardia. Any serious arrhythmia should be treated with antidigoxin Fab fragments (DIGIBIND), which are highly effective in binding digoxin and digitoxin and greatly enhance their renal excretion (*see* Chapter 33). Serum glycoside concentrations rise markedly with antidigitalis antibodies, but these represent bound (pharmacologically inactive) drug. Temporary cardiac pacing may be required for advanced sinus node or AV node dysfunction. Digitalis exerts direct arterial vasoconstrictor effects, which can be especially deleterious in patients with advanced atherosclerosis who receive intravenous drug; mesenteric and coronary ischemia have been reported.

Clinical Pharmacokinetics. The most commonly used digitalis glycoside in the United States is *digoxin* (LANOXIN), although *digitoxin* (various generic preparations) also is used for chronic oral therapy. Digoxin tablets are incompletely (75%) bioavailable, but capsules are more than 90% bioavailable. In some patients, intestinal microflora may metabolize digoxin, markedly reducing bioavailability. In

these patients, higher than usual doses are required for clinical efficacy; toxicity is a serious risk if antibiotics such as *tetracycline* or erythromycin are administered because these drugs can destroy intestinal microflora. Inhibition of P-glycoprotein (*see* below) also may play a role. Digoxin is 20% to 30% protein-bound. The antiarrhythmic effects of digoxin can be achieved with intravenous or oral therapy. However, digoxin undergoes relatively slow distribution to effector site(s); therefore, even with intravenous therapy, there is a lag of several hours between drug administration and the development of measurable antiarrhythmic effects such as PR-interval prolongation or slowing of the ventricular rate in atrial fibrillation. To avoid intoxication, a loading dose of approximately 1 to 1.5 mg digoxin is administered over 24 hours. Measurement of postdistribution serum digoxin concentration and adjustment of the daily dose (0.125 to 0.375 mg) to maintain concentrations of 0.5 to 2 ng/ml are useful during chronic digoxin therapy (Table 34–5). Some patients may require and tolerate higher concentrations, but with an increased risk of adverse effects.

DIGOXIN

DIGITOXIN

The elimination half-life of digoxin ordinarily is approximately 36 hours, so maintenance doses are administered once daily. Renal elimination of unchanged drug accounts for less than 80% of digoxin elimination. Digoxin doses should be reduced (or dosing interval increased) and serum concentrations monitored closely in patients with impaired excretion owing to renal failure or in patients who are hypothyroid. Digitoxin undergoes primarily hepatic metabolism and may be useful in patients with fluctuating or advanced renal dysfunction. Digitoxin metabolism is accelerated by drugs such as *phenytoin* and *rifampin* that induce hepatic metabolism (see Chapter 3). Digitoxin's elimination half-life is even longer than that of digoxin (about 7 days); it is highly protein-bound, and its therapeutic range is 10 to 30 ng/ml.

Amiodarone, quinidine, verapamil, diltiazem, *cyclosporine*, *itraconazole*, propafenone, and flecainide decrease digoxin clearance, likely by inhibiting P-glycoprotein, the major route of digoxin elimination (Fromm *et al.*, 1999). New steady-state digoxin concentrations are approached after 4 to 5 half-lives, *i.e.*, in about a week. Digitalis toxicity results so often with quinidine or amiodarone that it is routine to decrease the dose of digoxin if these drugs are started. In all cases, digoxin concentrations should be measured regularly and the dose adjusted if necessary. Hypokalemia, which can be caused by many drugs (*e.g.*, diuretics, *amphotericin B*, and corticosteroids), will potentiate digitalis-induced arrhythmias.

Disopyramide. *Disopyramide* (NORPACE, others) exerts electrophysiological effects very similar to those of quinidine, but the drugs have different adverse effect profiles (Morady *et al.*, 1982). Disopyramide is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or ventricular fibrillation. Disopyramide is prescribed as a racemate. Its structure is given below.

Pharmacological Actions and Adverse Effects. The *in vitro* electrophysiological actions of *S*-(+)-disopyramide are similar to those of quinidine. The *R*-(-)-enantiomer produces similar Na⁺ channel block but does not prolong cardiac

action potentials. Unlike quinidine, racemic disopyramide is not an α adrenergic receptor antagonist, but it does exert prominent anticholinergic actions that account for many of its adverse effects. These include precipitation of glaucoma, constipation, dry mouth, and urinary retention; the latter is most common in males with prostatism but can occur in females. Disopyramide commonly depresses contractility, which can precipitate heart failure (Podrid *et al.*, 1980), and also can cause *torsades de pointes*.

Clinical Pharmacokinetics. Disopyramide is well absorbed. Binding to plasma proteins is concentration dependent, so a small increase in total concentration may represent a disproportionately larger increase in free drug concentration (Lima *et al.*, 1981). Disopyramide is eliminated by both hepatic metabolism (to a weakly active metabolite) and renal excretion of unchanged drug. The dose should be reduced in patients with renal dysfunction. Higher than usual dosages may be required in patients receiving drugs that induce hepatic metabolism, such as phenytoin.

Dofetilide. *Dofetilide* (TIKOSYN) is a potent and “pure” I_{Kr} blocker. As a result of this specificity, it has virtually no extracardiac pharmacological effects. Dofetilide is effective in maintaining sinus rhythm in patients with atrial fibrillation. In the DIAMOND studies (Torp-Pedersen *et al.*, 1999), dofetilide did not affect mortality in patients with advanced heart failure or in those convalescing from acute myocardial infarction. Dofetilide currently is available through a restricted distribution system that includes only physicians, hospitals, and other institutions that have received special educational programs covering proper dosing and treatment initiation.

Adverse Effects. *Torsades de pointes* occurred in 1% to 3% of patients in clinical trials where strict exclusion criteria (*e.g.*, hypokalemia) were applied and continuous ECG monitoring was used to detect marked QT prolongation in the hospital. The incidence of this adverse effect during more widespread use of the drug, marketed since 2000, is unknown. Other adverse effects were no more common than with placebo during premarketing clinical trials.

Clinical Pharmacokinetics. Most of a dose of dofetilide is excreted unchanged by the kidneys. In patients with mild to moderate renal failure, decreases in dosage based

on creatinine clearance are required to minimize the risk of *torsades de pointes*. The drug should not be used in patients with advanced renal failure or with inhibitors of renal cation transport. Dofetilide also undergoes minor hepatic metabolism.

Flecainide. The effects of flecainide (TAMBOCOR) therapy are thought to be attributable to the drug's very long τ_{recovery} from Na^+ channel block (Roden and Woosley, 1986a). In the CAST study, flecainide increased mortality in patients convalescing from myocardial infarction (CAST Investigators, 1989). However, it continues to be approved for the maintenance of sinus rhythm in patients with supraventricular arrhythmias, including atrial fibrillation, in whom structural heart disease is absent (Anderson *et al.*, 1989; Henthorn *et al.*, 1991).

Pharmacological Effects. Flecainide blocks Na^+ current and delayed rectifier K^+ current (I_{Kr}) *in vitro* at similar concentrations, 1 to 2 μM (Ikeda *et al.*, 1985; Follmer and Colatsky, 1990). It also blocks Ca^{2+} currents *in vitro*. Action potential duration is shortened in Purkinje cells, probably owing to block of late-opening Na^+ channels, but prolonged in ventricular cells, probably owing to block of delayed rectifier current (Ikeda *et al.*, 1985). Flecainide does not cause EADs *in vitro* or *torsades de pointes*. In atrial tissue, flecainide disproportionately prolongs action potentials at fast rates, an especially desirable antiarrhythmic drug effect; this effect contrasts with that of quinidine, which prolongs atrial action potentials to a greater extent at slower rates (Wang *et al.*, 1990). Flecainide prolongs the duration of PR, QRS, and QT intervals even at normal heart rates.

Adverse Effects. Flecainide produces few subjective complaints in most patients; dose-related blurred vision is the most common noncardiac adverse effect. It can exacerbate congestive heart failure in patients with depressed left ventricular performance. The most serious adverse effects are provocation or exacerbation of potentially lethal arrhythmias. These include acceleration of ventricular rate in patients with atrial flutter, increased frequency of episodes of re-entrant ventricular tachycardia, and increased mortality in patients convalescing from myocardial infarction (Crijns *et al.*, 1988; CAST Investigators, 1989; Ranger *et al.*, 1989). As discussed earlier, it is like-

ly that all these effects can be attributed to Na^+ channel block. Flecainide also can cause heart block in patients with conduction system disease.

Clinical Pharmacokinetics. Flecainide is well absorbed. The elimination half-life is shorter with urinary acidification (10 hours) than with urinary alkalization (17 hours), but it is nevertheless sufficiently long to allow dosing twice daily (Table 34–5). Elimination occurs by both renal excretion of unchanged drug and hepatic metabolism to inactive metabolites. The latter is mediated by the polymorphically distributed enzyme CYP2D6 (Gross *et al.*, 1989) (*see* Chapter 3). However, even in patients in whom this pathway is absent because of genetic polymorphism or inhibition by other drugs (*i.e.*, quinidine and fluoxetine), renal excretion ordinarily is sufficient to prevent drug accumulation. In the rare patient with renal dysfunction and lack of active CYP2D6, flecainide may accumulate to toxic plasma concentrations. Flecainide is a racemate, but there are no differences in the electrophysiological effects or disposition kinetics of its enantiomers (Kroemer *et al.*, 1989). Some reports have suggested that plasma flecainide concentrations greater than 1 $\mu\text{g}/\text{ml}$ should be avoided to minimize the risk of flecainide toxicity; however, in susceptible patients, the adverse electrophysiological effects of flecainide therapy can occur at therapeutic plasma concentrations.

Ibutilide. Ibutilide (CORVERT) is an I_{Kr} blocker that in some systems also activates an inward Na^+ current (Murray, 1998). The action potential–prolonging effect of the drug may arise from either mechanism. Ibutilide is administered as a rapid infusion (1 mg over 10 minutes) for the immediate conversion of atrial fibrillation or flutter to sinus rhythm. The drug's efficacy rate is higher in patients with atrial flutter (50% to 70%) than in those with atrial fibrillation (30% to 50%). In atrial fibrillation, the conversion rate is lower in those in whom the arrhythmia has been present for weeks or months compared with those in whom it has been present for days. The major toxicity with ibutilide is *torsades de pointes*, which occurs in up to 6% of patients and requires immediate cardioversion in up to one-third of these. The drug undergoes extensive first-pass metabolism and so is not used orally. It is eliminated by hepatic metabolism and has a half-life of 2 to 12 hours (average of 6 hours).

Lidocaine. Lidocaine (XYLOCAINE) is a local anesthetic that also is useful in the acute intravenous therapy of ventricular arrhythmias. When lidocaine was administered to all patients with suspected myocardial infarction, the incidence of ventricular fibrillation was reduced (Lie *et al.*, 1974). However, survival to hospital discharge tended to be decreased (Hine *et al.*, 1989) perhaps because of lidocaine-exacerbated heart block or congestive heart failure. Therefore, lidocaine no longer is administered routinely to all patients in coronary care units.

Pharmacological Effects. Lidocaine blocks both open and inactivated cardiac Na^+ channels. *In vitro* studies suggest that lidocaine-induced block reflects an increased likelihood that the Na^+ channel protein assumes a nonconducting conformation in the presence of drug (Balser *et al.*, 1996). Recovery from block is very rapid, so lidocaine exerts greater effects in depolarized (*e.g.*, ischemic) and/or rapidly driven tissues. Lidocaine is not useful in atrial arrhythmias possibly because atrial action potentials are so short that the Na^+ channel is in the inactivated state only briefly compared with diastolic (recovery) times, which are relatively long (Snyders *et al.*, 1991). In some studies, lidocaine increased current through inward rectifier channels, but the clinical significance of this effect is not known. Lidocaine can hyperpolarize Purkinje fibers depolarized by low $[\text{K}]_o$ or stretch; the resulting increased conduction velocity may be antiarrhythmic in re-entry.

Lidocaine decreases automaticity by reducing the slope of phase 4 and altering the threshold for excitability. Action potential duration usually is unaffected or is shortened; such shortening may be due to block of the few Na^+ channels that inactivate late during the cardiac action potential. Lidocaine usually exerts no significant effect on PR or QRS duration; QT is unaltered or slightly shortened. The drug exerts little effect on hemodynamic function, although rare cases of lidocaine-associated exacerbations of heart failure have been reported, especially in patients with very poor left ventricular function.

Adverse Effects. When a large intravenous dose of lidocaine is administered rapidly, seizures can occur. When plasma concentrations of the drug rise slowly above the therapeutic range, as may occur during maintenance therapy, tremor, dysarthria, and altered levels of

consciousness are more common. Nystagmus is an early sign of lidocaine toxicity.

Clinical Pharmacokinetics. Lidocaine is well absorbed but undergoes extensive though variable first-pass hepatic metabolism; thus oral use of the drug is inappropriate. In theory, therapeutic plasma concentrations of lidocaine may be maintained by intermittent intramuscular administration, but the intravenous route is preferred (Table 34–5). Lidocaine's metabolites, glycine xylidide (GX) and monoethyl GX, are less potent as Na^+ channel blockers than the parent drug. GX and lidocaine appear to compete for access to the Na^+ channel, suggesting that with infusions during which GX accumulates, lidocaine's efficacy may be diminished (Bennett *et al.*, 1988). With infusions lasting longer than 24 hours, the clearance of lidocaine falls—an effect that has been attributed to competition between parent drug and metabolites for access to hepatic drug-metabolizing enzymes.

Plasma concentrations of lidocaine decline biexponentially after a single intravenous dose, indicating that a multicompartment model is necessary to analyze lidocaine disposition. The initial drop in plasma lidocaine following intravenous administration occurs rapidly, with a half-life of approximately 8 minutes, and represents distribution from the central compartment to peripheral tissues. The terminal elimination half-life, usually approximately 100 to 120 minutes, represents drug elimination by hepatic metabolism. Lidocaine's efficacy depends on maintenance of therapeutic plasma concentrations in the central compartment. Therefore, the administration of a single bolus dose of lidocaine can result in transient arrhythmia suppression that dissipates rapidly as the drug is distributed and concentrations in the central compartment fall. To avoid this distribution-related loss of efficacy, a loading regimen of 3 to 4 mg/kg over 20 to 30 minutes is used—*e.g.*, an initial 100 mg followed by 50 mg every 8 minutes for three doses. Subsequently, stable concentrations can be maintained in plasma with an infusion of 1 to 4 mg/min, which replaces drug removed by hepatic metabolism. The time to steady-state lidocaine concentrations is approximately 8 to 10 hours. If the maintenance infusion rate is too low, arrhythmias may recur hours after the institution of apparently successful therapy. On the other hand, if the rate is too high, toxicity may result. In either case, routine measurement of plasma lidocaine concentration at the time of expected steady state is useful in adjusting maintenance infusion rate.

In heart failure, the central volume of distribution is decreased, so the total loading dose should be decreased. Since lidocaine clearance also is decreased, the rate of the maintenance infusion should be decreased. Lidocaine

clearance also is reduced in hepatic disease, during treatment with *cimetidine* or β -blockers, and during prolonged infusions (Nies *et al.*, 1976). Frequent measurement of plasma lidocaine concentration and dose adjustment to ensure that plasma concentrations remain within the therapeutic range (1.5 to 5 $\mu\text{g}/\text{ml}$) are necessary to minimize toxicity in these settings. Lidocaine is bound to the acute-phase reactant α_1 -acid glycoprotein. Diseases such as acute myocardial infarction are associated with increases in α_1 -acid glycoprotein and protein binding and hence a decreased proportion of free drug. These findings may explain why some patients require and tolerate higher than usual total plasma lidocaine concentrations to maintain antiarrhythmic efficacy (Kessler *et al.*, 1984).

Mexiletine and Tocainide. *Mexiletine* (MEXITIL) and *tocainide* (TONOCARD; no longer marketed in the United States) are analogs of lidocaine that have been modified to reduce first-pass hepatic metabolism and permit chronic oral therapy (Roden and Woosley, 1986b; Campbell, 1987). Their electrophysiological actions are similar to those of lidocaine. Tremor and nausea, the major dose-related adverse effects, can be minimized by taking the drugs with food. Because tocainide can cause potentially fatal bone marrow aplasia and pulmonary fibrosis, it is used rarely; it is no longer available in the United States.

Mexiletine undergoes hepatic metabolism, which is inducible by drugs such as phenytoin. Mexiletine is approved for treating ventricular arrhythmias; combinations of mexiletine with quinidine or sotalol may increase efficacy while reducing adverse effects. *In vitro* studies and clinical anecdotes have suggested a role for mexiletine (or flecainide) in correcting the molecular defect in the form of congenital long QT syndrome caused by abnormal Na^+ channel inactivation (Shimizu and Antzelevitch, 1997).

Moricizine. *Moricizine* (ETHMOZINE) is a phenothiazine analog with Na^+ channel-blocking properties used in the

chronic treatment of ventricular arrhythmias (Clyne *et al.*, 1992). In a randomized, double-blind trial (CAST II), moricizine increased mortality in patients shortly after a myocardial infarction and did not improve survival during long-term therapy (Cardiac Arrhythmia Suppression Trial II Investigators, 1992). Moricizine undergoes extensive first-pass hepatic metabolism; despite its short elimination half-life, its antiarrhythmic effect can persist for many hours after a single dose, suggesting that some of its metabolites may be active.

Procainamide. Procainamide (PROCAN SR, others) is an analog of the local anesthetic procaine. It exerts electrophysiological effects similar to those of quinidine but lacks quinidine's vagolytic and α adrenergic blocking activity. Procainamide is better tolerated than quinidine when given intravenously. Loading and maintenance intravenous infusions are used in the acute therapy of many supraventricular and ventricular arrhythmias. However, long-term oral treatment is poorly tolerated and often is stopped owing to adverse effects.

Pharmacological Effects. Procainamide is a blocker of open Na^+ channels with an intermediate time constant of recovery from block. It also prolongs cardiac action potentials in most tissues probably by blocking outward K^+ current(s). Procainamide decreases automaticity, increases refractory periods, and slows conduction. Its major metabolite, *N*-acetyl procainamide, lacks the Na^+ channel-blocking activity of the parent drug but is equipotent in prolonging action potentials. Since the plasma concentrations of *N*-acetyl procainamide often exceed those of procainamide, increased refractoriness and QT prolongation during chronic procainamide therapy may be partly attributable to the metabolite. However, it is the parent drug that slows conduction and produces QRS-interval prolongation. Although hypotension may occur at high plasma concentrations, this effect usually is attribut-

able to ganglionic blockade rather than to any negative inotropic effect, which is minimal.

Adverse Effects. Hypotension and marked slowing of conduction are major adverse effects of high concentrations (>10 $\mu\text{g/ml}$) of procainamide, especially during intravenous use. Dose-related nausea is frequent during oral therapy and may be attributable in part to high plasma concentrations of *N*-acetyl procainamide. *Torsades de pointes* can occur, particularly when plasma concentrations of *N*-acetyl procainamide rise to greater than 30 $\mu\text{g/ml}$. Procainamide produces potentially fatal bone marrow aplasia in 0.2% of patients; the mechanism is not known, but high plasma drug concentrations are not suspected.

During long-term therapy, most patients will develop biochemical evidence of the drug-induced lupus syndrome, such as circulating antinuclear antibodies (Woosley *et al.*, 1978). Therapy need not be interrupted merely because of the presence of antinuclear antibodies. However, 25% to 50% of patients eventually develop symptoms of the lupus syndrome; common early symptoms are rash and small-joint arthralgias. Other symptoms of lupus, including pericarditis with tamponade, can occur, although renal involvement is unusual. The lupuslike symptoms resolve on cessation of therapy or during treatment with *N*-acetyl procainamide (*see below*).

Clinical Pharmacokinetics. Procainamide is eliminated rapidly ($t_{1/2} = 3$ to 4 hours) by both renal excretion of unchanged drug and hepatic metabolism. The major pathway for hepatic metabolism is conjugation by *N*-acetyl transferase, whose activity is determined genetically, to form *N*-acetyl procainamide. *N*-Acetyl procainamide is eliminated by renal excretion ($t_{1/2} = 6$ to 10 hours) and is not significantly converted back to procainamide. Because of the relatively rapid elimination rates of both the parent drug and its major metabolite, oral procainamide usually is administered as a slow-release formulation. In patients with renal failure, procainamide and/or *N*-acetyl procainamide can accumulate to potentially toxic plasma concentrations. Reduction of procainamide dose and dosing frequency and monitoring of plasma concentrations of both compounds are required in this situation. Because the parent drug and metabolite exert different pharmacological effects, the practice of using the sum of their concentrations to guide therapy is inappropriate.

In individuals who are “slow acetylators,” the procainamide-induced lupus syndrome develops more often and earlier during treatment than among rapid acetylators (Woosley *et al.*, 1978). In addition, the symptoms of procainamide-induced lupus resolve during treatment with *N*-acetyl procainamide. Both these findings support results of *in vitro* studies suggesting that it is chronic

exposure to the parent drug (or an oxidative metabolite) that results in the lupus syndrome; these findings also provided one rationale for the further development of *N*-acetyl procainamide and its analogs as antiarrhythmic agents (Roden, 1993).

Propafenone. *Propafenone* (RYTHMOL) is an Na^+ channel blocker with a relatively slow time constant for recovery from block (Funck-Brentano *et al.*, 1990). Some data suggest that, like flecainide, propafenone also blocks K^+ channels. Its major electrophysiological effect is to slow conduction in fast-response tissues. The drug is prescribed as a racemate; while the enantiomers do not differ in their Na^+ channel-blocking properties, *S*-(+)-propafenone is a β adrenergic receptor antagonist *in vitro* and in some patients. Propafenone prolongs PR and QRS durations. Chronic therapy with oral propafenone is used to maintain sinus rhythm in patients with supraventricular tachycardias, including atrial fibrillation; like other Na^+ channel blockers, it also can be used in ventricular arrhythmias, but with only modest efficacy.

Adverse effects during propafenone therapy include acceleration of ventricular response in patients with atrial flutter, increased frequency or severity of episodes of re-entrant ventricular tachycardia, exacerbation of heart failure, and the adverse effects of β adrenergic blockade, such as sinus bradycardia and bronchospasm (*see above* and Chapter 10).

Clinical Pharmacokinetics. Propafenone is well absorbed and is eliminated by both hepatic and renal routes. The activity of CYP2D6, an enzyme that functionally is absent in approximately 7% of Caucasians and African-Americans (*see Chapter 3*), is a major determinant of plasma propafenone concentration and thus the clinical action of the drug. In most subjects (“extensive metabolizers”), propafenone undergoes extensive first-pass hepatic metabolism to 5-hydroxy propafenone, a metabolite equipotent to propafenone as an Na^+ channel blocker but much less potent as a β adrenergic receptor antagonist. A second metabolite, *N*-desalkyl propafenone, is formed by non-CYP2D6-mediated metabolism and is a less potent blocker of Na^+ channels and β adrenergic receptors. CYP2D6-mediated metabolism of propafenone is saturable, so small increases in dose can increase plasma propafenone concentration dis-

proportionately. In “poor metabolizer” subjects, in whom functional CYP2D6 is absent, first-pass hepatic metabolism is much less than in extensive metabolizers, and plasma propafenone concentrations will be much higher after an equal dose. The incidence of adverse effects during propafenone therapy is significantly higher in poor metabolizers.

CYP2D6 activity can be inhibited markedly by a number of drugs, including quinidine and fluoxetine. In extensive metabolizer subjects receiving such drugs or in poor metabolizer subjects, plasma propafenone concentrations of more than 1 $\mu\text{g/ml}$ are associated with clinical effects of β adrenergic receptor blockade, such as reduction of exercise heart rate (Lee *et al.*, 1990). It is recommended that dosage in patients with moderate to severe liver disease should be reduced to approximately 20% to 30% of the usual dose, with careful monitoring. It is not known if propafenone doses must be decreased in patients with renal disease. A slow-release formulation allows twice-daily dosing.

Quinidine. As early as the 18th century, the bark of the cinchona plant was used to treat “rebellious palpitations” (Levy and Azoulay, 1994). Studies in the early 20th century identified quinidine, a diastereomer of the antimalarial quinine, as the most potent of the antiarrhythmic substances extracted from the cinchona plant, and by the 1920s, quinidine was used as an antiarrhythmic agent. Quinidine is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or ventricular fibrillation (Grace and Camm, 1998).

Pharmacological Effects. Quinidine (various generic preparations) blocks Na^+ current and multiple cardiac K^+ currents. It is an open-state blocker of Na^+ channels, with a time constant of recovery in the intermediate (~ 3 seconds) range; as a consequence, QRS duration increases modestly, usually by 10% to 20%, at therapeutic dosages. At therapeutic concentrations, quinidine commonly prolongs the QT interval up to 25%, but the effect is highly

variable. At concentrations as low as 1 μM , quinidine blocks Na^+ current and the rapid component of delayed rectifier (I_{Kr}); higher concentrations block the slow component of delayed rectifier, inward rectifier, transient outward current, and L-type Ca^{2+} current.

Quinidine’s Na^+ channel-blocking properties result in an increased threshold for excitability and decreased automaticity. As a consequence of its K^+ channel-blocking actions, quinidine prolongs action potentials in most cardiac cells, most prominently at slow heart rates. In some cells, such as midmyocardial cells and Purkinje cells, quinidine consistently elicits EADs at slow heart rates, particularly when $[\text{K}]_o$ is low (Priori *et al.*, 1999). Quinidine prolongs refractoriness in most tissues probably as a result of both prolongation of action potential duration and Na^+ channel blockade.

In intact animals and humans, quinidine also produces α adrenergic receptor blockade and vagal inhibition. Thus the intravenous use of quinidine is associated with marked hypotension and sinus tachycardia. Quinidine’s vagolytic effects tend to inhibit its direct depressant effect on AV nodal conduction, so the effect of drug on the PR interval is variable. Moreover, quinidine’s vagolytic effect can result in increased AV nodal transmission of atrial tachycardias such as atrial flutter (Table 34–1).

Adverse Effects. Noncardiac. Diarrhea is the most common adverse effect during quinidine therapy, occurring in 30% to 50% of patients; the mechanism is not known. Diarrhea usually occurs within the first several days of quinidine therapy but can occur later. Diarrhea-induced hypokalemia may potentiate *torsades de pointes* due to quinidine.

A number of immunological reactions can occur during quinidine therapy. The most common is thrombocytopenia, which can be severe but which resolves rapidly with discontinuation of the drug. Hepatitis, bone marrow depression, and lupus syndrome occur rarely. None of these effects is related to elevated plasma quinidine concentrations.

Quinidine also can produce cinchonism, a syndrome that includes headache and tinnitus. In contrast to other adverse responses to quinidine therapy, cinchonism usually is related to elevated plasma quinidine concentrations and can be managed by dose reduction.

Cardiac. Between 2% and 8% of patients who receive quinidine therapy will develop marked QT-interval prolongation and *torsades de pointes*. In contrast to effects of sotalolol, *N*-acetyl procainamide, and many other drugs, quinidine-associated *torsades de pointes* generally occurs at therapeutic or even subtherapeutic plasma concentrations. The reasons for individual susceptibility to this adverse effect are not known.

At high plasma concentrations of quinidine, marked Na^+ channel block can occur, with resulting ventricular tachycardia. This adverse effect occurs when very high doses of quinidine are used to try to convert atrial fibrillation to normal rhythm; this aggressive approach to quinidine dosing has been abandoned, and quinidine-induced ventricular tachycardia is unusual.

Quinidine can exacerbate heart failure or conduction system disease. However, in most patients with congestive heart failure, quinidine is well tolerated, perhaps because of its vasodilating actions.

Clinical Pharmacokinetics. Quinidine is well absorbed and is 80% bound to plasma proteins, including albumin and, like lidocaine, the acute-phase reactant α_1 -acid glycoprotein. As with lidocaine, greater than usual doses (and total plasma quinidine concentrations) may be required to maintain therapeutic concentrations of free quinidine in high-stress states such as acute myocardial infarction (Kessler *et al.*, 1984). Quinidine undergoes extensive hepatic oxidative metabolism, and approximately 20% is excreted unchanged by the kidneys. One metabolite, 3-hydroxyquinidine, is nearly as potent as quinidine in blocking cardiac Na^+ channels and prolonging cardiac action potentials. Concentrations of unbound 3-hydroxyquinidine equal to or exceeding those of quinidine are tolerated by some patients. Other metabolites are less potent than quinidine, and their plasma concentrations are lower; thus they are unlikely to contribute significantly to the clinical effects of quinidine.

There is substantial individual variability in the range of dosages required to achieve therapeutic plasma concentrations of 2 to 5 $\mu\text{g}/\text{ml}$. Some of this variability may be assay-dependent because not all assays exclude quinidine metabolites. In patients with advanced renal disease or congestive heart failure, quinidine clearance is decreased only modestly. Thus, dosage requirements in these patients are similar to those in other patients.

Drug Interactions. Quinidine is a potent inhibitor of CYP2D6. As a result, the administration of quinidine to patients receiving drugs that undergo extensive CYP2D6-mediated metabolism may result in altered drug effects owing to accumulation of parent drug and failure of metabolite formation. For example, inhibition of CYP2D6-mediated metabolism of *codeine* to its active metabolite *morphine* results in decreased analgesia. On the other hand, inhibition of CYP2D6-mediated metabolism of propafenone results in elevated plasma propafenone concentrations and increased β adrenergic receptor blockade. Quinidine reduces the clearance of digoxin and digitoxin; inhibition of P-glycoprotein-mediated digoxin transport has been implicated (Fromm *et al.*, 1999).

Quinidine metabolism is induced by drugs such as *phenobarbital* and phenytoin (Data *et al.*, 1976). In patients receiving these agents, very high doses of quinidine may be required to achieve therapeutic concentrations. If therapy with the inducing agent is then stopped, quinidine concentrations may rise to very high levels, and its dosage must be adjusted downward. Cimetidine and verapamil also elevate plasma quinidine concentrations, but these effects usually are modest.

Sotalol. Sotalol (BETAPACE, BETAPACE AF) is a nonselective β adrenergic receptor antagonist that also prolongs cardiac action potentials by inhibiting delayed rectifier and possibly other K^+ currents (Hohnloser and Woosley, 1994). Sotalol is prescribed as a racemate; the L-enantiomer is a much more potent β adrenergic receptor antagonist than the D-enantiomer, but the two are equipotent as K^+ channel blockers. Its structure is shown below:

In the United States, racemic sotalol is approved for use in patients with both ventricular tachyarrhythmias and atrial fibrillation or flutter. Clinical trials suggest that it is at least as effective as most Na^+ channel blockers in ventricular arrhythmias (Mason, 1993).

Sotalol prolongs action potential duration throughout the heart and QT interval on the ECG. It decreases automaticity, slows AV nodal conduction, and prolongs AV refractoriness by blocking both K^+ channels and β adrenergic receptors, but it exerts no effect on conduction velocity in fast-response tissue. Sotalol causes EADs and triggered activity *in vitro* and can cause *torsades de pointes*, especially when the serum K^+ concentration is low. Unlike the situation with quinidine, the incidence of *torsades de pointes* seems to depend on the dose of sotalol; indeed, *torsades de pointes* is the major toxicity with sotalol overdose. Occasional cases occur at low dosages, often in patients with renal dysfunction, because sotalol is eliminated by renal excretion of unchanged drug. The other adverse effects of sotalol therapy are those associated with β adrenergic receptor blockade (*see* above and Chapter 10).

Magnesium. The intravenous administration of 1 to 2 g MgSO_4 reportedly is effective in preventing recurrent episodes of *torsades de pointes*, even if the serum Mg^{2+} concentration is normal (Tzivoni *et al.*, 1988). However, con-

trolled studies of this effect have not been performed. The mechanism of action is unknown because the QT interval is not shortened; an effect on the inward current, possibly a Ca^{2+} current, responsible for the triggered upstroke arising from EADs (*black arrow*, Figure 34–6B) is possible. Intravenous Mg^{2+} also has been used successfully in arrhythmias related to digitalis intoxication. Large placebo-controlled trials of intravenous magnesium to improve outcome in acute myocardial infarction have yielded conflicting results (Woods and Fletcher, 1994; ISIS-4 Collaborative Group, 1995). While oral Mg^{2+} supplements may be useful in preventing hypomagnesemia, there is no evidence that chronic Mg^{2+} ingestion exerts a direct antiarrhythmic action.

DRUG THERAPY FOR HYPERCHOLESTEROLEMIA AND DYSLIPIDEMIA

Robert W. Mahley and Thomas P. Bersot

Hyperlipidemia is a major cause of atherosclerosis and atherosclerosis-associated conditions, such as coronary heart disease (CHD), ischemic cerebrovascular disease, and peripheral vascular disease. Although the incidence of these atherosclerosis-related events has declined in the United States, these conditions still account for the majority of morbidity and mortality among middle-aged and older adults. The incidence and absolute number of annual events will likely increase over the next decade because of the epidemic of obesity and the aging of the U.S. population. Dyslipidemias, including hyperlipidemia (hypercholesterolemia) and low levels of high-density-lipoprotein cholesterol (HDL-C), are major causes of increased atherogenic risk; both genetic disorders and lifestyle (sedentary behavior and diets high in calories, saturated fat, and cholesterol) contribute to the dyslipidemias seen in developed countries around the world. This chapter focuses on drug therapy: 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors—the statins—which are the most effective and best tolerated drugs currently in use for treating dyslipidemia, bile acid-binding resins, nicotinic acid (*niacin*), fibric acid derivatives, and the cholesterol absorption inhibitor *ezetimibe*. Despite the efficacy of drug therapy, alterations in lifestyle have a far greater potential for reducing vascular disease risk and at a lower cost.

Recognition that dyslipidemia is a risk factor has led to the development of drugs that reduce cholesterol levels. These drugs provide benefit in patients across the entire spectrum of cholesterol levels, primarily by reducing levels of low-density lipoprotein cholesterol (LDL-C). In well-controlled clinical trials, fatal and nonfatal CHD events and strokes were reduced by as much as 30% to 40% (Scandinavian Simvastatin Survival Study, 1994;

Shepherd *et al.*, 1995; The Long-Term Intervention with Pravastatin in Ischaemic Disease [LIPID] Study Group, 1998; Heart Protection Study Collaborative Group, 2002; Heart Protection Study Collaborative Group, 2003; Law *et al.*, 2003).

Clinical trial data support extending lipid-lowering therapy to high-risk patients whose major lipid risk factor is a reduced plasma level of HDL-C, even if their LDL-C level does not meet the existing threshold values for initiating hypolipidemic drug therapy (The Expert Panel, 2002). In patients with low HDL-C and average LDL-C levels, appropriate drug therapy reduced CHD endpoint events by 20% to 35% (Heart Protection Study Collaborative Group, 2002; Downs *et al.*, 1998; Rubins *et al.*, 1999). Since two-thirds of patients with CHD in the United States have low HDL-C levels (<40 mg/dl), it is important to include low-HDL patients in management guidelines for dyslipidemia, even if their LDL-C levels are in the normal range (Bersot *et al.*, 2003).

Severe hypertriglyceridemia (*i.e.*, triglyceride levels of >1000 mg/dl) requires therapy to prevent pancreatitis. Moderately elevated triglyceride levels (150 to 400 mg/dl) also are of concern because they often occur as part of the metabolic syndrome, which includes insulin resistance, obesity, hypertension, low HDL-C levels, and substantially increased CHD risk. The atherogenic dyslipidemia in patients with the metabolic syndrome is characterized by moderately elevated triglycerides, low HDL-C levels, and lipid-depleted LDL (sometimes referred to as “small, dense LDL”) (Reaven, 2002; Reaven, 2003; Grundy *et al.*, 2004a; Grundy *et al.*, 2004c). The metabolic syndrome affects ~25% of adults and is common in CHD patients; hence, identification of moderate hypertriglyceridemia in a patient, even if the total cholesterol level is normal, should trigger

an evaluation to identify this disorder (Ford *et al.*, 2002; The Expert Panel, 2002).

Hyperlipidemia (elevated levels of triglycerides or cholesterol) and reduced HDL-C levels occur as a consequence of several interrelated factors that affect the concentrations of the various plasma lipoproteins. These factors may be lifestyle or behavioral (*e.g.*, diet or exercise), genetic (*e.g.*, mutations in a gene regulating lipoprotein levels), or metabolic (*e.g.*, diabetes mellitus or other conditions that influence plasma lipoprotein metabolism). An understanding of these factors requires a brief description of lipoprotein metabolism. A more detailed description can be found elsewhere (Mahley *et al.*, 2003).

PLASMA LIPOPROTEIN METABOLISM

Lipoproteins are macromolecular assemblies that contain lipids and proteins. The lipid constituents include free and esterified cholesterol, triglycerides, and phospholipids. The protein components, known as apolipoproteins or apoproteins, provide structural stability to the lipoproteins, and also may function as ligands in lipoprotein–receptor interactions or as cofactors in enzymatic processes that regulate lipoprotein metabolism. In all spherical lipoproteins, the most water-insoluble lipids (cholesteryl esters and triglycerides) are core components, and the more polar, water-soluble components (apoproteins, phospholipids, and unesterified cholesterol) are located on the surface. The major classes of lipoproteins and a number of their properties are presented in Table 35–1.

Table 35–2 describes apoproteins that have well-defined roles in plasma lipoprotein metabolism. These apolipoproteins include apolipoprotein (apo) A-I, apoA-II, apoA-IV, apoA-V, apoB-100, apoB-48, apoC-I, apoC-II, apoC-III, apoE, and apo(a). Except for apo(a), the lipid-binding regions of all apoproteins contain structural features called amphipathic helices that interact with the polar, hydrophilic lipids (such as surface phospholipids) and with the aqueous plasma environment in which the lipoproteins circulate. Differences in the non-lipid-binding regions determine the functional specificities of the apolipoproteins.

Chylomicrons. Chylomicrons are synthesized from the fatty acids of dietary triglycerides and cholesterol absorbed from the small intestine by epithelial cells.

Intestinal cholesterol and plant sterol absorption is mediated by Niemann-Pick C1-like 1 protein (NPC1L1), which appears to be

the target of ezetimibe, a cholesterol absorption inhibitor (Altmann *et al.*, 2004). Plant sterols, unlike cholesterol, are not normally esterified and incorporated into chylomicrons. Two ATP-binding cassette (ABC) half-transporters, ABCG5 and ABCG8, which reside on the apical plasma membrane of enterocytes, channel plant sterols back into the intestinal lumen, preventing their assimilation into the body (Graf *et al.*, 2002; Repa *et al.*, 2002). Patients with the autosomal recessive disorder sitosterolemia have mutations in either of the genes that encode ABCG5 and ABCG8. As a result, they absorb unusually large amounts of plant sterols, fail to excrete dietary sterols into the bile, and thus accumulate plant sterols in the blood and tissues; this accumulation is associated with tendon and subcutaneous xanthomas and a markedly increased risk of premature CHD (Berge *et al.*, 2000; Lee *et al.*, 2001). Triglyceride synthesis is regulated by diacylglycerol transferase, an enzyme that regulates triglyceride synthesis in many tissues (Buhman *et al.*, 2001). After their synthesis in the endoplasmic reticulum, triglycerides are transferred by microsomal triglyceride transfer protein (MTP) to the site where newly synthesized apoB-48 is available to form chylomicrons.

Dietary cholesterol is esterified by the type 2 isozyme of acyl coenzyme A:cholesterol acyltransferase (ACAT). ACAT-2 is found in the intestine and in the liver, where cellular free cholesterol is esterified before triglyceride-rich lipoproteins [chylomicrons and very-low-density lipoproteins (VLDL)] are assembled. In the intestine, ACAT-2 regulates the absorption of dietary cholesterol, and thus may be a potential pharmacological target for reducing blood cholesterol levels (Buhman *et al.*, 2001). Another ACAT enzyme, ACAT-1, is expressed in macrophages, including foam cells, adrenocortical cells, and skin sebaceous glands. Although ACAT-1 esterifies cholesterol and promotes foam-cell development, ACAT-1 knockout mice do not have reduced susceptibility to atherosclerosis (Buhman *et al.*, 2001).

Chylomicrons, the largest plasma lipoproteins, are the only lipoproteins that float to the top of a tube of plasma that has been allowed to stand undisturbed for 12 hours. The buoyancy of chylomicrons reflects their high fat content (98% to 99%), of which 85% is dietary triglyceride. In chylomicrons, the ratio of triglycerides to cholesterol is ~10 or greater. In normolipidemic individuals, chylomicrons are present in plasma for 3 to 6 hours after a fat-containing meal has been ingested. After a fast of 10 to 12 hours, no chylomicrons remain.

The apolipoproteins of chylomicrons include some that are synthesized by intestinal epithelial cells (apoB-48, apoA-I, and apoA-IV), and others acquired from HDL (apoE and apoC-I, C-II, and C-III) after chylomicrons have been secreted into the lymph and enter the plasma (Table 35–2). The apoB-48 of chylomicrons is one of two forms of apoB present in lipoproteins. ApoB-48, synthesized only by intestinal epithelial cells, is unique to chylomicrons. ApoB-100 is synthesized by the liver and incorporated into VLDL and intermediate-density lipoproteins (IDL) and LDL, which are products of VLDL catabolism. The apparent molecular weight of apoB-48 is 48% that of apoB-100, which accounts for the name “apoB-48.” The amino acid sequence of apoB-48 is identical to the first 2152 of the 4536 residues of apoB-100. An RNA-editing mechanism unique to the intestine accounts for the premature termination of the translation of the apoB-100 mRNA (Anant and Davidson, 2001). ApoB-48 lacks the portion of the sequence of apoB-100 that allows apoB-100 to bind to the LDL receptor, so apoB-48 functions primarily as a structural component of chylomicrons.

Table 35-1**Characteristics of Plasma Lipoproteins**

LIPOPROTEIN CLASS	DENSITY OF FLOTATION, G/ML	MAJOR LIPID CONSTITUENT	TG:CHOL RATIO	SIGNIFICANT APOPROTEINS	SITE OF SYNTHESIS	MECHANISM(S) OF CATABOLISM
Chylomicrons and remnants	<<1.006	Dietary triglycerides and cholesterol	10:1	B-48, E, A-I, A-IV, C-I, C-II, C-III	Intestine	Triglyceride hydrolysis by LPL ApoE-mediated remnant uptake by liver
VLDL	<1.006	“Endogenous” or hepatic triglycerides	5:1	B-100, E, C-I, C-II, C-III	Liver	Triglyceride hydrolysis by LPL
IDL	1.006–1.019	Cholesteryl esters and “endogenous” triglycerides	1:1	B-100, E, C-II, C-III	Product of VLDL catabolism	50% converted to LDL mediated by HL, 50% apoE-mediated uptake by liver 50% apoE-mediated uptake by liver
LDL	1.019–1.063	Cholesteryl esters	NS	B-100	Product of VLDL catabolism	ApoB-100-mediated uptake by LDL receptor (~75% in liver)
HDL	1.063–1.21	Phospholipids, cholesteryl esters	NS	A-I, A-II, E, C-I, C-II, C-III	Intestine, liver, plasma	Complex: Transfer of cholesteryl ester to VLDL and LDL Uptake of HDL cholesterol by hepatocytes
Lp(a)	1.05–1.09	Cholesteryl esters	NS	B-100, apo(a)	Liver	Unknown

Abbreviations: apo, apolipoprotein; CHOL, cholesterol; HDL, high-density lipoproteins; IDL, intermediate-density lipoproteins; Lp(a), lipoprotein(a); LDL, low-density lipoproteins; NS, not significant (triglyceride is less than 5% of LDL and HDL); TG, triglyceride; VLDL, very-low-density lipoproteins; HL, hepatic lipase; LPL, lipoprotein lipase.

Table 35–2
Apolipoproteins

APOLIPOPROTEIN	AVERAGE CONCENTRATION, MG/DL	CHROMOSOME	MOLECULAR MASS, KD	SITES OF SYNTHESIS	FUNCTIONS
ApoA-I	130	11	~29	Liver, intestine	Structural in HDL; LCAT cofactor; ligand of ABCA1 receptor; reverse cholesterol transport
ApoA-II	40	1	~17	Liver	Forms –S–S– complex with apoE-2 and E-3, which inhibits E-2 and E-3 binding to lipoprotein receptors
Apo A-V	<1	11	~40	Liver	Modulates triglyceride incorporation into hepatic VLDL; activates LPL
ApoB-100	85	2	~513	Liver	Structural protein of VLDL, IDL, LDL; LDL receptor ligand
ApoB-48	Fluctuates according to dietary fat intake	2	~241	Intestine	Structural protein of chylomicrons
ApoC-I	6	19	~6.6	Liver	LCAT activator. Modulates receptor binding of remnants
ApoC-II	3	19	8.9	Liver	Lipoprotein lipase cofactor
ApoC-III	12	11	8.8	Liver	Modulates receptor binding of remnants
ApoE	5	19	34	Liver, brain, skin, gonads, spleen	Ligand for LDL receptor and receptors binding remnants; reverse cholesterol transport (HDL with apoE)
Apo(a)	Variable (under genetic control)	6	Variable	Liver	Modulator of fibrinolysis

Abbreviations: apo, apolipoprotein; HDL, high-density lipoproteins; IDL, intermediate-density lipoproteins; LCAT, lecithin:cholesterol acyltransferase; LDL, low-density lipoproteins; LPL, lipoprotein lipase; VLDL, very-low-density lipoproteins.

After gaining entry to the circulation *via* the thoracic duct, chylomicrons are metabolized initially at the capillary luminal surface of tissues that synthesize lipoprotein lipase (LPL), a triglyceride hydrolase (Figure 35–1). These tissues include adipose tissue, skeletal and cardiac muscle, and breast tissue of lactating women. As the triglycerides are hydrolyzed by LPL, the resulting free fatty acids are taken up and utilized by the

adjacent tissues. The interaction of chylomicrons and LPL requires apoC-II as an absolute cofactor. The absence of functional LPL or functional apoC-II prevents the hydrolysis of triglycerides in chylomicrons and results in severe hypertriglyceridemia and pancreatitis during childhood or even infancy (chylomicronemia syndrome). Potentially atherogenic roles for LPL have been identified that affect the metabolism and

Figure 35–1. The major pathways involved in the metabolism of chylomicrons synthesized by the intestine and VLDL synthesized by the liver. Chylomicrons are converted to chylomicron remnants by the hydrolysis of their triglycerides by LPL. Chylomicron remnants are rapidly cleared from the plasma by the liver. “Remnant receptors” include the LDL receptor-related protein (LRP), LDL, and perhaps other receptors. FFA released by LPL is used by muscle tissue as an energy source or taken up and stored by adipose tissue. FFA, free fatty acid; HL, hepatic lipase; IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; LPL, lipoprotein lipase; VLDL, very-low-density lipoproteins.

uptake of atherogenic lipoproteins by the liver and the arterial wall, and that impact the dyslipidemia of insulin resistance (Stein and Stein, 2003).

The concentration of chylomicrons can be controlled only by reducing dietary fat consumption. There is no current therapeutic approach that will enhance chylomicron catabolism except for insulin replacement in patients with type I diabetes mellitus. Insulin has a “permissive effect” on LPL-mediated triglyceride hydrolysis.

Chylomicron Remnants. After LPL-mediated removal of much of the dietary triglycerides, the chylomicron remnants, which still contain all of the dietary cholesterol, detach from the capillary surface and within minutes are removed from the circulation by the liver in a multi-step process mediated by apoE (Figure 35–1) (Mahley and Huang, 1999; Mahley and Ji, 1999). First, the remnants are sequestered by the interaction of apoE with heparan sulfate proteoglycans on the surface of hepatocytes and are processed by hepatic lipase (HL), further reducing the remnant triglyceride content. Next, apoE mediates remnant uptake by interacting with the hepatic LDL receptor or the LDL receptor-related protein (LRP) (Herz and Strickland, 2001). The multifunctional LRP recognizes a variety of ligands, including apoE, HL, and LPL, and several ligands unrelated to lipid metabolism.

In plasma lipid metabolism, the LRP is important because it is the back-up receptor responsible for the uptake of apoE-enriched remnants of chylomicrons and VLDL. Cell-surface heparan sulfate proteoglycans facilitate the interaction of apoE-containing remnant lipoproteins with the LRP, which mediates uptake by hepatocytes (Mahley and Huang, 1999). Inherited absence of either functional HL (very rare) or functional apoE impedes remnant clearance by the LDL receptor and the LRP, increasing triglyceride- and cholesterol-rich remnant lipoproteins in the plasma (type III hyperlipoproteinemia) (Mahley and Rall, 2001).

During the initial hydrolysis of chylomicron triglycerides by LPL, apoA-I and phospholipids are shed from the surface of chylomicrons and remain in the plasma. This is one mechanism by which nascent (precursor) HDL are generated. Chylomicron remnants are not precursors of LDL, but the dietary cholesterol delivered to the liver by remnants increases plasma LDL levels by reducing LDL receptor-mediated catabolism of LDL by the liver.

Very-Low-Density Lipoproteins. VLDL are produced in the liver when triglyceride production is stimulated by an increased flux of free fatty acids or by increased *de novo* synthesis of fatty acids by the liver. VLDL parti-

cles are 40 to 100 nm in diameter and are large enough to cause plasma turbidity, but unlike chylomicrons, do not float spontaneously to the top of a tube of undisturbed plasma.

ApoB-100, apoE, and apoC-I, C-II, and C-III are synthesized constitutively by the liver and incorporated into VLDL (Table 35–2). If triglycerides are not available to form VLDL, the newly synthesized apoB-100 is degraded by hepatocytes. Triglycerides are synthesized in the endoplasmic reticulum, and along with other lipid constituents, are transferred by MTP to the site in the endoplasmic reticulum where newly synthesized apoB-100 is available to form nascent (precursor) VLDL. Small amounts of apoE and the C apoproteins are incorporated into nascent particles within the liver before secretion, but most of these apoproteins are acquired from plasma HDL after the VLDL are secreted by the liver.

ApoA-V modulates plasma triglyceride levels, possibly by affecting hepatic VLDL triglyceride secretion and by promoting LPL-mediated hydrolysis of chylomicrons and VLDL triglycerides (Oliva *et al.*, 2005). ApoA-V is produced solely by the liver, and despite its very low plasma concentration (~0.1% of the concentration of apoA-I), profoundly affects plasma triglyceride levels in mice and humans (van der Vliet *et al.*, 2001; Pennacchio *et al.*, 2002). Overexpression of apoA-V in transgenic mice reduces triglyceride levels by half, while inactivation of the apoA-V gene increases triglyceride levels fourfold (Pennacchio *et al.*, 2001). Polymorphisms in the human apoA-V gene are associated with significant variability in triglyceride levels, but the precise mechanism by which apoA-V modulates plasma triglyceride levels is unknown (Pennacchio *et al.*, 2002).

Without MTP, hepatic triglycerides cannot be transferred to apoB-100. As a consequence, patients with dysfunctional MTP fail to make any of the apoB-containing lipoproteins (VLDL, IDL, or LDL). MTP also plays a key role in the synthesis of chylomicrons in the intestine, and mutations of MTP that result in the inability of triglycerides to be transferred to either apoB-100 in the liver or apoB-48 in the intestine prevent VLDL and chylomicron production and cause the genetic disorder abetalipoproteinemia (Berriot-Varoqueaux *et al.*, 2000).

Plasma VLDL is then catabolized by LPL in the capillary beds in a process similar to the lipolytic processing of chylomicrons (Figure 35–1). When triglyceride hydrolysis is nearly complete, the VLDL remnants, usually termed IDL, are released from the capillary endothelium and reenter the circulation. ApoB-100 containing small VLDL and IDL (VLDL remnants), which have a half-life of less than 30 minutes, have two potential fates. About 40% to 60% are cleared from the plasma by the liver *via* interaction with LDL receptors and LRP, which recognize ligands (apoB-100 and apoE) on the remnants. LPL and HL convert the remainder of the IDL to LDL by removal of additional triglycerides. The C apoproteins and apoE redistribute to HDL. *Virtually all LDL particles in the plasma are derived from VLDL.*

ApoE plays a major role in the metabolism of triglyceride-rich lipoproteins (chylomicrons, chylomicron remnants, VLDL, and IDL) and has a number of major functions related to the binding and

uptake of plasma lipoproteins and to the redistribution of lipids locally among cells (Mahley and Huang, 1999; Mahley and Rall, 2000). About half of the apoE in the plasma of fasting subjects is associated with triglyceride-rich lipoproteins, and the other half is a constituent of HDL. ApoE controls the catabolism of the apoE-containing lipoproteins by mediating their binding to cell-surface heparan sulfate proteoglycans (especially in the liver) and to LDL receptors and the LRP (Mahley and Ji, 1999).

About three-fourths of the apoE in plasma is synthesized by the liver, and the remainder is synthesized by a variety of tissues. The brain is the second most abundant site of apoE mRNA synthesis, which occurs in both astrocytes and neurons (Mahley and Rall, 2000). ApoE also is synthesized by macrophages, where it appears to play a role in modulating cholesterol accumulation. In transgenic mice, overexpression of apoE by macrophages inhibits hypercholesterolemia-induced atherogenesis (Bellosta *et al.*, 1995; Hasty *et al.*, 1999).

Three alleles of the apoE gene (designated ϵ_2 , ϵ_3 , and ϵ_4) occur with a frequency of ~8%, 77%, and 15%, respectively, and code for the three major forms of apoE: E2, E3, and E4. Consequently, there are three homozygous apoE phenotypes (E2/2, E3/3, and E4/4) and three heterozygous phenotypes (E2/3, E2/4, and E3/4). Approximately 60% of the population is homozygous for apoE3.

Single amino acid substitutions result from the genetic polymorphisms in the apoE gene (Mahley and Rall, 2000). ApoE2, with a cysteine at residue 158, differs from apoE3, which has arginine at this site. ApoE3, with a cysteine at residue 112, differs from apoE4, which has arginine at this site. These single amino acid differences affect both receptor binding and lipid binding of the three apoE isoforms. Both apoE3 and apoE4 can bind to the LDL receptor, but apoE2 binds much less effectively, and as a consequence causes the remnant lipoprotein dyslipidemia of type III hyperlipoproteinemia. ApoE2 and apoE3 bind preferentially to the phospholipids of HDL, whereas apoE4 binds preferentially to VLDL triglycerides.

Low-Density Lipoproteins. The LDL particles arising from the catabolism of IDL have a half-life of 1.5 to 2 days, which accounts for the higher plasma concentration of LDL than of VLDL and IDL. In subjects without hypertriglyceridemia, two-thirds of plasma cholesterol is found in the LDL. Plasma clearance of LDL particles is mediated primarily by LDL receptors; a small component is mediated by nonreceptor clearance mechanisms (Brown and Goldstein, 1986). More than 900 mutations of the LDL receptor gene have been identified in association with defective or absent LDL receptors that cause high levels of plasma LDL and familial hypercholesterolemia (Rader *et al.*, 2003). ApoB-100, the only apoprotein of LDL, is the ligand that binds LDL to its receptor. Residues 3000 to 3700 in the carboxyl-terminal sequence are critical for binding. Mutations in this region disrupt binding and are a cause of hypercholesterolemia (familial defective apoB-100) (Innerarity *et al.*, 1990). Autosomal recessive hypercholesterolemia closely resembles familial hypercholesterolemia, but is not caused by LDL receptor mutations; the autosomal recessive hypercholesterolemia protein is required for internalization of LDL receptor

complexes to which LDL binds on the surface of hepatocytes (Rader *et al.*, 2003).

The liver expresses a large complement of LDL receptors and removes ~75% of all LDL from the plasma. Consequently, manipulation of hepatic LDL receptor expression is a most effective way to modulate plasma LDL-C levels. Thyroxine and estrogen enhance LDL receptor gene expression, which explains their LDL-C-lowering effects (Shin and Osborne, 2003).

The most effective dietary alteration (decreased consumption of saturated fat and cholesterol) and pharmacological treatment (statins) for hypercholesterolemia act by enhancing hepatic LDL receptor expression (Xie *et al.*, 2002). Regulation of LDL receptor expression is part of a complex process by which cells regulate their free cholesterol content. This regulatory process is mediated by transcription factors called *sterol regulatory element binding proteins* (SREBPs) and *SREBP cleavage activating protein* (Horton *et al.*, 2002). The SREBP cleavage activating protein is both a sensor of cellular cholesterol content and an escort of SREBPs. When cellular cholesterol content is reduced, SREBPs undergo proteolytic cleavage in the Golgi apparatus, and the amino-terminal domain, guided by the SREBP cleavage activating protein, translocates to the nucleus, where it activates expression of the LDL receptor and of other enzymes involved in cholesterol biosynthesis.

LDL become atherogenic when they are modified by oxidation (Witztum and Steinberg, 2001), a required step for LDL uptake by the scavenger receptors of macrophages. This process leads to foam-cell formation in arterial lesions. At least two scavenger receptors (SRs) are involved (SR-AI/II and CD36). Knocking out either receptor in transgenic mice retards the uptake of oxidized LDL by macrophages. Expression of the two receptors is regulated differently: SR-AI/II appears to be expressed more in early atherogenesis, and CD36 expression is greater as foam cells form during lesion progression (Dhaliwal and Steinbrecher, 1999; Nakata *et al.*, 1999). Despite the large body of evidence implicating oxidation of LDL as a requisite step during atherogenesis, controlled clinical trials have failed to show efficacy of antioxidant vitamins in preventing vascular disease (Yusuf, 2002; Brown *et al.*, 2002).

High-Density Lipoproteins. The metabolism of HDL is complex because of the multiple mechanisms by which HDL particles are modified in the plasma compartment and by which HDL particles are synthesized. ApoA-I is the major HDL apoprotein, and its plasma concentration is a more powerful inverse predictor of CHD risk than is the HDL-C level (Tall *et al.*, 2000; Mahley *et al.*, 2003).

ApoA-I synthesis is required for normal production of HDL. Mutations in the apoA-I gene that cause HDL deficiency are variable in their clinical expression and often are associated with accelerated atherogenesis (Assmann *et al.*, 2001). Conversely, overexpression of apoA-I in transgenic mice protects against experimentally induced atherogenesis.

Mature HDL can be separated by ultracentrifugation into HDL₂ ($d = 1.063$ to 1.125 g/ml), which are larger, more cholesterol-rich lipoproteins (70 to 100 Å in diameter), and HDL₃ ($d = 1.125$ to 1.21 g/ml), which are smaller particles (50 to 70 Å in diameter). In addition, two major subclasses of mature HDL particles in the plasma

can be differentiated by their content of the major HDL apoproteins, apoA-I and apoA-II (Duriez and Fruchart, 1999). Mature HDL particles have α electrophoretic mobility. Some α -migrating HDL particles contain only apoA-I and no apoA-II and are called LpA-I HDL particles. Others contain both apoA-I and apoA-II and are called LpA-I/A-II HDL particles. LpA-I particles are larger than LpA-I/A-II and are primarily associated with HDL₂. LpA-I/A-II particles are smaller and are primarily associated with HDL₃. Patients with reduced HDL-C levels and CHD have lower levels of LpA-I, but not of LpA-I/A-II, than subjects with normal HDL-C levels (Duriez and Fruchart, 1999). This finding suggests that HDL particles containing apoA-I and apoA-II may not be atheroprotective. In fact, overexpression of apoA-II in transgenic mice enhances susceptibility to atherosclerosis (Schultz *et al.*, 1993). ApoA-II deficiency is not associated with any apparent deleterious effects in humans (Deeb *et al.*, 1990).

The precursor of most of the α -migrating plasma HDL is a discoidal particle containing apoA-I and phospholipid, called pre- β 1 HDL because of its pre- β 1 electrophoretic mobility. Pre- β 1 HDL are synthesized by the liver and the intestine, and they also arise when surface phospholipids and apoA-I of chylomicrons and VLDL are lost as the triglycerides of these lipoproteins are hydrolyzed. Phospholipid transfer protein plays an important role in the transfer of phospholipids to HDL (Tall *et al.*, 2000).

Discoidal pre- β 1 HDL can then acquire free (unesterified) cholesterol from the cell membranes of tissues, such as arterial wall macrophages, by an interaction with the class B, type I scavenger receptor (SR-BI), to which the apoA-I of HDL docks, so that free cholesterol can be transferred to or from the HDL particle (Williams *et al.*, 1999). SR-BI facilitates the movement of excess free cholesterol from cells with excess cholesterol (*e.g.*, foam cells in the arterial wall) (Williams *et al.*, 1999; Assmann and Nofer, 2003). Hepatic SR-BI facilitates the uptake of cholesteryl esters from the HDL without internalizing and degrading the lipoproteins. In mice, overexpression of SR-BI reduces susceptibility to atherosclerosis, and elimination of SR-BI significantly increases atherosclerosis (Krieger and Kozarsky, 1999). A homologue of SR-BI, CLA-1, has been identified in humans (Dhaliwal and Steinbrecher, 1999). Modulation of CLA-1 expression may offer new avenues for the management of atherogenesis (Krieger, 1999).

The membrane transporter ABCA1 facilitates the transfer of free cholesterol from cells to HDL (Attie *et al.*, 2001). When ABCA1 is defective, the acquisition of cholesterol by HDL is greatly diminished, and HDL levels are markedly reduced because poorly lipidated nascent HDL are metabolized rapidly. Loss-of-function mutations of ABCA1 cause the defect observed in Tangier disease, a genetic disorder characterized by extremely low levels of HDL and cholesterol accumulation in the liver, spleen, tonsils, and neurons of peripheral nerves. Transgenic animals overexpressing ABCA1 in the liver and macrophages have elevated plasma levels of HDL and apoA-I and reduced susceptibility to atherosclerosis (Vaisman *et al.*, 2001; Joyce *et al.*, 2002).

After free cholesterol is acquired by the pre- β 1 HDL, it is esterified by lecithin:cholesterol acyltransferase. The newly esterified and nonpolar cholesterol moves into the core of the discoidal HDL. As the cholesteryl ester content increases, the HDL particle becomes spherical and less dense. These newly formed spherical HDL particles (HDL₃) further enlarge by accepting more free cholesterol, which is in turn esterified by lecithin:cholesterol acyltransferase. In this way, HDL₃ are converted to HDL₂, which are larger and less dense than HDL₃.

As the cholesteryl ester content of the HDL₂ increases, the cholesteryl esters of these particles begin to be exchanged for triglycerides derived from any of the triglyceride-containing lipoproteins (chylomicrons, VLDL, remnant lipoproteins, and LDL). This exchange is mediated by the cholesteryl ester transfer protein (CETP), and in humans accounts for the removal of about two-thirds of the cholesterol associated with HDL. The transferred cholesterol subsequently is metabolized as part of the lipoprotein into which it was transferred. The triglyceride that is transferred into HDL₂ is hydrolyzed in the liver by HL, a process that regenerates smaller, spherical HDL₃ particles that recirculate and acquire additional free cholesterol from tissues containing excess free cholesterol.

HL activity is regulated and modulates HDL-C levels. Both androgens and estrogens affect HL gene expression, but with opposite effects (Brinton, 1996). Androgens increase HL activity, which accounts for the lower HDL-C values observed in men than in women. Estrogens reduce HL activity, but their impact on HDL-C levels in women is substantially less than that of androgens on HDL-C levels in men. HL appears to have a pivotal role in regulating HDL-C levels, as HL activity is increased in many patients with low HDL-C levels.

HDL are protective lipoproteins that decrease the risk of CHD; thus, high levels of HDL are desirable. This protective effect may result from the participation of HDL in reverse cholesterol transport, the process by which excess cholesterol is acquired from cells and transferred to the liver for excretion (Assmann and Nofer, 2003). HDL also may protect against atherogenesis by mechanisms not directly related to reverse cholesterol transport. These functions include putative antiinflammatory, antioxidative, platelet antiaggregatory, anticoagulant, and profibrinolytic activities (Nofer *et al.*, 2002).

Lipoprotein(a). Lipoprotein(a) [Lp(a)] is composed of an LDL particle that has a second apoprotein in addition to apoB-100 (Ginsberg and Goldberg, 2001; Mahley *et al.*, 2003). The second apoprotein, apo(a), is attached to apoB-100 by at least one disulfide bond and does not function as a lipid-binding apoprotein. Apo(a) of Lp(a) is structurally related to plasminogen and appears to be atherogenic by interfering with fibrinolysis of thrombi on the surfaces of plaques.

HYPERLIPIDEMIA AND ATHEROSCLEROSIS

Despite a continuing decline in the incidence of atherosclerosis-related deaths in the past 39 years, deaths from CHD, cerebrovascular disease, and peripheral vascular disease accounted for 38.5% of the 2.4 million deaths in the United States during 2001. Two-thirds of atherosclerosis deaths were due to CHD. About 85% of CHD deaths occurred in individuals over 65 years of age. Among the 15% dying prematurely (below age 65), 80% died during their first CHD event. Among those dying of sudden cardiac death in 1997, 50% of the men and 64% of the women had previously been asymptomatic (American Heart Association, 2003). It is estimated that an average

of 11.5 years of life are lost as a consequence of having a myocardial infarction.

These statistics illustrate the importance of identifying and managing risk factors for CHD. *The major conventional risk factors are elevated LDL-C, reduced HDL-C, cigarette smoking, hypertension, type 2 diabetes mellitus, advancing age, and a family history of premature (men <55 years; women <65 years) CHD events in a first-degree relative.* Control of the modifiable risk factors is especially important in preventing premature CHD. Observational studies suggest that modifiable risk factors account for 85% of excess risk (risk over and above that of individuals with optimal risk-factor profiles) for premature CHD (Stamler *et al.*, 1986; Wilson *et al.*, 1998). The presence of one or more conventional risk factors in 90% of patients with CHD belies claims that a large percentage of CHD, perhaps as much as 50%, is not attributable to conventional risk factors (Canto and Iskandrian, 2003). Furthermore, these studies indicate that, when total cholesterol levels are below 160 mg/dl, CHD risk is markedly attenuated, even in the presence of additional risk factors (Grundy *et al.*, 1998). This pivotal role of hypercholesterolemia in atherogenesis gave rise to the almost universally accepted cholesterol-diet-CHD hypothesis: elevated plasma cholesterol levels cause CHD; diets rich in saturated (animal) fat and cholesterol raise cholesterol levels; and lowering cholesterol levels reduces CHD risk (Thompson and Barter, 1999). Although the relationship between cholesterol, diet, and CHD was recognized nearly 50 years ago, proof that cholesterol lowering was safe and prevented CHD death required extensive epidemiological studies and clinical trials.

Epidemiological Studies. Epidemiological studies have demonstrated the importance of the relationship between excess saturated fat consumption and elevated cholesterol levels. Reducing the consumption of dietary saturated fat and cholesterol is the cornerstone of population-based approaches to the management of hypercholesterolemia. In addition, it is clearly established that the higher the cholesterol level, the higher the CHD risk (Stamler *et al.*, 1986).

Clinical Trials. Studies of the efficacy of cholesterol lowering began in the 1960s, and the results of the earliest trials showed that modest reductions in total cholesterol and LDL-C were associated with reductions in fatal and nonfatal CHD events, but not total mortality (Illingworth and Durrington, 1999). It was not until the advent of a more efficacious class of cholesterol-lowering drugs, the statins, that cholesterol reduction therapy was finally proven to prevent CHD events and reduce total mortality (Scandinavian Simvastatin Survival Study, 1994). Subsequently, many trials of statins have documented the efficacy and safety of cholesterol-lowering therapy (Table 35-3) (Law *et al.*, 2003). Patients benefit regardless of gender, age, or baseline lipid values whether or not they have a prior history of vascular disease (Heart Protection Study Collaborative Group, 2002). Since publication of the 2001 National Cholesterol Education Program (NCEP) Adult Treatment Panel (ATP) III guidelines, clinical trials have been com-

Table 35–4

Treatment Based on LDL-C Levels (2004 Revision of NCEP Adult Treatment Panel III Guidelines)

RISK CATEGORY	LDL-C GOAL	Adults	
		THERAPEUTIC LIFESTYLE CHANGE	DRUG THERAPY
<i>Very high risk</i> Atherosclerosis-induced CHD plus one of: (a) multiple risk factors, (b) diabetes mellitus, (c) a poorly controlled single factor, (d) acute coronary syndrome, (e) metabolic syndrome	<70 mg/dl*	No threshold	No threshold
<i>High risk</i> CHD or CHD equivalent	<100 mg/dl*	No threshold	No threshold
<i>Moderately high risk</i> 2+ risk factors 10-year risk: 10%–20%	<130 mg/dl (Optional <100 mg/dl)	≥100 mg/dl	≥130 mg/dl (100–129 mg/dl) [†]
<i>Moderate risk</i> 2+ risk factors 10-year risk <10%	<130 mg/dl	≥130 mg/dl	>160 mg/dl
<i>0–1 risk factor</i>	<160 mg/dl	≥160 mg/dl	≥190 mg/dl (Optional: 160–189 mg/dl) [‡]

*If pretreatment LDL-C is near or below LDL-C goal value, then a statin dose sufficient to lower LDL-C by 30%–40% should be prescribed. [†]Patients in this category include those with a 10-year risk of 10%–20% and one of the following: (a) age >60 years; (b) three or more risk factors; (c) a severe risk factor; (d) triglycerides >200 mg/dl and HDL-C <40 mg/dl; (e) metabolic syndrome; (f) highly sensitive C-reactive protein (CRP) >3 mg/l; (g) coronary calcium score (age/gender adjusted) >75th percentile. [‡]Patients include those with (a) any severe single risk factor; (b) multiple major risk factors; (c) 10-year risk >8%. *Abbreviations:* CHD, coronary heart disease; CHD equivalent, peripheral vascular disease, abdominal aortic aneurysm, symptomatic carotid artery disease, >20% 10-year CHD risk, or diabetes mellitus; LDL-C, low-density-lipoprotein cholesterol; NCEP, National Cholesterol Education Program.

pleted that have prompted a revision in the ATP III guidelines (Illingworth and Durrington, 1999; The Expert Panel, 2002).

The key features of the revision include abandoning the concept of a threshold LDL-C level that must be exceeded before initiating cholesterol-lowering drug therapy in CHD or CHD equivalent patients; adopting a new target LDL-C level (<70 mg/dl) for very high-risk patients; and employing a “standard statin dose” (a dosage sufficient to lower LDL-C by 30% to 40%) as a minimum therapy when initiating cholesterol-lowering therapy with statins (Grundy *et al.*, 2004b) (Table 35–4).

The clinical trials that provide information about threshold LDL-C levels, which must be exceeded before initiating cholesterol-lowering drug therapy for CHD patients, include the Cholesterol and Recurrent Events (CARE) and Long-Term Intervention with Pravastatin in Ischaemic Disease (LIPID) trial that employed pravastatin (40 mg daily) or placebo, and the Heart Protection Study (HPS) in which simvastatin (40 mg daily) was the treatment (Sacks *et al.*, 2000). The LIPID and CARE trials were secondary prevention studies lasting 5 years. There was no reduction in CHD events associated with taking pravastatin (40 mg daily) among the 20% of patients with baseline LDL-C <125 mg/dl. The results of these two clinical trials provided the only data per-

taining to CHD patients with low baseline LDL-C levels (<125 mg/dl) when the ATP III guidelines were published in 2001. The lack of treatment effect in this group accounts for the recommendation that cholesterol-lowering drug therapy be optional, not mandatory, for CHD patients with baseline LDL-C levels below 130 mg/dl (The Expert Panel, 2002). The HPS was a large secondary prevention trial comparing simvastatin (40 mg daily) to placebo. All subjects, including the 17.5% with baseline LDL-C <100 mg/dl (mean baseline LDL-C, 97 mg/dl; mean on-treatment LDL-C, 65 mg/dl) experienced a 24% reduction in the relative risk of sustaining a vascular event (Heart Protection Study Collaborative Group, 2002). Due to this outcome of the HPS, ATP III guidelines abandoned the concept of a threshold value for LDL-C that must be exceeded before prescribing cholesterol-lowering drug therapy for CHD patients (Grundy *et al.*, 2004b). Comparing the proven benefit of simvastatin (40 mg daily; ~41% reduction of LDL-C) in HPS to the lack of benefit of pravastatin (40 mg daily; ~34% reduction of LDL-C) in CARE and LIPID among patients with LDL-C <125 mg/dl, it is apparent that CHD patients with low baseline LDL-C levels require dosages of statins sufficient to lower LDL-C by at least 40%.

The new target of LDL-C <70 mg/dl for very high-risk patients was based on the outcome of the HPS, which showed that CHD

patients with baseline LDL-C levels below 100 mg/dl benefited from statin therapy, and the outcome of the Pravastatin or Atorvastatin Evaluation and Infection Therapy—Thrombolysis in Myocardial Infarction (PROVE IT–TIMI) 22 trial (Cannon *et al.*, 2004). This study compared the benefit of “intensive” LDL-C lowering with *atorvastatin*, 80 mg daily, versus “standard” LDL-C lowering with *pravastatin*, 40 mg daily, in hospitalized patients with acute coronary syndrome. Intensive treatment with *atorvastatin*, 80 mg daily, lowered the median LDL-C level to 62 mg/dl, and standard treatment with *pravastatin*, 40 mg daily, lowered median LDL-C to 95 mg/dl. High-intensity treatment with *atorvastatin* was associated with a 16% reduction in the relative risk of sustaining a primary endpoint event (a composite of death, nonfatal myocardial infarction, rehospitalization for unstable angina, revascularization, and stroke) after only 2 years of treatment. Taken together the results of HPS and PROVE IT suggest that LDL-C <70 mg/dl is indicated for patients with low baseline LDL-C levels (~100 mg/dl) and for high-risk acute coronary syndrome patients similar to those in the PROVE IT trial (Grundy *et al.*, 2004b). Other trials involving patients treated intensively or with standard therapy are nearly complete and will provide additional information about the value of lowering LDL-C to values substantially lower than 100 mg/dl.

The results of the clinical trials suggest that CHD risk is reduced by 1% for every 1% reduction in LDL-C. Consequently, use of minimal doses of statins to produce small LDL-C reductions that barely attain LDL-C goals would minimize the treatment benefit associated with standard doses of statins that lower LDL-C by up to 40% (Grundy *et al.*, 2004b). Thus, current recommendations for statin therapy are that LDL-C levels should be lowered by 30% to 40% from baseline as well as achieving a specific LDL-C goal (Grundy *et al.*, 2004b).

National Cholesterol Education Program (NCEP) Guidelines for Treatment: Managing Patients with Dyslipidemia

The current NCEP guidelines for management of patients are of two types. One is a population-based approach to reduce CHD risk, which includes recommendations to increase exercise (to expend ~2000 calories/week) and to lower blood cholesterol by dietary recommendations: reduce total calories from fat to less than 30% and from saturated and trans fats to less than 10%; consume less than 300 mg of cholesterol per day; eat a variety of oily fish twice a week (Kris-Etherton *et al.*, 2002) and oils/foods rich in α -linolenic acid (canola, flaxseed, and soybean oils, flaxseed, and walnuts); and maintain desirable body weight. The second is the patient-based approach that focuses on lowering LDL-C levels as the primary goal of therapy (The Expert Panel, 2002; Grundy *et al.*, 2004b).

The guidelines for the management of adults 20 years and older recommend a complete fasting lipoprotein profile (total cholesterol, LDL-C, HDL-C, and triglycerides). The classification of lipid levels is shown in Table 35–5. If the values for total cholesterol, LDL-C, and triglycerides are in the lowest category and the HDL-C level is

Table 35–5
Classification of Plasma Lipid Levels*

Total cholesterol	
<200 mg/dl	Desirable
200–239 mg/dl	Borderline high
≥240 mg/dl	High
HDL-C	
<40 mg/dl	Low (consider <50 mg/dl as low for women)
>60 mg/dl	High
LDL-C	
<70 mg/dl	Optimal for very high risk (minimal goal for CHD equivalent patients)
<100 mg/dl	Optimal
100–129 mg/dl	Near optimal
130–159 mg/dl	Borderline high
160–189 mg/dl	High
≥190 mg/dl	Very high
Triglycerides	
<150 mg/dl	Normal
150–199 mg/dl	Borderline high
200–499 mg/dl	High
≥500 mg/dl	Very high

Abbreviations: HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol. *2001 National Cholesterol Education Program guidelines.

not low, lifestyle recommendations (diet and exercise) should be made to ensure maintenance of a normal lipid profile. Other vascular disease risk factors (Table 35–6), if present, should be assessed and treated individually. For patients with elevated levels of total cholesterol, LDL-C, or triglycerides, or reduced HDL-C values, further treatment is based on the patient’s risk-factor status (Table 35–6), LDL-C levels (Table 35–4), and calculation of the Framingham risk score (Table 35–7) of primary prevention patients with two or more risk factors.

All patients who meet the criteria for lipid-lowering therapy should receive instruction about therapeutic lifestyle change. Dietary restrictions include less than 7% of calories from saturated and trans fatty acids, less than 200 mg of cholesterol daily, up to 20% of calories from monounsaturated fatty acids, up to 10% of calories from polyunsaturated fat, and total fat calories ranging between 25% and 35% of all calories. Two oily fish meals per week are especially important for post-myocardial infarction patients due to a substantial reduction in the risk of sudden cardiac death (Kris-Etherton *et al.*, 2002). Patients with CHD or a CHD equivalent (symptomatic peripheral or

Family history of premature CHD

A first-degree relative (male below 55 years or female below 65 years when the first CHD clinical event occurs)

Current cigarette smoking

Defined as smoking within the preceding 30 days

Hypertension

Blood pressure $\geq 140/90$ or use of antihypertensive medication, irrespective of blood pressure

Low HDL-C

<40 mg/dl (consider <50 mg/dl as “low” for women)

Obesity[†]

Body mass index >25 kg/m² and waist circumference above 40 inches (men) or 35 inches (women)

Abbreviations: CHD, coronary heart disease; HDL-C, high-density-lipoprotein cholesterol. *Diabetes mellitus is considered to be a CHD-equivalent disorder; therefore, the lipid management of diabetes patients is the same as that for patients with established vascular disease (American Diabetes Association, 1999). †Obesity was returned to the list of CHD risk factors in 1998, although it was not included as a risk factor in the 2001 NCEP guidelines (Pi-Sunyer *et al.*, 1998).

carotid vascular disease, abdominal aortic aneurysm, >20% 10-year CHD risk, or diabetes mellitus) should immediately start appropriate lipid-lowering drug therapy irrespective of their baseline LDL-C level (Heart Protection Study Collaborative Group, 2002; Grundy *et al.*, 2004b). Patients without CHD or CHD equivalent should be managed with lifestyle advice (diet, exercise, weight management) for 3 to 6 months before drug therapy is implemented.

Table 35–7
Guidelines Based on LDL-C and Total Cholesterol:HDL-C Ratio for Treatment of Low HDL-C Patients

RISK CATEGORY	Goals		Lifestyle Change Initiated for			Drug Therapy Initiated for		
	LDL-C	TC:HDL-C	LDL-C	TC:HDL-C	LDL-C	TC:HDL-C		
CHD or equivalent	<100	and <3.5	≥ 100	or ≥ 3.5	≥ 100	or ≥ 3.5		
2+ risk factors	<130	and <4.5	≥ 130	or ≥ 4.5	≥ 130	or ≥ 6.0		
0–1 risk factor	<160	and <5.5	≥ 160	or ≥ 5.5	≥ 160	or ≥ 7.0		

Abbreviations: CHD, coronary heart disease; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; TC, total cholesterol.

Before drug therapy is initiated, secondary causes of hyperlipidemia should be excluded. Most secondary causes (Table 35–8) can be excluded by ascertaining the patient’s medication history and by measuring serum creatinine, liver function tests, fasting glucose, and thyroid-stimulating hormone levels. Treatment of the disorder causing secondary dyslipidemia may preclude the necessity of treatment with hypolipidemic drugs.

Risk Assessment Using Framingham Risk Scores

The 2001 NCEP guidelines (The Expert Panel, 2002; Grundy *et al.*, 2004b) and those of the European Atherosclerosis Society (Wood *et al.*, 1998) employ risk assessment tables devised from the Framingham Heart Study in an attempt to match the intensity of treatment to the severity of CHD risk in patients without a prior history of symptomatic atherosclerotic vascular disease. High risk or “CHD equivalent” status is defined as >20% chance of sustaining a CHD event in the next 10 years. The tables used to determine a patient’s absolute risk do not take into account risk associated with a family history of premature CHD or obesity. As a consequence, the risk may be seriously underestimated, resulting in insufficiently aggressive management (Lloyd-Jones *et al.*, 2004). After calculation of the risk score, more aggressive therapy should be considered for obese patients or for patients with a family history of premature CHD. It is also unlikely that the Framingham risk model is appropriate for assessing risk in all ethnic groups (Bersot *et al.*, 2003; Liu *et al.*, 2004).

Arterial Wall Biology and Plaque Stability

More effective lipid-lowering agents and a better understanding of atherogenesis have helped to prove that aggressive lipid-lowering therapy has many beneficial effects

Table 35–8
Secondary Causes of Dyslipidemia

DISORDER	MAJOR LIPID EFFECT
Diabetes mellitus	Triglycerides > cholesterol; low HDL-C
Nephrotic syndrome	Triglycerides usually > cholesterol
Alcohol use	Triglycerides > cholesterol
Contraceptive use	Triglycerides > cholesterol
Estrogen use	Triglycerides > cholesterol
Glucocorticoid excess	Triglycerides > cholesterol
Hypothyroidism	Cholesterol > triglycerides
Obstructive liver disease	Cholesterol > triglycerides

Abbreviation: HDL-C, high-density-lipoprotein cholesterol.

over and above those obtained by simply decreasing lipid deposition in the arterial wall. Arteriographic trials have shown that, although aggressive lipid lowering results only in very small increases in lumen diameter, it promptly decreases acute coronary events (Cannon *et al.*, 2004; Brown *et al.*, 1993). Lesions causing less than 60% occlusion are responsible for more than two-thirds of the acute events. Aggressive lipid-lowering therapy may prevent acute events through its positive effects on the arterial wall; it corrects endothelial dysfunction, corrects abnormal vascular reactivity (spasm), and increases plaque stability.

Atherosclerotic lesions containing a large lipid core, large numbers of macrophages, and a poorly formed fibrous cap (Brown *et al.*, 1993; Libby, 2002; Corti *et al.*, 2003) are prone to plaque rupture and acute thrombosis. Aggressive lipid lowering appears to alter plaque architecture, resulting in less lipid, fewer macrophages, and a larger collagen and smooth muscle cell–rich fibrous cap. Stabilization of plaque susceptibility to thrombosis appears to be a direct result of LDL-C lowering or an indirect result of changes in cholesterol and lipoprotein metabolism or arterial wall biology (*see* “Potential Cardioprotective Effects Other Than LDL Lowering,” below).

Whom and When to Treat? Large-scale trials with statins have provided new insights into which patients with dyslipidemia should be treated and when treatment should be initiated.

Gender. Both men and women benefit from lipid-lowering therapy (Heart Protection Study Collaborative Group, 2002). Statins, rather than hormone-replacement therapy, are now the recommended first-line drug thera-

py for lowering lipids in postmenopausal women. This recommendation reflects the increased CHD morbidity in older women with established CHD who were treated with hormone-replacement therapy (Mosca *et al.*, 1999) (*see* Chapter 57).

Age. Age >45 years in men and >55 years in women is considered to be a CHD risk factor. The statin trials have shown that patients >65 years of age benefit from therapy as much as do younger patients (Law *et al.*, 2003). Old age *per se* is not a reason to refrain from initiating drug therapy in an otherwise healthy person.

Cerebrovascular Disease Patients. In most observational studies, plasma cholesterol levels correlate positively with the risk of ischemic stroke. In clinical trials, statins reduced stroke and transient ischemic attacks in patients with and without CHD (Heart Protection Study Collaborative Group, 2004).

Peripheral Vascular Disease Patients. Statins are beneficial in patients with peripheral vascular disease (Heart Protection Study Collaborative Group, 2002).

Hypertensive Patients and Smokers. The risk reduction for coronary events in hypertensive patients and in smokers is similar to that in subjects without these risk factors (Heart Protection Study Collaborative Group, 2002; Sever *et al.*, 2003).

Type 2 Diabetes Mellitus. Patients with type 2 diabetes benefit very significantly from aggressive lipid lowering (*see* “Treatment of Type 2 Diabetes,” below) (Heart Protection Study Collaborative Group, 2003).

Post-Myocardial Infarction or Revascularization Patients. As soon as CHD is diagnosed, it is essential to begin lipid-lowering therapy (NCEP guidelines: LDL-C goal <70 mg/dl for very high-risk patients) (Grundy *et al.*, 2004b). Compliance with drug therapy is greatly enhanced if treatment is initiated in the hospital (Fonarow and Gawlinski, 2000). It remains to be determined if statin therapy alters restenosis after angioplasty; however, the NHLBI Post Coronary Artery Bypass Graft trial showed that statin therapy improved the long-term outcome after bypass surgery and that the lower the LDL-C, the better (The Post Coronary Artery Bypass Graft Trial Investigators, 1997).

Can Cholesterol Levels Be Lowered Too Much? Are there total and LDL cholesterol levels below which adverse health consequences begin to increase? Observational studies initially were confusing. In the United States and western Europe, low cholesterol levels were associated with an increase in noncardiac mortality from chronic pulmonary disease, chronic liver disease, cancer (many primary sites), and hemorrhagic stroke. However, more recent data indicate that it is the noncardiac diseases that cause the low plasma cholesterol levels and not the low cholesterol levels that cause the noncardiac diseases (Law *et al.*, 1994). One exception may be hemorrhagic stroke. In the Multiple Risk Factor Intervention Trial (MRFIT), hemorrhagic stroke occurred more frequently in hypertensive patients with total cholesterol levels below 160 mg/dl; however, the

increased incidence of hemorrhagic stroke was more than offset by reduced CHD risk due to the low cholesterol levels (Neaton *et al.*, 1992). In addition, in a study of the Chinese population, in which cholesterol levels rarely exceeded 160 mg/dl, lower levels of total cholesterol were not associated with increases in hemorrhagic stroke or any other cause of noncardiac mortality (Chen *et al.*, 1991).

Abetalipoproteinemia and hypobetalipoproteinemia, two rare disorders associated with extremely low total cholesterol levels, are instructive because affected individuals have reduced CHD risk and no increase in noncardiac mortality (Welty *et al.*, 1998). Patients who are homozygous for the mutations that cause these disorders have total cholesterol levels below 50 mg/dl and triglyceride levels below 25 mg/dl.

Individuals consuming very low levels of total fat (less than 5% of total calories) and vegetarians, who consume no animal fat, usually have total cholesterol levels below 150 mg/dl and have no increase in noncardiac mortality (Appleby *et al.*, 1999).

Based on the lack of harm associated with low total cholesterol levels in these various groups, reducing cholesterol levels to similarly low levels with drugs does not appear to be contraindicated (Grundy *et al.*, 2004b). With the advent of more efficacious cholesterol-lowering agents, it soon may be possible to test the benefits and risks of lowering total cholesterol levels below 150 mg/dl. Whether even lower cholesterol levels will translate into a further reduction in clinical events (Figure 35–2) is not known, but many researchers are optimistic.

Treatment of Type 2 Diabetes

Diabetes mellitus is an independent predictor of high risk for CHD. CHD morbidity is two to four times higher in patients

Figure 35–2. Reduction in coronary heart disease events in clinical trials is associated with the extent of cholesterol lowering. As more potent cholesterol-reducing agents become available, will it be possible to reduce events by 50% or more in a typical 5-year trial? AFCAPS, Air Force/Texas Coronary Atherosclerosis Prevention Study; CARE, Cholesterol and Recurrent Events trial; LIPID, Long-Term Intervention with Pravastatin in Ischaemic Disease (LIPID) study; LRC, Lipid Research Clinics Coronary Primary Prevention Trial; POSCH, Program on the Surgical Control of the Hyperlipidemias; 4S, Scandinavian Simvastatin Survival Study; WOS, West of Scotland Coronary Prevention Study. (Adapted from Thompson and Barter, 1999, and used by permission of Lippincott Williams & Wilkins.)

with diabetes than in nondiabetics, and the mortality from CHD is up to 100% higher in diabetic patients over a 6-year period (Grundy *et al.*, 1999). Glucose control is essential but provides only minimal benefit with respect to CHD prevention. Aggressive treatment of diabetic dyslipidemia through diet, weight control, and drugs is critical in reducing risk.

Diabetic dyslipidemia is usually characterized by high triglycerides, low HDL-C, and moderate elevations of total cholesterol and LDL-C. In fact, diabetics without diagnosed CHD have the same level of risk as nondiabetics with established CHD (Haffner, 1998). Thus, the dyslipidemia treatment guidelines for diabetic patients are the same as for patients with CHD, irrespective of whether the diabetic patient has had a CHD event (The Expert Panel, 2002). The first line of treatment for diabetic dyslipidemia usually should be a statin (Grundy *et al.*, 1999; American Diabetes Association, 2004).

Clinical trials with simvastatin, pravastatin, and *lovastatin* have clearly established that diabetics profit from cholesterol lowering as much as other subgroups (Heart Protection Study Collaborative Group, 2003; American Diabetes Association, 2004). A 3-year arteriographic study demonstrated a 40% decrease of focal coronary stenoses in type 2 diabetics treated with *fenofibrate* ($p = 0.029$) (Diabetes Atherosclerosis Intervention Study Investigators, 2001).

Metabolic Syndrome

There is an increased CHD risk associated with the insulin-resistant, prediabetic state described under the rubric of “metabolic syndrome.” This syndrome consists of a constellation of five CHD risk factors (Table 35–9). The prevalence of metabolic syndrome among patients with premature vascular disease may be as high as 50% (Solyomoss *et al.*, 2003). Treatment should focus on weight loss and increased physical activity, since being overweight or obese usually precludes optimal risk factor reduction. Specific treatment of increased LDL-C and triglyceride levels and low HDL-C levels should also be undertaken.

Treatment of Hypertriglyceridemia

There is increased CHD risk associated with the presence of triglyceride levels above 150 mg/dl. Three categories of hypertriglyceridemia are recognized (Table 35–5), and treatment is recommended based on the degree of elevation. Weight loss, increased exercise, and alcohol restriction are important for all hypertriglyceridemic patients. The LDL-C goal should be ascertained based on each patient’s risk factors or CHD status (Table 35–4). If triglycerides remain above 200 mg/dl after the LDL-C goal is reached, further reduction in triglycerides may be

Table 35–9**Clinical Identification of the Metabolic Syndrome**

RISK FACTOR	DEFINING LEVEL
Abdominal obesity*	Waist circumference [†]
Men	>102 cm (>40 in)
Women	>88 cm (>35 in)
Triglycerides	≥150 mg/dl
HDL-C	
Men	<40 mg/dl
Women	<50 mg/dl
Blood pressure	≥130/≥85 mm Hg
Fasting glucose	>110 mg/dl [†]

The 2001 NCEP guidelines define the metabolic syndrome as the presence of three or more of these risk factors. *Abbreviation:* HDL-C, high-density-lipoprotein cholesterol. *Overweight and obesity are associated with insulin resistance and the metabolic syndrome. However, the presence of abdominal obesity is more highly correlated with the metabolic risk factors than is an elevated body mass index. Therefore, the simple measurement of waist circumference is recommended to identify the body weight component of the metabolic syndrome. [†]Some male patients can develop multiple metabolic risk factors when the waist circumference is only marginally increased [e.g., 94–102 cm (37–39 in.)]. Such patients may have a strong genetic contribution to insulin resistance, and like men with categorical increases in waist circumference, they should benefit from changes in life habits.

achieved by increasing the dose of a statin or of niacin. Combination therapy (statin plus niacin or statin plus fibrate) may be required, but caution is necessary with these combinations to avoid myopathy (*see* “Statins in Combination with Other Lipid-Lowering Drugs,” below).

Table 35–10**Benefit of Lipid-Lowering Therapy in Patients with Low HDL-C and “Normal” LDL-C Levels**

	AFCAPS/TexCAPS (Lovastatin, 30 mg Once Daily)		VA HIT (Gemfibrozil, 0.6 g Twice Daily)	
	BASELINE	ON TREATMENT	BASELINE	ON TREATMENT
Total cholesterol (mg/dl)	228	184	175	170
LDL-C (mg/dl)	156	115	111	115
HDL-C (mg/dl)	37	39	32	35
Triglycerides (mg/dl)	163	143	161	122
Total cholesterol:HDL-C ratio	6.2	4.7	5.5	4.9
Primary event reduction		37%		22%

Abbreviations: AFCAPS/TexCAPS, Air Force/Texas Coronary Atherosclerosis Prevention Study; HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; VA HIT, Veterans Affairs High Density Lipoprotein Intervention Trial.

Treatment of Low HDL-C. The most frequent risk factor for premature CHD is low HDL-C. In one study of men with angiographically documented CHD, ~60% had HDL-C levels of <35 mg/dl and only 25% had LDL-C >160 mg/dl (Genest *et al.*, 1991). In a separate study of older men with CHD, 38% had HDL-C levels <35 mg/dl and two-thirds had HDL-C <40 mg/dl (Rubins *et al.*, 1995). Subjects with “normal” cholesterol levels of <200 mg/dl but with low HDL-C (<40 mg/dl) have as much CHD risk as subjects with higher total cholesterol levels (230 to 260 mg/dl) and more normal HDL-C (40 to 49 mg/dl) (Castelli *et al.*, 1986).

In patients with low HDL-C, the total cholesterol:HDL-C ratio is a particularly useful predictor of CHD risk. A favorable ratio is ≤3.5 and a ratio of >4.5 is associated with increased risk (Castelli, 1994). American men, who are a high-risk group, have a typical ratio of ~4.5. Patients with low HDL-C may have what are considered to be “normal” total and LDL cholesterol levels; however, because of their low HDL-C levels, such patients may be at high risk based on the total cholesterol:HDL-C ratio (e.g., a total cholesterol, 180 mg/dl; HDL-C, 30 mg/dl; ratio, 6). A desirable total cholesterol level in low-HDL-C patients may be considerably lower than 200 mg/dl, especially since low-HDL-C patients may also have moderately elevated triglycerides, which may reflect increased levels of atherogenic remnant lipoproteins (Grundy, 1998). Patients with average or low LDL-C, low HDL-C, and high total cholesterol:HDL-C ratios have benefitted from treatment. See Table 35–10 for a summary of trial results (Downs *et al.*, 1998; Rubins *et al.*, 1999).

The treatment of low HDL-C patients focuses on lowering LDL-C to the target level based on the patient’s risk

factor or CHD status (Table 35–4) and a reduction of VLDL cholesterol (estimated by dividing the plasma triglyceride level by 5) below 30 mg/dl. Satisfactory treatment results are a ratio of total cholesterol:HDL-C that is 3.5 or less. Patients with total cholesterol:HDL-C ratios >4.5 are at risk even if their “non-HDL-C” levels (LDL-C and VLDL cholesterol) are at the goal values recommended by the 2001 NCEP guidelines. Consequently, it is useful to base treatment of patients with low HDL-C levels on both LDL-C levels and the total cholesterol:HDL-C ratio (Tables 35–7 and 35–10) (Bersot *et al.*, 2003).

DRUG THERAPY OF DYSLIPIDEMIA

Statins

The statins are the most effective and best-tolerated agents for treating dyslipidemia. These drugs are competitive inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, which catalyzes an early, rate-limiting step in cholesterol biosynthesis. Higher doses of the more potent statins (*e.g.*, atorvastatin and simvastatin) also can reduce triglyceride levels caused by elevated VLDL levels. Some statins also are indicated for raising HDL-C levels, although the clinical significance of these effects on HDL-C remains to be proven.

Multiple well-controlled clinical trials have documented the efficacy and safety of simvastatin, pravastatin, lovastatin, and atorvastatin in reducing fatal and nonfatal CHD events, strokes, and total mortality (Table 35–3) (Law *et al.*, 2003). Rates of adverse events in statin trials were the same in the placebo groups and in the groups receiving the drug. This was true with regard to noncardiac illness and the two laboratory tests, hepatic transaminases and creatine kinase (CK), that are commonly monitored in patients taking statins (Law *et al.*, 2003).

History. Statins were isolated from a mold, *Penicillium citrinum*, and identified as inhibitors of cholesterol biosynthesis in 1976 by Endo and colleagues. Subsequent studies by Brown and Goldstein established that statins act by inhibiting HMG-CoA reductase. The first statin studied in humans was *compactin*, renamed *mevastatin*, which demonstrated the therapeutic potential of this class of drugs. However, Alberts and colleagues at Merck developed the first statin approved for use in humans, lovastatin (formerly known as mevinoлин), which was isolated from *Aspergillus terreus*. Five other statins are also available. Pravastatin and simvastatin are chemically modified derivatives of lovastatin (Figure 35–3). Atorvastatin, *fluvastatin*, and *rosuvastatin* are structurally distinct synthetic compounds.

Chemistry. The structural formulas of the original statin (mevastatin) and the six statins currently available in the United States are shown in

Figure 35–3 along with the reaction (conversion of HMG-CoA to mevalonate) catalyzed by HMG-CoA reductase, the enzyme they competitively inhibit. The statins possess a side group that is structurally similar to HMG-CoA. Mevastatin, lovastatin, simvastatin, and pravastatin are fungal metabolites, and each contains a hexahydronaphthalene ring. Lovastatin differs from mevastatin in having a methyl group at carbon 3. There are two major side chains. One is a methylbutyrate ester (lovastatin and pravastatin) or a dimethylbutyrate ester (simvastatin). The other contains a hydroxy acid that forms a six-membered analog of the intermediate compound in the HMG-CoA reductase reaction (Figure 35–3). Fluvastatin, atorvastatin, and rosuvastatin are entirely synthetic compounds containing a heptanoic acid side chain that forms a structural analog of the HMG-CoA intermediate. As a result of their structural similarity to HMG-CoA, statins are reversible competitive inhibitors of the enzyme’s natural substrate, HMG-CoA. The inhibition constant (K_i) of the statins is in the 1 nmol range; the dissociation constant of HMG-CoA is three orders of magnitude higher.

Lovastatin and simvastatin are lactone prodrugs that are modified in the liver to active hydroxy acid forms. Since they are lactones, they are less soluble in water than are the other statins, a difference that appears to have little if any clinical significance. Pravastatin (an acid in the active form), fluvastatin (sodium salt), and atorvastatin and rosuvastatin (calcium salts), are all administered in the active, open-ring form.

Mechanism of Action. Statins exert their major effect—reduction of LDL levels—through a mevalonic acid–like moiety that competitively inhibits HMG-CoA reductase. By reducing the conversion of HMG-CoA to mevalonate, statins inhibit an early and rate-limiting step in cholesterol biosynthesis.

Statins affect blood cholesterol levels by inhibiting hepatic cholesterol synthesis, which results in increased expression of the LDL receptor gene. In response to the reduced free cholesterol content within hepatocytes, membrane-bound SREBPs are cleaved by a protease and translocated to the nucleus. The transcription factors then bind the sterol-responsive element of the LDL receptor gene, enhancing transcription and increasing the synthesis of LDL receptors (Horton *et al.*, 2002). Degradation of LDL receptors also is reduced. The greater number of LDL receptors on the surface of hepatocytes results in increased removal of LDL from the blood, thereby lowering LDL-C levels.

Some studies suggest that statins also can reduce LDL levels by enhancing the removal of LDL precursors (VLDL and IDL) and by decreasing hepatic VLDL production (Aguila-Salinas *et al.*, 1998). Since VLDL remnants and IDL are enriched in apoE, a statin-induced increase in the number of LDL receptors, which recognize both apoB-100 and apoE, enhances the clearance of these LDL precursors. The reduction in hepatic VLDL production induced by statins is thought to be mediated by reduced synthesis of cholesterol, a required component of VLDL (Thompson, 1996). This mechanism also likely accounts for the triglyceride-lowering effect of statins (Ginsberg, 1998) and may account for the reduction (~25%) of LDL-C levels in patients with homozygous familial hypercholesterolemia treated with 80 mg of atorvastatin or simvastatin.

Triglyceride Reduction by Statins. Triglyceride levels >250 mg/dl are reduced substantially by statins, and the percent reduction

Figure 35–3. Chemical structures of the statins and the reaction catalyzed by 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase.

achieved is similar to the percent reduction in LDL-C (Stein *et al.*, 1998). Accordingly, hypertriglyceridemic patients taking the highest doses of the most potent statins (simvastatin and atorvastatin, 80 mg/day; rosuvastatin, 40 mg/day) experience a 35% to 45% reduction in LDL-C and a similar reduction in fasting triglyceride levels (Bakker-Arkema *et al.*, 1996; Ose *et al.*, 2000; Hunninghake *et al.*, 2004). If baseline triglyceride levels are below 250 mg/dl, reductions in triglycerides do not exceed 25% irrespective of the dose or statin used (Stein *et al.*, 1998). Similar reductions (35% to 45%) in triglycerides can be accomplished with doses of fibrates or niacin (*see below*), although these drugs do not reduce LDL-C to the same extent as atorvastatin or simvastatin at the 80-mg dose.

Effect of Statins on HDL-C Levels. Most studies of patients treated with statins have systematically excluded patients with low HDL-C levels. In studies of patients with elevated LDL-C levels and gender-appropriate HDL-C levels (40 to 50 mg/dl for men; 50 to 60 mg/dl for women), an increase in HDL-C of 5% to 10% was observed, irrespective of the dose or statin employed. However, in patients with reduced HDL-C levels (<35 mg/dl), statins may differ in their effects on HDL-C levels. Simvastatin, at its highest dose of 80 mg, increases HDL-C and apoA-I levels more than a comparable

dose of atorvastatin (Crouse *et al.*, 2000). In preliminary studies of patients with hypertriglyceridemia and low HDL-C, rosuvastatin appears to raise HDL-C levels by as much as 15% to 20% (Hunninghake *et al.*, 2004). More studies are needed to ascertain whether the effects of statins on HDL-C in patients with low HDL-C levels are clinically significant.

Effects of Statins on LDL-C Levels. Statins lower LDL-C by 20% to 55%, depending on the dose and statin used. In large trials comparing the effects of the various statins, equivalent doses appear to be 5 mg of simvastatin = ~15 mg of lovastatin = ~15 mg of pravastatin = ~40 mg of fluvastatin (Pedersen and Tobert, 1996); 20 mg of simvastatin = ~10 mg of atorvastatin (Jones *et al.*, 1998; Crouse *et al.*, 1999), and 20 mg of atorvastatin = 10 mg of rosuvastatin (Jones *et al.*, 2003). Analysis of dose-response relationships for all statins demonstrates that the efficacy of LDL-C lowering is log-linear; LDL-C is reduced by ~6% (from baseline) with each doubling of the dose (Pedersen and Tobert, 1996; Jones *et al.*, 1998). Maximal effects on plasma cholesterol levels are achieved within 7 to 10 days.

Table 35–11 provides information on the statin doses required to reduce LDL-C by 20% to 55%. The fractional reductions achieved with the various doses are the same regardless of the absolute value of the

Table 35–11**Doses (mg) of Statins Required to Achieve Various Reductions in Low-Density-Lipoprotein Cholesterol from Baseline**

	20%–25%	26%–30%	31%–35%	36%–40%	41%–50%	51%–55%
Atorvastatin	—	—	10	20	40	80
Fluvastatin	20	40	80			
Lovastatin	10	20	40	80		
Pravastatin	10	20	40			
Rosuvastatin	—	—	—	5	10	20, 40
Simvastatin	—	10	20	40	80	

baseline LDL-C level. The statins are effective in almost all patients with high LDL-C levels. The exception is patients with homozygous familial hypercholesterolemia, who have very attenuated responses to the usual doses of statins because both alleles of the LDL receptor gene code for dysfunctional LDL receptors; the partial response in these patients is due to a reduction in hepatic VLDL synthesis associated with the inhibition of HMG-CoA reductase–mediated cholesterol synthesis. Statin therapy does not reduce Lp(a) levels (Kostner *et al.*, 1989).

Potential Cardioprotective Effects Other Than LDL Lowering.

Although the statins clearly exert their major effects on CHD by lowering LDL-C and improving the lipid profile as reflected in plasma cholesterol levels (Figure 35–2) (Thompson and Barter, 1999), a multitude of potentially cardioprotective effects are being ascribed to these drugs (Liao and Laufs, 2005). However, the mechanisms of action for non-lipid-lowering roles of statins have not been established, and it is not known whether these potential pleiotropic effects represent a class-action effect, differ among statins, or are biologically or clinically relevant. Until these questions are resolved, selection of a specific statin should not be based on any one of these effects. Nevertheless, the potential importance of the nonlipid roles of statins merits discussion.

Statins and Endothelial Function. A variety of studies have established that the vascular endothelium plays a dynamic role in vasoconstriction/relaxation. Hypercholesterolemia adversely affects the processes by which the endothelium modulates arterial tone. Statin therapy enhances endothelial production of the vasodilator nitric oxide, leading to improved endothelial function after a month of therapy (O’Driscoll *et al.*, 1997; Laufs *et al.*, 1998). However, similar results have been observed after a single acute reduction of LDL levels by apheresis (Tamai *et al.*, 1997). In nonhuman primates fed a high-cholesterol diet, statin therapy improved endothelial function independent of significant changes in plasma cholesterol levels (Williams *et al.*, 1998).

Statins and Plaque Stability. The vulnerability of plaques to rupture and thrombosis is of greater clinical relevance than the degree of stenosis they cause (Corti *et al.*, 2003). Statins may affect plaque stability in a variety of ways. They reportedly inhibit monocyte infiltration into the artery wall in a rabbit model (Bustos *et al.*, 1998) and inhibit macrophage secretion of matrix metalloproteinases *in vitro* (Bellosta *et al.*, 1998). The metalloproteinases degrade extracellular matrix components and thus weaken the fibrous cap of atherosclerotic plaques.

Statins also appear to modulate the cellularity of the artery wall by inhibiting proliferation of smooth muscle cells and enhancing apoptotic cell death (Corsini *et al.*, 1998). It is debatable whether

these effects would be beneficial or harmful if they occurred *in vivo*. Reduced proliferation of smooth muscle cells and enhanced apoptosis could retard initial hyperplasia and restenosis, but also could weaken the fibrous cap and destabilize the lesion. Interestingly, statin-induced suppression of cell proliferation and the induction of apoptosis have been extended to tumor biology. The effects of statins on isoprenoid biosynthesis and protein phenylation associated with reduced synthesis of the cholesterol precursor mevalonate may alter the development of malignancies (Davignon and Laaksonen, 1999; Wong *et al.*, 2002; Li *et al.*, 2003).

Statins and Inflammation. Appreciation of the importance of inflammatory processes in atherogenesis is growing (Libby, 2002), and statins may have an antiinflammatory role (Libby and Aikawa, 2003). Statins decreased the risk of CHD and levels of C-reactive protein (CRP, an independent marker for inflammation and high CHD risk) independently of cholesterol lowering (Libby and Aikawa, 2003; Libby and Ridker, 2004). Body weight and the metabolic syndrome are associated with elevated levels of highly sensitive CRP, leading some to suggest that the CRP may simply be a marker of obesity and insulin resistance (Pearson *et al.*, 2003). It remains to be determined whether the C-reactive protein is simply a marker of inflammation or if it contributes to the pathogenesis of atherosclerosis. The clinical utility of measuring CRP with “highly sensitive” assays appears to be limited to those primary prevention subjects with a moderate (10% to 20%) 10-year risk of sustaining a CHD event. Values of highly sensitive CRP above 3 mg/L suggests that such patients should be managed as secondary prevention patients (Pearson *et al.*, 2003).

Statins and Lipoprotein Oxidation. Oxidative modification of LDL appears to play a key role in mediating the uptake of lipoprotein cholesterol by macrophages and in other processes, including cytotoxicity within lesions (Steinberg, 1997). Statins reduce the susceptibility of lipoproteins to oxidation both *in vitro* and *ex vivo* (Hussein *et al.*, 1997).

Statins and Coagulation. Statins reduce platelet aggregation (Hussein *et al.*, 1997) and reduce the deposition of platelet thrombi in the porcine aorta model (Lacoste *et al.*, 1995). In addition, the different statins have variable effects on fibrinogen levels, the significance of which remains to be determined (Rosenson and Tangney, 1998). Elevated plasma fibrinogen levels are associated with an increase in the incidence of CHD (Ernst and Resch, 1993); however, it remains to be determined whether fibrinogen is a contributor to or a marker of disease.

Absorption, Metabolism, and Excretion. **Absorption from the Small Intestine.** After oral administration, intestinal absorption of the statins varies between 30% and 85%. All the statins, except simvastatin and

lovastatin, are administered in the β -hydroxy acid form, which is the form that inhibits HMG-CoA reductase. Simvastatin and lovastatin are administered as inactive lactones, which must be transformed in the liver to their respective β -hydroxy acids, simvastatin acid (SVA) and lovastatin acid (LVA). There is extensive first-pass hepatic uptake of all statins, but the mechanisms by which they enter the liver differ. Atorvastatin, pravastatin, and rosuvastatin uptake is mediated by the organic anion transporter 2 (OATP2) (Hsiang *et al.*, 1999; Schneck *et al.*, 2004). The highly lipophilic lactone forms of simvastatin and lovastatin are thought to enter the liver by simple diffusion (Ohtawa *et al.*, 1999). Due to extensive first-pass hepatic uptake, systemic bioavailability of the statins and their hepatic metabolites varies between 5% and 30% of administered doses. The metabolites of all statins, except fluvastatin and pravastatin, have some HMG-CoA reductase inhibitory activity (Bellosta *et al.*, 2004). Under steady-state conditions, small amounts of the parent drug and its metabolites produced in the liver can be found in the systemic circulation. After the lactones of simvastatin and lovastatin are transformed in the liver to SVA and LVA, small amounts of these active inhibitors of HMG-CoA reductase can be found in the systemic circulation as well as small amounts of the lactone forms. In the plasma, greater than 95% of statins and their metabolites are protein bound with the exception of pravastatin and its metabolites, which are only 50% bound.

After an oral dose, plasma concentrations of statins peak in 1 to 4 hours. The half-lives of the parent compounds are 1 to 4 hours, except in the case of atorvastatin and rosuvastatin, which have half-lives of about 20 hours. The longer half-lives of atorvastatin and rosuvastatin may contribute to their greater cholesterol-lowering efficacy (Corsini *et al.*, 1999). The liver biotransforms all statins, and more than 70% of statin metabolites are excreted by the liver with subsequent elimination in the feces (Bellosta *et al.*, 2004). As noted below, inhibition by other drugs of OATP2 activity (which transports several statins into hepatocytes) and inhibition or induction of CYP3A4 by a variety of pharmacologic agents provide rationales for drug-drug interactions involving statins.

Adverse Effects and Drug Interactions. Hepatotoxicity. Initial post-marketing surveillance studies of the statins revealed an elevation in hepatic transaminase to values greater than three times the upper limit of normal, with an incidence as great as 1%. The incidence appeared to be dose related. However, as of 2003, in the placebo-controlled outcome trials in which 10- to 40-mg doses of simvastatin, lovastatin, fluvastatin, atorvastatin, or pravastatin were used, the incidence of threefold elevations in hepatic transaminases was 1% to 3% in the active drug treatment groups and 1.1% in placebo patients (Law *et al.*, 2003). No cases of liver failure occurred in these trials. Although serious hepatotoxicity is rare, 30 cases of liver failure associated with statin use were reported to the FDA between 1987 and 2000, a rate of about one case per million person-years of use (Law *et al.*, 2003). It is therefore reasonable to measure alanine aminotransferase (ALT) at baseline and thereafter when clinically indicated. Patients taking 80-mg doses (or 40 mg of rosuvastatin) should have their ALT checked after 3 months. If the ALT values are normal, it is not necessary to repeat the ALT test unless clinically indicated.

Myopathy. The major adverse effect of clinical significance associated with statin use is myopathy. Between 1987 and 2001, the FDA recorded 42 deaths from rhabdomyolysis induced by statins (except *cerivastatin*, which has been withdrawn from the market worldwide). This is a rate of one death per million prescriptions (30-day

supply). In the statin trials described above (under hepatotoxicity), rhabdomyolysis occurred in eight active drug recipients *versus* five placebo subjects. Among active drug recipients, 0.17% had CK values exceeding 10 times the upper limit of normal, the value commonly used to define statin-induced rhabdomyolysis; among placebo-treated subjects, the incidence was 0.13%. Only 13 out of 55 drug-treated subjects and 4 out of 43 placebo subjects with greater than tenfold elevations of CK reported any muscle symptoms (Law *et al.*, 2003).

The incidence of myopathy is quite low (~0.01%), but the risk of myopathy and rhabdomyolysis increases in proportion to plasma statin concentrations (Omar *et al.*, 2001). Consequently, factors inhibiting statin catabolism are associated with increased myopathy risk, including advanced age (especially >80 years of age), hepatic or renal dysfunction, perioperative periods, multisystem disease (especially in association with diabetes mellitus), small body size, and untreated hypothyroidism (Pasternak *et al.*, 2002; Thompson *et al.*, 2003). Concomitant use of drugs that diminish statin catabolism is associated with myopathy and rhabdomyolysis in 50% to 60% of cases (Thompson *et al.*, 2003). The most common statin interactions occurred with fibrates, especially *gemfibrozil*, 38%; *cyclosporine*, 4%; *digoxin*, 5%; *warfarin*, 4%; macrolide antibiotics, 3%; *mibefradil*, 2%; and azole antifungals, 1% (Thompson *et al.*, 2003). Other drugs that increase the risk of statin-induced myopathy include niacin (rare), HIV protease inhibitors, *amiodarone*, and *nefazodone* (Pasternak *et al.*, 2002).

There are a variety of pharmacokinetic mechanisms by which these drugs increase myopathy risk when administered concomitantly with statins. Gemfibrozil, the drug most commonly associated with statin-induced myopathy, inhibits both uptake of the active hydroxy acid forms of statins into hepatocytes by OATP2 and interferes with the transformation of most statins by CYPs and glucuronidases. Primarily due to inhibition of OATP2-mediated hepatic uptake, coadministration of gemfibrozil nearly doubles the plasma concentration of rosuvastatin (Schneck *et al.*, 2004). This occurs despite the fact that gemfibrozil has little effect on rosuvastatin glucuronidation or oxidation, which are important pathways in the catabolism of the other statins (Prueksaritanont *et al.*, 2002a; Prueksaritanont *et al.*, 2002b; Prueksaritanont *et al.*, 2002c). Other fibrates, especially fenofibrate, do not interfere with the glucuronidation of statins and pose less risk of myopathy when used in combination with statin therapy (for reviews of statin interactions with other drugs, *see* Corsini, 2003; Bellosta *et al.*, 2004). Concomitant therapy with simvastatin, 80 mg daily, and fenofibrate, 160 mg daily, results in no clinically significant pharmacokinetic interaction (Bergman *et al.*, 2004). Similar results were obtained in a study of low-dose rosuvastatin, 10 mg daily, plus fenofibrate, 67 mg three times a day (Martin *et al.*, 2003). When statins are administered with niacin, the myopathy is probably caused by an enhanced inhibition of skeletal muscle cholesterol synthesis (a pharmacodynamic interaction) (Christians *et al.*, 1998).

Other drugs that interfere with statin oxidation are those metabolized primarily by CYP3A4 and include certain macrolide antibiotics (*e.g.*, *erythromycin*); azole antifungals (*e.g.*, *itraconazole*); cyclosporine; a phenylpiperazine antidepressant, nefazodone; and HIV protease inhibitors (Christians *et al.*, 1998; Corsini, 2003; Bellosta *et al.*, 2004). These pharmacokinetic interactions are associated with increased plasma concentrations of statins and their active metabolites. Atorvastatin, lovastatin, and simvastatin are primarily metabolized by CYP3A4. Fluvastatin is mostly (50% to 80%) metabolized by CYP2C9 to inactive metabolites, but CYP3A4 and CYP2C8 also

contribute to its metabolism. Pravastatin, however, is not metabolized to any appreciable extent by the CYP system (Corsini *et al.*, 1999) and is excreted unchanged in the urine. Pravastatin, fluvastatin, and rosuvastatin are not extensively metabolized by CYP3A4. Pravastatin and fluvastatin may be less likely to cause myopathy when used with one of the predisposing drugs. However, because cases of myopathy have been reported with both drugs, the benefits of combined therapy with any statin should be carefully weighed against the risk of myopathy. Although rosuvastatin is not transformed to any appreciable extent by oxidation, cases of myopathy have been reported, particularly in association with concomitant use of gemfibrozil (Schneck *et al.*, 2004).

The myopathy syndrome is characterized by intense myalgia similar to flu-related myalgia, first in the arms and thighs and then in the entire body, along with weakness and fatigue. Symptoms progress as long as the patient continues to take the statin. Myoglobinuria, renal failure, and death have been reported (Staffa *et al.*, 2002). Serum CK levels in affected patients typically are tenfold higher than the upper limit of normal. As soon as myopathy is suspected, a blood sample should be drawn to document the presence of a significantly elevated (approaching tenfold elevation) CK level, since many patients complain of muscle pain unrelated to true statin-induced myopathy. The statin, and any other drug suspected of contributing to myopathy, should be discontinued if true myopathy is suspected, even if it is not possible to measure CK activity to document the presence of myopathy. Rhabdomyolysis should be excluded and renal function monitored.

Since myopathy rarely occurs in the absence of combination therapy, routine CK monitoring is not recommended unless the statins are used with one of the predisposing drugs. Such monitoring is not sufficient to protect patients, as myopathy can occur months to years after combined therapy is initiated. As a rule, statins may be used in combination with one of these predisposing drugs with reduced risk of myopathy if the statin is administered at no more than 25% of its maximal dose (Christians *et al.*, 1998; Corsini, 2003; Bellosta *et al.*, 2004). This dose would be 10 mg for rosuvastatin and 20 mg for all other statins.

Early concerns about statin-induced eye pathology have not been substantiated (Bradford *et al.*, 1991). Likewise, speculation that the more lipid-soluble statins might penetrate to the CNS and cause effects there has proven unfounded; except as they affect statin uptake by hepatic OATP2 (*see above*), differences in lipid solubility among statins do not appear to be clinically relevant.

Pregnancy. *The safety of statins during pregnancy has not been established.* Women wishing to conceive should not take statins. During their childbearing years, women taking statins should use highly effective contraception (*see Chapter 57*). Nursing mothers also are advised to avoid taking statins.

Therapeutic Uses. Each statin has a low recommended starting dose that reduces LDL-C by 20% to 30%. Dyslipidemic patients frequently remain on their initial dose, are not titrated to achieve their target LDL-C level, and thus remain undertreated. For this reason, it is advisable to start each patient on a dose that will achieve the patient's target goal for LDL-C lowering. For example, a patient with a baseline LDL-C of 150 mg/dl and a goal of 100 mg/dl requires a 33% reduction

in LDL-C and should be started on a dose expected to provide it (Table 35–11).

Hepatic cholesterol synthesis is maximal between midnight and 2:00 A.M. Thus, statins with half-lives of 4 hours or less (all but atorvastatin and rosuvastatin) should be taken in the evening.

The manufacturer's initial recommended dose of lovastatin (MEVACOR) is 20 mg and is slightly more effective if taken with the evening meal than if it is taken at bedtime, although bedtime dosing is preferable to missing doses. The dose of lovastatin may be increased every 3 to 6 weeks up to a maximum of 80 mg per day. The 80-mg dose is slightly (2% to 3%) more effective if given as 40 mg twice daily. Lovastatin, at 20 mg, is marketed in combination with 500, 750, or 1000 mg of extended-release niacin (ADVICOR). Few patients are appropriate candidates for this fixed-dose combination (*see section on nicotinic acid, below*). Alternate-day statin therapy has been associated with nearly equivalent efficacy, as judged by serum lipid profiles and reduced cost, and has been proposed as a means to enhance compliance; clinical trials are needed to evaluate the efficacy of alternate-day dosing with regard to reducing clinical events.

The approved starting dose of simvastatin (ZOCOR) for most patients is 20 mg at bedtime unless the required LDL-C reduction exceeds 45% or the patient is a high-risk secondary prevention patient, in which case a 40-mg starting dose is indicated. The maximal dose is 80 mg, and the drug should be taken at bedtime. In patients taking cyclosporine, fibrates, or niacin, the daily dose should not exceed 20 mg.

Pravastatin (PRAVACHOL) therapy is initiated with a 20- or 40-mg dose that may be increased to 80 mg. This drug should be taken at bedtime. Since pravastatin is a hydroxy acid, it is bound by bile-acid sequestrants, which reduces its absorption. Practically, this is rarely a problem since the resins should be taken before meals and pravastatin should be taken at bedtime. Pravastatin is also marketed in combination with buffered aspirin (PRAVIGARD). The small advantage of combining these two drugs should be weighed against the disadvantages inherent in fixed-dose combinations.

The starting dose of fluvastatin (LESCOL) is 20 or 40 mg, and the maximum is 80 mg per day. Like pravastatin, it is administered as a hydroxy acid and should be taken at bedtime, several hours after ingesting a bile-acid sequestrant (if the combination is used).

Atorvastatin (LIPITOR) has a long half-life, which allows administration of this statin at any time of the day. The starting dose is 10 mg, and the maximum is 80 mg per day.

Atorvastatin is marketed in combination with the Ca²⁺-channel blocker amlodipine (CADUET), for patients with hypertension or angina as well as hypercholesterolemia. The physician should weigh any advantage of combination against the associated risks and disadvantages.

Rosuvastatin (CRESTOR) is available in doses ranging between 5 and 40 mg. It has a half-life of 20 to 30 hours and may be taken at any time of day. Since experience with rosuvastatin is limited, treatment should be initiated with 5 to 10 mg daily, increasing stepwise, if needed, until the incidence of myopathy is better defined. If the combination of gemfibrozil with rosuvastatin is used, the dose of rosuvastatin should not exceed 10 mg. Rosuvastatin at a dose of 80 mg (dose not approved by the FDA) was noted to cause proteinuria and hematuria and isolated cases of renal failure. Other statins have also been observed to cause proteinuria, apparently by inhibiting

tubular protein reabsorption. Whether statin-induced proteinuria is harmful or beneficial, especially in patients with chronic kidney disease, remains to be determined (Agarwal, 2004). The significance and etiology of the hematuria caused by the 80-mg dose of rosuvastatin remains to be determined.

The choice of statins should be based on efficacy (reduction of LDL-C) and cost. Three drugs (lovastatin, simvastatin, and pravastatin) have been used safely in clinical trials involving thousands of subjects for 5 or more years. The documented safety records of these statins should be considered, especially when initiating therapy in younger patients. Once drug treatment is initiated, it is almost always lifelong. Baseline determinations of alanine aminotransferase (ALT) and repeat testing at 3 to 6 months are recommended. If ALT is normal after the initial 3 to 6 months, then it need not be repeated more than once every 6 to 12 months. Creatine kinase (CK) measurements are not routinely necessary unless the patient also is taking a drug that enhances the risk of myopathy. Because myopathy may develop months to years after the start of combined therapy, it is unlikely that routine monitoring for the accompanying rise in CK will consistently herald the onset, even if monitoring is performed every 3 to 4 months.

Statin Use by Children. Some statins have been approved for use in children with heterozygous familial hypercholesterolemia. Atorvastatin, lovastatin, and simvastatin are indicated for children age 11 or older. Pravastatin is approved for children age 8 or older.

Statins in Combination with Other Lipid-Lowering Drugs. Statins, in combination with the bile acid-binding resins *cholestyramine* and *colestipol*, produce 20% to 30% greater reductions in LDL-C than can be achieved with statins alone (Tikkanen, 1996). Preliminary data indicate that *colesevelam hydrochloride* plus a statin lowers LDL-C by 8% to 16% more than statins alone. Niacin also can enhance the effect of statins, but the occurrence of myopathy increases when statin doses greater than 25% of maximum (e.g., 20 mg of simvastatin or atorvastatin) are used with niacin (Guyton and Capuzzi, 1998). The combination of a fibrate (*clofibrate*, gemfibrozil, or fenofibrate) with a statin is particularly useful in patients with hypertriglyceridemia and high LDL-C levels. This combination increases the risk of myopathy but usually is safe with a fibrate at its usual maximal dose and a statin at no more than 25% of its maximal dose (Tikkanen, 1996; Athyros *et al.*, 1997). Fenofibrate, which is least likely to interfere with statin metabolism, appears to be the safest fibrate to use with statins (Prueksaritanont *et al.*, 2002b).

Triple therapy with resins, niacin, and statins can reduce LDL-C by up to 70% (Malloy *et al.*, 1987). VYTORIN, a fixed combination of simvastatin (10, 20, 40, or 80 mg) and ezetimibe (10 mg), decreased LDL-C levels by up to 60% at 24 weeks.

Bile-Acid Sequestrants

The two established bile-acid sequestrants or resins (cholestyramine and colestipol) are among the oldest of the hypolipidemic drugs, and they are probably the safest, since they are not absorbed from the intestine. These resins are also recommended for patients 11 to 20 years of age. Because statins are so effective as monotherapy, the resins are most often used as second agents if statin therapy does not lower LDL-C levels sufficiently. When used with a statin, cholestyramine and colestipol usually are prescribed at submaximal doses. Maximal doses can reduce LDL-C by up to 25% but are associated with unacceptable gastrointestinal side effects (bloating and constipation) that limit compliance. Colesevelam is a newer bile-acid sequestrant that is prepared as an anhydrous gel and taken as a tablet. It lowers LDL-C by 18% at its maximum dose. The safety and efficacy of colesevelam have not been studied in pediatric patients or pregnant women.

Cholestyramine was used in the Coronary Primary Prevention Trial, one of the first studies to document that lowering LDL-C prevents heart disease events (Lipid Research Clinics Program, 1984). Cholestyramine therapy reduced total cholesterol by 13% and LDL-C by 20%, compared with diet-induced reductions of 5% in total cholesterol and 8% in LDL-C. CHD events (fatal and nonfatal) were reduced by 19%, suggesting that a 1% reduction in total cholesterol is associated with at least a 2% reduction in CHD events.

Chemistry. Figure 35-4 shows the structure of these agents. Cholestyramine and colestipol are anion-exchange resins. Cholestyramine, a polymer of styrene and divinylbenzene with active sites formed from trimethylbenzylammonium groups, is a quaternary amine. Colestipol, a copolymer of diethylenetriamine and 1-chloro-2,3-epoxypropane, is a mixture of tertiary and quaternary diamines. Cholestyramine and colestipol are hygroscopic powders administered as chloride salts and are insoluble in water. Colesevelam is a polymer, poly(allylamine hydrochloride), cross-linked with epichlorohydrin and alkylated with 1-bromodecane and (6-bromohexyl)-trimethylammonium bromide. It is a hydrophilic gel and insoluble in water.

Mechanism of Action. The bile-acid sequestrants are highly positively charged and bind negatively charged bile acids. Because of their large size, the resins are not absorbed, and the bound bile acids are excreted in the

Figure 35–4. Structures of cholestyramine, colestipol, and colesevelam.

stool. Since over 95% of bile acids are normally reabsorbed, interruption of this process depletes the pool of bile acids, and hepatic bile-acid synthesis increases. As a result, hepatic cholesterol content declines, stimulating the production of LDL receptors, an effect similar to that of statins. The increase in hepatic LDL receptors increases LDL clearance and lowers LDL-C levels, but this effect is partially offset by the enhanced cholesterol

synthesis caused by upregulation of HMG-CoA reductase (Shepherd *et al.*, 1980). Inhibition of reductase activity by a statin substantially increases the effectiveness of the resins.

The resin-induced increase in bile-acid production is accompanied by an increase in hepatic triglyceride synthesis, which is of consequence in patients with significant hypertriglyceridemia (baseline triglyceride level >250 mg/dl). In such patients, bile-acid sequestrant therapy may cause striking increases in triglyceride levels. An initial report suggests that colesevelam may not raise triglyceride levels significantly (Davidson *et al.*, 1999); until this issue is resolved, use of colesevelam to lower LDL-C levels in hypertriglyceridemic patients should be accompanied by frequent (every 1 to 2 weeks) monitoring of fasting triglyceride levels until the triglyceride level is stable, or the use of colesevelam in these patients should be avoided.

Effects on Lipoprotein Levels. The reduction in LDL-C by resins is dose-dependent. Doses of 8 to 12 g of cholestyramine or 10 to 15 g of colestipol are associated with 12% to 18% reductions in LDL-C. Maximal doses (24 g of cholestyramine, 30 g of colestipol) may reduce LDL-C by as much as 25%, but will cause GI side effects that are poorly tolerated by most patients. One to two weeks is sufficient to attain maximal LDL-C reduction by a given resin dose. In patients with normal triglyceride levels, triglycerides may increase transiently and then return to baseline. HDL-C levels increase 4% to 5%. Statins plus resins or niacin plus resins can reduce LDL-C by as much as 40% to 60%. Colesevelam, in doses of 3 to 3.75 g, reduces LDL-C levels by 9% to 19%.

Adverse Effects and Drug Interactions. The resins are generally safe, as they are not systemically absorbed. Since they are administered as chloride salts, rare instances of hyperchloremic acidosis have been reported. Severe hypertriglyceridemia is a contraindication to the use of cholestyramine and colestipol since these resins increase triglyceride levels (Crouse, 1987). At present, there are insufficient data on the effect of colesevelam on triglyceride levels.

Cholestyramine and colestipol both are available as a powder that must be mixed with water and drunk as a slurry. The gritty sensation is unpleasant to patients initially but can be tolerated. Colestipol is available in a tablet form that reduces the complaint of grittiness but not the gastrointestinal symptoms. Colesevelam is available as a hard capsule that absorbs water and creates a soft, gelatinous material that allegedly minimizes the potential for gastrointestinal irritation.

Patients taking cholestyramine and colestipol complain of bloating and dyspepsia. These symptoms can be substantially reduced if the drug is completely suspended in liquid several hours before ingestion (*e.g.*, evening doses can be mixed in the morning and refrigerated; morning doses can be mixed the previous evening and refrigerated). Constipation may occur but sometimes can be prevented by adequate daily water intake and psyllium, if necessary. Colesevelam may be less likely to cause the dyspepsia, bloating, and constipation observed in patients treated with cholestyramine or colestipol (Davidson *et al.*, 1999).

Cholestyramine and colestipol bind and interfere with the absorption of many drugs, including some thiazides, *furosemide*, *propranolol*, *l-thyroxine*, digoxin, warfarin, and some of the statins

(Farmer and Gotto, 1994). The effect of cholestyramine and colestipol on the absorption of most drugs has not been studied. For this reason, it is wise to administer all drugs either 1 hour before or 3 to 4 hours after a dose of cholestyramine or colestipol. Colesevelam does not appear to interfere with the absorption of fat-soluble vitamins or of drugs such as digoxin, lovastatin, warfarin, *metoprolol*, *quinidine*, and *valproic acid*. The maximum concentration and the AUC of sustained-release *verapamil* are reduced by 31% and 11%, respectively, when the drug is coadministered with colesevelam. Since the effect of colesevelam on the absorption of other drugs has not been tested, it seems prudent to recommend that patients take other medications 1 hour before or 3 or 4 hours after a dose of colesevelam.

Therapeutic Uses. Cholestyramine resin (QUESTRAN, others) is available in bulk (with scoops that measure a 4-g dose) or in individual packets of 4 g. Additional flavorings are added to increase palatability. The “light” preparations contain artificial sweeteners rather than sucrose. Colestipol hydrochloride (COLESTID, others) is available in bulk, in individual packets containing 5 g of colestipol, or as 1-g tablets.

Resins should never be taken in the dry form. The powdered forms of cholestyramine (4 g per dose) and colestipol (5 g per dose) are either mixed with a fluid (water or juice) and drunk as a slurry or mixed with crushed ice in a blender. Ideally, patients should take the resins before breakfast and before supper, starting with one scoop or packet twice daily, and increasing the dosage after several weeks or longer as needed and as tolerated. Patients generally will not take more than two doses (scoops or packets) twice a day.

Colesevelam hydrochloride (WELCHOL) is available as a solid tablet containing 0.625 g of colesevelam. The starting dose is either three tablets taken twice daily with meals or all six tablets taken with a meal. The tablets should be taken with a liquid. The maximum daily dose is 7 tablets (4.375 g).

Niacin (Nicotinic Acid)

Niacin, *nicotinic acid* (pyridine-3-carboxylic acid), one of the oldest drugs used to treat dyslipidemia, favorably affects virtually all lipid parameters (Knopp, 1998).

Niacin is a water-soluble B-complex vitamin that functions as a vitamin only after its conversion to NAD or NADP, in which it occurs as an amide. Both niacin and its amide may be given orally as a source of niacin for its functions as a vitamin but only niacin affects lipid levels. The hypolipidemic effects of niacin require larger doses than are required for its vitamin effects. Niacin is the best agent available for increasing HDL-C (increments of 30% to 40%); it also lowers triglycerides by 35% to 45% (as effectively as fibrates and the more

potent statins) and reduces LDL-C levels by 20% to 30% (Knopp *et al.*, 1985; Vega and Grundy, 1994; Martin-Jadraque *et al.*, 1996). Niacin also is the only lipid-lowering drug that reduces Lp(a) levels significantly, by about 40% (Carlson *et al.*, 1989); however, adequate control of other lipid abnormalities renders an elevation of Lp(a) harmless (Maher *et al.*, 1995). Estrogen and neomycin also significantly lower Lp(a) levels (Espeland *et al.*, 1998; Shlipak *et al.*, 2000). Despite its salutary effect on lipids, niacin has side effects that limit its use (see “Adverse Effects,” below).

Mechanism of Action. In adipose tissue, niacin inhibits the lipolysis of triglycerides by hormone-sensitive lipase, which reduces transport of free fatty acids to the liver and decreases hepatic triglyceride synthesis. Niacin and related compounds (*e.g.*, 5-methylpyrazine-2-carboxylic-4-oxide, *acipimox*) may exert their effects on lipolysis by inhibiting adipocyte adenylyl cyclase. A GPCR for niacin has been identified and designated as HM74A (Wise *et al.*, 2003); its mRNA is highly expressed in the adipose tissue and spleen, sites of high-affinity nicotinic acid binding (Lorenzen *et al.*, 2001). Niacin stimulates the HM74A (HM74b)-G_i-adenylyl cyclase pathway in adipocytes, inhibiting cAMP production and decreasing hormone-sensitive lipase activity, triglyceride lipolysis, and release of free fatty acids. Niacin may also inhibit a rate-limiting enzyme of triglyceride synthesis, diacylglycerol acetyltransferase 2 (Ganji, *et al.*, 2004). Identification of the nicotinic acid receptor may permit the development of new compounds that may affect fatty acid metabolism, dyslipidemia, and ultimately, atherogenesis (Karpe and Frayn, 2004).

In the liver, niacin reduces triglyceride synthesis by inhibiting both the synthesis and esterification of fatty acids, effects that increase apoB degradation (Jin *et al.*, 1999). Reduction of triglyceride synthesis reduces hepatic VLDL production, which accounts for the reduced LDL levels. Niacin also enhances LPL activity, which promotes the clearance of chylomicrons and VLDL triglycerides. Niacin raises HDL-C levels by decreasing the fractional clearance of apoA-I in HDL rather than by enhancing HDL synthesis. This effect is due to a reduction in the hepatic clearance of HDL-apoA-I, but not of cholesteryl esters, thereby increasing the apoA-I content of plasma and augmenting reverse cholesterol transport (Jin *et al.*, 1997). In macrophages, niacin stimulates expression of the scavenger receptor CD36 and the cholesterol exporter ABCA1. The net effect of niacin on monocytic cells (“foam cells”) is HDL-mediated reduction of cellular cholesterol content (Rubic *et al.*, 2004).

Effects on Plasma Lipoprotein Levels. Regular or crystalline niacin in doses of 2 to 6 g per day reduces trigly-

cerides by 35% to 50%, and the maximal effect occurs within 4 to 7 days (Figge *et al.*, 1988). Reductions of 25% in LDL-C levels are possible with doses of 4.5 to 6 g per day, but 3 to 6 weeks are required for maximal effect. HDL-C increases less in patients with low HDL-C levels (<35 mg/dl) than in those with higher levels. Average increases of 15% to 30% occur in patients with low HDL-C levels; greater increases may occur in patients with normal HDL-C levels at baseline (Vega and Grundy, 1994; Sprecher, 2000). Combination therapy with resins can reduce LDL-C levels by as much as 40% to 60% (Malloy *et al.*, 1987).

Absorption, Fate, and Excretion. The pharmacological doses of regular (crystalline) niacin used to treat dyslipidemia are almost completely absorbed, and peak plasma concentrations (up to 0.24 mmol) are achieved within 30 to 60 minutes. The half-life is about 60 minutes, which accounts for the necessity of twice- or thrice-daily dosing. At lower doses, most niacin is taken up by the liver; only the major metabolite, nicotinuric acid, is found in the urine. At higher doses, a greater proportion of the drug is excreted in the urine as unchanged nicotinic acid (Iwaki *et al.*, 1996).

Adverse Effects. Two of niacin's side effects, flushing and dyspepsia, limit patient compliance. The cutaneous effects include flushing and pruritus of the face and upper trunk, skin rashes, and acanthosis nigricans. Flushing and associated pruritus are prostaglandin-mediated (Stern *et al.*, 1991). Flushing is worse when therapy is initiated or the dosage is increased, but ceases in most patients after 1 to 2 weeks of a stable dose. Taking an aspirin each day alleviates the flushing in many patients. Flushing recurs if only one or two doses are missed, and the flushing is more likely to occur when niacin is consumed with hot beverages (coffee, tea) or with ethanol-containing beverages. Flushing is minimized if therapy is initiated with low doses (100 to 250 mg twice daily) and if the drug is taken after breakfast or supper. Dry skin, a frequent complaint, can be dealt with by using skin moisturizers, and acanthosis nigricans can be dealt with by using lotions or creams containing *salicylic acid*. Dyspepsia and rarer episodes of nausea, vomiting, and diarrhea are less likely to occur if the drug is taken after a meal. Patients with any history of peptic ulcer disease should not take niacin because it can reactivate ulcer disease.

The most common, medically serious side effects are hepatotoxicity, manifested as elevated serum transaminases and hyperglycemia. Both regular (crystalline) niacin and sustained-release niacin, which was developed to reduce flushing and itching, have been reported to cause severe liver toxicity, and sustained-release niacin can cause fulminant hepatic failure (Tatò *et al.*, 1998). An extended-release niacin (NIASPAN), appears to be less likely to cause severe hepatotoxicity (Capuzzi *et al.*, 1998), perhaps simply because it is administered once daily instead of more frequently (Guyton *et al.*, 1998). The incidence of flushing and pruritus with this preparation is not substantially different from that with regular niacin. Severe hepatotoxicity is more likely to occur when patients take more than 2 g of sustained-release, over-the-counter preparations. Affected patients experience flu-like fatigue and weakness. Usually, aspartate transaminase and ALT are elevated, serum albu-

min levels decline, and total cholesterol and LDL-C levels decline substantially. In fact, reductions in LDL-C of 50% or more in a patient taking niacin should be viewed as a sign of niacin toxicity (Tatò *et al.*, 1998).

In patients with diabetes mellitus, niacin should be used cautiously, since niacin-induced insulin resistance can cause severe hyperglycemia (Knopp *et al.*, 1985; Henkin *et al.*, 1991; Schwartz, 1993). Niacin use in patients with diabetes mellitus often mandates a change to insulin therapy. In a study of patients with type 2 diabetes taking NIASPAN, 4% stopped taking the drug because of inadequate glycemic control (Grundy *et al.*, 2002). If niacin is prescribed for patients with known or suspected diabetes, blood glucose levels should be monitored at least weekly until proven to be stable. Niacin also elevates uric acid levels and may reactivate gout. A history of gout is a relative contraindication for niacin use. Rarer reversible side effects include toxic amblyopia and toxic maculopathy. Atrial tachyarrhythmias and atrial fibrillation have been reported, more commonly in elderly patients. *Niacin, at doses used in humans, has been associated with birth defects in experimental animals and should not be taken by pregnant women.*

Therapeutic Uses. Niacin is indicated for hypertriglyceridemia and elevated LDL-C; it is especially useful in patients with both hypertriglyceridemia and low HDL-C levels. There are two commonly available forms of niacin. Crystalline niacin (immediate-release or regular) refers to niacin tablets that dissolve quickly after ingestion. Sustained-release niacin refers to preparations that continuously release niacin for 6 to 8 hours after ingestion. NIASPAN is the only preparation of niacin that has been approved by the FDA for treating dyslipidemia and that requires a prescription.

Crystalline niacin tablets are available over the counter in a variety of strengths from 50- to 500-mg tablets. To minimize the flushing and pruritus, it is best to start with a low dose (*e.g.*, 100 mg twice daily taken after breakfast and supper). The dose may be increased stepwise every 7 days by 100 to 200 mg to a total daily dose of 1.5 to 2 g. After 2 to 4 weeks at this dose, transaminases, serum albumin, fasting glucose, and uric acid levels should be measured. Lipid levels should be checked and the dose increased further until the desired effect on plasma lipids is achieved. After a stable dose is attained, blood should be drawn every 3 to 6 months to monitor for the various toxicities.

Since concurrent use of niacin and a statin can cause myopathy, the statin should be administered at no more than 25% of its maximal dose. Patients also should be instructed to discontinue therapy if flulike muscle aches occur. Routine measurement of CK in patients taking niacin and statins does not assure that severe myopathy will be detected before onset of symptoms, as patients have developed myopathy after several years of concomitant use of niacin with a statin.

Over-the-counter, sustained-release niacin preparations and NIASPAN are effective up to a total daily dose of 2 g per day. All doses of sustained-release niacin, but particularly doses above 2 g per day, have been reported to cause hepatotoxicity, which may occur soon after beginning therapy or after several years of use (Knopp *et al.*, 1985). The potential for severe liver damage should preclude its use in most patients, including those who have taken an equivalent dose of crystalline niacin safely for many years and are considering switching to a sustained-release preparation (Tatò *et al.*, 1998). NIASPAN may be less likely to cause hepatotoxicity.

Fibric Acid Derivatives: PPAR Activators

History. In 1962, Thorp and Waring reported that ethyl chlorophenoxyisobutyrate lowered lipid levels in rats. In 1967, the ester form (clofibrate) was approved for use in the United States and became the most widely prescribed hypolipidemic drug. Its use declined dramatically, however, after the World Health Organization reported that, despite a 9% reduction in cholesterol levels, clofibrate treatment did not reduce fatal cardiovascular events, although nonfatal infarcts were reduced (Committee of Principal Investigators, 1978). Total mortality was significantly greater in the clofibrate group. The increased mortality was due to multiple causes, including cholelithiasis. Interpretation of these negative results was clouded by failure to analyze the data according to the intention-to-treat principle. A later analysis demonstrated that the apparent increase in noncardiac mortality did not persist in the clofibrate-treated patients after discontinuation of the drug (Heady *et al.*, 1992). Clofibrate use was virtually abandoned after publication of the results of the 1978 WHO trial. Clofibrate as well as two other fibrates, gemfibrozil and fenofibrate, remain available in the United States.

Two subsequent trials involving only men have reported favorable effects of gemfibrozil therapy on fatal and nonfatal cardiac events without an increase in morbidity or mortality (Frick *et al.*, 1987; Rubins *et al.*, 1999). A third trial of men and women reported fewer events in a subgroup characterized by high triglyceride and low HDL-C levels (Haim *et al.*, 1999).

Chemistry. Clofibrate, the prototype of the fibric acid derivatives, is the ethyl ester of *p*-chlorophenoxyisobutyrate. Gemfibrozil is a non-halogenated phenoxyisobutyric acid and thus is distinct from the halogenated fibrates. A number of fibric acid analogs (*e.g.*, fenofibrate, bezafibrate, and ciprofibrate) have been developed and are used in Europe and elsewhere (*see* Figure 35–5 for structural formulas).

Mechanism of Action. Despite extensive studies in humans, the mechanisms by which fibrates lower lipoprotein levels, or raise HDL levels, remain unclear (Illingworth, 1991). Recent studies suggest that many of the effects of these compounds on blood lipids are mediated by their interaction with peroxisome proliferator activated receptors (PPARs) (Kersten *et al.*, 2000), which regulate gene transcription. Three PPAR isotypes (α , β , and γ) have been identified. Fibrates bind to PPAR α , which is expressed primarily in the liver and brown adipose tissue and to a lesser extent in kidney, heart, and skeletal muscle. Fibrates reduce triglycerides through PPAR α -mediated stimulation of fatty acid oxidation, increased LPL synthesis, and reduced expression of apoC-III. An increase in LPL would enhance the clearance of triglyceride-rich lipoproteins. A reduction in hepatic production of apoC-III, which serves as an inhibitor of lipolytic processing and receptor-mediated clearance, would enhance the clearance of VLDL. Fibrate-mediated increases in HDL-C are due to PPAR α stimulation of apoA-I and apoA-II expression (Staels and Auwerx, 1998), which increases HDL levels. Fenofibrate is more effective than gemfibrozil at increasing HDL levels (Rader, 2003).

CLOFIBRATE

GEMFIBROZIL

FENOFIBRATE

CIPROFIBRATE

BEZAFIBRATE

Figure 35–5. Structures of the fibric acids.

LDL levels rise in many patients treated with gemfibrozil, especially those with hypertriglyceridemia. However, LDL levels are unchanged or fall in others, especially those whose triglyceride levels are not elevated or who are taking a second-generation agent, such as fenofibrate, bezafibrate, or ciprofibrate. The decrease in LDL levels may be due in part to changes in the cholesterol and triglyceride contents of LDL that are mediated by CETP; such changes can alter the affinity of LDL for the LDL receptor. There also is evidence that a PPAR α -mediated increase in hepatic SREBP-1 production enhances hepatic expression of LDL receptors (Kersten *et al.*, 2000). Lastly, fibrates reduce the plasma concentration of small, dense, more easily oxidized LDL particles (Yuan *et al.*, 1994; Vakkilainen *et al.*, 2003).

Most of the fibric acid agents have potential antithrombotic effects, including inhibition of coagulation and enhancement of fibrinolysis. These salutary effects also could alter cardiovascular outcomes by mechanisms unrelated to any hypolipidemic activity (Watts and Dimmitt, 1999).

Effects on Lipoprotein Levels. The effects of the fibric acid agents on lipoprotein levels differ widely, depending on the starting lipoprotein

profile, the presence or absence of a genetic hyperlipoproteinemia, the associated environmental influences, and the specific fibrate used.

Patients with type III hyperlipoproteinemia (dysbetalipoproteinemia) are among the most sensitive responders to fibrates (Mahley and Rall, 2001). Elevated triglyceride and cholesterol levels are dramatically lowered, and tuberous and palmar xanthomas may regress completely. Angina and intermittent claudication also improve (Kuo *et al.*, 1988).

In patients with mild hypertriglyceridemia (*e.g.*, triglycerides <400 mg/dl), fibrate treatment decreases triglyceride levels by up to 50% and increases HDL-C concentrations about 15%; LDL-C levels may be unchanged or increase. The second-generation agents, such as fenofibrate, bezafibrate, and ciprofibrate, lower VLDL levels to a degree similar to that produced by gemfibrozil, but they also are more likely to decrease LDL levels by 15% to 20%. In patients with more marked hypertriglyceridemia (*e.g.*, 400 to 1000 mg/dl), a similar fall in triglycerides occurs, but LDL increases of 10% to 30% are seen frequently. Normotriglyceridemic patients with heterozygous familial hypercholesterolemia usually experience little change in LDL levels with gemfibrozil; with the other fibric acid agents, reductions as great as 20% may occur in some patients.

Fibrates usually are the drugs of choice for treating severe hypertriglyceridemia and the chylomicronemia syndrome. While the primary therapy is to remove alcohol and as much fat from the diet as possible, fibrates help both by increasing triglyceride clearance and by decreasing hepatic triglyceride synthesis. In patients with chylomicronemia syndrome, fibrate maintenance therapy and a low-fat diet keep triglyceride levels well below 1000 mg/dl and thus prevent episodes of pancreatitis.

In a 5-year study of hyperlipidemic men, gemfibrozil reduced total cholesterol by 10% and LDL-C by 11%, raised HDL-C levels by 11%, and decreased triglycerides by 35% (Frick *et al.*, 1987). Overall, there was a 34% decrease in the sum of fatal plus nonfatal cardiovascular events without any effect on total mortality. No increased incidence of gallstones or cancers was observed. Subgroup analysis suggested that the greatest benefit occurred in the subjects with the highest levels of VLDL or combined VLDL and LDL and in those with the lowest HDL-C levels (<35 mg/dl). Gemfibrozil may have affected the outcome by influencing platelet function, coagulation factor synthesis, or LDL size. In a recent secondary prevention trial, gemfibrozil reduced fatal and nonfatal CHD events by 22% despite a lack of effect on LDL-C levels. HDL-C levels increased by 6%, which may have contributed to the favorable outcome (Rubins *et al.*, 1999).

Absorption, Fate, and Excretion. All of the fibrate drugs are absorbed rapidly and efficiently (>90%) when given with a meal but less efficiently when taken on an empty stomach. The ester bond is hydrolyzed rapidly, and peak plasma concentrations are attained within 1 to 4 hours. More than 95% of these drugs in plasma are bound to protein, nearly exclusively to albumin. The half-lives of fibrates differ significantly (Miller and Spence, 1998), ranging from 1.1 hours (gemfibrozil) to 20 hours (fenofibrate). The drugs are widely distributed throughout the body, and concentrations in liver, kidney, and intestine exceed the plasma level. Gemfibrozil is transferred across the placenta. The fibrate drugs are excreted predominantly as glucuronide conjugates; 60% to 90% of an oral dose is excreted in the urine, with smaller amounts appearing in the feces. Excretion of these drugs is impaired in renal failure, though excretion of gemfibrozil is less severely compromised in renal insufficiency than is excretion of other fibrates

(Evans *et al.*, 1987). Nevertheless, the use of fibrates is contraindicated in patients with renal failure.

Adverse Effects and Drug Interactions. Fibric acid compounds usually are well tolerated (Miller and Spence, 1998). Side effects may occur in 5% to 10% of patients but most often are not sufficient to cause discontinuation of the drug. Gastrointestinal side effects occur in up to 5% of patients. Other side effects are reported infrequently and include rash, urticaria, hair loss, myalgias, fatigue, headache, impotence, and anemia. Minor increases in liver transaminases and alkaline phosphatase have been reported. Clofibrate, bezafibrate, and fenofibrate have been reported to potentiate the action of oral anticoagulants, in part by displacing them from their binding sites on albumin. Careful monitoring of the prothrombin time and reduction in dosage of the anticoagulant may be appropriate when treatment with a fibrate is begun.

A myopathy syndrome occasionally occurs in subjects taking clofibrate, gemfibrozil, or fenofibrate, and may occur in up to 5% of patients treated with a combination of gemfibrozil and higher doses of statins. To diminish the risk of myopathy, statin doses should be reduced when combination therapy of a statin plus a fibrate is employed. Several drug interactions may contribute to this adverse response. Gemfibrozil inhibits hepatic uptake of statins by OATP2. Gemfibrozil also competes for the same glucuronosyl transferases that metabolize most statins. As a consequence, levels of both drugs may be increased when they are coadministered. (Prueksaritanont *et al.*, 2002b; Prueksaritanont *et al.*, 2002c). Patients taking this combination should be instructed to be aware of the potential symptoms and should be followed at 3-month intervals with careful history and determination of CK values until a stable pattern is established. Patients taking fibrates with rosuvastatin should be followed especially closely even if low doses (5 to 10 mg) of rosuvastatin are employed until there is more experience with and knowledge of the safety of this specific combination. Fenofibrate is glucuronidated by enzymes that are not involved in statin glucuronidation. Thus, fenofibrate-statin combinations are less likely to cause myopathy than combination therapy with gemfibrozil and statins.

All of the fibrates increase the lithogenicity of bile. Clofibrate use has been associated with increased risk of gallstone formation; gemfibrozil and fenofibrate reportedly do not increase biliary tract disease.

Renal failure is a relative contraindication to the use of fibric acid agents, as is hepatic dysfunction. Combined statin-fibrate therapy should be avoided in patients with compromised renal function. Gemfibrozil should be used with caution and at a reduced dosage to treat the hyperlipidemia of renal failure. *Fibrates should not be used by children or pregnant women.*

Therapeutic Uses. Clofibrate is available for oral administration. The usual dose is 2 g per day in divided doses. This compound is little used but may be useful in patients who do not tolerate gemfibrozil or fenofibrate. Gemfibrozil (LOPID) is usually administered as a 600-mg dose taken twice a day, 30 minutes before the morning and evening meals. The TRICOR brand of fenofibrate is available in tablets or 48 and 145 mg. The usual daily dose is 145 mg. Generic fenofibrate (LOFIBRA) is available in capsules containing 67, 134, and 200 mg. TRICOR, 145 mg, and LOFIBRA, 200 mg, are equivalent doses.

Fibrates are the drugs of choice for treating hyperlipidemic subjects with type III hyperlipoproteinemia as well as subjects with severe hypertriglyceridemia (triglycerides >1000 mg/dl) who are at risk for pancreatitis. Fibrates appear to have an important role in subjects with high triglycerides and low HDL-C levels associated with the metabolic syndrome or type 2 diabetes mellitus (Robins, 2001). When fibrates are used in such patients, the LDL levels need to be monitored; if LDL levels rise, the addition of a low dose of a statin may be needed. Many experts now treat such patients first with a statin (Heart Protection Study Collaborative Group, 2003), and then add a fibrate, based on the reported benefit of gemfibrozil therapy (Rubins *et al.*, 1999). However, statin-fibrate combination therapy has not been evaluated in outcome studies (American Diabetes Association, 2004). If this combination is used, there should be careful monitoring for myopathy.

Ezetimibe and the Inhibition of Dietary Cholesterol Uptake

Ezetimibe is the first compound approved for lowering total and LDL-C levels that inhibits cholesterol absorption by enterocytes in the small intestine (van Heek *et al.*, 2000). It lowers LDL-C levels by about 18% and is used primarily as adjunctive therapy with statins. Outcome studies employing ezetimibe with statins are beginning, but no results are anticipated for several years (Baigent and Landry, 2003).

History. Ezetimibe (SCH58235) was developed by pharmaceutical chemists studying inhibition of intestinal acyl coenzyme A:cholesterol acyltransferase (ACAT) (Burnett *et al.*, 1994). Several compounds were found to inhibit cholesterol absorption, but by inhibiting intestinal cholesterol absorption rather than ACAT (van Heek *et al.*, 1997).

Mechanism of Action. Recent data indicate that ezetimibe inhibits a specific transport process in jejunal enterocytes, which take up cholesterol from the lumen. The putative transport protein is NPC1L1 (Altmann *et al.*, 2004; Davis *et al.*, 2004). In wild-type mice, ezetimibe inhibits cholesterol absorption by about 70%; in NPC1L1 knockout mice, cholesterol absorption is 86% lower than in wild-type mice, and ezetimibe has no effect on cholesterol absorption (Altmann *et al.*, 2004). Ezetimibe does not affect intestinal triglyceride absorption. In human subjects, ezetimibe reduced cholesterol absorption by 54%, precipitating a compensatory increase in cholesterol synthesis, which can be inhibited with a cholesterol synthesis inhibitor such as a statin (Sudhop *et al.*, 2002). There is also a substantial reduction of plasma levels of plant sterols (campesterol and sitosterol concentrations are reduced by 48% and 41%, respective-

ly), indicating that ezetimibe also inhibits intestinal absorption of plant sterols.

The consequence of inhibiting intestinal cholesterol absorption is a reduction in the incorporation of cholesterol into chylomicrons. The reduced cholesterol content of chylomicrons diminishes the delivery of cholesterol to the liver by chylomicron remnants. The diminished remnant cholesterol content may decrease atherogenesis directly, as chylomicron remnants are very atherogenic lipoproteins. In experimental animal models of remnant dyslipidemia, ezetimibe profoundly diminished diet-induced atherosclerosis (Davis *et al.*, 2001a).

Reduced delivery of intestinal cholesterol to the liver by chylomicron remnants stimulates expression of the hepatic genes regulating LDL receptor expression and cholesterol biosynthesis. The greater expression of hepatic LDL receptors enhances LDL-C clearance from the plasma. Indeed, ezetimibe reduces LDL-C levels by 15% to 20% (Gagné *et al.*, 2002; Knopp *et al.*, 2003). Fasting triglyceride levels decrease about 5%, and HDL-C levels increase about 1% to 2% (Dujovne *et al.*, 2002).

Combination Therapy (Ezetimibe Plus Statins). The maximal efficacy of ezetimibe for lowering LDL-C is between 15% and 20% when used as monotherapy (Gagné *et al.*, 2002; Knopp *et al.*, 2003). This reduction is equivalent to, or less than, that attained with 10- to 20-mg doses of most statins. Consequently, the role of ezetimibe as monotherapy of patients with elevated LDL-C levels appears to be limited to the small group of statin-intolerant patients.

The actions of ezetimibe are complementary to those of statins. Statins, which inhibit cholesterol biosynthesis, increase intestinal cholesterol absorption (Miettinen and Gylling, 2003). Ezetimibe, which inhibits intestinal cholesterol absorption, enhances cholesterol biosynthesis by as much as 3.5 times in experimental animals (Davis *et al.*, 2001b). Dual therapy with these two classes of drugs prevents the enhanced cholesterol synthesis induced by ezetimibe and the increase in cholesterol absorption induced by statins. This combination provides additive reductions in LDL-C levels irrespective of the statin employed (Ballantyne *et al.*, 2003; Melani *et al.*, 2003; Ballantyne *et al.*, 2004). There is a further reduction of 15% to 20% in LDL-C when ezetimibe is combined with any statin at any dose. Increasing statin dosages from the usual starting dose of 20 mg to 80 mg normally yields only an additional 12% reduction in LDL-C, whereas adding ezetimibe, 10 mg daily, to 20 mg of a statin will reduce LDL-C by an additional 18% to 20%.

A combination tablet containing ezetimibe, 10 mg, and various doses of simvastatin (10, 20, 40, and 80 mg) has been approved (VYTORIN). At the highest simvastatin dose (80 mg), plus ezetimibe (10 mg), average LDL-C reduction was 60%, which is greater than can be attained with any statin as monotherapy (Feldman *et al.*, 2004).

Absorption, Fate, and Excretion. Ezetimibe is highly water insoluble, precluding studies of its bioavailability. After ingestion, it is glucuronidated in the intestinal epithelium, absorbed, and enters an enterohepatic recirculation (Patrick *et al.*, 2002). Pharmacokinetic studies indicate that about 70% is excreted in the feces and about 10% in the urine (as a glucuronide conjugate) (Patrick *et al.*, 2002). Bile acid sequestrants inhibit absorption of ezetimibe, and the two agents should not be administered together. Otherwise, no significant drug interactions have been reported.

Adverse Effects and Drug Interactions. Other than rare allergic reactions, specific adverse effects have not been observed in patients taking ezetimibe. The safety of ezetimibe during pregnancy has not been established. With doses of ezetimibe sufficient to increase exposure 10 to 150 times compared with a 10-mg dose in humans, fetal skeletal abnormalities were noted in rats and rabbits. *Since all statins are contraindicated in pregnant and nursing women, combination products containing ezetimibe and a statin should not be used by women in childbearing years in the absence of contraception.*

Therapeutic Uses. Ezetimibe (ZETIA) is available as a 10-mg tablet that may be taken at any time during the day, with or without food. Ezetimibe may be taken with any medication other than bile acid sequestrants, which inhibit its absorption.

Inhibitors of Cholesteryl Ester Transfer Protein

The cholesteryl ester transfer protein (CETP) is a plasma glycoprotein synthesized by the liver that mediates the transfer of cholesteryl esters from the larger subfractions of HDL (HDL₂) to triglyceride-rich lipoproteins and LDL in exchange for a molecule of triglyceride. Enrichment of HDL₂ with triglycerides enhances its catabolism by the liver. In animal models, inhibition of CETP results in higher HDL levels, decreased LDL levels, and resistance to developing atherosclerosis. Observational studies of humans with CETP gene mutations associated with reduced CETP activity indicate that HDL levels are increased and LDL levels are lower in affected patients. However, there are reports of both increased and decreased prevalence of CHD, or no effect on CHD prevalence in patients with naturally occurring CETP mutations.

Clinical trials of CETP inhibitors in human subjects are under way (*see review by Forrester et al., 2005*). Two CETP inhibitors, JTT-705 and *torcetrapib*, are being tested (de Grooth *et al.*, 2002; Brousseau *et al.*, 2004; Clark *et al.*, 2004). JTT-705 forms a disulfide bond with CETP, and torcetrapib is thought to stabilize the association of CETP with its lipoprotein substrate, creating a nonfunctional complex. The levels of HDL-C are increased by 45% to 106% in normal subjects and in patients with low HDL-C levels. Further studies of the safety of these compounds and proof that this approach prevents clinical vascular disease are required before CETP inhibitors can be routinely used in managing dyslipidemic patients.

CLINICAL SUMMARY

Patients with any type of dyslipidemia (*e.g.*, elevated levels of cholesterol, low levels of HDL-C with or without hypercholesterolemia, or moderately elevated triglyceride levels with low HDL-C levels) are at risk of develop-

ing atherosclerosis-induced vascular disease. Maintaining ideal body weight, eating a diet low in saturated fat and cholesterol, and regular exercise are the cornerstones of managing dyslipidemia. In the absence of vascular disease, type 2 diabetes mellitus, or metabolic syndrome, adoption of these behaviors will alleviate the need for cholesterol-lowering medications in many subjects. Patients should be treated to achieve target lipid values after assessing their future risk for a vascular disease event. In virtually every type of dyslipidemic patient, statins have been proven to reduce the risk of subsequent CHD events and nonhemorrhagic stroke. For this reason, statin therapy should be the first-line choice when choosing between classes of lipid-lowering agents.

A second principle is to treat with statin doses adequate to reduce the patient's lipid values to goal levels. Most patients are not adequately treated and do not reach goal values. Safety is greatly enhanced if doctors discuss with their patients the rare but serious side effects of hepatotoxicity and rhabdomyolysis with associated renal failure. In patients requiring combination therapy, long-term compliance may be improved in a subset of patients by using a fixed-dose preparation: lovastatin plus extended-release niacin (ADVICOR) or simvastatin plus ezetimibe (VYTORIN).

Finally, patients with low HDL-C levels may not receive the maximum benefit of lipid-lowering therapy as prescribed by the ATP III guidelines based on levels of LDL-C or non-HDL-C. For this reason, treatment of patients with low HDL-C levels should be based on both LDL-C levels and the ratio of total cholesterol:HDL-C (Table 35–7).

SECTION VI

Drugs Affecting Gastrointestinal Function

CHAPTER

36

PHARMACOTHERAPY OF GASTRIC ACIDITY, PEPTIC ULCERS, AND GASTROESOPHAGEAL REFLUX DISEASE

Willemijntje A. Hoogerwerf and Pankaj Jay Pasricha

The acid-peptic diseases are those disorders in which gastric acid and pepsin are necessary, but usually not sufficient, pathogenic factors. While inherently caustic, acid and pepsin in the stomach normally do not produce damage or symptoms because of intrinsic defense mechanisms. Barriers to the reflux of gastric contents into the esophagus comprise the primary esophageal defense. If these protective barriers fail and reflux occurs, dyspepsia and/or erosive esophagitis may result. Therapies are directed at decreasing gastric acidity, enhancing the lower esophageal sphincter, or stimulating esophageal motility (*see* Chapter 37). In the stomach, mucus and bicarbonate, stimulated by the local generation of prostaglandins, protect the gastric mucosa. If these defenses are disrupted, a gastric or duodenal ulcer may form. The treatment and prevention of these acid-related disorders are accomplished either by decreasing the level of gastric acidity or by enhancing mucosal protection. The appreciation that an infectious agent, *Helicobacter pylori*, plays a key role in the pathogenesis of acid-peptic diseases has stimulated new approaches to prevention and therapy.

PHYSIOLOGY OF GASTRIC SECRETION

Gastric acid secretion is a complex, continuous process in which multiple central and peripheral factors contribute to a common endpoint: the secretion of H^+ by parietal cells. Neuronal (acetylcholine, ACh), paracrine (histamine), and endocrine (gastrin) factors all regulate acid secretion (Figure 36–1). Their specific receptors (M_3 , H_2 , and CCK_2 receptors, respectively) are on the basolateral membrane of parietal cells in the body and fundus of the stomach. The H_2 receptor is a GPCR that activates the G_s -adenylylcyclase–cyclic AMP–PKA pathway. ACh and gastrin signal through GPCRs that couple to the G_q -PLC- IP_3 - Ca^{2+} pathway in parietal cells. In parietal cells, the cyclic AMP and the Ca^{2+} -dependent pathways activate H^+ , K^+ -ATPase (the proton pump), which exchanges hydrogen and potassium ions across the parietal cell membrane. This pump generates the largest known ion gradient in vertebrates, with an intracellular pH of about 7.3 and an intracanalicular pH of about 0.8.

The most important structures for CNS stimulation of gastric acid secretion are the dorsal motor nucleus of the vagal nerve, the hypothalamus, and the solitary tract nucleus. Efferent fibers originating in the dorsal motor nuclei descend to the stomach *via* the vagus nerve and synapse with ganglion cells of the enteric nervous system. ACh release from postganglionic vagal fibers directly stimulates gastric acid secretion through muscarinic M_3 receptors on the

Figure 36–1. Physiological and pharmacological regulation of gastric secretion: the basis for therapy of acid-peptic disorders.

Shown are the interactions among an enterochromaffin-like (ECL) cell that secretes histamine, a parietal cell that secretes acid, and a superficial epithelial cell that secretes cytoprotective mucus and bicarbonate. Physiological pathways, shown in solid black, may be stimulatory (+) or inhibitory (–). 1 and 3 indicate possible inputs from postganglionic cholinergic fibers, while 2 shows neural input from the vagus nerve. Physiological agonists and their respective membrane receptors include: acetylcholine (ACh), muscarinic (M), and nicotinic (N) receptors; gastrin, cholecystinin receptor 2 (CCK₂); histamine (HIST), H₂ receptor; and prostaglandin E₂ (PGE₂), EP₃ receptor. Drug actions are indicated by dashed lines. A blue X indicates targets of pharmacological antagonism. A light blue dashed arrow indicates a drug action that mimics or enhances a physiological pathway. Shown in blue are drugs used to treat acid-peptic disorders. NSAIDs are nonsteroidal antiinflammatory drugs and are ulcerogenic.

basolateral membrane of parietal cells. The CNS predominantly modulates the activity of the enteric nervous system *via* ACh, stimulating gastric acid secretion in response to the sight, smell, taste, or anticipation of food (the “cephalic” phase of acid secretion). ACh also indirectly affects parietal cells by increasing the release of histamine from the enterochromaffin-like (ECL) cells in the fundus of the stomach and of gastrin from G cells in the gastric antrum.

ECL cells, the source of gastric histamine secretion, usually are in close proximity to parietal cells. Histamine acts as a paracrine mediator, diffusing from its site of release to nearby parietal cells, where it activates H₂ receptors. The critical role of histamine in gastric acid secretion is dramatically demonstrated by the efficacy of H₂-receptor antagonists in decreasing gastric acid secretion (*see below*).

Gastrin, which is produced by antral G cells, is the most potent inducer of acid secretion. Multiple pathways stimulate gastrin

release, including CNS activation, local distention, and chemical components of the gastric contents. Gastrin stimulates acid secretion indirectly by inducing the release of histamine by ECL cells; a direct effect on parietal cells also plays a lesser role.

Somatostatin (SST), which is produced by antral D cells, inhibits gastric acid secretion. Acidification of the gastric luminal pH to <3 stimulates SST release, which in turn suppresses gastrin release in a negative feedback loop. SST-producing cells are decreased in patients with *H. pylori* infection, and the consequent reduction of SST’s inhibitory effect may contribute to excess gastrin production.

Gastric Defenses Against Acid. The extremely high concentration of H⁺ in the gastric lumen requires robust defense mechanisms to protect the esophagus and the stomach. The primary esophageal defense is the lower esophageal sphincter, which prevents reflux of acidic gastric contents into the esophagus. The stomach protects

itself from acid damage by a number of mechanisms that require adequate mucosal blood flow, perhaps because of the high metabolic activity and oxygen requirements of the gastric mucosa. One key defense is the secretion of a mucus layer that protects gastric epithelial cells. Gastric mucus is soluble when secreted but quickly forms an insoluble gel that coats the mucosal surface of the stomach, slows ion diffusion, and prevents mucosal damage by macromolecules such as pepsin. Mucus production is stimulated by prostaglandins E_2 and I_2 , which also directly inhibit gastric acid secretion by parietal cells. Thus, alcohol, aspirin, and other drugs that inhibit prostaglandin formation decrease mucus secretion and predispose to the development of acid-peptic disease. A second important part of the normal mucosal defense is the secretion of bicarbonate ions by superficial gastric epithelial cells. Bicarbonate neutralizes the acid in the region of the mucosal cells, thereby raising pH and preventing acid-mediated damage.

Figure 36-1 outlines the rationale and pharmacological basis for the therapy of acid-peptic diseases. The proton pump inhibitors are used most commonly, followed by the histamine H_2 -receptor antagonists.

PROTON PUMP INHIBITORS

Chemistry; Mechanism of Action; Pharmacology.

The most potent suppressors of gastric acid secretion are inhibitors of the gastric H^+,K^+ -ATPase (proton pump) (Figure 36-2A). In typical doses, these drugs diminish the daily production of acid (basal and stimulated) by 80% to 95%. Five proton pump inhibitors are available for clinical use: *omeprazole* (PRILOSEC, RAPINEX, ZEGERID) and its *S*-isomer, *esomeprazole* (NEXIUM), *lansoprazole* (PREVACID), *rabeprazole* (ACIPHEX), and *pantoprazole* (PROTONIX). These drugs have different substitutions on their pyridine and/or benzimidazole groups but are remarkably similar in their pharmacological properties (see Appendix II). Omeprazole is a racemic mixture of *R*- and *S*-isomers; the *S*-isomer, esomeprazole (*S*-omeprazole), is eliminated less rapidly than *R*-omeprazole, which theoretically provides a therapeutic advantage because of the increased half-life. Despite claims to the contrary, all proton pump inhibitors have equivalent efficacy at comparable doses.

Proton pump inhibitors are prodrugs that require activation in an acid environment. After absorption into the systemic circulation, the prodrug diffuses into the parietal cells of the stomach and accumulates in the acidic secretory canaliculi. Here, it is activated by proton-catalyzed formation of a tetracyclic sulfenamide (Figure 36-2), trapping the drug so that it cannot diffuse back across the canalicular membrane. The activated form then binds covalently with sulfhydryl groups of cysteines in the H^+,K^+ -ATPase, irreversibly inactivating the pump molecule. Acid secretion resumes only after new pump mole-

cules are synthesized and inserted into the luminal membrane, providing a prolonged (up to 24- to 48-hour) suppression of acid secretion, despite the much shorter plasma half-lives (0.5 to 2 hours) of the parent compounds. Because they block the final step in acid production, the proton pump inhibitors are effective in acid suppression regardless of other stimulating factors.

To prevent degradation of proton pump inhibitors by acid in the gastric lumen, oral dosage forms are supplied in different formulations: (1) enteric-coated drugs contained inside gelatin capsules (omeprazole, esomeprazole, and lansoprazole); (2) enteric-coated granules supplied as a powder for suspension (lansoprazole); (3) enteric-coated tablets (pantoprazole, rabeprazole, and omeprazole); and (4) powdered drug combined with sodium bicarbonate (omeprazole). The delayed-release and enteric-coated tablets dissolve only at alkaline pH, while admixture of omeprazole with sodium bicarbonate simply neutralizes stomach acid; both strategies substantially improve the oral bioavailability of these acid-labile drugs. Until recently, the requirement for enteric coating posed a challenge to the administration of proton pump inhibitors in patients for whom the oral route of administration is not available (Freston *et al.*, 2003). These patients and those requiring immediate acid suppression now can be treated parenterally with pantoprazole or lansoprazole, both of which are approved for intravenous administration in the United States. A single intravenous bolus of 80 mg of pantoprazole inhibits acid production by 80% to 90% within an hour, and this inhibition persists for up to 21 hours, permitting once-daily dosing to achieve the desired degree of hypochlorhydria. The FDA-approved dose of intravenous pantoprazole for gastroesophageal reflux disease is 40 mg daily for up to 10 days. Higher doses (*e.g.*, 160 to 240 mg in divided doses) are used to manage hypersecretory conditions such as the Zollinger-Ellison syndrome. An intravenous formulation of esomeprazole is available in Europe but not in the United States.

Pharmacokinetics. Since an acidic pH in the parietal cell acid canaliculi is required for drug activation, and since food stimulates acid production, these drugs ideally should be given about 30 minutes before meals. Concurrent administration of food may reduce somewhat the rate of absorption of proton pump inhibitors, but this effect is not thought to be clinically significant. Concomitant use of other drugs that inhibit acid secretion, such as H_2 -receptor antagonists, might be predicted to lessen the effectiveness of the proton pump inhibitors, but the clinical relevance of this potential interaction is unknown.

Once in the small bowel, proton pump inhibitors are rapidly absorbed, highly protein bound, and extensively metabolized by hepatic CYPs, particularly CYP2C19 and CYP3A4. Several variants of CYP2C19 have been identified. Asians are more likely than Cau-

Figure 36-2. Proton pump inhibitors. **A.** Inhibitors of gastric H^+,K^+ -ATPase (proton pump). **B.** Conversion of omeprazole to a sulfenamide in the acidic secretory canaliculi of the parietal cell. The sulfenamide interacts covalently with sulfhydryl groups in the proton pump, thereby irreversibly inhibiting its activity. The other three proton pump inhibitors undergo analogous conversions.

casians or African-Americans to have the CYP2C19 genotype that correlates with slow metabolism of proton pump inhibitors (23% vs. 3%, respectively), which has been suggested to contribute to heightened efficacy and/or toxicity in this ethnic group (Dickson and Stuart, 2003). Although the CYP2C19 genotype is correlated with the magnitude of gastric acid suppression by proton pump inhibitors in patients with gastroesophageal reflux disease, there is no evidence that the CYP2C19 genotype predicts clinical efficacy of these drugs (Chong and Ensom, 2003).

Because not all pumps or all parietal cells are active simultaneously, maximal suppression of acid secretion requires several doses of the proton pump inhibitors. For example, it may take 2 to 5 days of therapy with once-daily dosing to achieve the 70% inhibition of proton pumps that is seen at steady state (Wolfe and Sachs, 2000). More frequent initial dosing (e.g., twice daily) will reduce the time to achieve full inhibition but is not proven to improve patient outcome. Since the proton pump inhibition is irreversible, acid secretion will be suppressed for 24 to 48 hours, or more, until new proton pumps are synthesized and incorporated into the luminal membrane of parietal cells.

Chronic renal failure does not lead to drug accumulation with once-a-day dosing of the proton pump inhibitors. Hepatic disease substantially reduces the clearance of esomeprazole and lansoprazole. Thus, in patients with severe hepatic disease, dose reduction is recommended for esomeprazole and should be considered for lansoprazole.

Adverse Effects and Drug Interactions. Proton pump inhibitors generally cause remarkably few adverse effects. The most common side effects are nausea, abdominal pain, constipation, flatulence, and diarrhea. Subacute myopathy, arthralgias, headaches, and skin rashes also have been reported. As noted above, proton pump inhibitors are metabolized by hepatic CYPs and therefore may interfere with the elimination of other drugs cleared by this route. Proton pump inhibitors have been observed to interact with *warfarin* (esomeprazole, lansoprazole, omeprazole, and rabeprazole), *diazepam* (esomeprazole and omeprazole), and *cyclosporine* (omeprazole and rabeprazole). Among the proton pump inhibitors, only omeprazole inhibits CYP2C19 (thereby decreasing the clearance of *disulfiram*, *phenytoin*, and other drugs) and induces the expression of CYP1A2 (thereby increasing the clearance of *imipramine*, several antipsychotic drugs, *tacrine*, and *theophylline*).

Chronic treatment with omeprazole decreases the absorption of vitamin B_{12} , but the clinical relevance of this effect is not clear. Loss of gastric acidity also may affect the bioavailability of such drugs as *ketoconazole*, *ampicillin* esters, and iron salts.

Hypergastrinemia is more frequent and more severe with proton pump inhibitors than with H_2 -receptor antagonists, and gastrin levels of >500 ng/L occur in approximately 5% to 10% of users with chronic omeprazole administration. This hypergastrinemia may predispose to rebound hypersecretion of gastric acid upon discontinuation of therapy (see below) and also may promote the growth of

gastrointestinal tumors. In rats, long-term administration of proton pump inhibitors causes hyperplasia of enterochromaffin-like cells and the development of gastric carcinoid tumors. Although the gastrin levels observed in rats are about tenfold higher than those seen in human beings, this finding has raised concerns about the possibility of similar complications of proton pump inhibitors in humans, for which there is no unequivocal evidence. The proton pump inhibitors have a track record of approximately 25 years of use worldwide without the emergence of major safety concerns (Klinkenberg-Knol *et al.*, 1994; Kuipers and Meuwissen, 2000).

Therapeutic Uses. Proton pump inhibitors are used principally to promote healing of gastric and duodenal ulcers and to treat gastroesophageal reflux disease (GERD), including erosive esophagitis, which is either complicated or unresponsive to treatment with H₂-receptor antagonists. Proton pump inhibitors also are the mainstay in the treatment of pathological hypersecretory conditions, including the Zollinger-Ellison syndrome. Lansoprazole is FDA approved for treatment and prevention of recurrence of nonsteroidal antiinflammatory drug (NSAID)-associated gastric ulcers in patients who continue NSAID use. In addition, all proton pump inhibitors are FDA approved for reducing the risk of duodenal ulcer recurrence associated with *H. pylori* infections. Therapeutic applications of proton pump inhibitors are further discussed below under “Specific Acid-Peptic Disorders and Therapeutic Strategies.”

Use in Children. In children, omeprazole is safe and effective for treatment of erosive esophagitis and GERD. Younger patients generally have increased metabolic capacity, which may explain the need for higher dosages of omeprazole per kilogram in children compared to adults.

H₂-RECEPTOR ANTAGONISTS

The description of selective histamine H₂-receptor blockade was a landmark in the treatment of acid-peptic disease (Black, 1993). Before the availability of the H₂-receptor antagonists, the standard of care was simply acid neutralization in the stomach lumen, generally with inadequate results. The long history of safety and efficacy with the H₂-receptor antagonists eventually led to their availability without a prescription. Increasingly, however, proton pump inhibitors are replacing the H₂-receptor antagonists in clinical practice.

Chemistry; Mechanism of Action; Pharmacology.

The H₂-receptor antagonists inhibit acid production by reversibly competing with histamine for binding to H₂

receptors on the basolateral membrane of parietal cells. Four different H₂-receptor antagonists, which differ mainly in their pharmacokinetics (*see* Appendix II) and propensity to cause drug interactions, are available in the United States (Figure 36–3): *cimetidine* (TAGAMET), *ranitidine* (ZANTAC), *famotidine* (PEPCID), and *nizatidine* (AXID). These drugs are less potent than proton pump inhibitors but still suppress 24-hour gastric acid secretion by about 70%. The H₂-receptor antagonists predominantly inhibit basal acid secretion, which accounts for their efficacy in suppressing nocturnal acid secretion. Because the most important determinant of duodenal ulcer healing is the level of nocturnal acidity, evening dosing of H₂-receptor antagonists is adequate therapy in most instances. Ranitidine and nizatidine also may stimulate GI motility, but the clinical importance of this effect is unknown.

Figure 36–3. Histamine and H₂-receptor antagonists.

All four H₂-receptor antagonists are available as prescription and over-the-counter formulations for oral administration. Intravenous and intramuscular preparations of cimetidine, ranitidine, and famotidine also are available. When the oral or nasogastric routes are not an option, these drugs can be given in intermittent intravenous boluses or by continuous intravenous infusion (Table 36–1). The latter provides better control of gastric pH, but is not proven to be more effective in preventing clinically significant bleeding in critically ill patients.

Pharmacokinetics. The H₂-receptor antagonists are rapidly absorbed after oral administration, with peak serum concentrations within 1 to 3 hours. Absorption may be enhanced by food or decreased by antacids, but these effects probably are unimportant clinically. Therapeutic levels are achieved rapidly after intravenous dosing and are maintained for 4 to 5 hours (cimetidine), 6 to 8 hours (ranitidine), or 10 to 12 hours (famotidine). Unlike proton pump inhibitors, only a small percentage of H₂-receptor antagonists are protein-bound. Small amounts (from <10% to ~35%) of these drugs undergo metabolism in the liver, but liver disease *per se* is not an indication for dose adjustment. The kidneys excrete these drugs and their metabolites by filtration and renal tubular secretion, and it is important to reduce doses of H₂-receptor antagonists in patients with decreased creatinine clearance. Neither hemodialysis nor peritoneal dialysis clears significant amounts of the drugs.

Adverse Reactions and Drug Interactions. Like the proton pump inhibitors, the H₂-receptor antagonists generally are well tolerated, with a low (<3%) incidence of adverse effects. Side effects usually are minor and include diarrhea, headache, drowsiness, fatigue, muscular pain, and constipation. Less common side effects include those affecting the CNS (confusion, delirium, hallucinations, slurred speech, and headaches), which occur primarily with intravenous administration of the drugs or in elderly subjects. Long-term use of cimetidine at high doses—seldom used clinically today—decreases testosterone binding to the androgen receptor and inhibits a CYP that hydroxylates estradiol. Clinically, these effects can cause galactorrhea in women and gynecomastia, reduced sperm count, and impotence in men. Several reports have associated H₂-receptor antagonists with various blood dyscrasias, including thrombocytopenia. H₂-receptor antagonists cross the placenta and are excreted in breast milk. Although no major teratogenic risk has been associated with these

agents, caution nevertheless is warranted when they are used in pregnancy (*see below*).

All agents that inhibit gastric acid secretion may alter the rate of absorption and subsequent bioavailability of the H₂-receptor antagonists (*see* “Antacids,” *below*). Drug interactions with H₂-receptor antagonists occur mainly with cimetidine, and its use has decreased markedly. Cimetidine inhibits CYPs (*e.g.*, CYP1A2, CYP2C9, and CYP2D6), and thereby can increase the levels of a variety of drugs that are substrates for these enzymes. Ranitidine also interacts with hepatic CYPs, but with an affinity of only 10% of that of cimetidine; thus, ranitidine interferes only minimally with hepatic metabolism of other drugs. Famotidine and nizatidine are even safer in this regard, with no significant drug interactions mediated by inhibiting hepatic CYPs. Slight increases in blood-alcohol concentration may result from concomitant use of H₂-receptor antagonists, but this is unlikely to be clinically significant.

Therapeutic Uses. The major therapeutic indications for H₂-receptor antagonists are to promote healing of gastric and duodenal ulcers, to treat uncomplicated GERD, and to prevent the occurrence of stress ulcers. More information about the therapeutic applications of H₂-receptor antagonists is provided below under “Specific Acid-Peptic Disorders and Therapeutic Strategies.”

TOLERANCE AND REBOUND WITH ACID-SUPPRESSING MEDICATIONS

Tolerance to the acid-suppressing effects of H₂-receptor antagonists is well described and may account for a diminished therapeutic effect with continued drug administration (Sandevik *et al.*, 1997). Tolerance can develop within 3 days of starting treatment and may be resistant to increased doses of the medications. Diminished sensitivity to these drugs may result from the effect of the secondary hypergastrinemia to stimulate histamine release from ECL cells. Proton pump inhibitors, despite even greater elevations of endogenous gastrin, do not cause this phenomenon, probably because their site of action is distal to the action of histamine on acid release. On the other hand, rebound increases in gastric acidity can occur

Table 36–1
Intravenous Doses of H₂-Receptor Antagonists

	CIMETIDINE	RANITIDINE	FAMOTIDINE
Intermittent bolus	300 mg every 6–8 hours	50 mg every 6–8 hours	20 mg every 12 hours
Continuous infusion	37.5–100 mg/hour	6.25–12.5 mg/hour	1.7–2.1 mg/hour

when either of these drug classes is discontinued, possibly reflecting changes in function and justifying a gradual drug taper or the substitution of alternatives (e.g., antacids) in at-risk patients.

AGENTS THAT ENHANCE MUCOSAL DEFENSE

Prostaglandin Analogs: Misoprostol

Chemistry; Mechanism of Action; Pharmacology. Prostaglandin E₂ (PGE₂) and prostacyclin (PGI₂) are the major prostaglandins synthesized by the gastric mucosa. They bind to the EP₃ receptor on parietal cells (see Chapter 26) and stimulate the G_i pathway, thereby decreasing intracellular cyclic AMP and gastric acid secretion. PGE₂ also can prevent gastric injury by cytoprotective effects that include stimulation of mucin and bicarbonate secretion and increased mucosal blood flow. Although smaller doses than those required for acid suppression can protect the gastric mucosa in laboratory animals, this has not been convincingly demonstrated in humans; acid suppression appears to be the most important effect clinically (Wolfe and Sachs, 2000). Since NSAIDs diminish prostaglandin formation by inhibiting cyclooxygenase, synthetic prostaglandin analogs offer a logical approach to reducing NSAID-induced mucosal damage (see below). *Misoprostol* (15-deoxy-16-hydroxy-16-methyl-PGE₁; CYTOTEC) is a synthetic analog of prostaglandin E₁. Structural modifications include an additional methyl ester group at C1 that increases potency and duration of antisecretory effect, and transfer of a hydroxyl group from C15 to C16 and addition of a methyl group that increases oral bioactivity, duration of antisecretory action, and safety. The degree of inhibition of gastric acid secretion by misoprostol is directly related to dose; oral doses of 100 to 200 μg significantly inhibit basal acid secretion (up to 85% to 95% inhibition) or food-stimulated acid secretion (up to 75% to 85% inhibition). The usual recommended dose for ulcer prophylaxis is 200 μg four times a day.

Pharmacokinetics. Misoprostol is rapidly absorbed after oral administration and then is rapidly and extensively de-esterified to form misoprostol acid, the principal and active metabolite of the drug. Some of this conversion may occur in the parietal cells. A single dose inhibits acid production within 30 minutes; the therapeutic effect peaks at 60 to 90 minutes and lasts for up to 3 hours. Food and antacids decrease the rate of misoprostol absorption, resulting in

delayed and decreased peak plasma concentrations of the active metabolite. The free acid is excreted mainly in the urine, with an elimination half-life of about 20 to 40 minutes.

Adverse Effects. Diarrhea, with or without abdominal pain and cramps, occurs in up to 30% of patients who take misoprostol. Apparently dose-related, it typically begins within the first 2 weeks after therapy is initiated and often resolves spontaneously within a week; more severe or protracted cases may necessitate drug discontinuation. *Misoprostol can cause clinical exacerbations of inflammatory bowel disease (see Chapter 38) and should be avoided in patients with this disorder. Misoprostol is contraindicated during pregnancy because it can increase uterine contractility.*

Therapeutic Use. Misoprostol is FDA approved to prevent NSAID-induced mucosal injury. However, it rarely is used because of its adverse effects and the inconvenience of four-times-daily dosing. The proton pump inhibitors and H₂-receptor antagonists also are used to diminish the gastrointestinal side effects of NSAIDs, but only lansoprazole holds an FDA approved indication for this purpose.

SUCRALFATE

Chemistry; Mechanism of Action; Pharmacology. In the presence of acid-induced damage, pepsin-mediated hydrolysis of mucosal proteins contributes to mucosal erosion and ulcerations. This process can be inhibited by sulfated polysaccharides. *Sucralfate* (CARAFATE) consists of the octasulfate of sucrose to which Al(OH)₃ has been added. In an acid environment (pH <4), sucralfate undergoes extensive cross-linking to produce a viscous, sticky polymer that adheres to epithelial cells and ulcer craters for up to 6 hours after a single dose. In addition to inhibiting hydrolysis of mucosal proteins by pepsin, sucralfate may have additional cytoprotective effects, including stimulation of local production of prostaglandins and epidermal growth factor. Sucralfate also binds bile salts; thus, some clinicians use sucralfate to treat individuals with the syndromes of biliary esophagitis or gastritis (the existence of which is controversial).

Therapeutic Uses. The use of sucralfate to treat peptic acid disease has diminished in recent years. Nevertheless, because increased gastric pH may be a factor in the development of nosocomial pneumonia in critically ill patients, sucralfate may offer an advantage over proton pump inhibitors and H₂-receptor antagonists for the prophylaxis

Table 36–2
Composition and Neutralizing Capacities of Popular Antacid Preparations

PRODUCT	Al(OH) ₃ *	Mg(OH) ₂ *	CaCO ₃ *	SIMETHICONE*	ACID NEUTRALIZING CAPACITY†
<i>Tablets</i>

*Contents, milligrams per tablet or per 5 ml. †Acid-neutralizing capacity, milliequivalents per tablet or per 5 ml. The United States marketplace for antacids is fluid. The current trend of “reusing” well-known brand names to introduce new products that contain an active ingredient different from expected is a source of confusion that can present a danger to patients. Medication safety experts encourage clinical practitioners to refer to the active ingredient(s) in conjunction with the proprietary (brand) name when selecting OTC products.

of stress ulcers (*see* below). Due to its unique mechanism of action, sucralfate also has been used in several other conditions associated with mucosal inflammation/ulceration that may not respond to acid suppression, including oral mucositis (radiation and aphthous ulcers) and bile reflux gastropathy. Administered by rectal enema, sucralfate also has been used for radiation proctitis and solitary rectal ulcers.

Since it is activated by acid, sucralfate should be taken on an empty stomach 1 hour before meals. The use of antacids within 30 minutes of a dose of sucralfate should be avoided. The usual dose of sucralfate is 1 g four times daily (for active duodenal ulcer) or 1 g twice daily (for maintenance therapy).

Adverse Effects. The most common side effect of sucralfate is constipation (about 2%). As some aluminum can be absorbed, sucralfate should be avoided in patients with renal failure who are at risk for aluminum overload. Likewise, aluminum-containing antacids should not be combined with sucralfate in these patients. Sucralfate forms a viscous layer in the stomach that may inhibit absorption of other drugs, including phenytoin, digoxin, cimetidine, ketoconazole, and fluoroquinolone antibiotics. Sucralfate therefore should be taken at least 2 hours after the administration of other drugs. The “sticky” nature of the viscous gel produced by sucralfate in the stomach also may be responsible for the development of bezoars in some patients, particularly in those with underlying gastroparesis.

ANTACIDS

Although hallowed by tradition, the antacids largely have been replaced by more effective and convenient drugs. Nevertheless, they continue to be used by patients for a variety of indications, and some knowledge of their pharmacology is important for the medical professional (*see* Table 36–2 for a comparison of some commonly used antacid preparations).

Many factors, including palatability, determine the effectiveness and choice of antacid. Although sodium bicarbonate effectively neutralizes acid, it is very water-soluble and rapidly absorbed from the stomach, and the alkali and sodium loads may pose a risk for patients with cardiac or renal failure. Depending on particle size and crystal structure, CaCO₃ rapidly and effectively neutralizes gastric H⁺, but the release of CO₂ from bicarbonate- and carbonate-containing antacids can cause belching, nausea, abdominal distention, and flatulence. Calcium also may induce rebound acid secretion, necessitating more frequent administration.

Combinations of Mg²⁺ (rapidly reacting) and Al³⁺ (slowly reacting) hydroxides provide a relatively balanced and sustained neutralizing capacity and are preferred by most experts. *Magaldrate* is a hydroxymagne-

sium aluminate complex that is converted rapidly in gastric acid to $\text{Mg}(\text{OH})_2$ and $\text{Al}(\text{OH})_3$, which are absorbed poorly and thus provide a sustained antacid effect. Although fixed combinations of magnesium and aluminum theoretically counteract the adverse effects of each other on the bowel (Al^{3+} can relax gastric smooth muscle, producing delayed gastric emptying and constipation, while Mg^{2+} exerts the opposite effects), such balance is not always achieved in practice.

Simethicone, a surfactant that may decrease foaming and hence esophageal reflux, is included in many antacid preparations. However, other fixed combinations, particularly those with aspirin, that are marketed for “acid indigestion” are irrational choices, are potentially unsafe in patients predisposed to gastroduodenal ulcers, and should not be used.

The relative effectiveness of antacid preparations is expressed as milliequivalents of acid-neutralizing capacity (defined as the quantity of 1N HCl, expressed in milliequivalents, that can be brought to pH 3.5 within 15 minutes); according to FDA requirements, antacids must have a neutralizing capacity of at least 5 mEq per dose. Due to discrepancies between *in vitro* and *in vivo* neutralizing capacities, antacid doses in practice are titrated simply to relieve symptoms. For uncomplicated ulcers, antacids are given orally 1 and 3 hours after meals and at bedtime. This regimen, providing about 120 mEq of a Mg-Al combination per dose, may be almost as effective as conventional dosing with an H_2 -receptor antagonist. For severe symptoms or uncontrolled reflux, antacids can be given as often as every 30 to 60 minutes. In general, antacids should be administered in suspension form, as this probably has a greater neutralizing capacity than do powder or tablet dosage forms. If tablets are used, they should be thoroughly chewed for maximum effect.

Antacids are cleared from the empty stomach in about 30 minutes. However, the presence of food is sufficient to elevate gastric pH to about 5 for approximately 1 hour and to prolong the neutralizing effects of antacids for about 2 to 3 hours.

Antacids vary in the extent to which they are absorbed, and hence in their systemic effects. In general, most antacids can elevate urinary pH by about one pH unit. Antacids that contain Al^{3+} , Ca^{2+} , or Mg^{2+} are absorbed less completely than are those that contain NaHCO_3 . With normal renal function, the modest accumulations of Al^{3+} and Mg^{2+} do not pose a problem; with renal insufficiency, however, absorbed Al^{3+} can contribute to osteoporosis, encephalopathy, and proximal myopathy. About 15% of orally administered Ca^{2+} is absorbed, causing a transient hypercalcemia. Although

this is not a problem in normal patients, the hypercalcemia from as little as 3 to 4 g of CaCO_3 per day can be problematic in patients with uremia. In the past, when large doses of NaHCO_3 and CaCO_3 were administered commonly with milk or cream for the management of peptic ulcer, the *milk-alkali syndrome* (alkalosis, hypercalcemia, and renal insufficiency) occurred frequently. Today, this syndrome is rare and generally results from the chronic ingestion of large quantities of Ca^{2+} (five to forty 500-mg tablets per day of calcium carbonate) taken with milk. Patients may be asymptomatic or may present with the insidious onset of hypercalcemia, reduced secretion of parathyroid hormone, retention of phosphate, precipitation of Ca^{2+} salts in the kidney, and renal insufficiency.

By altering gastric and urinary pH, antacids may affect a number of drugs (*e.g.*, thyroid hormones, allopurinol, and imidazole antifungals, by altering rates of dissolution and absorption, bioavailability, and renal elimination). Al^{3+} and Mg^{2+} antacids also are notable for their propensity to chelate other drugs present in the GI tract, forming insoluble complexes that pass through the GI tract without absorption. Thus, it generally is prudent to avoid concurrent administration of antacids and drugs intended for systemic absorption. Most interactions can be avoided by taking antacids 2 hours before or after ingestion of other drugs.

OTHER ACID SUPPRESSANTS AND CYTOPROTECTANTS

The M_1 muscarinic receptor antagonists *pirenzepine* and *telenzepine* (*see* Chapter 7) can reduce basal acid production by 40% to 50% and long have been used to treat patients with peptic ulcer disease in countries other than the United States. The ACh receptor on the parietal cell itself is of the M_3 subtype, and these drugs are believed to suppress neural stimulation of acid production via actions on M_1 receptors of intramural ganglia (Figure 36–1). Because of their relatively poor efficacy, significant and undesirable anticholinergic side effects, and risk of blood disorders (*pirenzepine*), they rarely are used today.

In the hope of providing more rapid onset of action and sustained acid suppression, reversible inhibitors of the gastric H^+, K^+ -ATPase (*e.g.*, the pyrrolopyridazine derivative AKU517) are being developed for clinical use. Antagonists of the CCK2 gastrin receptor on parietal cells also are under study. The precise role that these agents

will play in the therapy of acid-peptic disorders in the future is yet to be determined.

Rebamipide (2-(4-chlorobenzoylamino)-3-[2(1*H*)-quinolinon-4-yl]-propionic acid) is used for ulcer therapy in parts of Asia. It appears to exert a cytoprotective effect both by increasing prostaglandin generation in gastric mucosa and by scavenging reactive oxygen species. *Eca-bet* (GASTROM; 12-sulfodehydroabiatic acid monosodium), which appears to increase the formation of PGE₂ and PGI₂, also is used for ulcer therapy, mostly in Japan. *Carbenoxolone*, a derivative of glycyrrhizic acid found in licorice root, has been used with modest success for ulcer therapy in Europe. Its exact mechanism of action is not clear, but it may alter the composition and quantity of mucin. Unfortunately, carbenoxolone inhibits the type I isozyme of 11 β -hydroxysteroid dehydrogenase, which protects the mineralocorticoid receptor from activation by cortisol in the distal nephron; it therefore causes hypokalemia and hypertension due to excessive mineralocorticoid receptor activation (see Chapter 59). *Bismuth compounds* (see Chapter 37) may be as effective as cimetidine in patients with peptic ulcers and are frequently prescribed in combination with antibiotics to eradicate *H. pylori* and prevent ulcer recurrence. Bismuth compounds bind to the base of the ulcer, promote mucin and bicarbonate production, and have significant antibacterial effects. Bismuth compounds are an important component of many anti-*Helicobacter* regimens (see below); however, given the availability of more effective drugs, bismuth compounds seldom are used alone as cytoprotective agents.

SPECIFIC ACID-PEPTIC DISORDERS AND THERAPEUTIC STRATEGIES

The success of acid-suppressing agents in a variety of conditions is critically dependent upon their ability to keep intragastric pH above a certain target, generally pH 3 to 5; this target varies to some extent with the disease being treated (Figure 36–4).

Gastroesophageal Reflux Disease

In the United States, gastroesophageal reflux disease (GERD) is common, and it is estimated that one in five adults has symptoms of heartburn or gastroesophageal regurgitation at least once a week. Although most cases follow a relatively benign course, GERD in some individuals can cause severe erosive esophagitis; serious

Figure 36–4. Comparative success of therapy with proton pump inhibitors and H₂-receptor antagonists. Data show the effects of a proton pump inhibitor (given once daily) and an H₂-receptor antagonist (given twice daily) in elevating gastric pH to the target ranges (i.e., pH 3 for duodenal ulcer, pH 4 for GERD, and pH 5 for antibiotic eradication of *H. pylori*). (Adapted from Wolfe and Sachs, 2000, with permission.)

sequelae include stricture formation and Barrett's metaplasia (replacement of squamous by intestinal columnar epithelium), which, in turn, is associated with a small but significant risk of adenocarcinoma. Most of the symptoms of GERD reflect injurious effects of the refluxed acid-peptic content on the esophageal epithelium, providing the rationale for suppression of gastric acid. The goals of GERD therapy are complete resolution of symptoms and healing of esophagitis. Proton pump inhibitors clearly are more effective than H₂-receptor antagonists in achieving these goals. Healing rates after 4 weeks and 8 weeks of therapy with protein pump inhibitors are approximately 80% and 90%, respectively, while the corresponding healing rates with H₂-receptor antagonists are 50% and 75%, respectively. Indeed, proton pump inhibitors are so effective that their empirical use is advocated as a therapeutic trial in patients in whom GERD is suspected to play a role in the pathogenesis of symptoms. Because of the wide clinical spectrum associated with GERD, the therapeutic approach is best tailored to the level of severity in the individual patient (Figure 36–5). In general, the optimal dose for each patient is determined based upon symptom control, and routine measurement of esophageal pH to guide dosing is not recommended. Strictures associated with GERD also respond better to proton pump inhibitors than to H₂-receptor antagonists; indeed, the use of

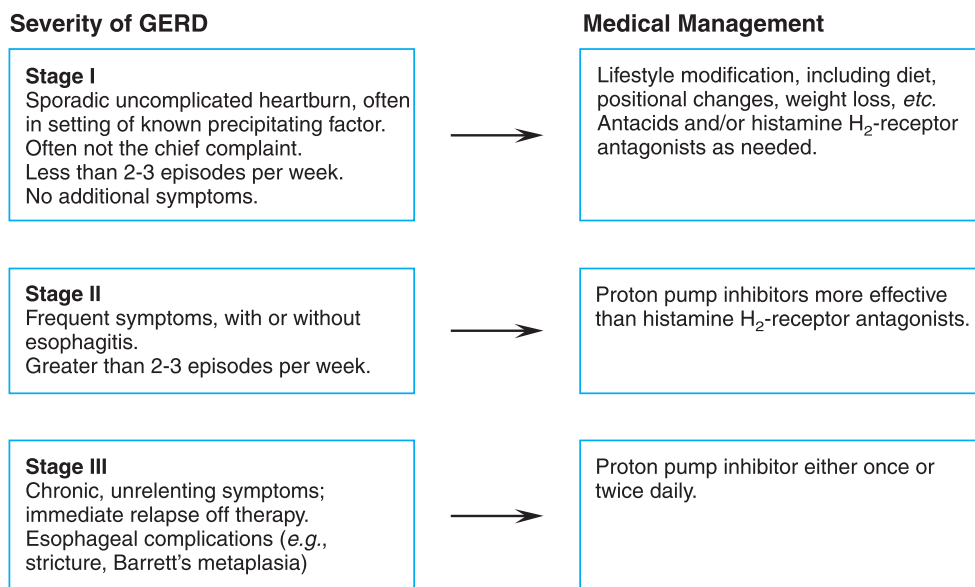

Figure 36–5. General guidelines for the medical management of gastroesophageal reflux disease (GERD). Only medications that suppress acid production or that neutralize acid are shown. (Adapted from Wolfe and Sachs, 2000, with permission.)

proton pump inhibitors reduces the requirement for esophageal dilation. Unfortunately, one of the other complications of GERD, Barrett's esophagus, appears to be more refractory to therapy, as neither acid suppression nor antireflux surgery has been shown convincingly to produce regression of metaplasia or to decrease the incidence of tumors.

Regimens for the treatment of GERD with proton pump inhibitors and histamine H₂-receptor antagonists are listed in Table 36–3. Although some patients with mild GERD symptoms may be managed by nocturnal doses of H₂-receptor antagonists, twice-daily dosing usually is required. Antacids are recommended only for the patient with mild, infrequent episodes of heartburn. In general, prokinetic agents (*see* Chapter 37) are not particularly useful for GERD, either alone or in combination with acid-suppressant medications.

GERD is a chronic disorder that requires long-term therapy. Some experts advocate “step-down” approaches that attempt to maintain symptomatic remission by either decreasing the dose of the proton pump inhibitor or switching to an H₂-receptor antagonist. Other experts have advocated intermittent, “on-demand” therapy with proton pump inhibitors for symptomatic relief in patients who have responded initially but continue to have symptoms. However, many patients will maintain their requirement for proton pump inhibitors, and several studies suggest that these

drugs are better than H₂-receptor antagonists for maintaining remission in GERD.

Severe Symptoms and Nocturnal Acid Breakthrough. In patients with severe symptoms or extraintestinal manifestations of GERD,

Table 36–3

Antisecretory Drug Regimens for Treatment and Maintenance of GERD

DRUG	DOSAGE
<i>H₂-Receptor Antagonists</i>	
Cimetidine	400*/800* mg <i>bid</i>
Famotidine	20/40 mg <i>bid</i>
Nizatidine	150*/300* mg <i>bid</i>
Ranitidine	150/300 mg <i>bid</i>
<i>Proton Pump Inhibitors</i>	
Esomeprazole	20/40 mg daily/40* mg <i>bid</i>
Lansoprazole	30*/60* mg daily/30* mg <i>bid</i>
Omeprazole	20/40* mg daily/20* mg <i>bid</i>
Pantoprazole	40/80* mg daily/40* mg <i>bid</i>
Rabeprazole	20/40* mg daily/20* mg <i>bid</i>

bid, twice daily. *Indicates unlabeled use.

twice-daily dosing with a proton pump inhibitor may be needed. However, it is difficult if not impossible to render patients achlorhydric—even on twice-daily doses of proton pump inhibitors—and two-thirds or more of subjects will continue to make acid, particularly at night. This phenomenon, called *nocturnal acid breakthrough*, has been invoked as a cause of refractory symptoms in some patients with GERD. However, decreases in gastric pH at night while on therapy generally are not associated with acid reflux into the esophagus, and the rationale for suppressing nocturnal acid secretion (even if feasible) remains to be established. Nevertheless, patients with continuing symptoms on twice-daily proton pump inhibitors are often treated by adding an H₂-receptor antagonist at night. While this can further suppress acid production, the effect is short-lived, probably due to the development of tolerance, as described above (Fackler *et al.*, 2002).

Therapy for Extraintestinal Manifestations of GERD. With varying levels of evidence, acid reflux has been implicated in a variety of atypical symptoms, including noncardiac chest pain, asthma, laryngitis, chronic cough, and other ear, nose, and throat conditions. Proton pump inhibitors have been used with some success in certain patients with these disorders, generally in higher doses and for longer periods of time than those used for patients with more classic symptoms of GERD.

GERD and Pregnancy. Heartburn is estimated to occur in 30% to 50% of pregnancies, with an incidence approaching 80% in some populations (Richter, 2003). In the vast majority of cases, GERD ends soon after delivery and thus does not represent an exacerbation of a preexisting condition. Nevertheless, because of its high prevalence and the fact that it can contribute to the nausea of pregnancy, treatment often is required. Treatment choice in this setting is complicated by the paucity of data for the most commonly used drugs. In general, most drugs used to treat GERD fall in FDA Category B, with the exception of omeprazole (FDA Category C).

Mild cases of GERD during pregnancy should be treated conservatively; antacids or sucralfate are considered the first-line drugs. If symptoms persist, H₂-receptor antagonists can be used, with ranitidine having the most established track record in this setting. Proton pump inhibitors are reserved for women with intractable symptoms or complicated reflux disease. In these situations, lansoprazole is considered the preferred choice among the proton pump inhibitors, based on animal data and available experience in pregnant women.

Peptic Ulcer Disease

The pathophysiology of peptic ulcer disease is best viewed as an imbalance between mucosal defense factors (bicarbonate, mucin, prostaglandin, nitric oxide, and other peptides and growth factors) and injurious factors (acid and pepsin). On average, patients with duodenal ulcers produce more acid than do control subjects, particularly at night (basal secretion). Although patients with gastric ulcers have normal or even diminished acid production, ulcers rarely if ever occur in the complete absence of acid. Presumably, a weakened mucosal defense and reduced bicarbonate production

contribute to the injury from the relatively lower levels of acid in these patients. *H. pylori* and exogenous agents such as nonsteroidal antiinflammatory drugs (NSAIDs) interact in complex ways to cause an ulcer. Up to 60% of peptic ulcers are associated with *H. pylori* infection of the stomach. This infection may lead to impaired production of somatostatin by D cells, and in time, decreased inhibition of gastrin production, resulting in increased acid production and reduced duodenal bicarbonate production.

NSAIDs also are very frequently associated with peptic ulcers (in up to 60% of patients, particularly those with complications such as bleeding). Topical injury by the luminal presence of the drug appears to play a minor role in the pathogenesis of these ulcers, as evidenced by the fact that ulcers can occur with very low doses of aspirin (10 mg) or with parenteral administration of NSAIDs. The effects of these drugs are instead mediated systemically; the critical element is suppression of the constitutive form of cyclooxygenase-1 (COX-1) in the mucosa and decreased production of the cytoprotective prostaglandins PGE₂ and PGI₂.

Table 36–4 summarizes current recommendations for drug therapy of gastroduodenal ulcers. Proton pump inhibitors relieve symptoms of duodenal ulcers and promote healing more rapidly than do H₂-receptor antagonists, although both classes of drugs are very effective in this setting. Peptic ulcer represents a chronic disease, and recurrence within 1 year is expected in the majority of patients who do not receive prophylactic acid suppression. With the appreciation that *H. pylori* plays a major etiopathogenic role in the majority of peptic ulcers (*see below*), prevention of relapse is focused on eliminating this organism from the stomach. Chronic acid suppression, once the mainstay of ulcer prevention, now is used mainly in patients who are *H. pylori*-negative or, in some cases, for maximum prevention of recurrence in patients who have had life-threatening complications.

Intravenous pantoprazole or lansoprazole clearly is the preferred therapy in patients with acute bleeding ulcers. The theoretical benefit of maximal acid suppression in this setting is to accelerate healing of the underlying ulcer. In addition, a higher gastric pH enhances clot formation and retards clot dissolution.

Treatment of Helicobacter pylori Infection. *H. pylori*, a gram-negative rod, has been associated with gastritis and the subsequent development of gastric and duodenal ulcers, gastric adenocarcinoma, and gastric B-cell lymphoma (Suerbaum and Michetti, 2002). Because of the

Table 36–4
Recommendations for Treatment of Gastroduodenal Ulcers

DRUG	ACTIVE ULCER	MAINTENANCE THERAPY
<i>H₂-Receptor Antagonists</i>		
Cimetidine	800 mg at bedtime/400 mg twice daily	400 mg at bedtime
Famotidine	40 mg at bedtime	20 mg at bedtime
Nizatidine/ranitidine	300 mg after evening meal or at bedtime/150 mg twice daily	150 mg at bedtime
<i>Proton Pump Inhibitors</i>		
Lansoprazole	15 mg (DU; NSAID risk reduction) daily 30 mg (GU including NSAID-associated) daily	
Omeprazole	20 mg daily	
Rabeprazole	20 mg daily	
<i>Prostaglandin Analogs</i>		
Misoprostol	200 µg four times daily (NSAID-associated ulcer prevention)*	

DU, duodenal ulcer; GU, gastric ulcer. *Only misoprostol 800 µg/day has been directly shown to reduce the risk of ulcer complications such as perforation, hemorrhage, or obstruction (Rostom *et al.*, 2004).

critical role of *H. pylori* in the pathogenesis of peptic ulcers, to eradicate this infection is standard care in patients with gastric or duodenal ulcers. Provided that patients are not taking NSAIDs, this strategy almost completely eliminates the risk of ulcer recurrence. Eradication of *H. pylori* also is indicated in the treatment of mucosa-associated lymphoid tissue lymphomas of the stomach, which can regress significantly after such treatment.

Many regimens for *H. pylori* eradication have been proposed. Evidence-based literature review suggests that the ideal regimen in this setting should achieve a cure rate of at least 80%. Five important considerations influence the selection of an eradication regimen (Graham, 2000) (Table 36–5). First, single-antibiotic regimens are ineffective in eradicating *H. pylori* infection and lead to microbial resistance. Combination therapy with two or three antibiotics (plus acid-suppressive therapy) is associated with the highest rate of *H. pylori* eradication. Second, a proton pump inhibitor or H₂-receptor antagonist significantly enhances the effectiveness of *H. pylori* antibiotic regimens containing amoxicillin or clarithromycin. Third, a regimen of 10 to 14 days of treatment appears to be better than shorter treatment regimens; in the United States, a 14-day course of therapy generally is preferred. Fourth, poor patient compliance is linked to the medication-related side effects experienced by as many as half of patients taking triple-agent regimens, and to the inconvenience of three- or four-drug regimens administered several times per day. Packaging that combines the daily doses into one convenient unit is avail-

able and may improve patient compliance (Table 36–5). Finally, the emergence of resistance to clarithromycin and metronidazole increasingly is recognized as an important factor in the failure to eradicate *H. pylori*. Clarithromycin resistance is related to mutations that prevent binding of the antibiotic to the ribosomes of the pathogen and is an all-or-none phenomenon. In contrast, metronidazole resistance is relative rather than absolute and may involve several adaptations by the bacteria. In the presence of *in vitro* evidence of resistance to metronidazole, amoxicillin should be used instead. In areas with a high frequency of resistance to clarithromycin and metronidazole, a 14-day, quadruple-drug regimen (three antibiotics combined with a proton pump inhibitor) generally is effective therapy.

NSAID-Related Ulcers. Chronic NSAID users have a 2% to 4% risk of developing a symptomatic ulcer, gastrointestinal bleeding, or perforation. Ideally, NSAIDs should be discontinued in patients with an ulcer if at all possible. If continued therapy is needed, selective COX-2 inhibitors may be considered, although this does not eliminate the risk of subsequent ulcer formation and the possible association of these drugs with adverse cardiovascular events mandates caution (*see* Chapter 25). Healing of ulcers despite continued NSAID use is possible with the use of acid-suppressant agents, usually at higher doses and for a considerably longer duration than standard regimens (*e.g.*, 8 weeks or longer). Again, proton pump inhibitors are superior to H₂-receptor antagonists and misoprostol in promoting the healing of active ulcers (healing rates of 80% to 90% for proton pump inhibitors *versus* 60% to 75% for the H₂-receptor antagonists), and in preventing recurrence of gastric and duodenal ulcers in the setting of continued NSAID administration (Lanza, 1998).

Table 36-5**Therapy of *Helicobacter pylori* Infection**

Triple therapy × 14 days: [Proton pump inhibitor + clarithromycin 500 mg + (metronidazole 500 mg or amoxicillin 1 g)] twice a day. (Tetracycline 500 mg can be substituted for amoxicillin or metronidazole.)

Quadruple therapy × 14 days: Proton pump inhibitor twice a day + metronidazole 500 mg three times daily + (bismuth subsalicylate 525 mg + tetracycline 500 mg four times daily)

or

H₂-receptor antagonist twice a day + (bismuth subsalicylate 525 mg + metronidazole 250 mg + tetracycline 500 mg) four times daily

Dosages:

Proton pump inhibitors:	H ₂ -receptor antagonists:
Omeprazole: 20 mg	Cimetidine: 400 mg
Lansoprazole: 30 mg	Famotidine: 20 mg
Rabeprazole: 20 mg	Nizatidine: 150 mg
Pantoprazole: 40 mg	Ranitidine: 150 mg
Esomeprazole: 40 mg

Stress-Related Ulcers. Stress ulcers are ulcers of the stomach or duodenum that occur in the context of a profound illness or trauma requiring intensive care. The etiology of stress-related ulcers differs somewhat from that of other peptic ulcers, involving acid and mucosal ischemia. Because of limitations on the oral administration of drugs in many patients with stress-related ulcers, intravenous H₂-receptor antagonists have been used extensively to reduce the incidence of GI hemorrhage due to stress ulcers. Now that intravenous preparations of proton pump inhibitors are available, it is likely that they will prove to be equally beneficial. *However, there is some concern over the risk of pneumonia secondary to gastric colonization by bacteria in an alkaline milieu.* In this setting, sucralfate appears to provide reasonable prophylaxis against bleeding without increasing the risk of aspiration pneumonia. This approach also appears to provide reasonable prophylaxis against bleeding, but is less convenient (Cook *et al.*, 1998).

Zollinger-Ellison Syndrome. Patients with this syndrome develop pancreatic or duodenal gastrinomas that stimulate the secretion of very large amounts of acid, sometimes in the setting of multiple endocrine neoplasia, type I. This can lead to severe gastroduodenal ulceration and other consequences of uncontrolled hyperchlorhydria. Proton pump inhibitors clearly are the drugs of choice, usually given at twice the routine dosage for peptic ulcers with the therapeutic goal of reducing acid secretion to 1 to 10 mmol/h.

Nonulcer Dyspepsia. This term refers to ulcer-like symptoms in patients who lack overt gastroduodenal ulceration. It may be associated with gastritis (with or without *H. pylori*) or with NSAID use, but the pathogenesis of this syndrome remains controversial.

Although empirical treatment with acid-suppressive agents is used routinely in patients with nonulcer dyspepsia, there is no convincing evidence of their benefit in controlled trials.

CLINICAL SUMMARY

The control of acid-peptic disease represents a major triumph for modern pharmacology. Proton pump inhibitors are considered superior for acid suppression in most clinically significant acid-peptic diseases, including gastroesophageal reflux disease, peptic ulcers, and NSAID-induced ulcers. Proton pump inhibitors also are employed in combination with antibiotics to eradicate infection with *H. pylori* and thereby play a role in preventing recurrent peptic ulcers. These agents largely have replaced the use of misoprostol and sucralfate, although the latter still is a low-cost alternative for prophylaxis against stress ulcers. The delay in maximal inhibition of acid secretion with the proton pump inhibitors (3 to 5 days) makes them less suited for use on an as-needed basis for symptom relief. In this setting, H₂-receptor antagonists, while less effective than proton pump inhibitors in suppressing acid secretion, have a more rapid onset of action that makes them useful for patient-directed management of mild or infrequent symptoms.

TREATMENT OF DISORDERS OF BOWEL MOTILITY AND WATER FLUX; ANTIEMETICS; AGENTS USED IN BILIARY AND PANCREATIC DISEASE

Pankaj Jay Pasricha

The longer I live, the more I am convinced that half the unhappiness in the world proceeds from little stoppages, from a duct choked up, from food pressing in the wrong place, from a vexed duodenum or an agitated pylorus.

—Sydney Smith (1771–1845)

INTRODUCTION TO GASTROINTESTINAL MOTILITY

The gastrointestinal tract is in a continuous contractile, absorptive, and secretory state. The control of this state is complex, with contributions by the muscle itself, local nerves (*i.e.*, the enteric nervous system, ENS), the central nervous system (CNS), and humoral pathways (Furness and Sanger, 2002; Galligan, 2002; Hansen, 2003). Of these, perhaps the most important regulator of physiological gut function is the ENS (Figure 37–1), which is an autonomous collection of nerves within the wall of the GI tract, organized into two connected networks of neurons: the *myenteric* (Auerbach's) plexus, found between the circular and longitudinal muscle layers, and the *submucosal* (Meissner's) plexus, found below the epithelium. The former is responsible for motor control, while the latter regulates secretion, fluid transport, and vascular flow.

The ENS is responsible for the largely autonomous nature of most gastrointestinal activity. This activity is organized into relatively distinct programs that respond to input from the local envi-

ronment of the gut and the CNS. Each program consists of a series of complex, but coordinated, patterns of secretion and movement that show regional and temporal variation. The fasting program of the gut is called the MMC (*migrating myoelectric complex* when referring to electrical activity and *migrating motor complex* when referring to the accompanying contractions) and consists of a series of four phasic activities. The most characteristic, phase III, consists of clusters of rhythmic contractions that occupy short segments of the intestine for a period of 6 to 10 minutes before proceeding caudally. One whole MMC cycle (*i.e.*, all four phases) takes about 80 to 110 minutes. The migrating motor complex occurs in the fasting state, during which it helps sweep debris caudad in the gut. The migrating motor complex cycles continually in animals that feed constantly, but is interrupted by another pattern of contractions—the fed program—in intermittently feeding animals such as humans. The fed program consists of high-frequency (12 to 15 per minute) contractions that are either propagated for short segments (*propulsive*) or are irregular and not propagated (*mixing*).

The basic motor tool used by the ENS to integrate its programs is the peristaltic reflex. Physiologically, peristalsis is a series of reflex responses to a bolus in the lumen of a given segment of the intestine; the ascending excitatory reflex results in contraction of the circular muscle on the oral side of the bolus, while the descending inhibitory reflex results in relaxation on the anal side. The net pressure gradient moves the bolus caudad. Three neural elements, responsible for sensory, relay, and effector functions, are required to produce these reflexes. Luminal factors stimulate sensory elements in the mucosa, leading to a coordinated pattern of muscle activity that is directly controlled by the motor neurons of the myenteric plexus to provide the effector component of the peristaltic reflex. Motor neurons receive input from ascending and descending interneurons (which constitute the relay and programming systems) that are of two broad types, excitatory and inhibitory. The primary neurotransmitter of the excitatory motor neurons is acetylcholine (ACh), although tachy-

Figure 37–1. The neuronal network that initiates and generates the peristaltic response. Mucosal stimulation leads to release of serotonin by enterochromaffin cells (8), which excites the intrinsic primary afferent neuron (1), which then communicates with ascending (2) and descending (3) interneurons in the local reflex pathways. The reflex results in contraction at the oral end *via* the excitatory motor neuron (6) and aboral relaxation *via* the inhibitory motor neuron (5). The migratory myoelectric complex (*see* text) is shown here as being conducted by a different chain of interneurons (4). Another intrinsic primary afferent neuron with its cell body in the submucosa also is shown (7). MP, myenteric plexus; CM, circular muscle; LM, longitudinal muscle; SM, submucosa; Muc, mucosa. (Adapted from Kunze and Furness, 1999, with permission.)

kinins, co-released by these neurons, also play a role. The principal neurotransmitter in the inhibitory motor neurons appears to be nitric oxide (NO), although important contributions may also be made by ATP, vasoactive intestinal peptide, and pituitary adenylyl cyclase-activating peptide (PACAP), all of which are variably coexpressed with NO synthase.

This view of nerve–muscle interaction within the GI tract may be oversimplified, and other cell types may be important. One of these is the interstitial cell of Cajal, distributed within the gut wall and responsible for setting the electrical rhythm, and hence the pace of contractions, in various regions of the gut. These cells also may translate or modulate neuronal communication to the muscle, by mechanisms yet to be worked out.

Excitation-Contraction Coupling in GI Smooth Muscle

Control of tension in gastrointestinal smooth muscle is in large part dependent on the intracellular Ca^{2+} concentration. In general, there are two types of excitation-contraction coupling. Ionotropic receptors can mediate changes in membrane potential, which in turn activate voltage-dependent Ca^{2+} channels to trigger an influx of Ca^{2+} (electromechanical coupling); metabotropic receptors activate various signal transduction pathways to release Ca^{2+} from intracellular stores (pharmacomechanical coupling). Inhibitory receptors also exist on smooth muscle and generally act *via* PKA and PKG, whose kinase activities can lead to hyperpolarization, decreased cytosolic $[\text{Ca}^{2+}]$, and reduced interaction of actin and myosin. As an example, NO may induce relaxation *via* activation

of guanylyl cyclase, GMP–pathway, and the opening of several types of K^+ channels.

OVERVIEW OF FUNCTIONAL AND MOTILITY DISORDERS OF THE BOWEL

Gastrointestinal motility disorders are a complex and heterogeneous group of syndromes whose pathophysiology is not completely understood. Typical motility disorders include achalasia of the esophagus (impaired relaxation of the lower esophageal sphincter associated with defective esophageal peristalsis that results in dysphagia and regurgitation), gastroparesis (delayed gastric emptying), myopathic and neuropathic forms of intestinal dysmotility, and others. These disorders can be congenital, idiopathic, or secondary to systemic diseases (*e.g.*, diabetes mellitus or scleroderma). This term also has traditionally (and perhaps inaccurately) included disorders—such as irritable bowel syndrome (*see* below) and noncardiac chest pain—in which disturbances in pain processing or sensory function may be more important than any associated motor patterns. For most

of these disorders, treatment remains empirical and symptom-based, reflecting our ignorance of the specific derangements in pathophysiology involved.

PROKINETIC AGENTS AND OTHER STIMULANTS OF GI CONTRACTILITY

Direct activation of muscarinic receptors, such as with the older cholinomimetic agents (*see* Chapter 7), is not a very effective strategy for treating GI motility disorders because these agents enhance contractions in a relatively uncoordinated fashion that produces little or no net propulsive activity. By contrast, *prokinetic* agents are medications that enhance coordinated GI motility and transit of material in the GI tract. Although ACh, when released from primary motor neurons in the myenteric plexus, is the principal immediate mediator of muscle contractility, most of the clinically useful prokinetic agents act “upstream” of ACh, at receptor sites on the motor neuron itself, or even more indirectly, on neurons one or two orders removed from it. Although pharmacologically and chemically diverse, these agents appear to enhance the release of excitatory neurotransmitter at the nerve-muscle junction without interfering with the normal physiological pattern and rhythm of motility. Coordination of activity among the segments of the gut, necessary for propulsion of luminal contents, therefore is maintained.

Agents useful clinically in altering GI motility are considered below.

Cholinergic Agents

Choline Derivatives. The effects of ACh on smooth muscle are mediated in large part by two types of G protein–coupled muscarinic receptors (mAChRs), M_2 and M_3 (*see* Chapter 7), that are present in the GI tract in a 4:1 ratio, respectively. Although less abundant, the M_3 receptor is more important; its activation increases intracellular Ca^{2+} , an effect mediated by the G_q -PLC-IP₃ pathway. ACh itself is not used pharmacologically because it affects all classes of cholinergic receptors (nicotinic and muscarinic) and is degraded rapidly by acetylcholinesterase. Modification of the structure of ACh has yielded drugs such as *bethanechol* that have increased receptor selectivity and that resist enzymatic hydrolysis. In addition to its lack of real prokinetic efficacy, bethanechol has significant side effects resulting from its broad muscarinic effects on contractility and secretion in the GI tract and other organs. These side effects include bradycardia, flushing, diarrhea and cramps, salivation, and blurred vision.

Acetylcholinesterase Inhibitors. These drugs inhibit the degradation of ACh by its esterase (*see* Chapter 8), thereby allowing ACh to accumulate at sites of release. Unlike muscarinic receptor agonists,

these parasympathomimetic drugs do not stimulate muscle directly, but rather accelerate GI transit times by enhancing the contractile effects of ACh released at synaptic and neuromuscular junctions. Among these cholinergic muscle stimulants, *neostigmine methylsulfate* has been used off-label for some gastroenterological disorders, particularly those associated with acute colonic pseudo-obstruction (Ogilvie’s syndrome) and paralytic ileus. The usual dose in the acute setting is 2 to 2.5 mg of neostigmine methylsulfate administered by IV push over 3 minutes with continuous monitoring of ECG, blood pressure, and O₂ saturation. Atropine should be available in case of severe bradycardia (heart rate of less than 50 bpm).

Dopamine-Receptor Antagonists

Dopamine is present in significant amounts in the GI tract and has several inhibitory effects on motility, including reduction of lower esophageal sphincter and intragastric pressures. These effects, which apparently result from suppression of ACh release from myenteric motor neurons, are mediated by D_2 dopaminergic receptors. By antagonizing the inhibitory effect of dopamine on myenteric motor neurons, dopamine receptor antagonists are effective as prokinetic agents; they have the additional advantage of relieving nausea and vomiting by antagonism of dopamine receptors in the chemoreceptor trigger zone (*see* below). Examples of such agents are *metoclopramide* and *domperidone*.

Metoclopramide. Chemistry, Mechanism of Action, and Pharmacological Properties. Metoclopramide (REGLAN) and other substituted benzamides are derivatives of *para*-aminobenzoic acid and are structurally related to *procainamide*. The chemical structure of metoclopramide is:

The mechanisms of action of metoclopramide are complex and involve 5-HT₄-receptor agonism, vagal and central 5-HT₃-antagonism, and possible sensitization of muscarinic receptors on smooth muscle, in addition to dopamine receptor antagonism. Metoclopramide is one of the oldest true prokinetic agents; its administration results in coordinated contractions that enhance transit. Its effects are confined largely to the upper digestive tract, where it increases lower esophageal sphincter tone and stimulates antral and small intestinal contractions. Despite having *in vitro* effects on the contractility of colonic smooth muscle, metoclopramide has no clinically significant effects on large-bowel motility.

Pharmacokinetics. Metoclopramide is absorbed rapidly after oral ingestion, undergoes sulfation and glucuronide conjugation by the liver, and is excreted principally in the urine, with a half-life of 4 to 6 hours. Peak concentrations occur within 1 hour after a single oral dose; the duration of action is 1 to 2 hours.

Therapeutic Use. Metoclopramide has been used in patients with gastroesophageal reflux disease to produce symptomatic relief of, but not healing of, associated esophagitis. It clearly is less effective than modern acid-suppressive medications, such as proton pump inhibitors or histamine H₂-receptor antagonists, and now rarely is used in this setting. Metoclopramide is indicated more often in symptomatic patients with gastroparesis, in whom it may cause mild to modest improvements of gastric emptying (Tonini *et al.*, 2004). Metoclopramide injection is used as an adjunctive measure in medical or diagnostic procedures such as intestinal intubation or contrast radiography of the GI tract. Although it has been used in patients with postoperative ileus, its ability to improve transit in disorders of small-bowel motility appears to be limited. *In general, its greatest utility lies in its ability to ameliorate the nausea and vomiting that often accompany GI dysmotility syndromes.* Metoclopramide has also been used in the treatment of persistent hiccups, but its efficacy in this condition is equivocal at best.

Metoclopramide is available in oral dosage forms (tablets and solution) and as a parenteral preparation for intravenous or intramuscular use. The usual initial oral dose range is 10 mg, 30 minutes before each meal and at bedtime. The onset of action is within 30 to 60 minutes after an oral dose. In patients with severe nausea, an initial dose of 10 mg can be given intramuscularly (onset of action 10 to 15 minutes) or intravenously (onset of action 1 to 3 minutes). For prevention of chemotherapy-induced emesis, metoclopramide can be given as an infusion of 1 to 2 mg per kg of body weight, administered over at least 15 minutes, beginning 30 minutes before the chemotherapy is begun and repeated as needed every 2 or 3 hours. Alternatively, a continuous intravenous infusion may be given (3 mg/kg of body weight before chemotherapy, followed by 0.5 mg/kg of body weight per hour for 8 hours). The usual pediatric dose for gastroparesis is 0.1 to 0.2 mg/kg of body weight per dose, given 30 minutes before meals and at bedtime.

Adverse Effects. The major side effects of metoclopramide include extrapyramidal effects, such as those seen with the phenothiazines (*see* Chapter 18). Dystonias, usually occurring acutely after intravenous administration, and parkinsonian-like symptoms that may occur several weeks after initiation of therapy generally respond to treatment with anticholinergic or antihistaminic drugs and are reversible upon discontinuation of metoclopramide. Tardive dyskinesia also can occur with chronic treatment (months to years) and may be irreversible. Extrapyramidal effects appear to occur more commonly in children and young adults and at higher doses. Like other dopamine antagonists, metoclopramide also can cause galactorrhea by blocking the inhibitory effect of dopamine on prolactin

release, but this adverse effect is relatively infrequent in clinical practice. Methemoglobinemia has been reported occasionally in premature and full-term neonates receiving metoclopramide.

Domperidone; D₂ Receptor Antagonists

In contrast to metoclopramide, domperidone predominantly antagonizes the dopamine D₂ receptor without major involvement of other receptors. It is not available for use in the United States but has been used elsewhere (MOTILIUM, others) and has modest prokinetic activity in doses of 10 to 20 mg three times a day. Although it does not readily cross the blood–brain barrier to cause extrapyramidal side effects, domperidone exerts effects in the parts of the CNS that lack this barrier, such as those regulating emesis, temperature, and prolactin release. As is the case with metoclopramide, domperidone does not appear to have any significant effects on lower gastrointestinal motility. Other D₂-receptor antagonists being explored as prokinetic agents include *levosulpiride*, the levoenantiomer of *sulpiride*.

Serotonin Receptor Modulators

Serotonin (5-HT) plays an important role in the normal motor and secretory function of the gut (Talley, 2001) (*see* Chapter 11). Indeed, more than 90% of the total 5-HT in the body exists in the GI tract. The enterochromaffin cell, a specialized cell lining the mucosa of the gut, produces most of this 5-HT and rapidly releases 5-HT in response to chemical and mechanical stimulation (*e.g.*, food boluses; noxious agents such as cis-platinum; certain microbial toxins; adrenergic, cholinergic, and purinergic receptor agonists). 5-HT triggers the peristaltic reflex (Figure 37–1) by stimulating intrinsic sensory neurons in the myenteric plexus (*via* variant 5-HT receptors, 5-HT_{1P}, and *via* 5-HT₄ receptors), as well as extrinsic vagal and spinal sensory neurons (*via* 5-HT₃ receptors). Additionally, stimulation of submucosal intrinsic afferent neurons activates secretomotor reflexes resulting in epithelial secretion. 5-HT receptors also are found on other neurons in the enteric nervous system, where they can be either stimulatory (5-HT₃ and 5-HT₄) or inhibitory (5-HT_{1a}). In addition, serotonin also stimulates the release of other neurotransmitters, depending upon the receptor subtype. Thus, 5-HT₁ stimulation of the gastric fundus results in release of nitric oxide and reduces smooth muscle tone. 5-HT₄ stimulation of excitatory motor neurons enhances ACh release at the neuromuscular junction, and both 5-HT₃ and 5-HT₄ receptors facilitate interneuronal sig-

Figure 37–2. Ligands of 5-HT₃ and 5-HT₄ receptors modulating gastrointestinal motility.

naling. Developmentally, 5-HT acts as a neurotrophic factor for enteric neurons *via* the 5-HT_{2B} and 5-HT₃ receptors.

Reuptake of serotonin by enteric neurons and epithelium is mediated by the same mechanism as 5-HT reuptake by serotonergic neurons in the CNS. This reuptake therefore also is blocked by selective serotonin reuptake inhibitors (*see* Chapter 17), which explains the common side effect of diarrhea that accompanies the use of these agents. In recent years, modulation of the multiple, complex, and sometimes opposing effects of 5-HT on gut motor function has become a major target for drug development.

Tegaserod Maleate. Chemistry, Mechanism of Action, and Pharmacological Properties. Tegaserod (ZELNORM), an aminoguanidine indole, is structurally related to serotonin and is a partial 5-HT₄ agonist with negligible affinity for other receptor subtypes (Figure 37–2). Tegaserod has multiple effects on the GI tract. It stimulates motility and accelerates transit in the esophagus, stomach, small bowel, and ascending colon. It also stimulates chloride secretion. Thus far, the clinical efficacy of tegaserod has been proven only in female patients with constipation-predominant irritable bowel syndrome (*see* below); however, the drug is being tested in a variety of other conditions,

including gastroparesis. In patients with constipation, tegaserod results in a statistically significant but mild-to-moderate improvement in stool frequency, with less consistent effects on other parameters such as stool form, bloating, and pain. The absolute improvement is modest at best, with a difference of only about one to two bowel movements per week between the drug and placebo groups. It is not clear that the drug has any greater efficacy in this regard than other agents used for constipation. Males with constipation also may respond to tegaserod, but existing studies did not include enough men to demonstrate a statistically significant effect.

In clinical trials, tegaserod also reduced bloating (a prominent symptom in patients with irritable bowel syndrome) and pain, but it is not clear whether this represents an independent effect on sensory nerves or simply a consequence of decreased fecal or air distention of the colon. As yet, there is no evidence for significant modulation of nociceptive signaling by 5-HT₄ receptors.

Tegaserod is available for oral administration in 2-mg and 6-mg tablets and is approved for use in women with constipation-dominant irritable bowel syndrome at a dose of 6 mg twice daily. Tegaserod also has been approved for the treatment of chronic constipation. Higher doses have been suggested for other prokinetic effects (*e.g.*, stimulation of gastric emptying) but such uses have not been validated clinically.

After oral administration, tegaserod is partially absorbed from the gut, reaching peak plasma levels after 1 to 1.3 hours. Absorption is slowed by the presence of food in the stomach, so tegaserod is best taken on an empty stomach. Once in circulation, tegaserod is approximately 98% bound to plasma proteins. Tegaserod is degraded by acid hydrolysis before absorption from the stomach, and by oxidation and glucuronidation in the liver to three inactive N-glucuronide metabolites. Approximately two-thirds of the orally administered dose of tegaserod is excreted unchanged in feces, with the remainder excreted in urine; the drug has an estimated half-life of about 11 hours.

Diarrhea and headache are the most common side effects of tegaserod, occurring in about 10% of patients. Tegaserod does not appear to have any significant cardiac toxicity, and no clinically relevant drug-drug interactions have been identified. No dosage adjustment is required in elderly patients or those with mild-to-moderate hepatic or renal impairment; however, tegaserod should not be used in patients with severe hepatic or renal impairment.

Cisapride. *Cisapride* (PROPULSID) is a substituted piperidyl benzamide (Figure 37–2) that appears to stimulate 5-HT₄ receptors and increase adenylyl cyclase activity within neurons. It also has weak 5-HT₃ antagonistic properties and may directly stimulate smooth muscle. Until recently, it was a commonly used prokinetic agent, particularly for gastroesophageal reflux disease and gastroparesis. However, it no longer is generally available in the United States because of its potential to induce serious and occasionally fatal cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, and *torsades de pointes*. These arrhythmias result from a prolonged QT interval through an interaction with pore-forming subunits of the HERG K⁺ channel. HERG K⁺ channels conduct the rapid delayed rectifier K⁺ current that is important for normal repolarization of the ventricle (see Chapter 34). Cisapride-induced ventricular arrhythmias occur most often when the drug is combined with other drugs that inhibit CYP3A4 (see Chapter 3); such combinations inhibit the metabolism of cisapride and lead to high plasma concentrations of the drug. Due to its association with ventricular arrhythmias, cisapride is contraindicated in patients with a history of prolonged QT interval, renal failure, ventricular arrhythmias, ischemic heart disease, congestive heart failure, respiratory failure, uncorrected electrolyte abnormalities (e.g., hypokalemia and hypomagnesemia), or concomitant medications known to prolong the QT interval. At this time, cisapride is available only through an investigational, limited-access program for patients who have failed all standard therapeutic modalities and undergone a thorough diagnostic evaluation, including an electrocardiogram.

Other 5-HT₄-Receptor Modulators. *Prucalopride* (Figure 37–2) is a benzofuran derivative and a specific 5-HT₄-receptor agonist that facilitates cholinergic neurotransmission. It enhances colonic contractility in experimental animals, and preliminary studies suggest that it accelerates colonic transit in human beings. Another investigational agent in this class, *mosapride*, is under development.

Motilin Agonists: Macrolides and Erythromycin.

Chemistry, Pharmacological Effects, and Mechanism of Action. Motilin is a 22-amino acid peptide hormone found in the gastrointestinal M cells, as well as in some enterochromaffin cells of the upper small bowel. Motilin is a potent contractile agent of the upper GI tract. Motilin levels fluctuate in association with the

migrating motor complex and appear to be responsible for the amplification, if not the actual induction, of phase III activity. In addition, motilin receptors are found on smooth muscle cells and enteric neurons. The effects of motilin can be mimicked by *erythromycin*, a discovery that arose from the frequent occurrence of GI side effects with the use of this antibiotic. This property is shared to varying extents by other macrolide antibiotics (see Chapter 46), including *oleandomycin*, *azithromycin*, and *clarithromycin*. In addition to its motilin-like effects, which are most pronounced at higher doses (250 to 500 mg), erythromycin at lower doses (e.g., 40 to 80 mg) also may act by other poorly defined mechanisms that may involve cholinergic facilitation.

Erythromycin induces phase III migrating motor complex activity in dogs and increases smooth muscle contractility. It has multiple effects on upper GI motility, increasing lower esophageal pressure and stimulating gastric and small-bowel contractility. By contrast, it has little or no effect on colonic motility. At doses higher than 3 mg/kg, it can produce a spastic type of contraction in the small bowel, resulting in cramps, impairment of transit, and vomiting.

Therapeutic Use. The best-established use of erythromycin as a prokinetic agent is in patients with diabetic gastroparesis, where it can improve gastric emptying in the short term. Erythromycin-stimulated gastric contractions can be intense and result in “dumping” of relatively undigested food into the small bowel. This potential disadvantage can be exploited clinically to clear the stomach of undigestible residue such as plastic tubes or bezoars. Anecdotally, erythromycin also has been of benefit in patients with small-bowel dysmotility such as that seen in scleroderma, ileus, or pseudo-obstruction. Rapid development of tolerance to erythromycin, possibly by down-regulation of the motilin receptor, and undesirable (in this context) antibiotic effects have limited the use of this drug as a prokinetic agent. Several nonantibiotic synthetic analogs of erythromycin and peptide analogs of motilin have been developed; to date, the clinical results have been disappointing.

A standard dose of erythromycin for gastric stimulation is 3 mg/kg intravenously or 200 to 250 mg orally every 8 hours. For small-bowel stimulation, a smaller dose (e.g., 40 mg intravenously) may be more useful, as higher doses may actually retard motility of this organ.

Miscellaneous Agents for Stimulating Motility.

The gastrointestinal hormone cholecystokinin (CCK) is released from the intestine in response to meals and delays gastric emptying. *Dexloxiglumide* is a CCK₁ (or CCK-A)–receptor antagonist that can improve gastric emptying and is being investigated in Europe as a treatment for gastroparesis and for constipation-dominant irritable bowel syndrome. Clonidine also has been reported to be of benefit in patients with gastroparesis. *Octreotide acetate* (SANDOSTATIN), a somatostatin analogue, also is used in some patients with intestinal dysmotility (see below).

In some disorders of motility, effective treatment does not necessarily require a “neuroenteric” approach. One such example is gastroesophageal reflux disease. Acid reflux is associated with transient lower esophageal sphincter relaxations that occur in the absence of a swallow. Since the damage to the esophagus ultimately is inflicted by acid, the most effective therapy for gastroesophageal reflux disease still is the suppression of acid production by the stomach (see Chapter 36). Neither metoclopramide nor cisapride by itself is particularly effective in gastroesophageal reflux disease. However, a

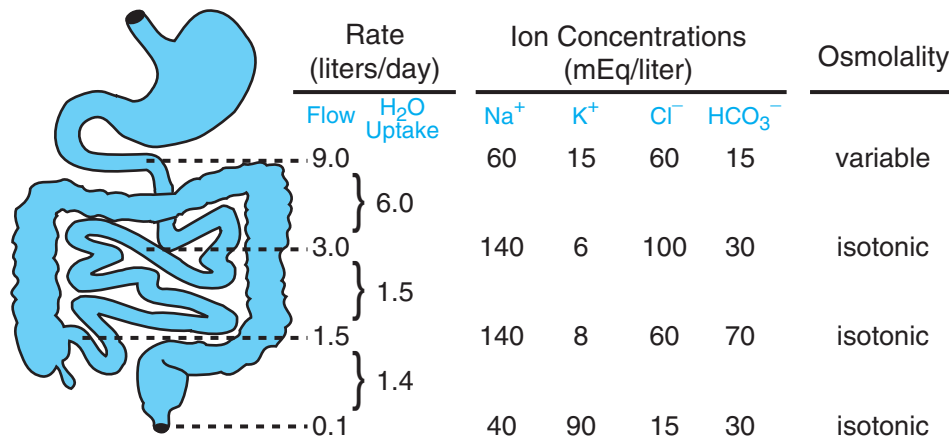

Figure 37-3. The approximate volume and composition of fluid that traverses the small and large intestines daily. Of the 9 liters of fluid presented to the small intestine each day, 2 liters are from the diet and 7 liters are from secretions (salivary, gastric, pancreatic, and biliary). The absorptive capacity of the colon is 4 to 5 liters per day.

new approach under investigation relies on suppression of the transient lower esophageal sphincter relaxations, as achieved by CCK₁-receptor antagonists (such as *loxiglumide*), GABA agonists (such as *baclofen*), and inhibitors of NO synthesis.

Other Agents That Suppress Motility. Smooth muscle relaxants such as organic nitrates and Ca²⁺ channel antagonists (see Chapter 31) often produce temporary, if partial, relief of symptoms in motility disorders such as achalasia, in which the lower esophageal sphincter fails to relax, resulting in a functional obstruction to the passage of food and severe difficulty in swallowing. A more recent approach relies on the use of *botulinum toxin*, injected directly into the lower esophageal sphincter *via* an endoscope, in doses of 80 to 200 units (Zhao and Pasricha, 2003). This potent agent inhibits ACh release from nerve endings (see Chapter 9) and can produce partial paralysis of the sphincter muscle, with significant improvements in symptoms and esophageal clearance. However, its effects dissipate over a period of several months, requiring repeated injections. Botulinum toxin also is being used increasingly in other gastrointestinal conditions such as chronic anal fissures.

LAXATIVES, CATHARTICS, AND THERAPY FOR CONSTIPATION

Overview of GI Water and Electrolyte Flux. Fluid content is the principal determinant of stool volume and consistency; water normally accounts for 70% to 85% of total stool weight. Net stool fluid content reflects a balance between luminal input (ingestion and secretion of water and electrolytes) and output (absorption) along the length of the GI tract. The daily challenge for the gut is to extract water, minerals, and nutrients from the luminal contents, leaving behind a manageable pool of fluid for proper

expulsion of waste material *via* the process of defecation. Normally about 8 to 9 liters of fluid enter the small intestine daily from exogenous and endogenous sources (Figure 37-3). Net absorption of the water occurs in the small intestine in response to osmotic gradients that result from the uptake and secretion of ions and the absorption of nutrients (mainly sugars and amino acids), with only about 1 to 1.5 liters crossing the ileocecal valve. The colon then extracts most of the remaining fluid, leaving about 100 ml of fecal water daily.

Under normal circumstances, these quantities are well within the range of the total absorptive capacity of the small bowel (about 16 liters) and colon (4 to 5 liters). Neurohumoral mechanisms, pathogens, and drugs can alter these processes, resulting in changes in either secretion or absorption of fluid by the intestinal epithelium. Altered motility also contributes in a general way to this process, as the extent of absorption parallels transit time. With decreased motility and excess fluid removal, feces can become inspissated and impacted, leading to constipation. When the capacity of the colon to absorb fluid is exceeded, diarrhea will occur.

Constipation: General Principles of Pathophysiology and Treatment. Scientific definitions rely mostly on stool number; most surveys have found the normal stool frequency on a Western diet to be at least 3 times a week. However, patients use the term *constipation* not only for decreased frequency, but also for difficulty in initiation or passage, passage of firm or small-volume feces, or a feeling of incomplete evacuation. By questionnaire, 25% of the population of the United States, more commonly women and elderly people, complain of constipation. A survey of bowel habits of adults in the United States showed that 18% of respondents used laxatives at least once a month, but nearly one-third of users did not have constipa-

tion. Approximately 2.5 million physician visits per year are attributed to constipation.

Constipation has many reversible or secondary causes, including lack of dietary fiber, drugs, hormonal disturbances, neurogenic disorders, and systemic illnesses. In most cases of chronic constipation, no specific cause is found. Up to 60% of patients presenting with constipation will have normal colonic transit. These patients either have irritable bowel syndrome or define constipation in terms other than stool frequency (*e.g.*, changes in consistency, excessive straining, or a feeling of incomplete evacuation). In the rest, attempts usually are made to categorize the underlying pathophysiology either as a disorder of delayed colonic transit because of an underlying defect in colonic motility, or less commonly, as an isolated disorder of defecation or evacuation (outlet disorder) due to dysfunction of the neuromuscular apparatus of the recto-anal region. Colonic motility is responsible for mixing luminal contents to promote absorption of water and moving them from proximal to distal segments by means of propulsive contractions. Mixing in the colon is accomplished in a way similar to that in the small bowel: by short- or long-duration, stationary (nonpropulsive) contractions. Propulsive contractions in the colon include giant migrating contractions, also known as colonic mass actions or mass movements, which propagate caudally over extended lengths in the colon and evoke mass transfer of feces from the right to the left colon once or twice a day. Disturbances in motility therefore may have complex effects on bowel movements. “Decreased motility” of the mass action type and “increased motility” of the nonpropulsive type may lead to constipation. In any given patient, the predominant factor often is not obvious. Consequently, the pharmacological approach to constipation remains empirical and is based, in most cases, on nonspecific principles.

In many cases, constipation can be corrected by adherence to a fiber-rich (20 to 30 g daily) diet, adequate fluid intake, appropriate bowel habits and training, and avoidance of constipating drugs. However, the association between constipation and either fluid intake or exercise has not withstood scientific scrutiny. Constipation related to medications can be corrected by use of alternative drugs where possible, or adjustment of dosage. If nonpharmacological measures alone are inadequate or unrealistic (*e.g.*, because of elderly age or infirmity), they may be supplemented with bulk-forming agents or osmotic laxatives. When stimulant laxatives are used, they should be administered at the lowest effective dosage and for the shortest period of time to avoid abuse. In addition to perpetuating dependence on drugs, the laxative habit may lead to excessive loss of water and electrolytes; secondary aldosteronism may occur if volume depletion is prominent. Steatorrhea, protein-losing enteropathy with hypoalbuminemia, and osteomalacia due to excessive loss of calcium in the stool have been reported.

In addition to treating constipation, laxatives frequently are employed before surgical, radiological, and endoscopic procedures where an empty colon is desirable.

The terms *laxatives*, *cathartics*, *purgatives*, *aperients*, and *evacuants* often are used interchangeably. There is a

distinction, however, between *laxation* (the evacuation of formed fecal material from the rectum) and *catharsis* (the evacuation of unformed, usually watery fecal material from the entire colon). Most of the commonly used agents promote laxation, but some are actually cathartics that act as laxatives at low doses.

Laxatives generally act in one of the following ways: (1) enhancing retention of intraluminal fluid by hydrophilic or osmotic mechanisms; (2) decreasing net absorption of fluid by effects on small- and large-bowel fluid and electrolyte transport; or (3) altering motility by either inhibiting segmenting (nonpropulsive) contractions or stimulating propulsive contractions. Based on their actions, laxatives can be classified as shown in Table 37–1; their known effects on motility and secretion are listed in Table 37–2. However, recent studies indicate considerable overlap among these traditional categories. A variety of laxatives, both osmotic agents and stimulants, increase the activity of NO synthase and the biosynthesis of platelet-activating factor in the gut. Platelet-activating factor is a phospholipid proinflammatory mediator that stimulates colonic secretion and GI motility (Izzo *et al.*, 1998). Nitric oxide also may stimulate intestinal secretion and inhibit segmenting contractions in the colon, thereby promoting laxation. Agents that reduce the expression of NO synthase or its activity can prevent the laxative effects of castor oil, cascara, and bisacodyl (but not senna), as well as magnesium sulfate.

An alternate way to classify laxatives is by the pattern of effects produced by the usual clinical dosage (Table 37–3).

Table 37–1
Classification of Laxatives

1. Luminally active agents

- a. Hydrophilic colloids; bulk-forming agents (bran, psyllium, *etc.*)
- b. Osmotic agents (nonabsorbable inorganic salts or sugars)
- c. Stool-wetting agents (surfactants) and emollients (docusate, mineral oil)

2. Nonspecific stimulants or irritants (with effects on fluid secretion and motility)

- Diphenylmethanes (bisacodyl)
- Anthraquinones (senna and cascara)
- Castor oil

3. Prokinetic agents (acting primarily on motility)

- 5-HT₄ receptor agonists
- Opioid receptor antagonists

Table 37–2

Summary of Effects of Some Laxatives on Bowel Function

AGENT	SMALL BOWEL		COLON		
	<i>Transit Time</i>	<i>Mixing Contractions</i>	<i>Propulsive Contractions</i>	<i>Mass Actions</i>	<i>Stool Water</i>
Dietary fiber	↓	?	↑	?	↑
Magnesium	↓	—	↑	↑	↑↑
Lactulose	↓	?	?	?	↑↑
Metoclopramide	↓	?	↑	?	—
Cisapride	↓	?	↑	?	↑
Erythromycin	↓	?	?	?	?
Naloxone	↓	↓	—	—	↑
Anthraquinones	↓	↓	↑	↑	↑↑
Diphenylmethanes	↓	↓	↑	↑	↑↑
Docusates	—	?	?	?	—

KEY: ↑, increased; ↓, decreased; ?, no data available; —, no effect on this parameter. Modified from Kreek, 1994, with permission.

Dietary Fiber and Supplements

Under normal circumstances, the bulk, softness, and hydration of feces depend on the fiber content of the diet. Fiber is defined as that part of food that resists enzymatic digestion and reaches the colon largely unchanged. Colonic bacteria ferment fiber to varying degrees, depending on its chemical nature and water solubility. Fermentation of fiber has two important effects: (1) it produces short-chain fatty acids that are trophic for colonic

epithelium, and (2) it increases bacterial mass. Although fermentation of fiber generally decreases stool water, short-chain fatty acids also may have a prokinetic effect, and increased bacterial mass may contribute to increased stool volume. On the other hand, fiber that is not fermented can attract water and increase stool bulk. The net effect on bowel movement therefore varies with different compositions of dietary fiber (Table 37–4). In general, insoluble, poorly fermentable fibers, such as lignin, are most effective in increasing stool bulk and transit.

Table 37–3

Classification and Comparison of Representative Laxatives

LAXATIVE EFFECT AND LATENCY IN USUAL CLINICAL DOSAGE		
<i>Softening of Feces, 1 To 3 Days</i>	<i>Soft or Semifluid Stool, 6 To 8 Hours</i>	<i>Watery Evacuation, 1 To 3 Hours</i>
<i>Bulk-forming laxatives</i>	<i>Stimulant laxatives</i>	<i>Osmotic laxatives*</i>
Bran	Diphenylmethane derivatives	Sodium phosphates
Psyllium preparations	Bisacodyl	Magnesium sulfate
Methylcellulose		Milk of magnesia
Calcium polycarbophil		Magnesium citrate
<i>Surfactant laxatives</i>	<i>Anthraquinone derivatives</i>	<i>Castor oil</i>
Docusates	Senna	
Poloxamers	Cascara sagrada	
Lactulose		

*Employed in high dosage for rapid cathartic effect and in lower dosage for laxative effect.

Table 37-4
Properties of Different Dietary Fibers

TYPE OF FIBER	WATER SOLUBILITY	% FERMENTED
Nonpolysaccharides		
Lignin	Poor	0
Cellulose	Poor	15
Noncellulose polysaccharides		
Hemicellulose	Good	56–87
Mucilages and gums	Good	85–95
Pectins	Good	90–95

Bran, the residue left when flour is made from cereals, contains more than 40% dietary fiber. Wheat bran, with its high lignin content, is most effective at increasing stool weight. Fruits and vegetables contain more *pectins* and *hemicelluloses*, which are more readily fermentable and produce less effect on stool transit. *Psyllium husk*, derived from the seed of the plantago herb (*Plantago ovata*; known as ispaghula or isabgol in many parts of the world), is a component of many commercial products for constipation (META-MUCIL, others). *Psyllium husk* contains a hydrophilic muciloid that undergoes significant fermentation in the colon, leading to an increase in colonic bacterial mass. The usual dose is 2.5 to 4 g (1 to 3 teaspoonfuls in 250 ml of fruit juice), titrated upwards until the desired goal is reached. A variety of semisynthetic celluloses—*e.g.*, *methylcellulose* (CITRUCEL, others) and the hydrophilic resin *calcium polycarboxiphil* (FIBERCON, FIBERALL, others), a polymer of acrylic acid resin—also are available. These poorly fermentable compounds absorb water and increase fecal bulk.

Fiber is contraindicated in patients with obstructive symptoms and in those with megacolon or megarectum. Fecal impaction should be treated before initiating fiber supplementation. Bloating is the most common side effect of soluble fiber products (perhaps due to colonic fermentation), but it usually decreases with time. Calcium polycarboxiphil preparations release Ca^{2+} in the GI tract and thus should be avoided by patients who must restrict their intake of calcium or who are taking tetracycline. Sugar-free bulk laxatives may contain aspartame and are contraindicated in patients with phenylketonuria. Allergic reactions to *psyllium* have been reported.

Osmotically Active Agents

Saline Laxatives. Laxatives containing magnesium cations or phosphate anions commonly are called *saline laxatives*: magnesium sulfate, magnesium hydroxide,

magnesium citrate, sodium phosphate. Their cathartic action is believed to result from osmotically mediated water retention, which then stimulates peristalsis. Other mechanisms may contribute to their effects, including the production of inflammatory mediators. Magnesium-containing laxatives may stimulate the release of cholecystokinin, which leads to intraluminal fluid and electrolyte accumulation and to increased intestinal motility. It is estimated that for every additional mEq of Mg^{2+} in the intestinal lumen, fecal weight increases by about 7 g. The usual dose of magnesium salts contains 40 to 120 mEq of Mg^{2+} and produces 300 to 600 ml of stool within 6 hours. The intensely bitter taste of some preparations may induce nausea and can be masked with citrus juices.

Phosphate salts are better absorbed than magnesium-based agents and therefore need to be given in larger doses to induce catharsis. The most frequently employed preparation of sodium phosphate is an oral solution (FLEET PHOSPHO-SODA), which contains 1.8 g of dibasic sodium phosphate and 4.8 g of monobasic sodium phosphate in 10 ml. The usual adult dose is 20 to 30 ml taken with ample water. For colonic preparation before a procedure, larger doses are used, typically in the form of two doses of 45 ml each, a few hours apart, the evening before the procedure. A newer preparation of phosphate salts (VISICOL) is available in tablet form, containing 1.5 g total sodium phosphate per tablet. For colon preparation, two doses of 20 tablets each (30 g sodium phosphate) are recommended before the procedure. Adequate fluid intake (1 to 3 L) is essential for any oral sodium phosphate regimen used for colonic preparation. Sodium phosphate also can be given as an enema for laxative purposes (*see below*).

Magnesium- and phosphate-containing preparations are tolerated reasonably well by most patients. However, they must be used with caution or avoided in patients with renal insufficiency, cardiac disease, or preexisting electrolyte abnormalities, and in patients on diuretic therapy. Patients taking more than 45 ml of oral sodium phosphate as a prescribed bowel preparation may experience electrolyte shifts that pose a risk for the development of symptomatic dehydration, renal failure, metabolic acidosis, tetany from hypocalcemia, and even death in medically vulnerable populations.

Nondigestible Sugars and Alcohols. *Lactulose* (CEPHULAC, CHRONULAC, others) is a synthetic disaccharide of galactose and fructose that resists intestinal disaccharidase activity.

LACTULOSE

SORBITOL

MANNITOL

This and other nonabsorbable sugars such as *sorbitol* and *mannitol*, whose structures are shown above, are hydrolyzed in the colon to short-chain fatty acids, which stimulate colonic propulsive motility by osmotically drawing water into the lumen. Sorbitol and lactulose are equally efficacious in the treatment of constipation caused by opioids and *vincristine*, of constipation in the elderly, and of idiopathic chronic constipation. They are available as 70% solutions, which are given in doses of 15 to 30 ml at night, with increases as needed up to 60 ml per day in divided doses. Effects may not be seen for 24 to 48 hours after dosing is begun. Abdominal discomfort or distention and flatulence are relatively common in the first few days of treatment but usually subside with continued administration. A few patients dislike the sweet taste of the preparations; dilution with water or administering the preparation with fruit juice can mask the taste.

Lactulose also is used to treat hepatic encephalopathy. Patients with severe liver disease have an impaired capacity to detoxify ammonia coming from the colon, where it is produced by bacterial metabolism of fecal urea. The drop in luminal pH that accompanies hydrolysis to short-chain fatty acids in the colon results in “trapping” of the ammonia by its conversion to the polar ammonium ion. Combined with the increases in colonic transit, this therapy significantly lowers circulating ammonia levels. The therapeutic goal in this condition is to give sufficient amounts of lactulose (usually 20 to 30 g, 3 to 4 times per day) to produce two to three soft stools a day with a pH of 5 to 5.5.

Polyethylene Glycol–Electrolyte Solutions. Long-chain *polyethylene glycols* (PEGs; molecular weight ~3350 daltons) are poorly absorbed, and PEG solutions are retained in the lumen by virtue of their high osmotic nature. When used in high volume, aqueous solutions of PEGs (COLYTE, GOLYTELY, others) produce an effective catharsis and are used widely for colonic cleansing for radiological, surgical, and endoscopic procedures (4 liters of this solution taken over 3 hours, beginning at least 4 hours before the procedure). To avoid net transfer of ions across the intestinal wall, these preparations contain an isotonic mixture of sodium sulfate, sodium bicarbonate, sodium chloride, and potassium chloride. The osmotic activity of the PEG molecules retains the added water and the electrolyte concentration assures little or no net ionic shifts.

PEGs are also increasingly being used in smaller doses (250 to 500 ml daily) for the treatment of constipation in difficult cases. A powder form of polyethylene glycol 3350 (MIRALAX) is now available for the short-term treatment (2 weeks or less) of occasional constipation, although the agent has been prescribed safely for longer periods in clinical practice. The usual dose is 17 g of powder per day in 8 ounces of water. This preparation does not contain electrolytes, so larger volumes may represent a risk for ionic shifts. As with other laxatives, prolonged, frequent, or excessive use may result in dependence or electrolyte imbalance.

Stool-Wetting Agents and Emollients

Docusate salts are anionic surfactants that lower the surface tension of the stool to allow mixing of aqueous and fatty substances, softening the stool and permitting easier defecation. However, these agents also stimulate intestinal fluid and electrolyte secretion (possibly by increasing mucosal cyclic AMP) and alter intestinal mucosal permeability. *Docusate sodium* (dioctyl sodium sulfosuccinate; COLACE, DOXINATE, others) and *docusate calcium* (dioctyl calcium sulfosuccinate; SURFAK, others), are available in several dosage forms. Despite their widespread use, these agents have marginal, if any, efficacy in most cases of constipation.

Mineral oil is a mixture of aliphatic hydrocarbons obtained from petrolatum. The oil is indigestible and absorbed only to a limited extent. When mineral oil is taken orally for 2 to 3 days, it penetrates and softens the stool and may interfere with resorption of water. The side effects of mineral oil preclude its regular use and include: interference with absorption of fat-soluble substances (such as vitamins), elicitation of foreign-body

reactions in the intestinal mucosa and other tissues, and leakage of oil past the anal sphincter. Rare complications such as lipid pneumonitis due to aspiration also can occur, so “heavy” mineral oil should not be taken at bedtime and “light” (topical) mineral oil should never be administered orally.

Stimulant (Irritant) Laxatives

Stimulant laxatives have direct effects on enterocytes, enteric neurons, and GI smooth muscle that only now are beginning to be understood. These agents probably induce a limited low-grade inflammation in the small and large bowel to promote accumulation of water and electrolytes and stimulate intestinal motility. Mechanisms include activation of prostaglandin–cyclic AMP and NO–cyclic GMP pathways, platelet-activating factor production (*see above*), and perhaps inhibition of Na⁺,K⁺-ATPase. Included in this group are *diphenylmethane derivatives*, *anthraquinones*, and *ricinoleic acid*.

Diphenylmethane Derivatives. *Phenolphthalein*, once among the most popular components of laxatives, has been withdrawn from the market in the United States because of potential carcinogenicity. *Oxyphenisatin*, another older drug, was withdrawn due to hepatotoxicity. *Sodium picosulfate* (LUBRILAX, SUR-LAX) is a diphenylmethane derivative widely available outside of the United States. It is hydrolyzed by colonic bacteria to its active form, and hence acts locally only in the colon. Effective doses of the diphenylmethane derivatives vary as much as four- to eightfold in individual patients. Consequently, recommended doses may be ineffective in some patients but may produce cramps and excessive fluid secretion in others.

Bisacodyl is the only diphenylmethane derivative available in the United States. It is marketed as an enteric-coated preparation (DULCOLAX, CORRECTOL, others) and as a suppository for rectal administration. The usual oral daily dose of bisacodyl is 10 to 15 mg for adults and 5 to 10 mg for children ages 6 to 12 years old. The drug requires hydrolysis by endogenous esterases in the bowel for activation, and so the laxative effects after an oral dose usually are not produced in less than 6 hours; taken at bedtime, it will produce its effect the next morning. Suppositories work much more rapidly, within 30 to 60 minutes. Due to the possibility of developing an atonic nonfunctioning colon, bisacodyl should not be used for more than 10 consecutive days.

Bisacodyl is mainly excreted in the stool; about 5% is absorbed and excreted in the urine as a glucuronide. Overdosage can lead to catharsis and fluid and electrolyte deficits. The diphenylmethanes can damage the mucosa and initiate an inflammatory response in the small bowel and colon. To avoid drug activation in the stomach with consequent gastric irritation and cramping, patients should

swallow tablets without chewing or crushing and avoid milk or anti-acid medications within 1 hour of the ingestion of bisacodyl.

Anthraquinone Laxatives. These derivatives of plants such as *aloe*, *cascara*, and *senna* share a tricyclic anthracene nucleus modified with hydroxyl, methyl, or carboxyl groups to form monoanthrones, such as rhein and frangula. Monoanthrones are irritating to the oral mucosa; however, the process of aging or drying converts them to more innocuous dimeric (dianthrones) or glycoside forms. This process is reversed by bacterial action in the colon to generate the active forms. Senna (SENOKOT, EX-LAX) is obtained from the dried leaflets on pods of *Cassia acutifolia* or *Cassia angustifolia* and contains the rhein dianthrone glycosides *senoside A* and *B*. *Cascara sagrada* (“sacred bark”; COLAMIN, SAGRADA-LAX) is obtained from the bark of the buckthorn tree and contains the glycosides *barbaloin* and *chrysaloin*. Barbaloin is also found in aloe. The rhubarb plant also produces anthraquinone compounds that have been used as laxatives. Anthraquinones can also be synthesized; however, the synthetic monoanthrone *danthron* was withdrawn from the United States market because of concerns over possible carcinogenicity. In addition, all aloe and cascara sagrada products sold as laxatives have been withdrawn from the United States market because of failure to demonstrate scientific evidence of efficacy and safety.

Anthraquinone laxatives can produce giant migrating colonic contractions and induce water and electrolyte secretion. They are poorly absorbed in the small bowel, but because they require activation in the colon, the laxative effect is not noted until 6 to 12 hours after ingestion. Active compounds are absorbed to a variable degree from the colon and excreted in the bile, saliva, milk, and urine.

The adverse consequences of long-term use of these agents have limited their use. A melanotic pigmentation of the colonic mucosa (*melanosis coli*) has been observed in patients using anthraquinone laxatives for long periods (at least 4 to 9 months). Histologically, this is caused by the presence of pigment-laden macrophages within the lamina propria. The condition is benign and reversible on discontinuation of the laxative. These agents also have been associated with the development of “cathartic colon,” which can be seen in patients (typically women) who have a long-standing history (typically years) of laxative abuse. Regardless of whether a definitive causal relationship can be demonstrated between the use of these agents and colonic pathology, it is clear that they should not be recommended for chronic or long-term use.

Castor Oil. An age-old home remedy, *castor oil* (PURGE, NEOLOID, others) is derived from the bean of the castor

plant, *Ricinus communis*, and contains two well-known noxious ingredients: an extremely toxic protein, *ricin*, and an oil composed chiefly of the triglyceride of ricinoleic acid. The triglyceride is hydrolyzed in the small bowel by the action of lipases into glycerol and the active agent, ricinoleic acid, which acts primarily in the small intestine to stimulate secretion of fluid and electrolytes and speed intestinal transit. When taken on an empty stomach, as little as 4 ml of castor oil may produce a laxative effect within 1 to 3 hours; however, the usual dose for a cathartic effect is 15 to 60 ml for adults. Because of its unpleasant taste and its potential toxic effects on intestinal epithelium and enteric neurons, castor oil is seldom recommended now.

Prokinetic and Other Agents for Constipation

Although several of the agents described above stimulate motility, they do so in nonspecific or indirect ways. By contrast, the term *prokinetic* generally is reserved for agents that enhance GI transit *via* interaction with specific receptors involved in the regulation of motility. Currently available prokinetic agents are not very useful in the treatment of constipation. However, newer agents, particularly the more potent 5-HT₄-receptor agonists such as tegaserod, may be useful for the treatment of chronic constipation. Another potentially useful agent is *misoprostol*, a synthetic prostaglandin analog primarily used for protection against gastric ulcers resulting from the use of nonsteroidal antiinflammatory agents (see Chapter 36). Prostaglandins can stimulate colonic contractions, particularly in the descending colon, and this may account for the diarrhea that limits the usefulness of misoprostol as a gastroprotectant. On the other hand, this property may be utilized for therapeutic gain in patients with intractable constipation. Another prostaglandin analog, RU-0211, is under development. *Colchicine*, a microtubule formation inhibitor used for gout (see Chapter 26), also has been shown to be effective in constipation (mechanism unknown), but its toxicity has limited widespread use. A novel biological agent, *neurotrophin-3* (NT-3), recently was shown to be effective in improving frequency and stool consistency and decreasing straining, again by an unknown mechanism of action.

Enemas and Suppositories

Enemas commonly are employed, either by themselves or as adjuncts to bowel preparation regimens, to empty the distal colon or rectum of retained solid material. Bowel distention by any means will produce an evacuation reflex in most people, and almost any form of enema, including normal saline solution, can achieve this. Specialized enemas contain additional substances that either are osmotically active or irritant; however, their safety and efficacy have not been studied in a rigorous manner. Repeated enemas with tap water or other hypotonic solutions can cause hyponatremia; repeated enemas with sodium phosphate-containing solution can cause hypocalcemia. Phosphate-containing enemas also are known to alter the appearance of rectal mucosa.

Glycerin is a trihydroxy alcohol that is absorbed orally, but acts as a hygroscopic agent and lubricant when given rectally. The resultant water retention stimulates peristalsis and usually produces a bowel movement in less than an hour. Glycerin is for rectal use only and is given in a single daily dose as a 2- or 3-g rectal suppository

or as 5 to 15 ml of an 80% solution in enema form. Rectal glycerin may cause local discomfort, burning, or hyperemia and (minimal) bleeding. Some glycerin suppositories contain sodium stearate, which can cause local irritation.

ANTIDIARRHEAL AGENTS

Diarrhea: General Principles and Approach to Treatment. Diarrhea (Greek and Latin: *dia*, through, and *rheia*, to flow or run) does not require any definition to people who suffer from “the too rapid evacuation of too fluid stools.” Scientists usually define diarrhea as excessive fluid weight, with 200 g per day representing the upper limit of normal stool water weight for healthy adults in the western world. Since stool weight is largely determined by stool water, most cases of diarrhea result from disorders of intestinal water and electrolyte transport.

An appreciation and knowledge of the underlying causative processes in diarrhea facilitates effective treatment. From a mechanistic perspective, diarrhea can be caused by an increased osmotic load within the intestine (resulting in retention of water within the lumen); excessive secretion of electrolytes and water into the intestinal lumen; exudation of protein and fluid from the mucosa; and altered intestinal motility resulting in rapid transit (and decreased fluid absorption). In most instances, multiple processes are affected simultaneously, leading to a net increase in stool volume and weight accompanied by increases in fractional water content.

Many patients with sudden onset of diarrhea have a benign, self-limited illness requiring no treatment or evaluation. In severe cases, dehydration and electrolyte imbalances are the principal risk, particularly in infants, children, and frail elderly patients. *Oral rehydration therapy* therefore is a cornerstone for patients with acute illnesses resulting in significant diarrhea. This is of particular importance in developing countries, where the use of such therapy saves many thousands of lives every year. This therapy exploits the fact that nutrient-linked cotransport of water and electrolytes remains intact in the small bowel in most cases of acute diarrhea. Sodium and chloride absorption is linked to glucose uptake by the enterocyte; this is followed by movement of water in the same direction. A balanced mixture of glucose and electrolytes in volumes matched to losses therefore can prevent dehydration. This can be provided by many commercial premixed formulas using glucose-electrolyte or rice-based physiological solutions.

Pharmacotherapy of diarrhea should be reserved for patients with significant or persistent symptoms. Nonspecific anti-diarrheal agents typically do not address the underlying pathophysiology responsible for the diarrhea; their principal utility is to provide symptomatic relief in mild cases of acute diarrhea. Many of these agents act by decreasing intestinal motility and should be avoided as much as possible in acute diarrheal illnesses caused by invasive organisms. In such cases, these agents may mask the clinical picture, delay clearance of organisms, and increase the risk of systemic invasion by the infectious organisms; they also may induce local complications such as toxic megacolon.

Bulk-Forming and Hydroscopic Agents. Hydrophilic and poorly fermentable colloids or polymers such as *carboxymethylcellulose* and calcium polycarboxophil absorb water and increase stool bulk (calcium polycarboxophil absorbs 60 times its weight in water). They usually are used for constipation (*see above*), but are sometimes useful in mild chronic diarrheas in patients suffering with irritable bowel syndrome. The mechanism of this effect is not clear, but they may work as gels to modify stool texture and viscosity and to produce a perception of decreased stool fluidity. Some of these agents also may bind bacterial toxins and bile salts. Clays such as *kaolin* (a hydrated aluminum silicate) and other silicates such as *attapulgit* (magnesium aluminum disilicate; DIASORB) bind water avidly (attapulgit absorbs eight times its weight in water) and also may bind enterotoxins. However, this effect is not selective and may involve other drugs and nutrients; hence these agents are best avoided within 2 to 3 hours of taking other medications. A mixture of kaolin and pectin (a plant polysaccharide) is a popular over-the-counter remedy (KAOPECTOLIN) and may provide useful symptomatic relief of mild diarrhea.

Bile Acid Sequestrants. *Cholestyramine*, *colestipol*, and *colesevalam* effectively bind bile acids and some bacterial toxins. Cholestyramine is useful in the treatment of bile salt–induced diarrhea, as in patients with resection of the distal ileum. In these patients, there is partial interruption of the normal enterohepatic circulation of bile salts, resulting in excessive concentrations reaching the colon and stimulating water and electrolyte secretion (*see below*). Patients with extensive ileal resection (usually more than 100 cm) eventually develop net bile salt depletion, which can produce steatorrhea because of inadequate micellar formation required for fat absorption. In such patients, the use of cholestyramine will aggravate the diarrhea. The drug also has had an historic role in treating

mild antibiotic-associated diarrhea and mild colitis due to *Clostridium difficile*. However, its use in infectious diarrheas generally is discouraged, as it may decrease clearance of the pathogen from the bowel.

In patients suspected of having bile salt–induced diarrhea, a trial of cholestyramine can be given at a dose of 4 g of the dried resin (contained in either 9 g [QUESTRAN, others] or 5 g [QUESTRAN LIGHT, others] of powder) four times a day. If successful, the dose may be titrated down to achieve the desired stool frequency.

Cholestyramine resin also is helpful for the relief of pruritus associated with partial biliary obstruction and in conditions such as primary biliary cirrhosis. In such conditions, excessive bile acids are thought to be deposited in the skin and cause irritation. Cholestyramine increases fecal excretion of bile acids and reduces circulating and eventually systemic levels with relief of pruritus in about 1 to 3 weeks.

Bismuth. Bismuth compounds have been used to treat a variety of gastrointestinal diseases and symptoms for centuries, although their mechanism of action remains poorly understood. PEPTO-BISMOL (*bismuth subsalicylate*) is an over-the-counter preparation estimated to be used by 60% of American households. It is a crystal complex consisting of trivalent bismuth and salicylate suspended in a mixture of magnesium aluminum silicate clay. In the low pH of the stomach, the bismuth subsalicylate reacts with hydrochloric acid to form bismuth oxychloride and salicylic acid. While 99% of the bismuth passes unaltered and unabsorbed into the feces, the salicylate is absorbed in the stomach and small intestine. Thus, caution should be used in patients taking salicylates for other indications.

Bismuth is thought to have antisecretory, antiinflammatory, and antimicrobial effects. Nausea and abdominal cramps also are relieved by bismuth. The clay in PEPTO-BISMOL also may have some additional benefits in diarrhea, but this is not clear. Bismuth subsalicylate has been used extensively for the prevention and treatment of traveler's diarrhea, but it also is effective in other forms of episodic diarrhea and in acute gastroenteritis. Today, the most common antibacterial use of this agent is in the treatment of *Helicobacter pylori* (*see Chapter 36*). A recommended dose of the bismuth subsalicylate (30 ml of regular strength PEPTO-BISMOL liquid or 2 tablets) contains approximately equal amounts of bismuth and salicylate (262 mg each). For control of indigestion, nausea, or diarrhea, the dose is repeated every 30 to 60 minutes, as needed, up to eight times a day. Bismuth products have a long track record of safety at recommended doses, although impaction may occur in infants and debilitated patients. Dark stools (sometimes mistaken for melena) and black staining of the tongue in association with bismuth compounds are caused by bismuth sulfide formed in a reaction between the drug and bacterial sulfides in the gastrointestinal tract.

Antimotility and Antisecretory Agents

Opioids. Opioids continue to be widely used in the treatment of diarrhea. They act by several different mech-

anisms, mediated principally through either μ - or δ -opioid receptors on enteric nerves, epithelial cells, and muscle (see Chapter 21). These mechanisms include effects on intestinal motility (μ receptors), intestinal secretion (δ receptors), or absorption (μ and δ receptors). Commonly used antidiarrheals such as *diphenoxylate*, *difenoxin*, and *loperamide* act principally via peripheral μ -opioid receptors and are preferred over opioids that penetrate the CNS.

Loperamide. Loperamide (IMODIUM, IMODIUM A-D, others), a piperidine butyramide derivative with μ -receptor activity, is an orally active antidiarrheal agent. The drug is 40 to 50 times more potent than morphine as an antidiarrheal agent and penetrates the CNS poorly. It increases small intestinal and mouth-to-cecum transit times. Loperamide also increases anal sphincter tone, an effect that may be of therapeutic value in some patients who suffer from anal incontinence. In addition, loperamide has antisecretory activity against cholera toxin and some forms of *E. coli* toxin, presumably by acting on G_i -linked receptors and countering the increase in cellular cyclic AMP generated in response to the toxins.

Because of its effectiveness and safety, loperamide is marketed for over-the-counter distribution and is available in capsule, solution, and chewable forms. It acts quickly after an oral dose, with peak plasma levels achieved within 3 to 5 hours. It has a half-life of about 11 hours and undergoes extensive hepatic metabolism. The usual adult dose is 4 mg initially followed by 2 mg after each subsequent loose stool, up to 16 mg per day. If clinical improvement in acute diarrhea does not occur within 48 hours, loperamide should be discontinued. Recommended maximum daily doses for children are 3 mg for ages 2 to 5 years, 4 mg for ages 6 to 8 years, and 6 mg for ages 8 to 12 years. Loperamide is not recommended for use in children younger than 2 years of age.

Loperamide has been shown to be effective against traveler's diarrhea, used either alone or in combination with antimicrobial agents (*trimethoprim*, *trimethoprim-sulfamethoxazole*, or a *fluoroquinolone*). Loperamide also has been used as adjunct treatment in almost all forms of chronic diarrheal disease, with few adverse effects. Loperamide lacks significant abuse potential and is more effective in treating diarrhea than diphenoxylate (see below). Overdosage, however, can result in CNS depression (especially in children) and paralytic ileus. In patients with active inflammatory bowel disease involving the colon (see Chapter 38), loperamide should be used with great caution, if at all, to prevent development of toxic megacolon.

Loperamide N-oxide, an investigational agent, is a site-specific prodrug; it is chemically designed for controlled

release of loperamide in the intestinal lumen, thereby reducing systemic absorption.

Diphenoxylate and Difenoxin. Diphenoxylate and its active metabolite difenoxin (diphenoxylate acid) are piperidine derivatives that are related structurally to meperidine. As antidiarrheal agents, diphenoxylate and difenoxin are somewhat more potent than morphine. Both compounds are extensively absorbed after oral administration, with peak levels achieved within 1 to 2 hours. Diphenoxylate is rapidly deesterified to difenoxin, which is eliminated with a half-life of about 12 hours. Both drugs can produce CNS effects when used in higher doses (40 to 60 mg per day) and thus have a potential for abuse and/or addiction. They are available in preparations containing small doses of atropine (considered subtherapeutic) to discourage abuse and deliberate overdose: 25 μ g of *atropine sulfate* per tablet with either 2.5 mg diphenoxylate hydrochloride (LOMOTIL) or 1 mg of difenoxin hydrochloride (MOTOFEN). The usual dosage is two tablets initially, then one tablet every 3 to 4 hours. With excessive use or overdose, constipation and (in inflammatory conditions of the colon) toxic megacolon may develop. In high doses, these drugs cause CNS effects as well as anticholinergic effects from the atropine (dry mouth, blurred vision, etc.) (see Chapter 7).

Other opioids used for diarrhea include codeine (in doses of 30 mg given three or four times daily) and opium-containing compounds.

Paregoric (camphorated opium tincture) contains the equivalent of 2 mg of morphine per 5 ml (0.4 mg/ml); *deodorized tincture of opium*, which is 25 times stronger, contains the equivalent of 50 mg of morphine per 5 ml (10 mg/ml). The two tinctures sometimes are confused in prescribing and dispensing, resulting in dangerous overdoses. The antidiarrheal dose of opium tincture for adults is 0.6 ml (equivalent to 6 mg morphine) four times daily; the adult dose of paregoric is 5 to 10 ml (equivalent to 2 or 4 mg morphine) one to four times daily. Paregoric is used in children at a dose of 0.25 to 0.5 ml/kg (equivalent to 0.1 to 0.2 mg morphine/kg) one to four times daily.

Enkephalins are endogenous opioids that are important enteric neurotransmitters. Enkephalins inhibit intestinal secretion without affecting motility. *Racecadotril* (acetorphan), a dipeptide inhibitor of enkephalinase, reinforces the effects of endogenous enkephalins on the δ -opioid receptor to produce an antidiarrheal effect.

α_2 Adrenergic Receptor Agonists. α_2 Adrenergic receptor agonists such as *clonidine* can interact with specific receptors on enteric neurons and enterocytes, thereby stimulating absorption and inhibiting secretion of fluid and electrolytes and increasing intestinal transit time. These agents may have a special role in diabetics with chronic diarrhea, in whom autonomic neuropathy can lead to loss of noradrenergic innervation. Oral clonidine (beginning at 0.1 mg twice a day) has been used in these patients; the use of a topical preparation (e.g., CATAPRES TTS, two patches a week) may result in more steady plasma levels of the drug. Clonidine also may be useful in patients with diarrhea caused by opiate withdrawal. Side effects such as hypotension, depression, and perceived fatigue may be dose limiting in susceptible patients.

Octreotide and Somatostatin. Octreotide (SANDOSTATIN) (see Chapter 55) is an octapeptide analog of somatostatin that is effective in inhibiting the severe secretory diarrhea brought about by hormone-secreting tumors of the pancreas and the gastrointestinal tract. Its mechanism of action appears to involve inhibition of hormone secretion, including serotonin and various other GI peptides (e.g., gastrin, vasoactive intestinal polypeptide, insulin, secretin, etc.). Octreotide has been used, with varying success, in other forms of secretory diarrhea such as chemotherapy-induced diarrhea, diarrhea associated with human immunodeficiency virus (HIV), and diabetes-associated diarrhea. Its greatest utility, however, may be in the “dumping syndrome” seen in some patients after gastric surgery and pyloroplasty. In this condition, octreotide inhibits the release of hormones (triggered by rapid passage of food into the small intestine) that are responsible for distressing local and systemic effects.

Octreotide has a half-life of 1 to 2 hours and is administered either subcutaneously or intravenously as a bolus dose. Standard initial therapy with octreotide is 50 to 100 μg , given subcutaneously two or three times a day, with titration to a maximum dose of 500 μg three times a day based on clinical and biochemical responses. A long-acting preparation of octreotide acetate enclosed in biodegradable microspheres (SANDOSTATIN LAR DEPOT) is available for use in the treatment of diarrheas associated with carcinoid tumors and vasoactive intestinal peptide-secreting tumors, as well as in the treatment of acromegaly (see Chapter 55). This preparation is injected intramuscularly once per month in a dose of 20 or 30 mg. Side effects of octreotide depend on the duration of therapy. Short-term therapy leads to transient nausea, bloating, or pain at sites of injection. Long-term therapy can lead to gallstone formation and hypoglycemia. Another long-acting somatostatin analog, *lanreotide* (SOMATULIN, others), is available in Europe but not in the United States; another, *vapreotide*, is under development. *Somatostatin* (STILAMIN) also is available in Europe but not in the United States.

Use in Variceal Bleeding. Vasoactive agents have been used to control variceal bleeding. Traditionally, *vasopressin* has been used (see Chapter 29), but its significant side effects—such as myocardial ischemia, peripheral vascular disease, and the release of plasminogen activator and factor VIII—have led to its decline. Somatostatin and octreotide are effective in reducing hepatic blood flow, hepatic venous wedge pressure, and azygos blood flow. These agents constrict the splanchnic arterioles by a direct action on vascular smooth muscle and by inhibiting the release of peptides contributing to the hyperdynamic circulatory syndrome of portal hypertension. Octreotide also may act through the autonomic nervous system. These agents can control bleeding acutely and decrease bleeding-related mortality, with an efficacy comparable to endoscopic therapy or balloon tamponade. The major advantage of somatostatin and octreotide over vasopressin is their safety. Because of the short half-life of somatostatin (1 to 2 minutes), it can be given only by intravenous infusion (a 250- μg bolus dose followed by 250 μg hourly). For patients with variceal bleeding, therapy with octreotide usually is initiated while the patient is awaiting endoscopy. It

is given intravenously as an infusion of 25 to 50 $\mu\text{g}/\text{hour}$ for 48 hours after a bolus of 100 μg . Some clinicians give 100 μg subcutaneously every 6 to 8 hours for an additional 72 hours until the patient has had the second endoscopic treatment.

Use in Intestinal Dysmotility. Octreotide has complex and apparently conflicting effects on GI motility, including inhibition of antral motor activity and colonic tone. However, octreotide also can rapidly induce phase III activity of the migrating motor complex in the small bowel to produce longer and faster contractions than those occurring spontaneously. Its use has been shown to result in improvement in selected patients with scleroderma and small-bowel dysfunction.

Use in Pancreatitis. Both somatostatin and octreotide inhibit pancreatic secretion and have been used for the prophylaxis and treatment of acute pancreatitis. The rationale for their use is to “put the pancreas to rest” so as to not aggravate inflammation by the continuing production of proteolytic enzymes, to reduce intraductal pressures, and to ameliorate pain. Octreotide probably is less effective than somatostatin in this regard because it may cause an increase in sphincter of Oddi pressure and perhaps also have a deleterious effect on pancreatic blood flow. Although some studies have suggested that these agents improve mortality in patients with acute pancreatitis, definitive data are lacking.

OTHER AGENTS

Calcium channel blockers such as *verapamil* and *nifedipine* (see Chapter 31) reduce motility and may promote intestinal electrolyte and water absorption. Constipation, in fact, is a significant side effect of these drugs. However, because of their systemic effects and the availability of other agents, they seldom if ever are used for diarrheal illnesses.

Berberine is a plant alkaloid that has been used for millennia in traditional Indian and Chinese medicine. It is produced by several genera of the families Ranunculaceae and Berberidaceae (e.g., *Berberis*, *Mahonia*, and *Coptis*) and has complex pharmacological actions that include antimicrobial actions, stimulation of bile flow, inhibition of ventricular tachyarrhythmias, and possible antineoplastic activity. It is used most commonly in bacterial diarrhea and cholera, but is also apparently effective against intestinal parasites. The antidiarrheal effects in part may be related to its antimicrobial activity, as well as its ability to inhibit smooth muscle contraction and delay intestinal transit by antagonizing the effects of acetylcholine (by competitive and noncompetitive mechanisms) and blocking the entry of Ca^{2+} into cells. In addition, it inhibits intestinal secretion.

Chloride channel blockers are effective antisecretory agents *in vitro* but are too toxic for human use and have not proven to be effective antidiarrheal agents *in vivo*. Calmodulin inhibitors, which include *chlorpromazine*, also are antisecretory. *Zaldaride maleate*, a new drug in this class, may be effective in traveler’s diarrhea by reducing secretion without affecting intestinal motility.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome, a condition that affects up to 15% of the population in the United States, is perhaps one of the more challenging nonfatal illnesses seen by gastro-

enterologists (Mertz, 2003). Patients may complain of a variety of symptoms, the most characteristic of which is recurrent abdominal pain associated with altered bowel movements. The pathophysiology of this condition is not clear; it appears to result from a varying combination of disturbances in visceral motor and sensory function, often associated with significant affective disorders. The disturbances in bowel function, which can be either constipation or diarrhea or both at different times, have led to the classical interpretation of irritable bowel syndrome as being a “motility disorder,” but motor disturbances cannot explain the entire clinical picture. Recently, more emphasis has been devoted to the pathogenesis of pain in these patients, and there now is considerable evidence to suggest a specific enhancement of visceral (as opposed to somatic) sensitivity to noxious, as well as physiological stimuli in this syndrome. The etiopathogenesis of this visceral hypersensitivity probably is multifactorial; a popular hypothesis is that transient visceral injury in genetically predisposed individuals leads to long-lasting sensitization of the neural pain circuit despite complete resolution of the initiating event. Increasingly, this concept is being extended to other so-called functional disorders of the gut characterized by unexplained pain, including noncardiac chest pain and nonulcer dyspepsia. These disorders, also considered for many years to arise from motor disturbances, may in fact represent part of a spectrum of a new syndrome of “visceral hyperalgesia.”

Many patients can be managed satisfactorily with a strong patient-physician relationship, simple counseling, and adjunctive measures, including dietary restrictions and fiber supplementation; overt psychological abnormalities should be treated appropriately. Despite these measures, a significant proportion of patients remain plagued by severe symptoms, and drug therapy is attempted almost invariably. However, there are very few effective pharmacological options for these patients, a situation that in part reflects our limited understanding of the pathogenesis of this syndrome.

The pharmacological approach to irritable bowel syndrome reflects its multifaceted nature. Treatment of bowel symptoms (either diarrhea or constipation) is predominantly symptomatic and nonspecific. Patients with mild symptoms often are started on fiber supplements; this approach may work for constipation and diarrhea (by binding water). Patients with episodic, discrete pain episodes often are treated with agents that may reduce smooth muscle contractility in the gut. These so-called antispasmodics include anticholinergic agents, Ca²⁺ channel antagonists, and peripheral opioid receptor antagonists. The use of most such drugs is hallowed by years of tradition, but seldom has been subjected to critical assessment; however, these drugs may be modestly effective in a subset of patients and are useful adjuncts.

In recent years, an increasing emphasis is being placed on the pharmacological treatment of visceral sensitivity. Although the biological basis of visceral hyperalgesia in irritable bowel syndrome patients is not known, a possible role for serotonin has been suggested

based on its known involvement in sensitization of nociceptor neurons in inflammatory conditions. This has led to the development of specific receptor modulators, such as tegaserod and *alosetron* (Figure 37–2). *Buspirone* and *sumatriptan* are serotonin 5-HT₁ receptor agonists (see Chapter 11) that can reduce gastric and colonic sensitivity to distention and are being evaluated in clinical trials.

The most effective class of agents in this regard has been the tricyclic antidepressants (see Chapter 17), which can have neuromodulatory and analgesic properties independent of their antidepressant effect. Tricyclic antidepressants have a proven track record in the management of chronic “functional” visceral pain. Effective analgesic doses of these drugs (e.g., 25 to 75 mg per day of *nortriptyline*) are significantly lower than those required to treat depression. Although changes in mood usually do not occur at these doses, there may be some diminution of anxiety and restoration of sleep patterns, which can be considered desirable effects in this group of patients. Selective serotonin reuptake inhibitors have fewer side effects and have been advocated particularly for patients with functional constipation as they can increase bowel movements and even cause diarrhea. However, they probably are not as effective as tricyclic antidepressants in the management of visceral pain.

α_2 Adrenergic receptor agonists, such as clonidine (see Chapter 10), also can increase visceral compliance and reduce distention-induced pain. The somatostatin analog octreotide (see above) has selective inhibitory effects on peripheral afferent nerves projecting from the gut to the spinal cord in healthy human beings and has been shown to blunt the perception of rectal distention in patients with irritable bowel syndrome. *Fedotozine*, an investigational opioid that appears to be a peripherally active, selective κ -receptor antagonist, produces marginal improvement in symptoms in patients with irritable bowel syndrome and functional dyspepsia. The lack of CNS effects is an advantage in such patients in whom chronic medication use is anticipated. Other agents of unproven value include leuprolide, a gonadotropin-releasing hormone analog (see Chapter 55).

Alosetron and Other 5-HT₃ Antagonists

The 5-HT₃ receptor participates in several important processes in the gut, including sensitization of spinal sensory neurons, vagal signaling of nausea, and peristaltic reflexes. Some of these effects in experimental models are potentially conflicting, with release of excitatory and inhibitory neurotransmitters. However, the clinical effect of 5-HT₃ antagonism is a general reduction in GI contractility with decreased colonic transit, along with an increase in fluid absorption. In general, therefore, these antagonists produce the opposite effects seen with 5-HT₄ agonists such as tegaserod. Although they also may blunt visceral sensation, a direct effect on spinal afferents has not been fully established. *Alosetron* (LOTROX) was the first agent in this class specifically approved for the treatment of diarrhea-predominant irritable bowel syndrome in women. *Alosetron* is a much more potent antagonist of the 5-HT₃ receptor than *ondansetron* (see below) and causes significant (though modest) improvements in abdominal pain as well as stool frequency, consistency, and urgency in these patients. Shortly after its initial release, *alosetron* was withdrawn from the U.S. market because of an unusually high incidence of ischemic colitis (up to 3 per 1000 patients), leading to surgery and even death in a small number of cases. The mechanism of this effect is not fully established, but may result from the drug's ability to suppress intestinal relaxation, thereby causing severe spasm in segments of the colon in susceptible individuals. It is not clear whether this is a nonspecific

effect or involves serotonergic mechanisms. Nevertheless, the FDA has recently reapproved this drug for diarrhea-predominant irritable bowel syndrome under a limited distribution system. However, concerns about the consequences of prescribing this drug are important, and the manufacturer requires a prescription program that includes physician certification and an elaborate patient education and consent protocol before dispensing.

Alosetron is rapidly absorbed from the GI tract; its duration of action (about 10 hours) is longer than expected from its half-life of 1.5 hours. It is metabolized by hepatic CYPs. The drug should be started at 1 mg per day for the first 4 weeks, and advanced to a maximum of 1 mg twice daily if an adequate response is not achieved.

Other 5-HT₃ antagonists currently available in the United States are approved for nausea and vomiting (*see below*). Newer agents in this category, such as *cilansetron*, have considerable promise for functional bowel disorders and are being tested.

ANTISPASMODICS AND OTHER AGENTS

Anticholinergic agents (“spasmolytics” or “antispasmodics”) often are used in patients with irritable bowel syndrome. The most common agents of this class available in the United States are nonspecific antagonists of the muscarinic receptor (*see Chapter 7*) and include the tertiary amines *dicyclomine* (BENTYL) and *hyoscyamine* (LEVSIN, others) and the quaternary ammonium compounds *glycopyrrolate* (ROBINUL) and *methscopolamine* (PAMINE). The advantage of the latter two compounds is that they have a limited propensity to cross the blood–brain barrier and hence a lower risk for neurological side effects such as light-headedness, drowsiness, or nervousness. These agents typically are given either on an as-needed basis (with the onset of pain) or before meals to prevent the pain and fecal urgency that predictably occur in some patients with irritable bowel syndrome (with presumed exaggerated gastrocolic reflex).

Dicyclomine is given in doses of 10 to 20 mg orally every 4 to 6 hours as necessary. Hyoscyamine is available in many forms, including oral capsules, tablets, elixir, drops, a nonaerosol spray (0.125 to 0.25 mg every 4 hours as needed), and an extended-release form for oral use (0.375 mg every 12 hours as needed). Glycopyrrolate also comes in extended-release tablets (2 mg once or twice a day), in addition to a standard-release form (1 mg up to three times a day). Methscopolamine is provided as 2.5-mg tablets and the dose is 1 or 2 tablets, three to four times a day.

Other Drugs. *Clidinium bromide*, another quaternary ammonium compound with antimuscarinic activity, is used in a fixed combination with *chlordiazepoxide hydrochloride* (2.5 mg of clidinium and 5 mg of chlordiazepoxide; LIBRAX); however, such combinations are of limited value in patients with irritable bowel syndrome because of the risk of habituation and rebound withdrawal. *Cimetropium*, another antimuscarinic compound that reportedly is

effective in patients with irritable bowel syndrome, is not available in the United States. *Otilonium bromide*, also not available in the United States, has been used extensively for patients with irritable bowel syndrome in other parts of the world. It is a quaternary ammonium salt with antimuscarinic effects that also appears to block Ca²⁺ channels and neurokinin NK-2 receptors. *Mebeverine hydrochloride* is a derivative of hydroxybenzamide that appears to have a direct effect on the smooth muscle cell, blocking K⁺, Na⁺, and Ca²⁺ channels. It is widely used outside of the United States as an antispasmodic agent for patients with irritable bowel syndrome.

ANTIEMETICS AND ANTIEMETIC AGENTS

Nausea and Vomiting

The act of emesis and the sensation of nausea that accompanies it generally are viewed as protective reflexes that serve to rid the stomach and intestine of toxic substances and prevent their further ingestion. Vomiting is a complex process that consists of a pre-ejection phase (gastric relaxation and retroperistalsis), retching (rhythmic action of respiratory muscles preceding vomiting and consisting of contraction of abdominal and intercostal muscles and diaphragm against a closed glottis), and ejection (intense contraction of the abdominal muscles and relaxation of the upper esophageal sphincter). This is accompanied by multiple autonomic phenomena including salivation, shivering, and vasomotor changes. During prolonged episodes, marked behavioral changes including lethargy, depression, and withdrawal may occur. The process appears to be coordinated by a central emesis center in the lateral reticular formation of the mid-brainstem adjacent to both the chemoreceptor trigger zone (CTZ) in the area postrema (AP) at the bottom of the fourth ventricle and the solitary tract nucleus (STN) of the vagus nerve. The lack of a blood–brain barrier allows the CTZ to monitor blood and cerebrospinal fluid constantly for toxic substances and to relay information to the emesis center to trigger nausea and vomiting. The emesis center also receives information from the gut, principally by the vagus nerve (*via* the STN) but also by splanchnic afferents *via* the spinal cord. Two other important inputs to the emesis center come from the cerebral cortex (particularly in anticipatory nausea or vomiting) and the vestibular apparatus (in motion sickness). In turn, the center sends out efferents to the nuclei responsible for respiratory, salivary, and vasomotor activity, as well as to striated and smooth muscle involved in the act. The CTZ has high concentrations of receptors for serotonin (5-HT₃), dopamine (D₂), and opioids, while the STN is rich in receptors for enkephalin, histamine, and ACh, and also contains

Table 37-5*General Classification of Antiemetic Agents*

ANTIEMETIC CLASS	EXAMPLES	TYPE OF VOMITING MOST EFFECTIVE AGAINST
5-HT ₃ receptor antagonists*	Ondansetron	Cytotoxic drug induced emesis
Centrally acting dopamine receptor antagonists	Metoclopramide*† Promethazine‡	Cytotoxic drug induced emesis
Histamine H ₁ receptor antagonists	Cyclizine	Vestibular (motion sickness)
Muscarinic receptor antagonists	Hyoscine (scopolamine)	Motion sickness
Neurokinin receptor antagonists	Investigational	Cytotoxic drug induced emesis (delayed vomiting)
Cannabinoid receptor agonists	Dronabinol	Cytotoxic drug induced emesis

*The most effective agents for chemotherapy-induced nausea and vomiting are the 5-HT₃ antagonists and metoclopramide. In addition to their use as single agents, they are often combined with other drugs to improve efficacy as well as reduce the incidence of side effects. †Also has some peripheral activity at 5-HT₃ receptors. ‡Also has some antihistaminic and anticholinergic activity.

Table 37–7**A. Some Antiemetic Regimens Used in Cancer Chemotherapy**

ANTIEMETIC AGENT	INITIAL DOSE
<i>For Severe Chemotherapy-Induced Emesis (Several Antiemetic Agents Used in Combination)</i>	
Dexamethasone	20 mg IV
Metoclopramide	3 mg/kg body weight IV every 2 h × 2
Diphenhydramine	25–50 mg IV every 2 h × 2
Lorazepam	1–2 mg IV
Dexamethasone	20 mg IV
Ondansetron	32 mg IV daily, in divided doses
<i>For Moderate Chemotherapy-Induced Emesis (Antiemetic Agents Used Singly)</i>	
Prochlorperazine	5–10 mg orally or IV, or 25 mg by rectal suppository
Thiethylperazine	10 mg orally, IM, or by rectal suppository
Dexamethasone	10–20 mg IV
Ondansetron	8 mg orally or 10 mg IV
Dronabinol	10 mg orally

B. Useful Combinations of Antiemetic Agents for Improved Antiemetic Effect

PRIMARY AGENT	SUPPLEMENTAL AGENT
5-HT ₃ receptor antagonist	Corticosteroid, phenothiazine, butyrophenone
Substituted benzamide	Corticosteroid ± muscarinic receptor antagonist
Phenothiazine/butyrophenone	Corticosteroid
Corticosteroid	Benzodiazepine
Cannabinoid	Corticosteroid

C. Useful Combinations of Antiemetic Agents Providing Decreased Toxicity of the Primary Agent

PRIMARY AGENT	SUPPLEMENTAL AGENT
Substituted benzamide	H ₁ receptor antagonist, corticosteroid, benzodiazepine
Phenothiazine/butyrophenone	H ₁ receptor antagonist
Cannabinoid	Phenothiazine

ABBREVIATIONS: H, histamine, 5-HT, serotonin; IV, intravenous; IM, intramuscular. SOURCE: All combination regimens are from Grunberg and Hesketh, 1993, with permission.

also is reduced in elderly patients, no adjustment in dosage for age is recommended. Granisetron also is metabolized predominantly by the liver, a process that appears to involve the CYP3A family, as it is inhibited by *ketoconazole*. Dolasetron is converted rapidly by plasma carbonyl reductase to its active metabolite, hydrodolasetron. A portion of this compound then undergoes subsequent biotransformation by CYP2D6 and CYP3A4 in the liver, while about one-third of it is excreted unchanged in the urine. Palonosetron is metabolized principally by CYP2D6 and excreted in the urine as the metabolized and the unchanged form in about equal proportions.

Therapeutic Use. These agents are most effective in treating chemotherapy-induced nausea and in treating nausea secondary to upper abdominal irradiation, where all three agents appear to be equally efficacious. They also are effective against hyperemesis of pregnancy, and to a lesser degree, postoperative nausea, but not against motion sickness. Unlike other agents in this class, palonosetron also may be helpful in delayed emesis (*see below*), perhaps a reflection of its long half-life.

These agents are available as tablets, oral solution, and intravenous preparations for injection. For patients on cancer chemotherapy, these drugs can be given in a single intravenous dose (Table 37–8) infused over 15 minutes, beginning 30 minutes before chemotherapy, or in two to three divided doses, with the first usually given 30 minutes before and subsequent doses at various intervals after chemotherapy. The drugs also can be used intramuscularly or orally.

Adverse Effects. In general, these drugs are very well tolerated, with the most common adverse effects being constipation or diarrhea, headache, and light-headedness. As a class, these agents have been shown experimentally to induce minor electrocardiographic changes, but these are not expected to be clinically significant in most cases.

Dopamine-Receptor Antagonists

Phenothiazines such as *prochlorperazine*, *thiethylperazine*, and *chlorpromazine* (*see* Chapter 18) are among the most commonly used “general purpose” antiemetics and antinauseants. Their effects in this regard are complex, but their principal mechanism of action is dopamine D₂ receptor antagonism at the CTZ. Compared to metoclopramide or ondansetron (*see above*), these drugs do not appear to be as uniformly effective in cancer chemotherapy–induced emesis. On the other hand, they also possess antihistaminic and anticholinergic activities, which are of value in other forms of nausea, such as motion sickness.

Antihistamines

Histamine H₁-receptor antagonists are primarily useful for motion sickness and postoperative emesis. They act

Table 37-8*5-HT₃ Antagonists in Chemotherapy-Induced Nausea/Emesis*

DRUG	CHEMICAL NATURE	RECEPTOR INTERACTIONS	T _{1/2}	DOSE (IV)
Ondansetron	Carbazole derivative	5-HT ₃ antagonist and weak 5-HT ₄ antagonist	3.9 hours	0.15 mg/kg
Granisetron	Indazole	5-HT ₃ antagonist	9–11.6 hours	10 μg/kg
Dolasetron	Indole moiety	5-HT ₃ antagonist	7–9 hours	0.6–3 mg/kg
Palonosetron	Isoquinoline	5-HT ₃ antagonist; highest affinity for 5-HT ₃ receptor in this class	40 hours	0.25 mg
Ramosetron	Benzidazolyl derivative	5-HT ₃ antagonist	5.8 hours	300 μg/kg

on vestibular afferents and within the brainstem. *Cyclizine*, *hydroxyzine*, *promethazine*, and *diphenhydramine* are examples of this class of agents. Cyclizine has additional anticholinergic effects that may be useful for patients with abdominal cancer. For a detailed discussion of these drugs, see Chapter 24.

Anticholinergic Agents

The most commonly used muscarinic receptor antagonist is *scopolamine* (hyoscine), which can be injected as the hydrobromide, but usually is administered as the free base in the form of a transdermal patch (TRANSDERM-SCOP). Its principal utility is in the prevention and treatment of motion sickness, although it has been shown to have some activity in postoperative nausea and vomiting, as well. In general, anticholinergic agents have no role in chemotherapy-induced nausea. For a detailed discussion of these drugs, see Chapter 7.

DRONABINOL

Dronabinol (delta-9-tetrahydrocannabinol; MARINOL) is a naturally occurring cannabinoid that can be synthesized chemically or extracted from the marijuana plant, *Cannabis sativa*. The exact mechanism of the antiemetic action of dronabinol is unknown but probably relates to stimulation of the CB₁ subtype of cannabinoid receptors on neurons in and around the vomiting center.

Pharmacokinetics. Dronabinol is a highly lipid-soluble compound that is absorbed readily after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2 to 4 hours. It undergoes extensive first-pass metabolism with limited systemic bioavailability after single doses (only 10% to 20%). Active and inactive metabolites are formed in the liver; the principal active metabolite is 11-OH-delta-9-tetrahydrocannabinol.

These metabolites are excreted primarily *via* the biliary-fecal route, with only 10% to 15% excreted in the urine. Both dronabinol and its metabolites are highly bound (>95%) to plasma proteins. Because of its large volume of distribution, a single dose of dronabinol can result in detectable levels of metabolites for several weeks.

Therapeutic Use. Dronabinol is a useful prophylactic agent in patients receiving cancer chemotherapy when other antiemetic medications are not effective. It also can stimulate appetite and has been used in patients with acquired immunodeficiency syndrome (AIDS) and anorexia. As an antiemetic agent, it is administered at an initial dose of 5 mg/m² given 1 to 3 hours before chemotherapy and then every 2 to 4 hours afterward for a total of four to six doses. If this is not adequate, incremental increases in dose can be made up to a maximum of 15 mg/m². For other indications, the usual starting dose is 2.5 mg twice a day; this can be titrated up to 20 mg a day.

Adverse Effects. Dronabinol has complex effects on the CNS, including a prominent central sympathomimetic activity. This can lead to palpitations, tachycardia, vasodilation, hypotension, and conjunctival injection (bloodshot eyes). Patient supervision is necessary because marijuana-like “highs” (*e.g.*, euphoria, somnolence, detachment, dizziness, anxiety, nervousness, panic, etc.) can occur, as can more disturbing effects such as paranoid reactions and thinking abnormalities. After abrupt withdrawal of dronabinol, an abstinence syndrome manifest by irritability, insomnia, and restlessness can occur. Because of its high affinity for plasma proteins, dronabinol can displace other plasma protein-bound drugs, whose doses may have to be adjusted as a consequence. Dronabinol should be prescribed with great caution to persons with a history of substance abuse (alcohol, drugs) because it also may be abused by these patients.

Glucocorticoids and Antiinflammatory Agents

Glucocorticoids such as *dexamethasone* can be useful adjuncts (Table 37–7) in the treatment of nausea in patients with widespread cancer, possibly by suppressing peritumoral inflammation and prostaglandin production. A similar mechanism has been invoked to explain beneficial effects of nonsteroidal antiinflammatory drugs in the nausea and vomiting induced by systemic irradiation. For a detailed discussion of these drugs, *see* Chapters 26 and 59.

Benzodiazepines

Benzodiazepines, such as *lorazepam* and *alprazolam*, by themselves are not very effective antiemetics, but their sedative, amnesic, and anti-anxiety effects can be helpful in reducing the anticipatory component of nausea and vomiting in patients. For a detailed discussion of these drugs, *see* Chapter 16.

Substance P Receptor Antagonists

APREPITANT

The nausea and vomiting associated with cisplatin (*see* Chapter 51) has two components: an acute phase that universally is experienced (within 24 hours after chemotherapy) and a delayed phase that affects only some patients (on days 2 to 5). 5-HT receptor antagonists are not very effective against delayed emesis. Antagonists of the NK₁ receptors for substance P, such as *aprepitant* (EMEND), have antiemetic effects in delayed nausea and improve the efficacy of standard antiemetic regimens in patients receiving multiple cycles of chemotherapy. Substance P belongs to the tachykinin family of neurotransmitters and is in vagal afferent fibers innervating the STN and area postrema. The tachykinins represent a novel, promising target for new antiemetic drugs.

After absorption, aprepitant is bound extensively to plasma proteins (>95%); it is metabolized avidly, primarily by hepatic CYP3A4, and is excreted in the stools; its half-life is 9 to 13 hours. Aprepitant has the potential to interact with other substrates of CYP3A4, requiring adjustment of other drugs, including *dexamethasone*, *methylprednisolone* (whose dose may need to be reduced by 50%), and *warfarin*. Aprepitant is contraindicated in

patients on cisapride (*see* above) or *pimozide*, in whom life-threatening QT prolongation has been reported.

Aprepitant is supplied in 80- and 125-mg capsules and is administered for 3 days in conjunction with highly emetogenic chemotherapy along with a 5-HT₃-receptor antagonist and a corticosteroid. The recommended adult dosage of aprepitant is 125 mg administered 1 hour before chemotherapy on day one, followed by 80 mg once daily in the morning on days 2 and 3 of the treatment regimen.

AGENTS USED FOR MISCELLANEOUS GASTROINTESTINAL DISORDERS

Chronic Pancreatitis and Steatorrhea

Pancreatic Enzymes. Chronic pancreatitis is a debilitating syndrome that results in symptoms from loss of glandular function (exocrine and endocrine) and inflammation (pain). Because there is no cure for chronic pancreatitis, the goals of pharmacological therapy are prevention of malabsorption and palliation of pain. The cornerstone of therapy for malabsorption still is the use of pancreatic enzymes. Although also used for pain, these agents are much less effective for this symptom.

Enzyme Formulations. The two common preparations of pancreatic enzymes for replacement therapy are obtained from the pancreas of the hog (*Sus scrofa* Linne var. *domesticus* Gray). *Pancreatin* (DONNAZYME, others) contains amylase, lipase, and protease and has one-twelfth of the lipolytic activity of *pancrelipase*, on a weight-by-weight basis. *Pancrelipase* is more commonly used and is available in uncoated forms, as well as capsules containing enteric-coated microspheres and enteric-coated microtablets, which withstand gastric acid (lipase is inactivated by acid) and disintegrate at pH > 6. Familiarity with these two classes of preparations is important clinically (Table 37–9).

Replacement Therapy for Malabsorption. Fat malabsorption (steatorrhea) and protein maldigestion occur when the pancreas loses more than 90% of its ability to produce digestive enzymes. The resultant diarrhea and malabsorption can be managed reasonably well if 30,000 USP units of pancreatic lipase are delivered to the duodenum during a 4-hour period with and after meals; this represents about 10% of the normal pancreatic output. Alternatively, one can titrate the dosage to the fat content of the diet, with approximately 8000 USP units of lipase activity required for each 17 g of dietary fat. Available preparations of pancreatic enzymes (Table 37–10) contain up to 20,000 units of lipase and 75,000 units of protease, and the typical dose of *pancrelipase* is 1 to 3 capsules or tablets with or just before meals and snacks, adjusted until a satisfactory symptomatic response is obtained. The loss of pancreatic amylase does not present a problem because of other sources of this enzyme (*e.g.*, salivary glands). Patients using uncoated preparations require concomitant pharmacological control of gastric acid production with a proton pump inhibitor (*see* Chapter 36).

Enzymes for Pain. Pain is the other cardinal symptom of chronic pancreatitis. The rationale for its treatment with pancreatic enzymes is based on the principle of negative feedback inhibition of the pan-

Table 37-9
Comparison of Uncoated and Enteric-Coated Pancreatic Enzyme Preparations*

	UNCOATED PREPARATIONS	ENTERIC-COATED PREPARATIONS
Number of tablets or capsules required per dose	2-8	2-3
Acid suppression required	Yes	No
Site of delivery	Duodenum	More distal small bowel and beyond
Symptoms relieved	Pain; malabsorption	Malabsorption

*The major components of these preparations are a lipase and a protease (see Table 37-10).

creas by the presence of duodenal proteases. The release of cholecystokinin (CCK), the principal secretagogue for pancreatic enzymes, is triggered by CCK-releasing monitor peptide in the duodenum, which normally is denatured by pancreatic trypsin. In chronic pancreatitis, trypsin insufficiency leads to persistent activation of this peptide and an increased release of CCK, which is thought to cause pancreatic pain because of continuous stimulation of pancreatic enzyme output and increased intraductal pressure. Delivery of active proteases to the duodenum (which can be done reliably only with uncoated preparations) therefore is important for the interruption of this loop. Although enzymatic therapy has become firmly entrenched for the treatment of painful pancreatitis, the evidence supporting this practice is equivocal at best.

Table 37-10
Pancreatic Enzyme Formulations

BRAND NAME	LIPASE*	PROTEASE*	AMYLASE
Conventional (uncoated)			
VIOKASE 8	8,000	30,000	30,000

*U.S. Pharmacopeia units per tablet or capsule. See Forsmark and Toskes, 2000.

In general, pancreatic enzyme preparations are tolerated extremely well by patients. For patients with hypersensitivity to pork protein, bovine enzymes are available. Hyperuricosuria in patients with cystic fibrosis can occur, and malabsorption of folate and iron has been reported. In the past, products with higher lipase content were available, but these were withdrawn after reports associating their use with the development of colonic strictures in patients with cystic fibrosis.

Octreotide (see above, and Chapter 55) also has been used, with questionable efficacy, to decrease refractory abdominal pain in patients with chronic pancreatitis. In the future, CCK antagonists may assume a therapeutic role.

BILE ACIDS

Bile acids and their conjugates are essential components of bile that are synthesized from cholesterol in the liver. The major bile acids in human adults are depicted in Figure 37-5. Bile acids induce bile flow, feedback-inhibit cholesterol synthesis, promote intestinal excretion of cholesterol, and facilitate the dispersion and absorption of lipids and fat-soluble vitamins. After secretion into the biliary tract, bile acids are largely (95%) reabsorbed in the intestine (mainly in the terminal ileum), returned to the liver, and then again secreted in bile (enterohepatic circulation). *Cholic acid*, *chenodeoxycholic acid*, and *deoxycholic acid* constitute 95% of bile acids, while *lithocholic acid* and *ursodeoxycholic acid* are minor constituents. The bile acids exist largely as glycine and taurine conjugates, the salts of which are called *bile salts*. Colonic bacteria convert primary bile acids (cholic and chenodeoxycholic acid) to secondary acids (mainly deoxycholic and lithocholic acid) by sequential deconjugation and dehydroxylation. These secondary bile acids also are absorbed in the colon and join the primary acids in the enterohepatic pool.

Dried bile from the Himalayan bear (Yutan) has been used for centuries in China to treat liver disease. Ursodeoxycholic acid (UDCA; ursodiol, ACTIGALL) (Figure 37-5) is a hydrophilic, dehydroxylated bile acid that is formed by epimerization of the bile acid chenodeoxycholic acid (CDCA; chenodiol) in the gut by intestinal bacteria; it com-

Bile Acid	R3	R7	R12	R24
Cholic acid	-OH	-OH	-OH	
Chenodeoxycholic acid	-OH	-OH	-H	glycine (75%)
Deoxycholic acid	-OH	-H	-OH	taurine (24%)
Lithocholic acid	-SO ₃ ⁻ / -OH	-H	-H	-OH (<1%)
Ursodeoxycholic acid	-OH	-OH	-H	

Figure 37-5. Major bile acids in adults.

prises approximately 1% to 3% of the total bile acid pool in human beings, but is present at much higher concentrations in bears. When administered orally, litholytic bile acids such as chenodiol and ursodiol can alter relative concentrations of bile acids, decrease biliary lipid secretion, and reduce the cholesterol content of the bile so that it is less lithogenic. Ursodiol also may have cytoprotective effects on hepatocytes and effects on the immune system that account for some of its beneficial effects in cholestatic liver diseases.

Bile acids were first used therapeutically for gallstone dissolution; use for this indication requires a functional gallbladder because the modified bile must enter the gallbladder to interact with gallstones. To be amenable to dissolution, the gallstones must be composed of cholesterol monohydrate crystals and generally must be smaller than 15 mm in diameter to provide a favorable ratio of surface to size. For these reasons, the overall efficacy of litholytic bile acids in the treatment of gallstones has been disappointing (partial dissolution occurs in 40% to 60% of patients completing therapy and is complete in only 33% to 50% of these). While a combination of chenodiol and ursodiol probably is better than either agent alone, ursodiol is preferred as a single agent because of its greater efficacy and less-frequent side effects (*e.g.*, hepatotoxicity).

Primary biliary cirrhosis is a chronic, progressive, cholestatic liver disease of unknown etiology that typically affects middle-aged to elderly women. Ursodiol (administered at 13 to 15 mg/kg per day in two divided doses) reduces the concentration of primary bile acids and improves biochemical and histological features of primary biliary cirrhosis. Ursodiol also has been used in a variety of other cholestatic liver diseases, including primary sclerosing cholangitis, and in cystic fibrosis; in general, it is less effective in these conditions than in primary biliary cirrhosis.

ANTIFLATULENCE AGENTS

“Gas” is a common but relatively vague gastrointestinal complaint, used in reference not only to flatulence and

eructation, but also bloating or fullness. Although few if any symptoms can be directly attributable to excessive intestinal gas, over-the-counter and herbal preparations that are touted as antiflatulent are very popular. One of these is *simethicone*, a mixture of siloxane polymers stabilized with silicon dioxide:

Simethicone is an inert, nontoxic insoluble liquid. Because of its ability to collapse bubbles by forming a thin layer on their surface, it is an effective antifoaming agent. Although it may be effective in diminishing gas volumes in the GI tract, it is not clear whether this accomplishes a therapeutic effect.

Simethicone is available in chewable tablets, liquid-filled capsules, or suspensions, either by itself or in combination with other over-the-counter medications including antacids and other digestants. The usual dosage in adults is 40 to 125 mg four times daily.

CLINICAL SUMMARY

GI Motility Disorders. As a group these are difficult disorders to treat because of a lack of effective therapeutic options. For patients with gastroparesis, first-line therapy consists of metoclopramide, which accelerates gastric emptying and also has antiemetic effects. Erythromycin, a motilin agonist, also has been used for these patients, but is most effective in the short-term. The role of newer agents such as tegaserod in this condition is under investigation. For patients with small-bowel dysmotility, the choices are even more limited: Metoclopramide and erythromycin generally do not work; therapy with octreotide may benefit a subset of patients.

Constipation. Although many choices exist for this condition, most therapies are empirical and nonspecific. Constipation often can be addressed by simple measures such as increasing fiber intake, avoiding constipating medications, and the judicious use of osmotic laxatives on an as-needed basis. For more persistent symptoms, a specific prokinetic 5-HT₄-receptor agonist, tegaserod, may be used with modest efficacy in women who also have irritable bowel syndrome. Stimulant laxatives,

although effective, should be avoided for long-term use. Patients with chronic constipation who do not respond to simple measures should undergo further testing to discover uncommon but specific disorders of colonic or anorectal motility.

Diarrhea. In most cases, an attempt should be made to find the underlying cause and target it specifically. If no such cause is found, chronic diarrhea can be treated empirically, with the simplest approach being bulk-forming and hygroscopic agents, followed by opioids such as loperamide or diphenoxylate/difenoxin.

Irritable Bowel Syndrome. This common syndrome requires a combination of pharmacological and behavioral approaches. Antispasmodics are useful by themselves in mild cases and as adjuncts in a regimen that includes tricyclic antidepressants for more persistent pain.

Nausea and Vomiting. The discovery of the 5-HT₃ receptor antagonists has led to a major advance in the treatment of nausea and vomiting, especially in the post-chemotherapy and postoperative settings. Anticholinergics are most effective in motion sickness. Antihistamines and related drugs still are useful for empiric treatment of nausea from a variety of causes. Dronabinol may be an effective agent for more refractory cases. The clinical utility of newer agents such as aprepitant in situations other than postchemotherapy nausea will be tested in coming years.

PHARMACOTHERAPY OF INFLAMMATORY BOWEL DISEASE

Joseph H. Sellin and Pankaj Jay Pasricha

Inflammatory bowel disease (IBD) is a spectrum of chronic idiopathic inflammatory intestinal conditions. IBD causes significant gastrointestinal symptoms that include diarrhea, abdominal pain, bleeding, anemia, and weight loss. IBD also is associated with a spectrum of extraintestinal manifestations, including arthritis, ankylosing spondylitis, sclerosing cholangitis, uveitis, iritis, pyoderma gangrenosum, and erythema nodosum.

IBD conventionally is divided into two major subtypes: ulcerative colitis and Crohn's disease. Ulcerative colitis is characterized by confluent mucosal inflammation of the colon starting at the anal verge and extending proximally for a variable extent (*e.g.*, proctitis, left-sided colitis, or pancolitis). Crohn's disease, by contrast, is characterized by transmural inflammation of any part of the gastrointestinal tract but most commonly the area adjacent to the ileocecal valve. The inflammation in Crohn's disease is not necessarily confluent, frequently leaving "skip areas" of relatively normal mucosa. The transmural nature of the inflammation may lead to fibrosis and strictures or, alternatively, fistula formation.

Medical therapy for IBD is problematic. Because no unique abnormality has been identified, current therapy for IBD seeks to dampen the generalized inflammatory response; however, no agent can reliably accomplish this, and the response of an individual patient to a given medicine may be limited and unpredictable. Based on this variable response, clinical trials generally employ standardized quantitative assessments of efficacy that take into account both clinical and laboratory parameters (*e.g.*, the Crohn's Disease Activity Index). The disease also exhibits marked fluctuations in activity—even in the absence of therapy—leading to a significant "placebo effect" in therapeutic trials.

Specific goals of pharmacotherapy in IBD include controlling acute exacerbations of the disease, maintaining remission, and treating specific complications such as fistulas. Specific drugs may be better suited for one or the other of these aims (Table 38–1). For example, steroids remain the treatment of choice for moderate to severe flares but are inappropriate for long-term use because of side effects and their inability to maintain remission. Other immunosuppressives, such as *azathioprine*, that require several weeks to achieve their therapeutic effect have a limited role in the acute setting but are preferred for long-term management.

For many years *glucocorticoids* and *sulfasalazine* were the mainstays of medical therapy for IBD. More recently, medicines used in other immune/inflammatory conditions, such as *azathioprine* and *cyclosporine*, have been adapted for IBD therapy. A more thorough appreciation of the intricacies of the inflammatory response and improved biotechnology have led to the development of biological agents that can target single steps in the immune cascade. Drug delivery to the appropriate site(s) along the gastrointestinal tract also has been a major challenge, and second-generation agents have been created with improved drug delivery, increased efficacy, and decreased side effects.

PATHOGENESIS OF INFLAMMATORY BOWEL DISEASE

Crohn's disease and ulcerative colitis are chronic idiopathic inflammatory disorders of the GI tract; a summary of proposed pathogenic events and potential sites of therapeutic intervention is shown in Figure 38–1. While

Figure 38–1. Proposed pathogenesis of inflammatory bowel disease and target sites for pharmacological intervention. Shown are the interactions among bacterial antigens in the intestinal lumen and immune cells in the intestinal wall. If the endothelial barrier is impaired, bacterial antigens (dark circles) can gain access to antigen-presenting cells (APCs) in the lamina propria. These cells then present the antigen(s) to CD4⁺ lymphocytes and also secrete IL-12, thereby inducing the differentiation of T_H1 cells in Crohn's disease (or type 2 helper T cells in ulcerative colitis). The T_H1 cells produce a characteristic array of lymphokines, including IFN- γ , which in turn activates macrophages. Macrophages positively regulate T_H1 cells by secreting additional IL-12 and TNF- α . In addition to general immunosuppressants that affect multiple sites of inflammation (e.g., glucocorticoids, thioguanine derivatives, methotrexate, and cyclosporine), more specific sites for therapeutic intervention involve the intestinal bacteria (antibiotics and probiotics) and therapy directed at TNF- α (see text for further details).

Crohn's disease and ulcerative colitis share a number of gastrointestinal and extraintestinal manifestations and can respond to a similar array of drugs, emerging evidence suggests that they result from fundamentally distinct pathogenetic mechanisms (Bouma and Strober, 2003). Histologically, the transmural lesions in Crohn's disease exhibit marked infiltration of lymphocytes and macrophages, granuloma formation, and submucosal fibrosis, whereas the superficial lesions in ulcerative colitis have lymphocytic and neutrophilic infiltrates. Within the diseased bowel in Crohn's disease, the cytokine profile includes increased levels of interleukin-12 (IL-12), interferon- γ , and tumor necrosis factor- α (TNF- α), findings

characteristic of T-helper 1 (T_H1)-mediated inflammatory processes. In contrast, the inflammatory response in ulcerative colitis resembles more closely that mediated by the T_H2 pathway.

Important insights into pathogenesis also have emerged from genetic analyses of Crohn's disease. Mutations in a gene called *nucleotide-binding oligomerization domain-2* (*NOD2*, also called *CARD15*) are associated with both familial and sporadic Crohn's disease in Caucasians (Hugot *et al.*, 2001; Ogura *et al.*, 2001). *NOD2* is expressed in monocytes, granulocytes, dendritic cells, and epithelial cells. It is proposed to function as an intracellular sensor for bacterial infection by recognizing pepti-

dolglycans, thereby playing an important role in the natural immunity to bacterial pathogens. Consistent with this model, other studies have identified bacterial antigens, including pseudomonal protein I2 (Dalwadi *et al.*, 2001) and a flagellin protein (Lodes *et al.*, 2004), as dominant superantigens that induce the T_H1 response in Crohn's disease (shown as bacterial products in Figure 38–1). Thus these converging experimental approaches are generating novel insights into the pathogenesis of Crohn's disease that soon may translate into novel therapeutic approaches to IBD. The major therapeutic agents available for IBD are described below.

MESALAMINE (5-ASA)-BASED THERAPY

Chemistry, Mechanism of Action, and Pharmacological Properties. First-line therapy for mild to moderate ulcerative colitis generally involves *mesalamine* (5-aminosalicylic acid, or 5-ASA). As shown in Figure 38–2, the archetype for this class of medications is sulfasalazine (AZULFIDINE), which consists of 5-ASA linked to *sulfapyridine* by an azo bond. Although this drug was developed originally as therapy for rheumatoid arthritis, clinical trials serendipitously demonstrated a beneficial effect on the gastrointestinal symptoms of subjects with concomitant ulcerative colitis. Sulfasalazine represents one of the first examples of an oral drug that is delivered effectively to the distal gastrointestinal tract. Given individually, either 5-ASA or sulfapyridine is absorbed in the upper gastrointestinal tract; the azo linkage in sulfasalazine prevents absorption in the stomach and small intestine, and the individual components are not liberated for absorption until colonic bacteria cleave the bond. 5-ASA is now regarded as the therapeutic moiety, with little, if any, contribution by sulfapyridine.

Although mesalamine is a salicylate, its therapeutic effect does not appear to be related to cyclooxygenase inhibition; indeed, traditional nonsteroidal antiinflammatory drugs actually may exacerbate IBD. Many potential sites of action have been demonstrated *in vitro* for either sulfasalazine or mesalamine: inhibition of the production of IL-1 and TNF- α , inhibition of the lipoxygenase pathway, scavenging of free radicals and oxidants, and inhibition of NF- κ B, a transcription factor pivotal to production of inflammatory mediators. Specific mechanisms of action of these drugs have not been identified.

Although not active therapeutically, sulfapyridine causes many of the side effects observed in patients taking sul-

Figure 38–2. Structures of sulfasalazine and related agents. The blue N atoms indicate the diazo linkage that is cleaved to generate the active moiety.

fasalazine. To preserve the therapeutic effect of 5-ASA without the side effects of sulfapyridine, several second-generation 5-ASA compounds have been developed (Figures 38–2, 38–3, and 38–4). They are divided into two groups: prodrugs and coated drugs. Prodrugs contain the same azo bond as sulfasalazine but replace the linked sulfapyridine with either another 5-ASA (*olsalazine*, DIPENTUM) or an inert compound (*balsalazide*, COLAZIDE). Thus, these compounds act at similar sites along the gastrointestinal tract as does sulfasalazine. The alternative approaches employ either a delayed-release formulation (PENTASA) or a

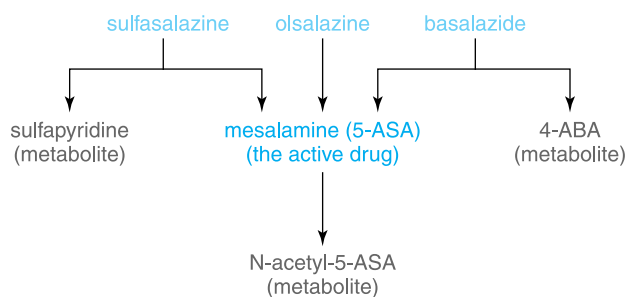

Figure 38–3. Metabolic fates of the different oral formulations of mesalamine (5-ASA). Chemical structures are in Figure 38–2.

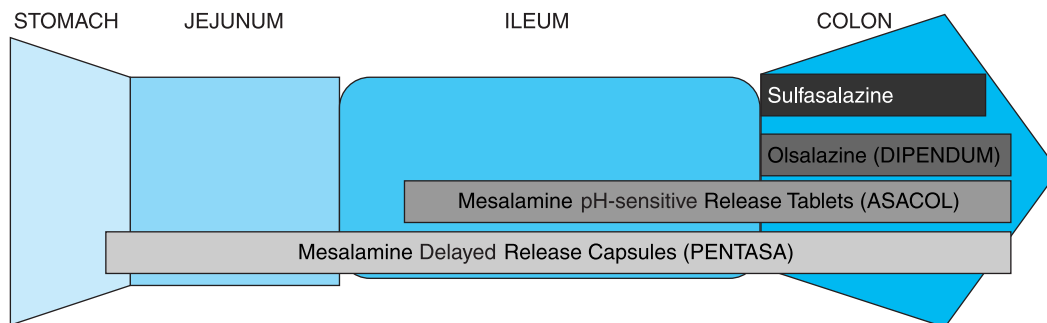

Figure 38–4. Sites of release of mesalamine (5-ASA) in the GI tract from different oral formulations.

pH-sensitive coating (ASACOL). Delayed-release mesalamine is released throughout the small intestine and colon, whereas pH-sensitive mesalamine is released in the terminal ileum and colon. These different distributions of drug delivery have potential therapeutic implications.

Oral sulfasalazine is of proven value in patients with mild or moderately active ulcerative colitis, with response rates in the range of 60% to 80% (Pranter *et al.*, 1999). The usual dose is 4 g/day in four divided doses with food; to avoid adverse effects, the dose is increased gradually from an initial dose of 500 mg twice a day. Doses as high as 6 g/day can be used but cause an increased incidence of side effects. For patients with severe colitis, sulfasalazine is of less certain value, even though it is often added as an adjunct to systemic glucocorticoids. Regardless of disease severity, the drug plays a useful role in preventing relapses once remission has been achieved. In general, newer 5-ASA preparations have similar therapeutic efficacy in ulcerative colitis with fewer side effects. Because they lack the dose-related side effects of sulfapyridine, the newer formulations can be used to provide higher doses of mesalamine with some improvement in disease control. The usual doses to treat active disease are 800 mg three times a day for ASACOL and 1 g four times a day for PENTASA. Lower doses are used for maintenance (*e.g.*, ASACOL, 800 mg twice a day). Although some studies have suggested that a given preparation may be superior in treating colonic disease, there is no consensus on this issue.

The efficacy of 5-ASA preparations (*e.g.*, sulfasalazine) in Crohn's disease is less striking, with modest benefit at best in controlled trials. Sulfasalazine has not been shown to be effective in maintaining remission and has been replaced by newer 5-ASA preparations. Some studies have reported that both ASACOL and PENTASA are more effective than placebo in inducing remission in patients with Crohn's disease (particularly colitis), although higher doses than those typically used in ulcerative colitis are required. The role of mesalamine in maintenance therapy for Crohn's disease is controversial, and there is no clear benefit of continued 5-ASA therapy in patients who achieve medical remission (Camma *et al.*, 1997). Because they largely bypass the small intestine, the second-generation 5-ASA prodrugs such as olsalazine and balsalazide do not have a significant effect in small bowel Crohn's disease.

Topical preparations of mesalamine suspended in a wax matrix suppository (ROWASA) or in a suspension enema (CANASA) are effective in active proctitis and distal ulcerative colitis, respectively. They appear to be superior to topical *hydrocortisone* in this setting, with response rates of 75% to 90%. Mesalamine enemas (4 g/60 ml)

should be used at bedtime and retained for at least 8 hours; the suppository (500 mg) should be used two to three times a day with the objective of retaining it for at least 3 hours. Response to local therapy with mesalamine may occur within 3 to 21 days; however, the usual course of therapy is from 3 to 6 weeks. Once remission has occurred, lower doses are used for maintenance.

Pharmacokinetics. Approximately 20% to 30% of orally administered sulfasalazine is absorbed in the small intestine. Much of this is taken up by the liver and excreted unmetabolized in the bile; the rest (about 10%) is excreted unchanged in the urine. The remaining 70% reaches the colon, where, if cleaved completely by bacterial enzymes, it generates 400 mg mesalamine for every gram of the parent compound. Thereafter, the individual components of sulfasalazine follow different metabolic pathways. Sulfapyridine, which is highly lipid-soluble, is absorbed rapidly from the colon. It undergoes extensive hepatic metabolism, including acetylation and hydroxylation, conjugation with glucuronic acid, and excretion in the urine. The acetylation phenotype of the patient determines plasma levels of sulfapyridine and the probability of side effects; rapid acetylators have lower systemic levels of the drug and fewer adverse effects. By contrast, only 25% of mesalamine is absorbed from the colon, and most of the drug is excreted in the stool. The small amount that is absorbed is acetylated in the intestinal mucosal wall and the liver and then excreted in the urine. Intraluminal concentrations of mesalamine therefore are very high (around 1500 $\mu\text{g}/\text{ml}$ or 10 mM in patients taking a typical dose of 3 g/day).

The pH-sensitive coating of ASACOL (EUDAGRIT-S) limits gastric and small intestinal absorption of 5-ASA, as assessed by urinary, ileostomal, and fecal measurements of the various metabolites. The pharmacokinetics of PENTASA differ somewhat. The ethylcellulose-coated microgranules are released in the upper gastrointestinal tract as discrete, prolonged-release units of mesalamine. Acetylated mesalamine can be detected in the circulation within an hour after ingestion, indicating some rapid absorption, but some intact microgranules also can be detected in the colon. Because it is released in the small bowel, a greater fraction of PENTASA is absorbed systemically compared with the other 5-ASA preparations.

Adverse Effects. Side effects of sulfasalazine occur in 10% to 45% of patients with ulcerative colitis and are related primarily to the sulfa moiety. Some are dose-related, including headache, nausea, and fatigue. These reactions can be minimized by giving the medication with meals or by decreasing the dose. Allergic reactions include rash, fever, Stevens-Johnson syndrome, hepatitis, pneumonitis, hemolytic anemia, and bone marrow suppression. Sulfalaza-

zine reversibly decreases the number and motility of sperm but does not impair female fertility. It also inhibits intestinal folate absorption; therefore, folate usually is given with sulfasalazine.

The newer mesalamine formulations generally are well tolerated, and side effects are relatively infrequent and minor. Headache, dyspepsia, and skin rash are the most common. Diarrhea appears to be particularly common with olsalazine (occurring in 10% to 20% of patients); this may be related to its ability to stimulate chloride and fluid secretion in the small bowel. Nephrotoxicity, although rare, is a more serious concern. Mesalamine has been associated with interstitial nephritis; while its pathogenic role is controversial, renal function should be monitored in all patients receiving these drugs. Both sulfasalazine and its metabolites cross the placenta but have not been shown to harm the fetus. Although they have not been studied as thoroughly, the newer formulations also appear to be safe in pregnancy. The risks to the fetus from the consequences of uncontrolled IBD in pregnant women are believed to outweigh the risks associated with the therapeutic use of these agents (*see below*).

GLUCOCORTICOIDS

The effects of glucocorticoids on the inflammatory response are numerous and well documented (*see Chapters 52 and 59*). Although glucocorticoids are universally recognized as effective in acute exacerbations, their use in either ulcerative colitis or Crohn's disease involves considerable challenges and pitfalls, and they are indicated only for moderate to severe IBD. Because the same issues have an impact on steroid use in both ulcerative colitis and Crohn's disease, they are addressed together.

The response to steroids in individual patients with IBD divides them into three general classes: steroid-responsive, steroid-dependent, and steroid-unresponsive. Steroid-responsive patients improve clinically, generally within 1 to 2 weeks, and remain in remission as the steroids are tapered and then discontinued. Steroid-dependent patients also respond to glucocorticoids but then experience a relapse of symptoms as the steroid dose is tapered. Steroid-unresponsive patients do not improve even with prolonged high-dose steroids. Approximately 40% of patients are steroid-responsive, 30% to 40% have only a partial response or become steroid-dependent, and 15% to 20% of patients do not respond to steroid therapy.

Steroids sometimes are used for prolonged periods to control symptoms in steroid-dependent patients. However, the failure to respond to steroids with prolonged remission (*i.e.*, a disease relapse) should prompt consideration of alternative therapies, including immunosuppressives and *infliximab* (*see below*). Steroids are not effective in maintaining remission in either ulcerative colitis or Crohn's disease (Steinhart *et al.*, 2003); thus their significant side effects (*see Chapter 59*) have led to increased

emphasis on limiting the duration and cumulative dose of steroids in IBD.

The approach to steroid therapy in IBD differs somewhat from that in diseases such as asthma or rheumatoid arthritis. Initial doses are between 40 to 60 mg *prednisone* or equivalent per day; higher doses generally are no more effective. The glucocorticoid dose in IBD is tapered over weeks to months. Even with these slow tapers, however, efforts should be made to minimize the duration of steroid therapy.

Glucocorticoids induce remission in the majority of patients with either ulcerative colitis or Crohn's disease (Faubion *et al.*, 2001). Oral prednisone is the preferred agent for moderate to severe disease, and the typical dose is 40 to 60 mg once a day. Most patients improve substantially within 5 days of initiating treatment; others require treatment for several weeks before remission occurs. For more severe cases, glucocorticoids are given intravenously. Generally, *methylprednisolone* or *hydrocortisone* is used for intravenous therapy, although some experts believe that *corticotropin* (ACTH) is more effective in patients who have not previously received any steroids.

Glucocorticoid enemas are useful in patients whose disease is limited to the rectum (proctitis) and left colon. Hydrocortisone is available as a retention enema (100 mg/60 ml), and the usual dose is one 60-ml enema per night for 2 or 3 weeks. When administered optimally, the drug can reach up to or beyond the descending colon. Patients with distal disease usually respond within 3 to 7 days. Absorption, while less than with oral preparations, is still substantial (up to 50% to 75%). Hydrocortisone also can be given once or twice daily as a 10% foam suspension (CORTIFOAM) that delivers 80 mg hydrocortisone per application; this formulation can be useful in patients with very short areas of distal proctitis and difficulty retaining fluid.

Budesonide (ENTOCORT ER) is an enteric-release form of a synthetic steroid that is used for ileocecal Crohn's disease (Greenberg *et al.*, 1994; McKeage and Goa, 2002). It is proposed to deliver adequate steroid therapy to a specific portion of inflamed gut while minimizing systemic side effects owing to extensive first-pass hepatic metabolism to inactive derivatives. Topical therapy (*e.g.*, enemas and suppositories) also is effective in treating colitis limited to the left side of the colon. While the topical potency of budesonide is 200 times higher than that of hydrocortisone, its oral systemic bioavailability is only 10%. In some studies, budesonide was associated with a lower incidence of systemic side effects than prednisone, although data also indicate that systemic steroids are more effective in patients with higher Crohn's Disease Activity Index scores. Budesonide (9 mg/day for 10 to 12 weeks) is effective in the acute management of mild-to-moderate exacerbations of Crohn's disease, but its role in maintaining remission has not been fully delineated (Hofer, 2003).

A significant number of patients with IBD fail to respond adequately to glucocorticoids and are either steroid-resistant or steroid-dependent. The reasons for this failure are poorly understood but may involve complications such as fibrosis or strictures in Crohn's disease, which will not respond to antiinflammatory measures alone; local complications such as abscesses, in which case the use of steroids may lead to uncontrolled sepsis; and intercurrent infections with organisms such as cytomegalovirus and *Clostridium difficile*. Steroid failures also may be related to specific pharmacogenomic factors such as up-regulation of the multidrug

resistance (*mdr*) gene (Farrell *et al.*, 2000) or altered levels of corticosteroid-binding globulin.

IMMUNOSUPPRESSIVE AGENTS

Several drugs developed initially for cancer chemotherapy or as immunosuppressive agents in organ transplants have been adapted for treatment of IBD. While their initial use in IBD was based on their immunosuppressive effects, their specific mechanisms of action are unknown. Increasing clinical experience has defined specific roles for each of these medicines as mainstays in the pharmacotherapy of IBD. However, both real and potential side effects mandate a careful assessment of potential risks and benefits in each patient.

Thiopurine Derivatives

The cytotoxic thiopurine derivatives *mercaptopurine* (6-MP, PURINETHOL) and *azathioprine* (IMMURAN) (*see* Chapters 51 and 52) are used to treat patients with severe IBD or those who are steroid-resistant or steroid-dependent (Pearson *et al.*, 1995). These thiopurine antimetabolites impair purine biosynthesis and inhibit cell proliferation. Both are prodrugs: Azathioprine is converted to mercaptopurine, which is subsequently metabolized to 6-thioguanine nucleotides that are the presumed active moiety (Figure 38–5). These drugs generally are used interchangeably with appropriate dose adjustments, typically azathioprine (2 to 2.5 mg/kg) or mercaptopurine (1.5 mg/kg). As discussed below, the pathways by which they are metabolized are clinically relevant, and specific assays can be used to assess clinical response and to avoid side effects. Because of concerns about side effects, these drugs were used initially only in Crohn's disease, which lacks a surgical curative option. They now are considered equally effective in Crohn's disease and ulcerative colitis. These drugs effectively maintain remission in both diseases; they also may prevent (or, more typically, delay) recurrence of Crohn's disease after surgical resection. Finally, they are used successfully to treat fistulas in Crohn's disease. The clinical response to azathioprine or mercaptopurine may take weeks to months, such that other drugs with a more rapid onset of action (*e.g.*, mesalamine, glucocorticoids, or infliximab) are preferred in the acute setting.

The decision to initiate immunosuppressive therapy depends on an accurate assessment of the risk/benefit ratio. In general, physicians who treat IBD believe that the long-term risks of azathioprine–mercaptopurine are lower than those of steroids. Thus, these purines are

Figure 38–5. Metabolism of azathioprine and 6-mercaptopurine. TPMT = thiopurine methyltransferase; XO = xanthine oxidase; HGPRT = hypoxanthine–guanine phosphoribosyl transferase. The activities of these enzymes vary among humans because genetic polymorphisms are expressed differentially, explaining responses and side effects when azathioprine–mercaptopurine therapy is employed. *See* text for details.

used in steroid-unresponsive or steroid-dependent disease and in patients who have had recurrent flares of disease requiring repeated courses of steroids. Additionally, patients who have not responded adequately to mesalamine but are not acutely ill may benefit by conversion from glucocorticoids to immunosuppressive drugs. Immunosuppressives therefore may be viewed as steroid-sparing agents.

Adverse effects of azathioprine–mercaptopurine can be divided into three general categories: idiosyncratic, dose-related, and possible. Although the therapeutic effects of azathioprine–mercaptopurine often are delayed, their side effects occur at any time after initiation of treatment and can affect up to 10% of patients. The most serious idiosyncratic reaction is pancreatitis, which affects approximately 5% of patients treated with these drugs. Fever, rash, and arthralgias are seen occasionally, whereas nausea and vomiting are somewhat more frequent. The major dose-related side effect is bone marrow suppression, and circulating blood counts should be monitored closely when therapy is initiated and at less frequent intervals during maintenance therapy (*e.g.*, every 3 months). Elevations in liver function tests also may be dose-related. Although keeping drug levels in the appropriate range diminishes these adverse effects, they can occur even with therapeutic serum levels of 6-thioguanine nucleotides. The serious side effect of cholestatic hepatitis is relatively rare. Although the increased risk of infection is a significant concern with immunosuppressives, especially if pancytopenia occurs, infections are linked more closely to concomitant glucocorticoid therapy than to the immunosuppressives (Aberra *et al.*, 2003).

There is some concern that the immunosuppressive agents may increase the risk of hematological malignancies. Immunosuppressive regimens given in the setting of cancer chemotherapy or organ transplants have been associated with an increased incidence of malignancy, particularly non-Hodgkin's lymphoma. Definitive conclusions about the causative roles of azathioprine–mercaptopurine in lymphomas are complicated by the possible increased incidence of lymphomas in IBD *per se* and by the relative rarity of these cancers. The increased risk, if any, must be relatively small.

Pharmacogenetics. Favorable responses to azathioprine–mercaptopurine are seen in up to two-thirds of patients.

Recent insights into the metabolism of the thiopurine agents and appreciation of genetic polymorphisms in these pathways have provided new insights into variability in response rates and side effects. As shown in Figure 38–4, mercaptopurine has three metabolic fates: (1) conversion by xanthine oxidase to 6-thiouric acid; (2) metabolism by thiopurine methyltransferase (TPMT) to 6-methyl-mercaptopurine (6-MMP); and (3) conversion by hypoxanthine–guanine phosphoribosyl transferase (HGPRT) to 6-thioguanine nucleotides and other metabolites. The relative activities of these different pathways may explain, in part, individual variations in efficacy and side effects of these immunosuppressives.

The plasma half-life of mercaptopurine is limited by its relatively rapid (*i.e.*, within 1 to 2 hours) uptake into erythrocytes and other tissues. Following this uptake, differences in TPMT activity determine the drug's fate. Approximately 80% of the United States population has what is considered “normal” metabolism, whereas one in 300 individuals has minimal TPMT activity. In the latter setting, mercaptopurine metabolism is shifted away from 6-methyl-mercaptopurine and driven toward 6-thioguanine nucleotides, which can severely suppress the bone marrow. About 10% of people have intermediate TPMT activity; given a similar dose, these individuals will tend to have higher 6-thioguanine levels than the normal metabolizers. Finally, approximately 10% of the population is considered rapid metabolizers. In these individuals, mercaptopurine is shunted away from 6-thioguanine nucleotides toward 6-MMP, which has been associated with abnormal liver function tests. In addition, relative to normal metabolizers, the 6-thioguanine levels of these rapid metabolizers are lower for an equivalent oral dose, possibly reducing therapeutic response. Given this variability, some experts evaluate an individual's TPMT activity status prior to initiating treatment with thiopurines and also measure 6-thioguanine/6-MMP levels in individuals not responding to therapy. To avoid these complexities, treatment with 6-thioguanine was explored; unfortunately, 6-thioguanine is associated with a high incidence of an uncommon liver abnormality, hepatic nodular regeneration, and associated portal hypertension; 6-thioguanine therapy of IBD therefore has been abandoned.

Xanthine oxidase in the small intestine and liver converts mercaptopurine to thiouric acid, which is inactive as an immunosuppressive. Inhibition of xanthine oxidase by *allopurinol* diverts mercaptopurine to more active metabolites such as 6-thioguanine and increases both immunosuppressive and potential toxic effects. Thus patients on mercaptopurine should be warned about potentially serious interactions with medications used to treat gout or hyperuricemia, and the dose should be decreased to 25% of the standard dose in subjects who are already taking allopurinol.

Methotrexate

Methotrexate was engineered to inhibit dihydrofolate reductase, thereby blocking DNA synthesis and causing cell death. First used in cancer treatment, methotrexate subsequently was recognized to have beneficial effects in autoimmune diseases such as rheumatoid arthritis and psoriasis (*see* Chapter 62 for a discussion of the use of

methotrexate in dermatologic disorders). The antiinflammatory effects of methotrexate may involve mechanisms in addition to inhibition of dihydrofolate reductase.

As with azathioprine–mercaptopurine, methotrexate generally is reserved for patients whose IBD is either steroid-resistant or steroid-dependent. In Crohn's disease, it both induces and maintains remission, generally with a more rapid response than that seen with mercaptopurine or azathioprine (Feagin *et al.*, 1995). Only limited studies have examined the role of methotrexate in ulcerative colitis.

Therapy of IBD with methotrexate differs somewhat from its use in other autoimmune diseases. Most important, higher doses (*e.g.*, 15 to 25 mg/week) are given parenterally. The increased efficacy with parenteral administration may reflect the unpredictable intestinal absorption at higher doses of methotrexate. For unknown reasons, the incidence of methotrexate-induced hepatic fibrosis in patients with IBD is lower than that seen in patients with psoriasis.

Cyclosporine

The calcineurin inhibitor cyclosporine is a potent immunomodulator used most frequently after organ transplantation (*see* Chapter 52). It is effective in specific clinical settings in IBD, but the high frequency of significant adverse effects limits its use as a first-line medication.

Cyclosporine is effective in severe ulcerative colitis that has failed to respond adequately to glucocorticoid therapy. Between 50% and 80% of these severely ill patients improve significantly (generally within 7 days) in response to intravenous cyclosporine (2 to 4 mg/kg per day), sometimes avoiding emergent colectomy. Careful monitoring of cyclosporine levels is necessary to maintain a therapeutic level in whole blood between 300 and 400 ng/ml.

Oral cyclosporine is less effective as maintenance therapy in IBD, perhaps because of its limited intestinal absorption. In this setting, long-term therapy with NEORAL (a microemulsion formulation of cyclosporine with increased oral bioavailability) may be more effective, but this has not been studied fully. The calcineurin inhibitors can be used to treat fistulous complications of Crohn's disease. A significant, rapid response to intravenous cyclosporine has been observed; however, frequent relapses accompany oral cyclosporine therapy, and other medical strategies are required to maintain fistula closure. Thus the calcineurin inhibitors generally are used to treat specific problems over a short term while providing a bridge to longer-term therapy (Sandborn, 1995).

Other immunomodulators are also being evaluated in IBD include *tacrolimus* (FK 506, PROGRAF) and *mycophenolate mofetil* (CELLCEPT) (*see* Chapter 52).

ANTI-TNF THERAPY

Infliximab (REMICADE, cA2), a chimeric immunoglobulin (25% mouse, 75% human) that binds to and neutralizes TNF- α , represents a new class of therapeutic agents for treating IBD (Targan *et al.*, 1997). Although a great many

of both pro- and antiinflammatory cytokines are generated in the inflamed gut in IBD (Figure 38–1), there is some rationale for targeting TNF- α because it is one of the principal cytokines mediating the T_H1 immune response characteristic of Crohn's disease.

Infliximab (5 mg/kg infused intravenously at intervals of several weeks to months) decreases the frequency of acute flares in approximately two-thirds of patients with moderate to severe Crohn's disease and also facilitates the closing of enterocutaneous fistulas associated with Crohn's disease (Present *et al.*, 1999). Its longer-term role in Crohn's disease is evolving, but emerging evidence supports its efficacy in maintaining remission (Rutgeerts *et al.*, 2004) and in preventing recurrence of fistulas (Sands *et al.*, 2004).

Although infliximab was designed specifically to target TNF- α , it also may have more complex actions. *Etanercept*, another anti-TNF- α therapy that uses a circulating receptor to clear soluble TNF- α , blocks its biologic effects but is ineffective in Crohn's disease. Infliximab binds membrane-bound TNF- α and may cause lysis of these cells by antibody-dependent or cell-mediated cytotoxicity. Thus, infliximab may deplete specific populations of subepithelial inflammatory cells. These effects, together with its mean terminal plasma half-life of 8 to 10 days, may explain the prolonged clinical effects of infliximab.

The use of infliximab as a biologic response modifier raises several important considerations. Both acute (fever, chills, urticaria, or even anaphylaxis) and subacute (serum sickness–like) reactions may develop after infliximab infusion. Anti–double-stranded DNA antibodies develop in 9% of patients, but a frank lupus-like syndrome occurs only rarely. Antibodies to infliximab can decrease its clinical efficacy; strategies to minimize the development of these antibodies (*e.g.*, treatment with glucocorticoids or other immunosuppressives) may be critical to preserving infliximab efficacy for either recurrent or chronic therapy (Farrell *et al.*, 2003). Other proposed strategies to overcome the problem of “antibody resistance” include increasing the dose of infliximab or decreasing the interval between infusions.

Infliximab therapy is associated with increased incidence of respiratory infections; of particular concern is potential reactivation of tuberculosis or other granulomatous infections with subsequent dissemination. The FDA recommends that candidates for infliximab therapy should be tested for latent tuberculosis with purified protein derivative, and patients who test positive should be treated prophylactically with *isoniazid*. However, anergy with a false-negative skin test has been noted in some patients with Crohn's disease, and some experts routinely perform chest radiographs to look for active or latent pulmonary disease. Infliximab also is contraindicated in patients with severe congestive heart failure (New York Heart Association classes III and IV) and should be used cautiously in class I or II patients. As with the immunosuppressives, there is concern about the possible increased incidence of non-Hodgkin's lymphoma, but a causal role has not been established. Finally, the significant cost of infliximab is an important consideration in some patients.

Additional anti-TNF therapies are being evaluated in treating Crohn's disease, including a more humanized monoclonal antibody (CDP571) that should be less antigenic, and *thalidomide* (THALOMID), a drug with significant anti-TNF- α effects (*see* Chapter 52). Despite the fact that ulcerative colitis does not appear to have a T_H1-type immune response mediated through TNF- α , some studies have

shown a beneficial effect of TNF- α modulation in this disorder as well. Clearly, this area of IBD therapy is evolving rapidly as new drugs emerge and clinical experience increases.

ANTIBIOTICS AND PROBIOTICS

An emerging concept is that a balance in the gastrointestinal tract normally exists among the mucosal epithelium, the normal gut flora, and the immune response (McCracken and Lorenz, 2001). Moreover, there are experimental and clinical data that colonic bacteria may either initiate or perpetuate the inflammation of IBD (Sartor, 1999), and—as discussed earlier under “Pathogenesis of Inflammatory Bowel Disease”—recent studies have implicated specific bacterial antigens in the pathogenesis of Crohn's disease. Thus, certain bacterial strains may be either pro- (*e.g.*, *Bacteroides*) or antiinflammatory (*e.g.*, *Lactobacillus*), prompting attempts to manipulate the colonic flora in patients with IBD. Traditionally, antibiotics have been used to this end, most prominently in Crohn's disease. More recently, probiotics have been used to treat specific clinical situations in inflammatory bowel disease (*see* below).

Antibiotics can be used as either (1) adjunctive treatment along with other medications for active inflammatory bowel disease; (2) treatment for a specific complication of Crohn's disease; or (3) prophylaxis for recurrence in postoperative Crohn's disease. *Metronidazole* (Sutherland *et al.*, 1991), *ciprofloxacin* (Arnold *et al.*, 2002), and *clarithromycin* are the antibiotics used most frequently. They are more beneficial in Crohn's disease involving the colon than in disease restricted to the ileum. Specific Crohn's disease–related complications that may benefit from antibiotic therapy include intra-abdominal abscess and inflammatory masses, perianal disease (including fistulas and perirectal abscesses), small bowel bacterial overgrowth secondary to partial small bowel obstruction, secondary infections with organisms such as *C. difficile*, and postoperative complications. Metronidazole may be particularly effective for the treatment of perianal disease. Postoperatively, metronidazole and related compounds have been shown to delay the recurrence of Crohn's disease. In one study, a 3-month course of metronidazole (20 mg/kg per day) prolonged the time to both endoscopic and clinical recurrence (Rutgeerts *et al.*, 1995). The significant side effects of prolonged systemic antibiotic use must be balanced against their potential benefits, and definitive data to support their routine use are lacking.

Probiotics are a mixture of putatively beneficial lyophilized bacteria given orally. Although probiotics are a promising alternative to more conventional therapies for

inflammatory bowel disease, their role in treating ulcerative colitis and Crohn's disease requires further evaluation. In one study, probiotics diminished the occurrence of pouchitis, a common inflammatory condition that occurs in surgically created ileal reservoirs after total proctocolectomy for ulcerative colitis (Gionchetti *et al.*, 2003).

SUPPORTIVE THERAPY IN INFLAMMATORY BOWEL DISEASE

Analgesic, anticholinergic, and antidiarrheal agents play supportive roles in reducing symptoms and improving quality of life. These drugs should be individualized based on a patient's symptoms and are supplementary to antiinflammatory medications. Oral iron, folate, and vitamin B₁₂ should be administered as indicated. *Loperamide* or *diphenoxylate* (see Chapter 37) can be used to reduce the frequency of bowel movements and relieve rectal urgency in patients with mild disease; these agents are contraindicated in patients with severe disease because they may predispose to the development of toxic megacolon. *Cholestyramine* can be used to prevent bile salt–induced colonic secretion in patients who have undergone limited ileocolic resections. Anticholinergic agents (*dicyclomine hydrochloride*, etc.; see Chapter 7) are used to reduce abdominal cramps, pain, and rectal urgency. As with the antidiarrheal agents, they are contraindicated in severe disease or when obstruction is suspected. Care should be taken to differentiate exacerbation of IBD from symptoms that may be related to coexistent functional bowel disease (see Chapter 37).

THERAPY OF INFLAMMATORY BOWEL DISEASE DURING PREGNANCY

IBD is a chronic disease that affects women in their reproductive years; thus the issue of pregnancy often has a significant impact on medical management. The effects of IBD on pregnancy and the effects of pregnancy on IBD are beyond the scope of this chapter. In general, decreased disease activity increases fertility and improves pregnancy outcomes. At the same time, limiting medication during pregnancy is always desired but sometimes conflicts with the goal of controlling the disease.

Mesalamine and glucocorticoids are FDA category B drugs that are used frequently in pregnancy and generally are considered safe, whereas methotrexate is clearly contraindicated in pregnant patients. The use of thiopurine immunosuppressives is more controversial. Because these medications are given long term, both their initiation and discontinuation are major management decisions. Although there are no controlled trials of these medications in pregnancy, considerable experience has emerged over the last several years. There does not appear to be an increase in adverse outcomes in pregnant patients maintained on thiopurine-based immunosuppressives (Francella *et al.*, 2003). Nonetheless, decisions regarding the use of these

medications in patients contemplating pregnancy are complex and necessarily must involve consideration of the risks and benefits involved.

CLINICAL SUMMARY

The treatment of IBD in any given patient may have several different goals, such as relief of symptoms, induction of remission in patients with active disease, prevention of relapse (*i.e.*, maintenance therapy), healing of fistulas, and avoidance of emergent surgery. Further, therapy may be tailored to some extent to the severity and location of disease. Acute exacerbations of ulcerative colitis are treated with colonic-release preparations of 5-ASA and, in most patients with significant inflammation, with glucocorticoids. For milder cases involving only the rectum, these drugs may be given topically (by enema). Maintenance therapy for patients with ulcerative colitis is principally in the form of 5-ASA compounds, which generally are effective and safe. In patients who relapse on these preparations, purine metabolites (*e.g.*, azathioprine–mercaptopurine) may be used. Other approaches being tested in this setting include the use of probiotic bacteria.

Drugs used in mild-to-moderately active Crohn's disease include sulfasalazine, budesonide, and oral corticosteroids. In contrast to their use in ulcerative colitis, the role of 5-ASA preparations in maintenance therapy of Crohn's disease is limited. Patients who relapse frequently may be treated with immunosuppressive agents (azathioprine–mercaptopurine or methotrexate). Steroid-dependent patients may be treated with long-term budesonide. Infliximab is particularly useful in closing fistulas associated with Crohn's disease but increasingly is used in acute flares of this condition. Its role in maintaining patients in remission is being evaluated but must be balanced against the risk of side effects. Antibiotics, particularly metronidazole, may be useful adjuncts for the acute treatment of complications associated with Crohn's disease (including perianal disease) but are not established as a routine therapy in this disorder.

SECTION VII

Chemotherapy of Parasitic Infections

CHAPTER

39

CHEMOTHERAPY OF PROTOZOAL INFECTIONS

Malaria

Theresa A. Shapiro and Daniel E. Goldberg

Malaria, especially that caused by *Plasmodium falciparum*, is the world's most devastating human parasitic infection. Malaria afflicts nearly 500 million people and causes some 2 million deaths each year (Bremner, 2001). Infection with *P. falciparum*, which preferentially affects children younger than 5 years of age, pregnant women, and non-immune individuals, is responsible for nearly all this mortality. Although mosquito-transmitted malaria now is rare in North America, Europe, and Russia, its increasing prevalence in many other parts of the world poses a major international health and economic burden and a serious risk to travelers from nonendemic areas.

Inexpensive and safe drugs, insecticides, and ultimately, vaccines still are needed to combat malaria. In the 1950s, attempts to eradicate this scourge failed primarily because of the development of resistance to insecticides. Since 1960, transmission of malaria has risen in most regions where the infection is endemic, drug-resistant strains of *P. falciparum* have spread, and the degree of drug resistance has increased. More recently, chloroquine-resistant strains of *P. vivax* also have been documented.

The discovery by Trager and Jensen of techniques for continuous maintenance of *P. falciparum* *in vitro* led to practical assays to screen for antimalarial drug candidates.

This important advance, together with the availability of the sequence of the entire *P. falciparum* genome (Gardner *et al.*, 2002), is revealing new molecular targets for antimalarial drug action and for vaccine development. To understand the actions and therapeutic uses of antimalarial drugs, it is essential to know the biology of the malaria parasite in humans.

BIOLOGY OF MALARIAL INFECTION

Nearly all human malaria is caused by four species of obligate intracellular protozoa of the genus *Plasmodium*. Although malaria can be transmitted by transfusion of infected blood, congenitally, and by sharing needles, infection usually is transmitted by the bite of infected female *Anopheles* mosquitoes. Sporozoites from the mosquito salivary glands rapidly enter the circulation after a bite and localize *via* specific recognition events in hepatocytes, where they transform, multiply, and develop into tissue schizonts (Figure 39–1). This primary asymptomatic tissue (preerythrocytic or exoerythrocytic) stage of infection lasts for 5 to 15 days, depending on the *Plasmodium* species. Tissue schizonts then rupture, each

releasing thousands of merozoites that enter the circulation, invade erythrocytes, and initiate the erythrocytic cycle. Once the tissue schizonts burst in *P. falciparum* and *P. malariae* infections, no forms of the parasite remain in the liver. However, in *P. vivax* and *P. ovale* infections, tissue parasites (hypnozoites) persist that can produce relapses of erythrocytic infection months to years after the primary attack. Once plasmodia enter the erythrocytic cycle, they cannot reinvade the liver; thus, there is no tissue stage of infection for malaria contracted by transfusion. In erythrocytes, most parasites undergo asexual development from young ring forms to trophozoites and finally to mature schizonts. Schizont-containing erythrocytes rupture, each releasing 6 to 32 merozoites depending on the *Plasmodium* species. It is this process that produces febrile clinical attacks. The merozoites invade more erythrocytes to continue the cycle, which proceeds until death of the host or modulation by drugs or acquired partial immunity. The periodicity of parasitemia and febrile clinical manifestations depends on the timing of schizogony of a generation of erythrocytic parasites. For *P. falciparum*, *P. vivax*, and *P. ovale*, it takes about 48 hours to complete this process; for *P. malariae*, about 72 hours is required.

For erythrocyte invasion, merozoites bind to specific ligands on the red cell surface (see Miller *et al.*, 2002; Sibley, 2004). *P. falciparum* has a family of binding proteins that can recognize a number of host cell molecules, including glycophorins A, B, and C, as well as band 3. It is able to invade all stages of erythrocytes and therefore can achieve high parasitemias. *P. vivax* is more selective in its binding; it needs to recognize the Duffy chemokine receptor protein as well as reticulocyte-specific proteins; thus, it will not establish infection in Duffy-negative individuals and will only invade reticulocytes. Because of this restricted subpopulation of suitable erythrocytes, *P. vivax* rarely exceeds 1% parasitemia in the bloodstream. *P. ovale* is similar to *P. vivax* in its predilection for young red blood cells, but the mechanism of its erythrocyte recognition is unknown. *P. malariae* recognizes only senescent red cells, maintains a very low parasitemia, and typically causes an indolent infection.

P. falciparum assembles cytoadherence proteins (the PfEMP3s encoded by a highly variable family of *var* genes) into structures called *knobs* on the erythrocyte surface. This allows the parasitized erythrocyte to bind to the vascular endothelium, to avoid the spleen, and to grow in a lower oxygen environment. For the patient, the consequences are microvascular blockage in the brain and organ beds and local release of cytokines and direct vascular mediators such as nitric oxide, leading to cerebral malaria (see Craig and Scherf, 2001, and Miller *et al.*, 2002, for reviews).

Some erythrocytic parasites differentiate into sexual forms known as *gametocytes*. After infected blood is ingested by a female mosquito, exflagellation of the male gametocyte is followed by fertilization of the female gametocyte in the insect gut. The resulting zygote, which develops as an oocyst in the gut wall, eventually gives rise to sporozoites, which invade the salivary

Figure 39-1. Life cycle of malaria parasites.

gland of the mosquito. The insect then can infect a human host by taking a blood meal.

Symptomatic malaria is typified by high spiking fevers that may have a periodic pattern (see above), chills, headache, myalgias, malaise, and gastrointestinal symptoms. In addition, each *Plasmodium* species causes a distinct illness: (1) *P. falciparum* is the most dangerous. By invading erythrocytes of any age, sequestering in the vasculature, and producing endotoxin-like products, this species can cause an overwhelming parasitemia, hypoglycemia, and shock with multiorgan failure. Delay in treatment may lead to death. If treated early, the infection usually responds within 48 hours. If treatment is inadequate, *recrudescence* of infection may result. (2) *P. vivax* infection has a low mortality rate in untreated adults and is characterized by relapses caused by the reactivation of latent tissue forms. (3) *P. ovale* causes a malarial infection with a periodicity and relapses similar to those of *P. vivax*, but it is milder. (4) *P. malariae* causes a generally indolent infection that is common in localized areas of the tropics. Clinical attacks may occur years or decades after infection.

CLASSIFICATION OF ANTIMALARIAL AGENTS

Antimalarials can be categorized by the stage of the parasite that they affect and by their intended use for either prophylaxis or treatment. The various stages of the malaria life cycle that occur in humans differ from one another not only in their morphology and metabolism but also in their drug sensitivity. For this reason, the classification of antimalarial drugs is best done in the context of the life cycle (Figure 39–2).

The tabulated spectrum of activity leads to several generalizations. The first relates to prophylaxis: *Since none of the drugs kills sporozoites, it is not truly possible to prevent infection but only to prevent the development of symptomatic malaria caused by the asexual erythrocytic forms.* The second relates to treatment of an established infection: *None of the antimalarials is effective against all liver and red cell stages of the life cycle that may coexist in the same patient. Complete cure therefore may require more than one drug.*

The patterns of clinically useful activity fall into three general classes. Class I agents are not reliable against primary or latent liver stages or against *P. falciparum* gametocytes. Their action is directed against the asexual erythrocytic forms. These drugs will treat, or prevent, clinically symptomatic malaria. When used prophylactically, the class I drugs must be taken for several weeks after exposure until parasites complete the liver phase and become susceptible to therapy. The spectrum is somewhat expanded for the class II agents, which target not only the asexual erythrocytic forms but also the primary liver stages of *P. falciparum*. This additional activity shortens to several days the required period for postexposure prophylaxis. Finally, primaquine is unique in its spectrum of activity, which includes reliable efficacy against primary and latent liver stages as well as gametocytes. Primaquine has no place in the treatment of symptomatic malaria but rather is used most commonly to eradicate the hypnozoites of *P. vivax* and *P. ovale*, which are responsible for relapsing infections.

Aside from their antiparasitic activity, the utility of antimalarials for prophylaxis or therapy is dictated by their

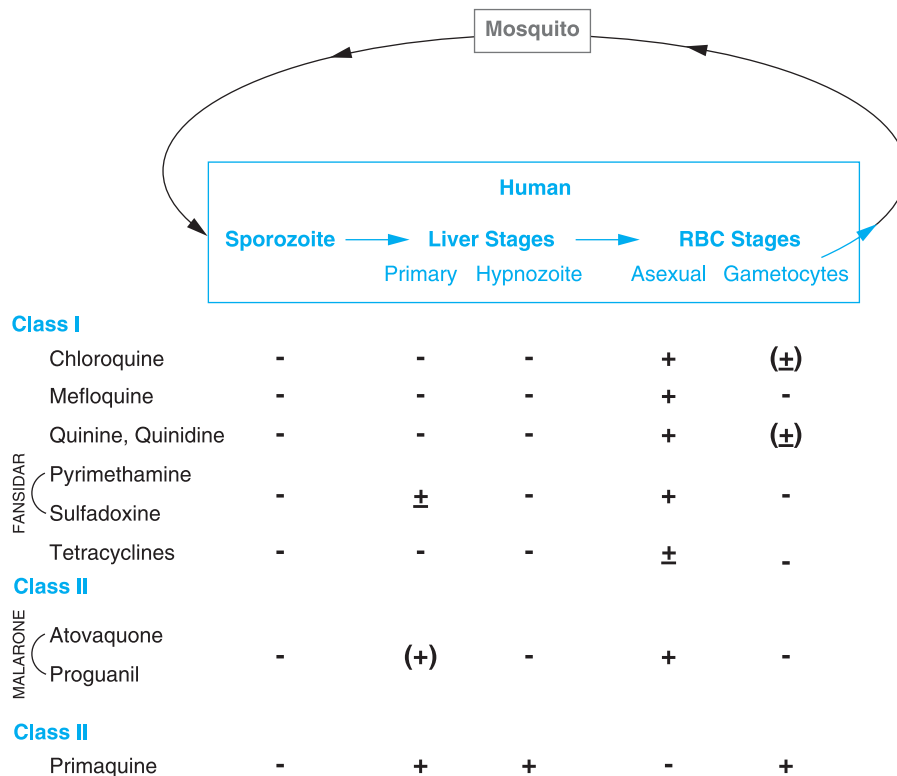

Figure 39–2. Spectrum of clinically useful activity for antimalarial drugs. For atovaquone and proguanil, reliable activity against the primary liver stage has been shown for *P. falciparum* only; for the class I agents, activity against gametocytes does not include *P. falciparum*.

pharmacokinetics and safety. Thus, quinine and primaquine, which have short half-lives and common toxicities, generally are reserved for treatment of established infection and not used for prophylaxis in a healthy traveler. In contrast, chloroquine is relatively safe and has a one-week half-life that is convenient for prophylactic dosing (in those few areas still reporting chloroquine-sensitive malaria).

Older classifications of the antimalarials are defined extensively in the 10th edition of this book. Briefly, causal prophylactics act on the initial hepatic stages, drugs for terminal prophylaxis and radical cure target hypnozoites, and agents for suppressive prophylaxis or cure target the asexual red cell forms.

Regimens currently recommended for *chemoprophylaxis* in nonimmune individuals are given in Table 39–1, whereas regimens for the *treatment* of malaria in nonimmune individuals are given in Table 39–2. Individual agents are discussed in more detail below.

ARTEMISININ AND DERIVATIVES

History. Artemisinin is a sesquiterpene lactone endoperoxide derived from the weed *qing hao* (*Artemisia annua*), also called *sweet wormwood* or *annual wormwood*. The Chinese have ascribed medicinal value to this plant for more than 2000 years (Klayman, 1985). As early as 340 A.D., Ge Hong prescribed tea made from *qing hao* as a remedy for fevers, and in 1596, Li Shizhen recommended it to relieve the symptoms of malaria. By 1972, Chinese scientists had extracted and crystallized the major antimalarial ingredient, *qinghaosu*, now known as *artemisinin*. Three semisynthetic derivatives with improved potency and bioavailability have since largely replaced the use of artemisinin. These include *dihydroartemisinin*, a reduced product; *artemether*, an oil-soluble methyl ether; and *artesunate*, the water-soluble hemisuccinate ester of dihydroartemisinin; their structures are:

As a class, the artemisinins are potent and fast-acting antimalarials with no clinical evidence of resistance. They are particularly well suited for the treatment of severe *P. falciparum* malaria and now play a key role in the combination therapy of drug-resistant infections. Millions of patients, especially in China and Southeast Asia, have been treated with endoperoxides, which generally are regarded to be safe. However, these agents have not been approved by the FDA for marketing in the United States, and inactive counterparts that closely mimic genuine drugs are common (Newton *et al.*, 2003b).

Antiparasitic Activity. Extensive structure–activity studies have confirmed the requirement for an endoperoxide moiety for antimalarial activity (O’Neill and Posner, 2004). These compounds act rapidly against the asexual erythrocytic stages of *P. vivax* and *P. falciparum*. Their potency *in vivo* is ten- to one hundredfold greater than that of other antimalarials (White, 1997). They are not cross-resistant with other drugs; indeed, sensitivity to the artemisinins may be increased paradoxically in chloroquine-resistant parasites. When used alone, the artemisinins are associated with a high level of parasite recrudescence; the reason for this is not clear but may be related to their rapid metabolism or perhaps to a post-antibiotic-like effect on the parasite. They have gametocytocidal activity but do not affect either primary or latent liver stages.

The current model of artemisinin action involves two steps (Meshnick, 2001). First, heme iron within the parasite catalyzes cleavage of the endoperoxide bridge. This is followed by rearrangement to produce a carbon-centered radical that alkylates and damages macromolecules in the parasite, likely including the ortholog of sarco/endoplasmic reticulum Ca²⁺-ATPase (Eckstein-Ludwig *et al.*, 2003). Artemisinin and its derivatives exhibit antiparasitic activity *in vitro* against other protozoa, including *Leishmania major* and *Toxoplasma gondii*, and have been used alone or in combination in patients with schistosomiasis (Utzinger *et al.*, 2003).

Absorption, Fate, and Excretion. The semisynthetic artemisinins have been formulated for several dosing routes, including oral (dihydroartemisinin, artesunate, and artemether), intramuscular (artesunate and artemether), intravenous (artesunate), and rectal (artesunate). In general, disposition of the artemisinins is incompletely understood (Giao and de Vries, 2001). Absorption after oral dosing typically is 30% or less. Peak plasma levels occur within minutes of artesunate administration and at 2 to 6 hours after artemether administration. The endoperoxides are not highly bound to plasma proteins, although the linkage may be covalent. Both artesunate and artemether are converted extensively to dihydroartemisinin, which provides much of their antimalarial activity and has a plasma half-life of just 1 to 2 hours; its major urinary metabolite is a glucuronide.

With repeated dosing, artemisinin and artesunate induce their own cytochrome P450 (CYP)-mediated metabolism, which may enhance clearance by up to fivefold. The complex and important

Table 39–1**Regimens for Malaria Chemoprophylaxis and Self-Treatment in Nonimmune Individuals***

These regimens, based on Centers for Disease Control and Prevention (CDC) recommendations current at the time of writing, may change over time. Up-to-date information should be obtained from the CDC at www.cdc.gov/travel/. Recommendations and available treatments vary in other countries.

Prophylaxis for infections with chloroquine-sensitive *P. falciparum*,[†] *P. vivax*, *P. malariae*, and *P. ovale*

Chloroquine phosphate (ARALEN) is available for oral administration. Adults take 500 mg chloroquine phosphate (300 mg base) weekly starting 1–2 weeks before entering an endemic area and continuing for 4 weeks after leaving. The pediatric dosage is 8.3 mg/kg chloroquine phosphate (5 mg base per kg, up to the maximum adult dose) taken orally by the same schedule. *Note: Primaquine phosphate* is used to eradicate latent tissue forms of *P. vivax* and *P. ovale* and effect a radical cure after individuals leave areas endemic for these infections (see Table 39–2 and text).

Prophylaxis for infections with drug-resistant strains of *P. falciparum*[‡] or *P. vivax*.[§] *Note:* The choice of regimen depends on the local geographic profile of drug resistance and other factors (see text).

Preferred regimens:

Atovaquone–proguanil (MALARONE) is available for oral dosing only as a fixed-combination tablet containing 250 mg atovaquone and 100 mg proguanil hydrochloride (adult tablet) or 62.5 mg atovaquone and 25 g proguanil hydrochloride (pediatric tablet). Adults and children over 40 kg should take one adult tablet per day beginning 1–2 days prior to exposure and continuing for 7 days after exposure. Smaller children should be dosed on the same schedule: 11–20 kg, 1 pediatric tablet daily; 21–30 kg, 2 pediatric tablets; 31–40 kg, 3 pediatric tablets. *Note:* For *P. vivax* malaria, atovaquone–proguanil may not be as effective as mefloquine. Atovaquone–proguanil is not recommended for children under 11 kg, pregnant women, or those breast-feeding infants. Contraindicated in persons with severe renal impairment.

Mefloquine hydrochloride (LARIAM) is available for oral administration only. Tablets marketed in the United States contain 250 mg mefloquine hydrochloride, equivalent to 228 mg mefloquine base (this may vary in Canada and elsewhere). The dosing below is expressed in mg salt. Adults and children over 45 kg body weight take 250 mg weekly starting 1–2 weeks before entering an endemic area and ending 4 weeks after leaving. Pediatric doses, taken by the same schedule, are 5 mg/kg for children up to 15 kg (may have to be prepared by a pharmacist); 62.5 mg ($\frac{1}{4}$ tablet) for 15–19 kg; 125 mg ($\frac{1}{2}$ tablet) for 20–30 kg; 187.5 mg ($\frac{3}{4}$ tablet) for 31–45 kg. *Note:* Mefloquine is not recommended for children weighing less than 5 kg or individuals with a history of seizures, severe neuropsychiatric disturbances, sensitivity to quinoline antimalarials, or cardiac conduction abnormalities.

Doxycycline hyclate (VIBRAMYCIN, others). Formulations of doxycycline are available in capsules, coated tablets, and liquid preparations for oral administration. The adult dose of doxycycline is 100 mg daily. For children over 8 years of age, the dosage is 2 mg/kg given once daily, up to the adult dose. Prophylaxis with doxycycline should begin 1 day before travel to an endemic area and end 4 weeks after leaving. This regimen is used in geographical areas where highly multidrug-resistant strains of *P. falciparum* are prevalent. *Note:* Doxycycline should not be given to children younger than 8 years of age or to pregnant women. Doxycycline is contraindicated in individuals who are hypersensitive to any tetracycline. Prophylaxis with doxycycline can be combined with the chloroquine phosphate regimen shown above for chloroquine-sensitive malaria. This strategy often is used in geographic areas where infection with more than one *Plasmodium* species is likely.

Primaquine phosphate USP. Tablets marketed in the United States contain 15 mg primaquine base per tablet (this may vary elsewhere); doses below are expressed as primaquine base. Primaquine may be used in special circumstances, such as when preferred agents cannot be tolerated or for multidrug-resistant *P. falciparum*. This should be done with caution and in consultation with malaria experts, such as those available through the CDC at 770-488-7788. The adult dose is 30 mg base (two tablets) daily starting several days before exposure and continued for 7 days after exposure. The same regimen at a dose of 0.6 mg/kg base is used for children. Primaquine is contraindicated in G6PD deficiency or pregnancy (see text).

Other regimens:

The mefloquine, doxycycline, or chloroquine prophylactic regimens listed above may be used together with a self-treatment regimen. The latter should be used for prompt treatment of presumed malaria if, for example, the traveler is in a very remote area. *Medical attention should be sought immediately.* The preferred regimen is *atovaquone–proguanil* (MALARONE). Adults and children greater than 41 kg should take 4 adult tablets as a single daily dose for three consecutive days; smaller children also should take adult tablets once daily for three consecutive days: 11–20 kg, 1 tablet; 21–30 kg, 2 tablets; 31–40 kg, 3 tablets.

*No chemoprophylactic regimen is always effective in preventing malaria. Recommended drug regimens always should be used in conjunction with other protective measures to avoid mosquito bites (see text). [†]These strains now exist only in Mexico, Central America west of the Panama Canal Zone, the Caribbean, and parts of South America and the Middle East; see Figure 39–4. [‡]These strains exist in other geographical areas endemic for *P. falciparum* malaria; see Figure 39–4. [§]Papua New Guinea and Indonesia are the two areas where chloroquine-resistant *P. vivax* are highly prevalent, resulting in a high failure rate with prophylaxis. Resistant *P. vivax* also has been found sporadically in India, Burma, and Central and South America.

Table 39–2**Regimens for Treatment of Malaria in the United States**

These regimens, modified from CDC recommendations current at the time of writing, may change over time. Up-to-date information should be obtained from the CDC at www.cdc.gov/travel/. Recommendations and available treatments vary in other countries.

Treatment of severe malarial infections

Note: Infections with *P. falciparum* in nonimmune or pregnant patients constitute medical emergencies because they can progress rapidly to a fatal outcome.* Chemotherapy should be initiated promptly and not await parasitological confirmation. Parenteral therapy with *quinidine gluconate* is advised for severely ill patients who cannot take oral medication; the regimen is identical for all species of *Plasmodium*. Exchange transfusion may benefit some patients.

Preferred regimen:

Quinidine gluconate is given intravenously to both adults and children starting with a loading dose of 10 mg of the salt per kg dissolved in 300 ml of normal saline and infused over 1 to 2 hours (maximum dose 600 mg of the salt). This is followed by continuous infusion at the rate of 0.02 mg of the salt per kg per minute for at least 24 hours and until oral therapy with quinine sulfate is feasible. During administration of quinidine gluconate, blood pressure (for hypotension) and ECG (for widening of the QRS complex and lengthening of the QT interval) should be monitored continuously and total blood glucose (for hypoglycemia) periodically. These complications, if severe, may warrant temporary discontinuation of the drug.

Quinine sulfate can be substituted for quinidine gluconate once patients can take oral medication. The dose for adults is 650 mg of the salt given every 8 hours. The pediatric dose is 10 mg of the salt per kg given every 8 hours. Therapy with quinidine/quinine usually is given for 3 to 7 days depending on the species of *Plasmodium* and geographical profile of drug resistance (7 days for *P. falciparum* in Southeast Asia). Previous use of mefloquine may mandate dosage reduction (*see text*).

Adjunctive therapy:

For optimal clinical response, any one of the following regimens should be used together with oral quinine sulfate therapy. The particular choice depends on the geographical profile of antimalarial drug resistance.

Doxycycline hyclate (VIBRAMYCIN, others). The adult dose is 100 mg taken orally twice a day for 7 days. For children over 8 years of age, the dosage is 2 mg/kg, increasing up to the adult dose and given by the same schedule. *Tetracycline* may be substituted if doxycycline hyclate is unavailable. Adults receive 250 mg every 6 hours for 7 days, whereas the pediatric dosage is 6.25 mg/kg every 6 hours for 7 days. *Note:* Because of adverse effects on bones and teeth, tetracyclines should not be given to children younger than 8 years of age or to pregnant women. These drugs are contraindicated in individuals who are hypersensitive to any tetracycline.

Clindamycin. The adult or pediatric dosage is 20 mg (base) per kg orally per day divided into three or four doses for 7 days.

Pyrimethamine–sulfadoxine (FANSIDAR). This combination is available for oral use only in tablets containing 25 mg pyrimethamine and 500 mg sulfadoxine. One dose is taken by mouth on the last day of quinine sulfate therapy: Adults take 3 tablets; children 5–10 kg, 0.5 tablet; 11–14 kg, 0.75 tablet; 15–20 kg, 1 tablet; 21–30 kg, 1.5 tablets; 31–40 kg, 2 tablets; 41–50 kg, 2.5 tablets; over 50 kg, 3 tablets. Owing to extensive drug resistance, pyrimethamine–sulfadoxine should be used as an adjunct treatment primarily in young children or women who are not able to tolerate clindamycin.

Other oral treatment regimens for infections with chloroquine-resistant *P. vivax*[†] and drug-resistant strains of *P. falciparum*[‡]

If quinine-based therapy cannot be used, mefloquine currently is the preferred alternative (except for Southeast Asia) but could be supplanted in this role by atovaquone–proguanil once more experience is obtained.

Mefloquine hydrochloride (LARIAM, MEPHAQUINE). The adult dose is 750 mg of the salt taken by mouth followed 6–12 hours later by 500 mg. The corresponding pediatric dose for children weighing less than 45 kg is 15 mg of the salt per kg followed 6–12 hours later by 10 mg of the salt per kg. (*Note:* The pediatric dosage is not approved by the FDA.) The initial dose should be repeated *only* if vomiting occurs within the first hour. Therapeutic doses of mefloquine may induce gastrointestinal and neuropsychiatric symptoms. Because of its long half-life and potential for serious drug interactions, extreme caution is advised in using certain antimalarial agents (*e.g.*, quinine or halofantrine) with or shortly after mefloquine. (*See text* for further details.)

(Continued)

Table 39–2
Regimens for Treatment of Malaria in the United States (Continued)

Atovaquone–proguanil hydrochloride (MALARONE). A fixed-dose combination of these drugs is available in tablets containing 250 mg atovaquone and 100 mg proguanil hydrochloride. The dose for adults is 1000 mg atovaquone plus 400 mg proguanil hydrochloride taken by mouth once each day for 3 days. The pediatric dose for children weighing 11 to 20 kg is 250 mg atovaquone plus 100 mg proguanil hydrochloride; 21 to 30 kg, 500 mg atovaquone plus 200 mg proguanil hydrochloride; 31 to 40 kg, 750 mg atovaquone plus 300 mg proguanil hydrochloride. These doses are given once daily for 3 days with food to increase drug bioavailability. If vomiting occurs within 30 minutes, the dose should be repeated. If nausea is severe, the dose may be split in half and given twice daily. Experience with children weighing under 11 kg is limited, but if necessary, pediatric tablets are available. Consult CDC recommendations for dosages.

Oral treatment of infections with *P. vivax*, *P. malariae*, *P. ovale*, and chloroquine-sensitive *P. falciparum**

Chloroquine phosphate (ARALEN) is available in 250- and 500-mg tablets (equivalent to 150 and 300 mg base, respectively) for oral administration. The adult dosage is two 500-mg tablets immediately, followed by one 500-mg tablet at 6, 24, and 48 hours. The dosage for children is 16.7 mg/kg (10 mg base per kg) immediately, followed by 8.3 mg/kg (5 mg base per kg) at 6, 24, and 48 hours, not to exceed the adult dosage.

Prevention of relapse:

To eradicate latent tissue forms of *P. vivax* and *P. ovale* that persist to cause relapses of infection, primaquine phosphate is supplied in tablets containing either 13.2 or 26.3 mg of the salt (7.5 or 15 mg base, respectively) for oral administration only. Therapy with primaquine is started after the acute attack (about day 4) at doses of 52.6 mg (30 mg base) daily for 14 days. Pediatric doses are 1.06 mg/kg (0.6 mg base per kg) daily, also for 14 days. The same primaquine regimen also can be used during the last 2 weeks of chloroquine phosphate prophylaxis for individuals who have left areas endemic for *P. vivax* or *P. ovale* infection. Alternatively, adults using chloroquine for prophylaxis against *P. vivax* or *P. ovale* may take 500 mg chloroquine phosphate (300 mg base) together with 78.9 mg primaquine phosphate (45 mg base) weekly for 8 weeks starting after leaving an endemic area to achieve a “radical” cure. Primaquine is contraindicated in pregnancy and in severe G6PD deficiency (*see text*).

*Emergency advice is available from the Division of Parasitic Diseases, Centers for Disease Control and Prevention (CDC) (telephone: 770-488-7788).

†Papua New Guinea and Indonesia are the two areas where chloroquine-resistant *P. vivax* are highly prevalent, resulting in a high failure rate. Resistant *P. vivax* also has been found sporadically in India, Burma, and Central and South America. Currently, patients acquiring *P. vivax* infections from regions other than Papua New Guinea and Indonesia should be treated with chloroquine. †See Figure 39–4.

questions of metabolic interaction between artemisinins and the other antimalarials with which they almost always are coadministered remain largely to be studied (Giao and de Vries, 2001); however, there appear to be no clinically significant pharmacokinetic or toxic interactions between the artemisinin compounds and mefloquine.

Therapeutic Uses. Given their rapid and potent activity against even multidrug-resistant parasites, the artemisinins are valuable for the initial treatment of severe *P. falciparum* infections. In this setting, intravenous artesunate compared favorably with a standard quinine regimen in terms of efficacy and safety (Newton *et al.*, 2003a). The artemisinins generally are not used alone because of their incomplete efficacy and to prevent the selection of resistant parasites. However, in a series of trials in Africa, South America, and Asia, artesunate has proven exceedingly useful when combined with other

antimalarials for the first-line treatment of malaria (Adjuik *et al.*, 2004). Artemisinin combination treatment (ACT) now is espoused because the addition of endoperoxides effects a rapid and substantial reduction of parasite burden, reduces the likelihood of resistance, and may decrease disease transmission by reducing gametocyte carriage. Artemisinins should not be used for prophylaxis because of their short half-life, incompletely characterized safety in healthy subjects, and unreliability when used alone.

Toxicity and Contraindications. Despite a relative lack of formal safety studies in humans, after three decades and use in millions of people, the artemisinins enjoy a reputation of safety (Taylor and White, 2004). There nevertheless remains a pressing need for systematic human safety data, especially in children (Johann-Liang and Albrecht, 2003). In preclinical toxicity studies, the principal target organs are brain, liver, bone marrow, and fetus.

Neurotoxicity in rats and dogs is most evident in brainstem nuclei and is more pronounced for the lipophilic derivatives. In patients, the many neurological changes that occur in severe malaria confound the evaluation of neurotoxicity; however, no systematic changes were attributable to treatment in patients older than 5 years of age. As in animals, dose-related and reversible changes have been seen in reticulocyte and neutrophil counts and in transaminase levels in patients. About 1 in 3000 patients develops an allergic reaction. The artemisinins are potent embryotoxins in animals. Only a few small studies have monitored the outcome of pregnancies in women treated with endoperoxides, but to date there are no reported increases in congenital or developmental abnormalities (McGready *et al.*, 1998). The question of early fetal loss in humans has not been studied. Given the current state of safety information, the artemisinins should be used with caution in very young children and pregnant women.

ATOVAQUONE

History. Based on the antiprotozoal activity of hydroxynaphthoquinones, atovaquone (MEPRON) was developed as a promising synthetic derivative with potent activity against *Plasmodium* species and the opportunistic pathogens *Pneumocystis carinii* and *Toxoplasma gondii* (Hudson *et al.*, 1991). After limited clinical trials, the FDA approved this compound in 1992 for treatment of mild-to-moderate *P. carinii* pneumonia in patients intolerant to trimethoprim-sulfamethoxazole (see Chapter 43). Subsequent clinical studies in patients with uncomplicated *P. falciparum* malaria revealed that atovaquone produced good initial responses but also high rates of relapse with parasites that were extremely atovaquone-resistant (Looareesuwan *et al.*, 1996). In contrast, use of proguanil with atovaquone evoked high cure rates with few relapses (of atovaquone-sensitive parasites) and minimal toxicity (Looareesuwan *et al.*, 1996, 1999b). A fixed combination of atovaquone with proguanil (MALARONE) now is available in the United States for malaria prophylaxis and treatment. Atovaquone has some efficacy against brain and eye infections with *T. gondii*, and its use in combination with other antiparasitic agents is still being explored. Atovaquone has the chemical structure shown below:

ATOVAQUONE

Antiparasitic Effects, Mechanism, and Resistance.

Atovaquone is a highly lipophilic analog of ubiquinone. In animal models and *in vitro* systems, it has potent activity against blood stages of plasmodia, tachyzoite and cyst

forms of *T. gondii*, the fungus *P. carinii*, and *Babesia* species (Hughes *et al.*, 1990; Hudson *et al.*, 1991; Hughes and Oz, 1995). It is active against liver stages of *P. falciparum* (Shapiro *et al.*, 1999) but not against *P. vivax* hypnozoites (Berman *et al.*, 2001). Atovaquone is highly potent against *P. falciparum* both in culture (IC₅₀ 0.7 to 4.3 nM) and in *Aotus* monkeys (Hudson *et al.*, 1991). This compound interferes with mitochondrial functions, such as ATP and pyrimidine biosynthesis, in susceptible malaria parasites. Thus, atovaquone acts selectively at the cytochrome bc₁ complex of malaria mitochondria to inhibit electron transport and collapse the mitochondrial membrane potential (see Vaidya and Mather, 2000). Synergism between proguanil and atovaquone appears to be due to the capacity of proguanil as a biguanide to enhance the membrane-collapsing activity of atovaquone (Srivastava and Vaidya, 1999). Atovaquone likewise affects mitochondrial function in permeabilized *T. gondii* tachyzoites (Vercesi *et al.*, 1998).

Resistance to atovaquone in *P. falciparum* develops readily *in vitro* and *in vivo* (Vaidya and Mather, 2000). Mutations in resistant organisms have been mapped to the mitochondrially encoded cytochrome b gene, particularly the region encoding the ubiquinol oxidation catalytic domain. Similar mutations have been reported in resistant isolates of rodent malaria species, as well as in *T. gondii* and perhaps *P. carinii*. The ease of selection of resistant mutants is at odds with the remarkable stability of the *P. falciparum* mitochondrial genome sequence across disparate isolates. It has been proposed that atovaquone action in the mitochondria generates mutagenic reactive oxygen species *via* electron transport blockade. This raises the interesting possibility that drug action promotes drug resistance. Resistance can be prevented by using proguanil in combination with atovaquone. It remains to be seen how long this will be effective. Atovaquone-proguanil treatment failure with drug-resistant organisms already has been documented (Fivelman *et al.*, 2002; Wichmann *et al.*, 2004).

Absorption, Fate, and Excretion. Absorption after a single oral dose is slow, erratic, and variable; increased two- to threefold by fatty food; and dose-limited above 750 mg. More than 99% of the drug is bound to plasma protein, and cerebrospinal fluid (CSF) levels are less than 1% of those in plasma. Plasma level-time profiles often show a double peak, albeit with considerable variability; the first peak appears in 1 to 8 hours, whereas the second occurs 1 to 4 days after a single dose. This pattern suggests an enterohepatic circulation, as does the long half-life, averaging 1.5 to 3 days. Humans do not metabolize atovaquone significantly. It is excreted in bile, and more than 94% of the drug is recovered unchanged in feces; only traces appear in the urine (Rolan *et al.*, 1997). Clearance of atovaquone may vary among different ethnic populations treated for *P. falciparum* malaria (Hussein *et al.*, 1997).

Therapeutic Uses. Atovaquone is used with a biguanide for prophylaxis and treatment of malaria to obtain

optimal clinical results and avoid emergence of drug-resistant plasmodial strains. A tablet containing a fixed dose of 250 mg atovaquone and 100 mg proguanil hydrochloride, taken orally, has been highly effective and safe in a 3-day regimen for treating mild-to-moderate attacks of drug-resistant *P. falciparum* malaria (Looareesuwan *et al.*, 1999a). The same regimen followed by primaquine appears to be fairly effective in treatment of *P. vivax* malaria (Looareesuwan *et al.*, 1999b; Lacy *et al.*, 2002), but experience in treatment of non-*P. falciparum* malaria is limited and should be reserved for chloroquine-resistant *P. vivax* cases in which quinine and mefloquine cannot be used. Atovaquone-proguanil also is useful for malaria prophylaxis, which can be discontinued 1 week after leaving the endemic area because both components have hepatic-phase activity. Here, as for treatment, experience in non-*P. falciparum* malaria is somewhat limited (Ling *et al.*, 2002).

Opportunistic infections owing to the fungus *P. carinii* or the protozoan *T. gondii* are especially serious threats to immunocompromised patients such as those with human immunodeficiency virus (HIV) infection and acquired immune deficiency syndrome (AIDS). Atovaquone remains an alternative for prophylaxis and treatment of pulmonary *P. carinii* infection in patients who can take oral medication but cannot tolerate trimethoprim-sulfamethoxazole or parenteral pentamidine (*see* Chapters 43 and 48 and the ninth edition of this book). *T. gondii* infections in these patients, especially cerebral lesions, have shown only limited dose-related positive responses to prolonged regimens of atovaquone (Torres *et al.*, 1997). *Toxoplasma* chorioretinitis in immunocompetent patients probably responds better to this drug (Pearson *et al.*, 1999). Atovaquone also is used in combination with azithromycin for infections owing to *Babesia* species (Krause, 2003).

Toxicity. Atovaquone causes few side effects that require cessation of therapy. The most common reactions are abdominal pain, nausea, vomiting, diarrhea, headache, and rash. Vomiting and diarrhea may result in therapeutic failure owing to decreased drug absorption. However, readministration of this drug within an hour of vomiting still may evoke a positive therapeutic response in patients with *P. falciparum* malaria (Looareesuwan *et al.*, 1999a). Patients treated with atovaquone exhibit occasional and usually transient abnormalities of serum transaminase or amylase levels.

Precautions and Contraindications. While atovaquone seems remarkably safe, the drug needs further evaluation in pediatric patients weighing less than 11 kg, pregnant women, and lactating mothers. Accordingly, the drug is not recommended in these individuals. Routine tests for carcinogenicity, mutagenicity, and teratogenicity have been negative. Further experience is necessary, especially regarding rare or long-term toxicity. Atovaquone may compete with certain drugs for binding to plasma proteins, and therapy with rifampin, a potent inducer of CYP-mediated drug metabolism, can reduce plasma levels of atovaquone substantially,

whereas plasma levels of rifampin are raised. Coadministration with tetracycline is associated with a 40% reduction in plasma concentration of atovaquone.

DIAMINOPYRIMIDINES

History. Based on their structural analogy with the antimalarial proguanil (*see* Proguanil below), in the late 1940s a large series of 2,4-diaminopyrimidines was tested for inhibitory activity against malaria parasites. Pyrimethamine (DARAPRIM) exhibited potent activity and was chosen by Hitchings for further development. Earlier studies, designed to overcome the ready selection of drug-resistant parasites, first described the profound antimalarial synergism that occurs when a sulfonamide is coadministered with proguanil. Accordingly, pyrimethamine was formulated and marketed as a fixed combination with sulfadoxine, a sulfonamide whose pharmacokinetics match those of pyrimethamine. For several decades this combination (FANSIDAR) has been used extensively for malaria therapy, especially against chloroquine-resistant strains of *P. falciparum*. Unfortunately, widespread resistance now seriously compromises its utility, and pyrimethamine-sulfadoxine is no longer recommended for prophylaxis because of the unacceptable risk of toxicity (*see* below). Because of its low cost, pyrimethamine-sulfadoxine still has some utility in the treatment of *P. falciparum* malaria in parts of Africa (Winstanley, 2001). Pyrimethamine has the following chemical structure:

Antiprotozoal Effects. Antimalarial Actions. Pyrimethamine is a slow-acting blood schizontocide with antimalarial effects *in vivo* similar to those of proguanil (*see* below). However, pyrimethamine has greater antimalarial potency, and its half-life is much longer than that of cycloguanil, the active metabolite of proguanil. Pyrimethamine's efficacy against hepatic forms of *P. falciparum* is less than that of proguanil, and at therapeutic doses, pyrimethamine fails to eradicate the latent tissue forms of *P. vivax* or gametocytes of any plasmodial species.

Action against Other Protozoa. High doses of pyrimethamine given concurrently with sulfadiazine is the preferred therapy for infection with *T. gondii* in infants and immunosuppressed individuals (*see* Chapter 40).

Mechanisms of Antimalarial Action and Resistance. The 2,4-diaminopyrimidines inhibit dihydrofolate reductase of plasmodia at concentrations far lower than those required to produce comparable inhibition of the

mammalian enzymes (Ferone *et al.*, 1969). Unlike its counterpart in human cells, the dihydrofolate reductase in malaria parasites resides on the same polypeptide chain as thymidylate synthase and, importantly, is not upregulated in the face of inhibition. The latter property contributes to the selective toxicity of the antifolates (Zhang and Rathod, 2002).

Synergism between pyrimethamine and the sulfonamides or sulfones has been attributed to inhibition of two steps in an essential metabolic pathway, although other mechanisms may contribute. The two steps involved are the utilization of *p*-aminobenzoic acid for the synthesis of dihydropteroic acid, which is catalyzed by dihydropteroate synthase and inhibited by sulfonamides, and the reduction of dihydrofolate to tetrahydrofolate, which is catalyzed by dihydrofolate reductase and inhibited by pyrimethamine. Inhibition by antifolates is manifested late in the life cycle of malarial parasites by failure of nuclear division at the time of schizont formation in erythrocytes and liver.

Several factors may affect the therapeutic response to antifolates, including host immunity to the parasite (which augments efficacy) and dietary *p*-aminobenzoic acid or folate, both of which can be imported by the malaria parasite and which can reduce drug efficacy substantially (Wang *et al.*, 1997). Resistance to pyrimethamine has developed in regions of prolonged or extensive drug use and can be attributed entirely to mutations in dihydrofolate reductase–thymidylate synthetase (Gregson and Plowe, 2005). This gene has been cloned and sequenced in strains of *P. falciparum* that are either sensitive or resistant to pyrimethamine. Several different mutations have been identified that introduce single-amino-acid changes linked to pyrimethamine resistance; these changes decrease the binding affinity of pyrimethamine for its active site in the dihydrofolate reductase moiety. The key mutation associated with pyrimethamine resistance is the substitution of asparagine for serine at position 108 (S108N). In clinical isolates from the field or with recombinant protein, it can be shown that a stepwise accumulating series of additional mutations at Arg⁵⁰, Ile⁵¹, Arg⁵⁹, and Leu¹⁶⁴ is associated with progressively increasing resistance. Interestingly, the pattern of amino acid substitutions is different in parasites resistant to cycloguanil, even though cross-resistance can occur between these structurally related inhibitors of plasmodial dihydrofolate reductase.

Absorption, Fate, and Distribution. After oral administration, pyrimethamine is slowly but completely absorbed; it reaches peak plasma levels in about 2 to 6 hours. The compound binds to plasma proteins and accumulates mainly in kidneys, lungs, liver, and spleen. It is eliminated slowly with a half-life in plasma of about 80 to 95 hours. Concentrations that are suppressive for responsive plasmodial strains remain in the blood for about 2 weeks, but these are lower in patients with malaria (Winstanley *et al.*, 1992). Several metabolites of pyrimethamine appear in the urine, but their identities and antimalarial properties have not been fully characterized. Pyrimethamine also is excreted in the milk of nursing mothers.

Therapeutic Uses. Pyrimethamine is virtually always given with either a sulfonamide or sulfone to enhance its antifolate activity, but it still acts slowly relative to the quinoline blood schizontocides, and its prolonged elimination encourages the selection of resistant parasites. The use of pyrimethamine should be restricted to the treatment of chloroquine-resistant *P. falciparum* malaria in areas where resistance to antifolates has not yet fully developed. Pyrimethamine together with a short-acting sulfonamide such as sulfadiazine also may be used as an adjunct to quinine to treat an acute malarial attack. Dosage regimens for this indication are given in Table 39–2. Pyrimethamine–sulfadoxine is no longer recommended for prophylaxis because of toxicity owing to the accompanying sulfonamide (*see below*).

High doses of pyrimethamine plus sulfadiazine are the treatment of choice for infections with *T. gondii* in immunocompromised adults; if such patients are left untreated, these infections progress rapidly to a fatal outcome (Kasper, 2001) (*see Chapter 40*). Initial therapy consists of an oral loading dose of 200 mg followed by 50 to 75 mg pyrimethamine daily for 4 to 6 weeks along with 4 to 6 g sulfadiazine daily in four divided doses. *Leucovorin* (folinic acid), 10 to 15 mg daily, should be taken for the same period to prevent bone marrow toxicity (*see below*). For subsequent long-term suppressive therapy, lower doses of pyrimethamine (25 to 50 mg daily) and sulfadiazine (2 to 4 g daily) may suffice. To deal with toxicity, pyrimethamine often has been used with agents such as *clindamycin*, *spiramycin*, or other *macrolides* (*see Kasper, 2001*). Infants with congenital, placentally transmitted toxoplasmosis usually respond positively to oral pyrimethamine (0.5 to 1.0 mg/kg daily) and oral sulfadiazine (100 mg/kg daily) given over a one year period.

Toxicity, Precautions, and Contraindications. Antimalarial doses of pyrimethamine alone cause little toxicity except occasional skin rashes and depression of hematopoiesis. Excessive doses produce a megaloblastic anemia resembling that of folate deficiency that responds readily to drug withdrawal or treatment with folinic acid. At high doses, pyrimethamine is teratogenic in animals, and in humans, trimethoprim–sulfamethoxazole therapy is associated with birth defects (Hernandez-Diaz *et al.*, 2000), but such toxicity has not been studied systematically for pyrimethamine in humans.

Sulfonamides or sulfones rather than pyrimethamine usually account for the toxicity associated with coadministration of these antifolate drugs (*see Chapter 43*). The combination of pyrimethamine (25 mg) and sulfadoxine (500 mg) (FANSIDAR) is no longer recommended for antimalarial prophylaxis because in about 1 in 5000 to 1 in 8000 individuals it causes severe and even fatal cutaneous reactions such as erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. This combination also has been associated with serum sickness–type reactions, urticaria, exfoliative dermatitis, and hepatitis. Pyrimethamine–sulfadoxine is contraindicated for individuals with previous reactions to sulfonamides, for lactating mothers, and for infants younger than 2 months of age. Administration of pyrimethamine with *dapsone* (MALOPRIM), a drug combination unavailable in the United States, occasionally has been associated with agranulocytosis. Higher doses of pyrimethamine

(75 mg daily) used along with sulfadiazine (4 to 6 g daily) to treat toxoplasmosis produce skin rashes, bone marrow suppression, and renal toxicity in about 40% of immunocompromised patients. However, much of this toxicity probably is due to sulfadiazine (*see* Kasper, 2001).

PROGUANIL

History. Proguanil (PALUDRINE) is the common name for *chloroguanide*, a biguanide derivative that emerged in 1945 as a product of British antimalarial drug research. The antimalarial activity of proguanil eventually was ascribed to cycloguanil, a cyclic triazine metabolite and selective inhibitor of the bifunctional plasmodial dihydrofolate reductase–thymidylate synthetase. Indeed, investigation of compounds bearing a structural resemblance to cycloguanil resulted in the development of antimalarial dihydrofolate reductase inhibitors such as pyrimethamine. Accrued evidence also indicates that proguanil itself has intrinsic antimalarial activity independent of its effect on parasite dihydrofolate reductase–thymidylate synthetase (*see* Fidock and Wellems, 1997).

Chemistry. Proguanil and its triazine metabolite cycloguanil have the following chemical structures:

Proguanil has the widest margin of safety of a large series of antimalarial biguanide analogs examined. Dihalogen substitution in positions 3 and 4 of the benzene ring yields *chlorproguanil* (LAPUDRINE), a more potent prodrug than proguanil that also is used clinically. Cycloguanil is structurally related to pyrimethamine.

Antimalarial Actions. In sensitive *P. falciparum* malaria, proguanil exerts activity against both the prima-

ry liver stages and the asexual red cell stages, thus adequately controlling the acute attack and usually eradicating the infection. Proguanil also is active against acute *P. vivax* malaria, but because the latent tissue stages of *P. vivax* are unaffected, relapses may occur after the drug is withdrawn. Proguanil treatment does not destroy gametocytes, but fertilized gametes encysted in the gut of the mosquito fail to develop normally.

Mechanisms of Antimalarial Action and Resistance. The active triazine metabolite of proguanil selectively inhibits the bifunctional dihydrofolate reductase–thymidylate synthetase of sensitive plasmodia, causing inhibition of DNA synthesis and depletion of folate cofactors. By cloning and sequencing dihydrofolate reductase–thymidylate synthetase genes from sensitive and resistant *P. falciparum*, investigators found that certain amino acid changes near the dihydrofolate reductase–binding site are linked to resistance to either cycloguanil, pyrimethamine, or both.

Specifically, resistance to cycloguanil (and chlorcycloguanil) can be linked to mutations leading to paired Val¹⁶/Thr¹⁰⁸ substitutions in plasmodial dihydrofolate reductase, such resistance being especially enhanced by an additional substitution at Leu¹⁶⁴. This pattern differs from that typically observed for pyrimethamine resistance described earlier. However, overlapping resistance to cycloguanil and pyrimethamine indicates that mutation patterns leading to the final resistance phenotype may be quite complex. Thus, genetic analyses of resistant *P. falciparum* strains, together with novel expression and assay systems, represent a powerful approach for identifying and monitoring new generations of antimalarials directed at vulnerable plasmodia biochemical targets (Sibley *et al.*, 2001).

The presence of plasmodial dihydrofolate reductase is not required for the intrinsic antimalarial activity of proguanil or chlorproguanil (Fidock and Wellems, 1997), but the molecular basis for this direct activity still is unknown. Proguanil as the biguanide accentuates the mitochondrial membrane-potential-collapsing action of atovaquone against *P. falciparum* but displays no such activity by itself (Srivastava and Vaidya, 1999) (*see* Atovaquone, above). In contrast to cycloguanil, resistance to the intrinsic antimalarial activity of proguanil itself, either alone or in combination with atovaquone, has yet to be well documented.

Absorption, Fate, and Excretion. Proguanil is slowly but adequately absorbed from the GI tract. After a single oral dose, peak concentrations of the drug in plasma usually are attained within 5 hours. The mean plasma elimination half-life is about 12 to 20 hours or longer depending on the rate of metabolism. Metabolism of proguanil in mammals cosegregates with mephenytoin oxidation polymorphism (Ward *et al.*, 1991) controlled by isoforms in the CYP2C subfamily. Only about 3% of Caucasians are deficient in this oxidation phenotype, as contrasted with about 20% of

Asians and Kenyans. Proguanil is oxidized to two major metabolites, cycloguanil and an inactive 4-chlorophenylbiguanide. On a 200-mg daily dosage regimen, extensive metabolizers develop plasma levels of cycloguanil that are above the therapeutic range, whereas poor metabolizers may not (Helsby *et al.*, 1993). Proguanil itself does not accumulate appreciably in tissues during long-term administration, except in erythrocytes, where its concentration is about three times that in plasma. Accumulation in infected erythrocytes could be critical for the intrinsic antimalarial effects of proguanil either by itself or with atovaquone. The inactive 4-chlorophenyl-biguanide metabolite is not readily detected in plasma but appears in increased quantities in the urine of poor proguanil metabolizers. In humans, from 40% to 60% of the absorbed proguanil is excreted in urine either as the parent drug or as the active metabolite.

Therapeutic Uses. Proguanil as a single agent is not available in the United States but is prescribed as such in England and Europe for Caucasians traveling to malarious areas. Strains of *P. falciparum* resistant to proguanil emerge rapidly in areas where the drug is used exclusively, but breakthrough infections also may result from deficient conversion of this compound to its active antimalarial metabolite. Proguanil is ineffective against multidrug-resistant strains of *P. falciparum* in Thailand and New Guinea. The drug can protect against certain strains of *P. falciparum* in sub-Saharan Africa that are resistant to chloroquine and pyrimethamine-sulfadoxine.

Proguanil is effective and well tolerated when given orally once daily for 3 days in combination with atovaquone for the treatment of malarial attacks owing to chloroquine- and multidrug-resistant strains of *P. falciparum* and *P. vivax* (see Atovaquone, above). Indeed, this drug combination (MALARONE) has been successful in Southeast Asia, where highly drug-resistant strains of *P. falciparum* prevail. *P. falciparum* readily develops clinical resistance to monotherapy with either proguanil or atovaquone, but resistance to the combination is uncommon unless the strain is initially resistant to atovaquone. In contrast, some strains resistant to proguanil do respond to proguanil plus atovaquone.

Toxicity and Side Effects. In prophylactic doses of 200 to 300 mg daily, proguanil causes few untoward effects except occasional nausea and diarrhea. Large doses (1 g or more daily) may cause vomiting, abdominal pain, diarrhea, hematuria, and the transient appearance of epithelial cells and casts in the urine. Gross accidental or deliberate overdose (as much as 15 g) has been followed by complete recovery. Doses as high as 700 mg twice daily have been taken for more than 2 weeks without serious toxicity. Proguanil is considered safe for use during pregnancy. It is remarkably safe when used in conjunction with other antimalarial drugs such as chloroquine, atovaquone, tetracyclines, and other antifolates.

QUINOLINES AND RELATED COMPOUNDS

Quinolines have been the mainstay of antimalarial chemotherapy starting with quinine nearly 400 years ago. In the last century, legions of related compounds were synthesized and tested for antimalarial activity. From these programs have come a number of drugs that are useful for the prophylaxis and treatment of malaria. The most important of these are shown in Figure 39–3.

Chloroquine and Hydroxychloroquine

History. Chloroquine (ARALEN) is one of a large series of 4-aminoquinolines investigated as part of the extensive cooperative program of antimalarial research in the United States during World War II. Beginning in 1943, thousands of compounds were synthesized and tested for activity. Chloroquine eventually proved most promising and was released for field trial. When hostilities ceased, it was discovered that the compound had been synthesized and studied as early as 1934 under the name of RESOCHIN by the Germans but rejected because of toxicity in avian models.

Chemistry. The structure of chloroquine is shown in Figure 39–3. The D, L, and DL forms of chloroquine have equal potency in duck malaria, but the D-isomer is somewhat less toxic than the L-isomer in mammals. A chlorine atom attached to position 7 of the quinoline ring confers the greatest antimalarial activity in both avian and human malarias. Research on the structure–activity relationships of chloroquine and related alkaloid compounds continues in an effort to find new, effective antimalarials with improved safety profiles that can be used successfully against chloroquine- and multidrug-resistant strains of *P. falciparum* (examples include the bisquinolines and short-chain chloroquinines).

Hydroxychloroquine (PLAQUENIL), in which one of the *N*-ethyl substituents of chloroquine is β -hydroxylated, is essentially equivalent to chloroquine against *P. falciparum* malaria. This analog is preferred over chloroquine for treatment of mild rheumatoid arthritis and lupus erythematosus because, given in the high doses required, it may cause less ocular toxicity than chloroquine (Easterbrook, 1999).

Pharmacological Effects. Antimalarial Actions. Chloroquine is highly effective against erythrocytic forms of *P. vivax*, *P. ovale*, *P. malariae*, and chloroquine-sensitive strains of *P. falciparum*. It is the prophylaxis and treatment of choice when these organisms are involved. It exerts activity against gametocytes of the first three plasmodial species but not against those of *P. falciparum*. The drug has no activity against latent tissue forms of *P. vivax* or *P. ovale*.

Other Effects. Chloroquine or its analogs are used for therapy of conditions other than malaria. Their use to treat hepatic amebiasis is

described in Chapter 40. Chloroquine and hydroxychloroquine have been used as secondary drugs to treat a variety of chronic diseases because both alkaloids concentrate in lysosomes and have anti-inflammatory properties. Thus, these compounds, often together with other agents, have clinical efficacy in rheumatoid arthritis, systemic lupus erythematosus, discoid lupus, sarcoidosis, and photosensitivity diseases such as porphyria cutanea tarda and severe polymorphous light eruption (Danning and Boumpas, 1998; Fazzi, 2003; Sarkany, 2001).

Mechanisms of Antimalarial Action and Resistance to Chloroquine and Other Antimalarial Quinolines. Asexual malaria parasites flourish in host erythrocytes by digesting hemoglobin in their acidic food vacuoles, a process that generates free radicals and heme (ferriprotoporphyrin IX) as highly reactive by-products. Perhaps aided by histidine-rich proteins and lipids, heme is sequestered as an insoluble unreactive malarial pigment termed *hemozoin*. Many theories for the mechanism of action of chloroquine have been advanced (Tilley *et al.*, 2001). The weight of the current evidence suggests that quinolines interfere with heme handling. Chloroquine concentrates in the food vacuoles of susceptible plasmodia, where it binds to heme as it is released during hemoglobin degradation and disrupts heme sequestration. Failure to inactivate heme or even enhanced toxicity of drug-heme complexes is thought to kill the parasites *via* oxidative damage to membranes, digestive proteases, and possibly other critical biomolecules. Other quinolines such as quinine, *amodiaquine*, and mefloquine, as well as other aminoalcohol analogs (*lumefantrine*, *halofantrine*) and Mannich base analogs (*pyronaridine*), may act by a similar mechanism, although differences in their actions have been proposed (Sullivan *et al.*, 1998; Tilley *et al.*, 2001).

Resistance of erythrocytic asexual forms of *P. falciparum* to antimalarial quinolines, especially chloroquine, now is common in most parts of the world (Figure 39-4). More than 5 years ago, Fitch and coworkers noted that chloroquine-sensitive *P. falciparum* parasites concentrated the drug to higher levels than did chloroquine-resistant organisms (Fitch *et al.*, 1979). Reasons for the relatively reduced levels of chloroquine in food vacuoles of chloroquine-resistant parasites have yet to be completely clarified. These could include differences in plasmodial uptake and transport of chloroquine to food vacuoles as well as differences in vacuolar influx, efflux, and trapping of drug (Tilley *et al.*, 2001).

The studies of Wellems and colleagues (Carlton *et al.*, 2001) have identified a gene (*crt*, for chloroquine resistance transporter) with alleles that confer chloroquine resistance on *P. falciparum* in culture. These alleles correlate with resistance in clinical field strains. Multiple mutations appear to be needed to confer resistance. Interestingly, different alleles confer resistance in African, Asian, and South American strains (Sidhu *et al.*, 2002). Papua New Guinea isolates have the South American pattern (Mehlotra *et al.*, 2001). The *crt* gene appears to encode a transporter that resides in the food vacuole membrane. Its physiological function is unknown, and its mechanism of action in conferring resistance to chloroquine is poorly understood. Chloroquine-resistant *P. vivax* isolates do not appear to have significant alterations in their *crt* ortholog and may have a different resistance mechanism. Isogenic strains of *P. falciparum* expressing sensitive or resistant *crt* alleles have similar sensitivity to amodiaquine, suggesting that this agent is not acted on by the chloroquine resistance mechanism (Sidhu *et al.*, 2002). The P-

glycoprotein transporter encoded by *Pfmdr1* and perhaps other transporters may play a modulatory role in chloroquine resistance (Mu *et al.*, 2003), and the glutathione system also could play a role (Ginsburg and Golenser, 2003).

Absorption, Fate, and Excretion. Chloroquine is well absorbed from the GI tract and rapidly from intramuscular and subcutaneous sites. The drug distributes relatively slowly into a very large apparent volume (over 100 L/kg) (*see* Krishna and White, 1996). This is due to extensive sequestration of chloroquine in tissues, particularly liver, spleen, kidney, lung, melanin-containing tissues, and to a lesser extent, brain and spinal cord. Chloroquine binds moderately (60%) to plasma proteins and undergoes appreciable biotransformation *via* hepatic CYPs to two active metabolites, desethylchloroquine and bisdesethylchloroquine (*see* Ducharme and Farinotti, 1996). These metabolites may reach concentrations in plasma 40% and 10% of that of chloroquine, respectively. The renal clearance of chloroquine is about half of its total systemic clearance. Unchanged chloroquine and its major metabolite account for more than 50% and 25% of the urinary drug products, respectively, and the renal excretion of both compounds is increased by acidification of the urine.

Both in adults and in children, chloroquine exhibits complex pharmacokinetics such that plasma levels of the drug shortly after dosing are determined primarily by the rate of distribution rather than the rate of elimination (*see* Krishna and White, 1996). Because of extensive tissue binding, a loading dose is required to achieve effective concentrations in plasma. After parenteral administration, rapid entry together with slow exit of chloroquine from a small central compartment can result in transiently high and potentially lethal concentrations of the drug in plasma. Hence, parenteral chloroquine is given either slowly by constant intravenous infusion or in small divided doses by the subcutaneous or intramuscular route. Chloroquine is safer when given orally because the rates of absorption and distribution are more closely matched; peak plasma levels are achieved in about 3 to 5 hours after dosing by this route. The half-life of chloroquine increases from a few days to weeks as plasma levels decline, reflecting the transition from slow distribution to even slower elimination from extensive tissue stores. The terminal half-life ranges from 30 to 60 days, and traces of the drug can be found in the urine for years after a therapeutic regimen.

Therapeutic Uses. Chloroquine is inexpensive and safe, but its usefulness has declined in those parts of the world where strains of *P. falciparum* have emerged that are relatively or absolutely resistant to its action. Except in areas where resistant strains of *P. vivax* are reported (Table 39-2), chloroquine is very effective in prophylaxis or treatment of acute attacks of malaria caused by *P. vivax*, *P. ovale*, and *P. malariae*. Chloroquine has no activity against primary or latent liver stages of the parasite. To prevent relapses in *P. vivax* and *P. ovale* infections, primaquine can be given either with chloroquine or reserved for use until after a patient leaves an endemic area. Chloroquine rapidly controls the clinical symptoms and parasitemia of acute malarial attacks. Most patients become completely afebrile within 24 to 48 hours after

receiving therapeutic doses, and thick smears of peripheral blood generally are negative by 48 to 72 hours. If patients fail to respond during the second day of chloroquine therapy, resistant strains of *P. falciparum* should be suspected and therapy instituted with quinine or another rapidly acting blood schizontocide. Although chloroquine can be given safely by parenteral routes to comatose or vomiting patients until the drug can be taken orally, quinidine gluconate usually is given in the United States. In comatose children, chloroquine is well absorbed and effective when given through a nasogastric tube. Tables 39–1 and 39–2 provide information about recommended prophylactic and therapeutic dosage regimens involving the use of chloroquine. These regimens are subject to modification according to clinical judgment, geographic patterns of chloroquine resistance, and regional usage.

Toxicity and Side Effects. Taken in proper doses, chloroquine is an extraordinarily safe drug; however, its safety margin is narrow, and a single dose of 30 mg/kg may be fatal (Taylor and White, 2004). Acute chloroquine toxicity is encountered most frequently when therapeutic or high doses are administered too rapidly by parenteral routes (*see above*). Toxic manifestations relate primarily to the cardiovascular system and the CNS. Cardiovascular effects include hypotension, vasodilation, suppressed myocardial function, cardiac arrhythmias, and eventual cardiac arrest. Confusion, convulsions, and coma indicate CNS dysfunction. Chloroquine doses of more than 5 g given parenterally usually are fatal. Prompt treatment with mechanical ventilation, epinephrine, and diazepam may be lifesaving.

Doses of chloroquine used for oral therapy of the acute malarial attack may cause GI upset, headache, visual disturbances, and urticaria. Pruritus also occurs, most commonly among dark-skinned persons. Prolonged medication with suppressive doses occasionally causes side effects such as headache, blurring of vision, diplopia, confusion, convulsions, lichenoid skin eruptions, bleaching of hair, widening of the QRS interval, and T-wave abnormalities. These complications usually disappear soon after the drug is withheld. Rare instances of hemolysis and blood dyscrasias have been reported. Chloroquine may cause discoloration of nail beds and mucous membranes. Chloroquine can interfere with the immunogenicity of certain vaccines (Horowitz and Carbonaro, 1992; Pappaioanou *et al.*, 1986).

High daily doses (>250 mg) leading to cumulative total doses of more than 1 g of base per kilogram of chloroquine or hydroxychloroquine, such as those used for treatment of diseases other than malaria, can result in irreversible retinopathy and ototoxicity. Retinopathy presumably is related to drug accumulation in melanin-rich tissues and can be avoided if the daily dose is 250 mg or less (*see Rennie, 1993*). Prolonged therapy with high doses of 4-aminoquinoline also can cause toxic myopathy, cardiopathy, and peripheral neuropathy; these reactions improve if the drug is withdrawn promptly (Estes *et al.*, 1987). Rarely, neuropsychiatric disturbances, including suicide, may be related to overdose.

Precautions and Contraindications. This topic has been reviewed by Taylor and White (2004). Chloroquine is not recommended for treating individuals with epilepsy or myasthenia gravis. The drug

should be used cautiously if at all in the presence of hepatic disease or severe gastrointestinal, neurological, or blood disorders. The dose must be adjusted in renal failure. In rare cases, chloroquine can cause hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency (*see Primaquine below*). Concomitant use of *gold* or *phenylbutazone* (no longer available in the United States) with chloroquine should be avoided because of the tendency of all three agents to produce dermatitis. Chloroquine should not be prescribed for patients with psoriasis or other exfoliative skin conditions because it causes severe reactions. It should not be used for malaria in patients with porphyria cutanea tarda but is used in smaller doses for treatment of the underlying disease (*see Chapter 63*). Chloroquine is an inhibitor of CYP2D6 and interacts with a variety of different agents. It should not be given with mefloquine because of increased risk of seizures. Most important, this antimalarial opposes the action of anticonvulsants and increases the risk of ventricular arrhythmias from coadministration with *amiodarone* or *halofantrine*. By increasing plasma levels of *digoxin* and *cyclosporine*, chloroquine also can increase the risk of toxicity from these agents. For patients receiving long-term, high-dose therapy, ophthalmological and neurological evaluations are recommended every 3 to 6 months.

Quinine and Quinidine. **History.** The medicinal use of quinine dates back more than 350 years (Rocco, 2003). Quinine is the chief alkaloid of cinchona, the powdered bark of the South American cinchona tree, otherwise known as Peruvian, Jesuit's, or Cardinal's bark. It had been used by indigenous Peruvians to treat shivering. In 1633, an Augustinian monk named Calancha, of Lima, Peru, first wrote that a powder of cinchona "given as a beverage, cures the fevers and tertians." By 1640, cinchona was used to treat fevers in Europe. The Jesuit fathers were the main importers and distributors of cinchona in Europe.

For almost two centuries the bark was employed for medicine as a powder, extract, or infusion. In 1820, Pelletier and Caventou isolated quinine from cinchona. Quinine still is a mainstay for treating attacks of chloroquine- and multidrug-resistant *P. falciparum* malaria (Table 39–2). However, multitherapy with other antimalarials is beginning to supplant quinine regimens because of increasing resistance of *P. falciparum* to quinine together with its toxicity.

Chemistry. Cinchona contains a mixture of more than 20 structurally related alkaloids, the most important of which are quinine and quinidine. Both compounds contain a quinoline group attached through a secondary alcohol linkage to a quinuclidine ring (Figure 39–3). A methoxy side chain is attached to the quinoline ring and a vinyl to the quinuclidine. They differ only in the steric configuration at two of the three asymmetrical centers: the carbon bearing the secondary alcohol group and at the quinuclidine junction. Although quinine and quinidine have been synthesized, the procedures are complex; hence they still are obtained from natural sources. Quinidine is both somewhat more potent as an antimalarial and more toxic than quinine (Karle *et al.*, 1992; Krishna and White, 1996) (cardiovascular effects are considered in Chapter 34). Structure-activity relationships of the cinchona alkaloids are detailed in earlier editions of this book. Such studies provided the basis for the discovery of more recent antimalarials such as mefloquine.

Pharmacological Effects. Antimalarial Actions. Quinine acts primarily against asexual erythrocytic forms; it has little effect on hepatic forms of malarial parasites. The alka-

loid also is gametocidal for *P. vivax* and *P. malariae* but not for *P. falciparum*. Quinine is more toxic and less effective than chloroquine against malarial parasites susceptible to both drugs. However, quinine, along with its stereoisomer quinidine, is especially valuable for the parenteral treatment of severe illness owing to drug-resistant strains of *P. falciparum*, even though these strains have become more resistant to both agents in certain parts of Southeast Asia and South America. Because of its toxicity and short half-life, quinine generally is not used for prophylaxis.

The mechanism of the antimalarial action of quinine and related quinoline antimalarials is reviewed under Chloroquine above. The basis of *P. falciparum* resistance to quinine is complex. Patterns of

P. falciparum resistance to quinine more closely resemble those of resistance to mefloquine and halofantrine rather than to chloroquine. Amplification of *pfmdr1* in *P. falciparum*, implicated in resistance to mefloquine and halofantrine, also can confer resistance to quinine *in vitro*. However, the correlation is inconsistent (Dorsey *et al.*, 2001; Sidhu *et al.*, 2002). Quinine and quinidine sensitivity also can diverge in different strains (Sidhu *et al.*, 2002). Recent evidence suggests the participation of a number of different transporter genes in conferring resistance to quinine (Mu *et al.*, 2003).

Action on Skeletal Muscle. Quinine and related cinchona alkaloids exert effects on skeletal muscle that have clinical implications. Quinine increases the tension response to a single maximal stimulus delivered to muscle directly or through nerves, but it also increases the refrac-

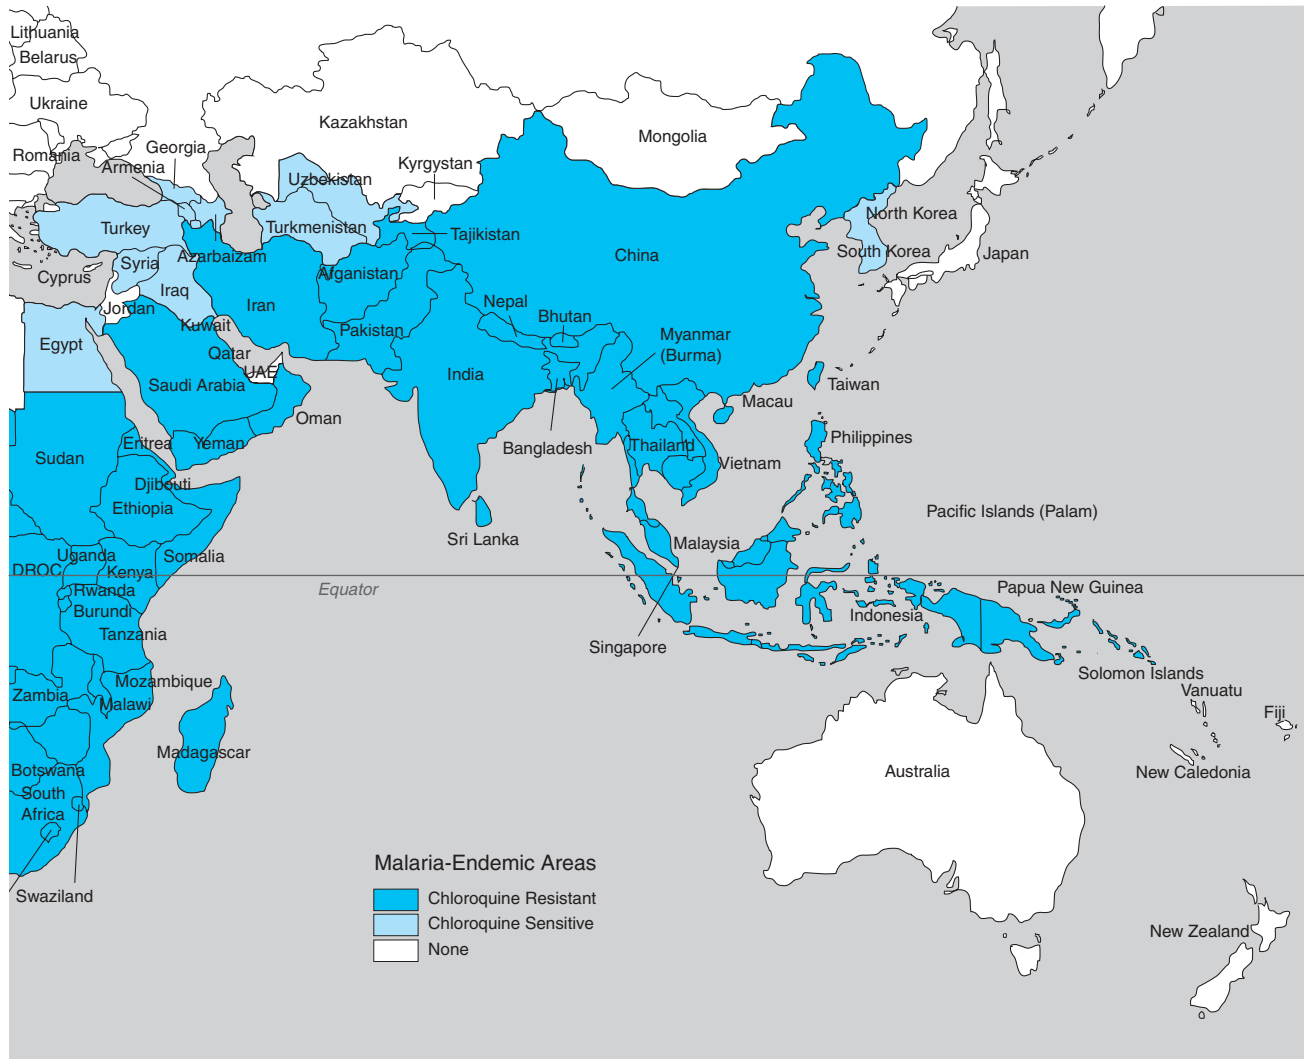

Figure 39–4. (continued) Distribution of malaria and chloroquine-resistant *Plasmodium falciparum*, 2002. From Centers for Disease Control and Prevention.

tory period of muscle so that the response to tetanic stimulation is diminished. The excitability of the motor endplate region decreases so that responses to repetitive nerve stimulation and to acetylcholine are reduced. Thus, quinine can antagonize the actions of *physostigmine* on skeletal muscle as effectively as *curare*. Quinine also may produce alarming respiratory distress and dysphagia in patients with myasthenia gravis. Quinine may cause symptomatic relief of myotonia congenita. This disease is the pharmacological antithesis of myasthenia gravis such that drugs effective in one syndrome aggravate the other.

Absorption, Fate, and Excretion. Quinine is readily absorbed when given orally or intramuscularly. In the former case, absorption

occurs mainly from the upper small intestine and is more than 80% complete, even in patients with marked diarrhea. After an oral dose, plasma levels of quinine reach a maximum in 3 to 8 hours and, after distributing into an apparent volume of about 1.5 L/kg in healthy individuals, decline with a half-life of about 11 hours after termination of therapy. As reviewed by Krishna and White (1996), the pharmacokinetics of quinine may change according to the severity of malarial infection. Values for both the apparent volume of distribution and the systemic clearance of quinine decrease, the latter more than the former, so that the average elimination half-life increases from 11 to 18 hours. After standard therapeutic doses, peak plasma levels of quinine may reach 15 to 20 mg/L in severely ill Thai patients without causing major toxicity (see below); in contrast, levels greater than 10 mg/L produce severe drug reactions in self-poisoning. The high levels of plasma α_1 -acid glycoprotein produced in severe malaria may prevent tox-

icity by binding the drug and thereby reducing the free fraction of quinine. Concentrations of quinine are lower in erythrocytes (33% to 40%) and CSF (2% to 5%) than in plasma, and the drug readily reaches fetal tissues.

The cinchona alkaloids are metabolized extensively, especially by hepatic CYP3A4 (Zhao *et al.*, 1996), so only about 20% of an administered dose is excreted unaltered in the urine. There is no accumulation of the drugs in the body on continued administration. However, the major metabolite of quinine, 3-hydroxyquinine, retains some antimalarial activity and can accumulate and possibly cause toxicity in patients with renal failure (Newton *et al.*, 1999). Renal excretion of quinine itself is more rapid when the urine is acidic.

Therapeutic Uses. Treatment of Malaria. It is a telling commentary of the current state of antimalarial therapy that quinine is the treatment of choice for drug-resistant *P. falciparum* malaria despite its antiquity and considerable toxicity. In severe illness, the prompt use of loading doses of intravenous quinine (or quinidine, where IV quinine is not available, as in the United States) is imperative and can be lifesaving. Oral medication to maintain therapeutic concentrations then is given as soon as it can be tolerated and is continued for 5 to 7 days. Especially for treatment of infections with multidrug-resistant strains of *P. falciparum*, slower-acting blood schizontocides such as a sulfonamide or a tetracycline are given concurrently to enhance the efficacy of quinine. Formulations of quinine and quinidine and specific regimens for their use in the treatment of *P. falciparum* malaria are shown in Table 39–2.

Recommendations shown in Table 39–2 are derived from practice and should be modified as appropriate. In a series of studies over the past two decades, White and associates derived rational regimens, including the institution of loading doses, for the use of quinine and quinidine in the treatment of *P. falciparum* malaria in Southeast Asia (*see* Krishna and White, 1996). Between 0.2 and 2.0 mg/L has been estimated as the therapeutic range for “free” quinine. Regimens needed to achieve this target may vary based on patient age, severity of illness, and the responsiveness of *P. falciparum* to the drug. For example, lower doses are more effective in treating children in Africa than adults in Southeast Asia because the pharmacokinetics of quinine differ in the two populations, as does the susceptibility of *P. falciparum* to the drug (Krishna and White, 1996). Dosage regimens for quinidine are similar to those for quinine, although quinidine binds less to plasma proteins and has a larger apparent volume of distribution, greater systemic clearance, and shorter terminal elimination half-life than quinine (*see* Krishna and White, 1996; Miller

et al., 1989). It has been suggested (Thompson *et al.*, 2003) that the dose of quinidine currently recommended by the Centers for Disease Control and Prevention (10 mg salt per kilogram initially, followed by 0.02 mg salt per kilogram per minute) may be too low and really should be 10 and 0.02 mg of base (60% of the salt is base). Clinical data on which to base a firm recommendation are lacking.

Treatment of Nocturnal Leg Cramps. Recumbency leg muscle cramps (night cramps) reportedly have been relieved by quinine in a dose of 200 to 300 mg (available until 1995 in products that did not require a prescription) before retiring. In some individuals, only a brief period of quinine therapy has been said to be required to provide relief, but in others, even large doses of the drug were ineffective. In 1995, the FDA issued a ruling that required drug manufacturers to stop marketing over-the-counter quinine products for nocturnal leg cramps. The FDA stated, as the basis for the ruling, that there were inadequate data to support the safety and effectiveness of quinine for use in treating nocturnal leg cramps.

Toxicity and Side Effects. The fatal oral dose of quinine for adults is about 2 to 8 g. Quinine is associated with a triad of dose-related toxicities when it is given at full therapeutic or excessive doses. These are cinchonism, hypoglycemia, and hypotension. Mild forms of cinchonism—consisting of tinnitus, high-tone deafness, visual disturbances, headache, dysphoria, nausea, vomiting, and postural hypotension—occur very frequently and disappear soon after the drug is withdrawn. Hypoglycemia also is common, mostly in the treatment of severe malaria, but can be life-threatening if not treated promptly with intravenous glucose. Hypotension is more rare but also serious and most often is associated with excessively rapid intravenous infusions of quinine or quinidine. Prolonged medication or high single doses also may produce GI, cardiovascular, and dermal manifestations. These and other drug-associated toxicities are discussed below.

Hearing and vision are particularly affected. Functional impairment of the eighth nerve results in tinnitus, decreased auditory acuity, and vertigo. Visual signs consist of blurred vision, disturbed color perception, photophobia, diplopia, night blindness, constricted visual fields, scotomata, mydriasis, and even blindness (Bateman and Dyson, 1986). The visual and auditory effects probably are the result of direct neurotoxicity, although secondary vascular changes may have a role. Marked spastic constriction of the retinal vessels occurs; the retina is ischemic, the discs are pale, and retinal edema may ensue. In severe cases, optic atrophy results.

Gastrointestinal symptoms also are prominent in cinchonism. Nausea, vomiting, abdominal pain, and diarrhea result from the local irritant action of quinine, but the nausea and emesis also have a central basis. The skin often is hot and flushed, and sweating is prominent. Rashes appear frequently. Angioedema, especially of the face, is observed occasionally.

Quinine and quinidine, even at therapeutic doses, may cause hyperinsulinemia and severe hypoglycemia through their powerful stimulatory effect on pancreatic beta cells. Despite treatment with glucose infusions, this complication can be serious and possibly life threatening, especially in pregnancy and prolonged severe infection.

Hypoglycemia is seen occasionally in uninfected patients who take quinine (Limburg *et al.*, 1993).

Quinine rarely causes cardiovascular complications unless therapeutic plasma concentrations are exceeded (Krishna and White, 1996). QTc prolongation is mild and does not appear to be affected by concurrent mefloquine treatment. However, severe hypotension is predictable when quinine is administered too rapidly by the intravenous route. Acute overdosage also may cause serious and even fatal cardiac dysrhythmias such as sinus arrest, junctional rhythms, AV block, and ventricular tachycardia and fibrillation (Bateman and Dyson, 1986). Quinidine is even more cardiotoxic than quinine; its effects on the heart are discussed in detail in Chapter 34. Cardiac monitoring of patients on intravenous quinidine is advisable where possible.

When small doses of cinchona alkaloids cause toxic manifestations, the individual usually is hypersensitive to the drug. Cutaneous flushing and pruritus, often accompanied by skin rashes, fever, gastric distress, dyspnea, ringing in the ears, and visual impairment, are the usual expressions of hypersensitivity. Hemoglobinuria and asthma from quinine may occur more rarely. “Blackwater fever”—the triad of massive hemolysis, hemoglobinemia, and hemoglobinuria leading to anuria, renal failure, and even death—is a rare type of hypersensitivity reaction to quinine therapy that occurs in pregnancy and in the treatment of malaria. Quinine may cause milder hemolysis upon occasion, especially in people with G6PD deficiency. Symptomatic thrombocytopenic purpura by an antibody- and complement-dependent mechanism also is rare, but this reaction can occur even in response to ingestion of tonic water, which has about one-twenty-fifth the therapeutic oral dose per 12 oz (“cocktail purpura”). Other rare reactions to the drug include hypoprothrombinemia, leukopenia, and agranulocytosis. High doses of quinine used to terminate pregnancy may cause fetal abnormalities.

Precautions, Contraindications, and Interactions. Quinine must be used with considerable caution, if at all, in patients who manifest hypersensitivity to the drug, especially when this takes the form of cutaneous, angioedematous, visual, or auditory symptoms. Quinine should be discontinued immediately if evidence of hemolysis appears. The drug should not be used in patients with tinnitus or optic neuritis. In patients with cardiac dysrhythmias, the administration of quinine requires the same precautions as for quinidine (see Chapter 34). Quinine appears to be fairly safe in pregnancy and is used commonly for treatment of malaria in this circumstance, but caution must be used to monitor the elevated risk of hypoglycemia.

Because parenteral solutions of quinine are highly irritating, the drug should not be given subcutaneously; concentrated solutions may cause abscesses when injected intramuscularly or thrombophlebitis when infused intravenously. Absorption of quinine from the gastrointestinal tract can be delayed by antacids containing aluminum. Quinine and quinidine can delay the absorption and elevate plasma levels of digoxin and related cardiac glycosides (see Chapters 33 and 34). Likewise, the alkaloid may raise plasma levels of *warfarin* and related anticoagulants. The action of quinine at neuromuscular junctions will enhance the effect of neuromuscular blocking agents and oppose the action of acetylcholinesterase inhibitors (see above). Prochlorperazine can amplify quinine’s cardiotoxicity, as can halofantrine. The renal clearance of quinine can be decreased by *cimetidine* and increased by acidification of the urine and by rifampin.

Mefloquine

History and Chemistry. Mefloquine (LARIAM) is a product of the Malaria Research Program established in 1963 by the Walter Reed Institute for Medical Research to develop promising new compounds to combat emerging strains of drug-resistant *P. falciparum*. Of many 4-quinoline methanols tested based on their structural similarity to quinine, mefloquine (Figure 39–3) displayed high antimalarial activity in animal models and emerged from clinical trials as safe and highly effective against drug-resistant strains of *P. falciparum* (Schmidt *et al.*, 1978). Mefloquine was first used to treat chloroquine-resistant *P. falciparum* malaria in Thailand, where it was formulated with pyrimethamine–sulfadoxine (FANSIMEF) to delay development of drug-resistant parasites. This strategy failed largely because slow elimination of mefloquine fostered the selection of resistant parasites at subtherapeutic drug concentrations (see White, 1999). Mefloquine is used for the prophylaxis and chemotherapy of drug-resistant *P. falciparum* and *P. vivax* malaria.

Antimalarial Actions. Mefloquine exists as a racemic mixture of four optical isomers with about the same antimalarial potency. It is a highly effective blood schizonticide. Mefloquine has no activity against early hepatic stages and mature gametocytes of *P. falciparum* or latent tissue forms of *P. vivax*. The drug may have some sporontocidal activity but is not used clinically for this purpose.

Mechanisms of Antimalarial Action and Resistance. The exact mechanism of action of mefloquine is unknown but may be similar to that of chloroquine (see Chloroquine, above). Certain isolates of *P. falciparum* exhibit resistance to mefloquine. The molecular basis of this resistance is not fully understood and is clearly multifactorial. The chloroquine-resistant alleles of the *pfert* gene actually confer increased sensitivity to mefloquine and some other quinolines (Sidhu *et al.*, 2002). Amplification of the *pfmdr1* gene is associated with resistance to mefloquine and quinine (Dorsey *et al.*, 2001). Correlation of mefloquine resistance with these changes is not absolute, suggesting that other factors yet to be determined are involved. The stereoselectivity of mefloquine resistance (and action) has yet to be characterized.

Absorption, Fate, and Excretion. Mefloquine is taken orally because parenteral preparations cause severe local reactions. The drug is well absorbed, a process enhanced by the presence of food. Probably owing to extensive enterogastric and enterohepatic circulation, plasma levels of mefloquine rise in a biphasic manner to their peak in about 17 hours. The drug is widely distributed, highly bound (~98%) to plasma proteins, and slowly eliminated with a terminal half-life of about 20 days. The biotransformation of mefloquine has not been well characterized in humans, although several metabolites are formed. Plasma levels of the inactive mefloquine 4-carboxylic acid exceed those of mefloquine itself and decline at about the same rate. Excretion is mainly by the fecal route; only about 10% of mefloquine appears unchanged in the urine. The stereoisomers of mefloquine exhibit quite different pharmacokinetic characteristics that relate to their biodisposition (Hellgren *et al.*, 1997). However, changes in the pharmacokinetics of racemic mefloquine that can

occur as a result of age, ethnicity, pregnancy, and malarial illness do not substantially affect dosing regimens (see Palmer *et al.*, 1993; Schlagenhauf, 1999).

Therapeutic Uses

Mefloquine should be reserved for the prevention and treatment of malaria caused by drug-resistant *P. falciparum* and *P. vivax*. The drug is especially useful as a prophylactic agent for nonimmune travelers who stay for only brief periods in areas where these infections are endemic (Table 39–1). In areas where malaria is due to drug-resistant strains of *P. falciparum*, recent evidence indicates that mefloquine is more effective when used in combination with an artemisinin compound (see Artemisinin, above).

Toxicity and Side Effects. The adverse effects of mefloquine have been reviewed in detail (Schlagenhauf, 1999; Taylor and White, 2004). Mefloquine given orally generally is well tolerated, particularly at prophylaxis dosages. Different trials vary widely with regard to frequency and severity of side effects. In part, this may be due to the varied populations studied. Early vomiting occurs more frequently at treatment dosages. Dividing the dose improves tolerance. The full dose should be repeated if vomiting occurs within the first hour. Nausea, late vomiting, dizziness, and neuropsychiatric side effects are increased at treatment dosages. Estimates for frequency of severe CNS toxicity after mefloquine treatment range up to 0.5% and include seizures, confusion or decreased sensorium, acute psychosis, and disabling vertigo. Such symptoms generally are reversible on drug discontinuation. At prophylactic dosages, the risk of serious neuropsychiatric effects is estimated to be about 0.01% (about the same as for chloroquine). Mild-to-moderate toxicities (*e.g.*, disturbed sleep, dysphoria, headache, GI disturbances, and dizziness) occur even at prophylactic dosages. Whether these symptoms are more common than with other antimalarial regimens is debated. Adverse effects usually are manifest after the first to third doses and often abate even with continued treatment. Reports of cardiac abnormalities, hemolysis, and agranulocytosis are rare.

Contraindications and Interactions. At very high doses, mefloquine causes teratogenesis and developmental abnormalities in rodents. Mefloquine is approved for use during pregnancy by the CDC and after the first trimester by the WHO. However, there have been studies suggesting an increased rate of still births with mefloquine use, especially during the first trimester (Taylor and White, 2004). The significance of these data has been debated, but it is fair to say that the evidence for mefloquine's safety in pregnancy is not fully convincing, and alternatives should be sought. Pregnancy also should be avoided for 3 months after mefloquine use because of the prolonged half-life of this agent. The drug is contraindicated for patients with a history of seizures, severe neuropsychiatric disturbances, or adverse reactions to quinoline antimalarials such as quinine, quinidine, halofantrine, mefloquine, and chloroquine. Although mefloquine can be taken safely 12 hours after a last dose of quinine, taking quinine shortly after mefloquine can be very hazardous because the latter is eliminated so slowly. Treatment with or after

halofantrine or within 2 months of prior mefloquine administration is contraindicated. Mefloquine is reported to increase the risk of seizures in epileptic patients controlled by *valproate*, and it may compromise adequate immunization by live typhoid vaccine. Until more data become available, caution is advised for use of mefloquine along with drugs that can perturb cardiac conduction. Recent studies do not indicate that mefloquine compromises the performance of tasks that require good motor coordination, for example, driving or operating machinery (Schlagenhauf, 1999). Even so, the WHO advises against use of mefloquine for patients in occupations that require great dexterity, such as pilots.

Primaquine

History. The weak plasmodicidal activity of methylene blue, first discovered by Ehrlich in 1891, later was exploited to develop the 8-aminoquinoline antimalarials. From a large series of quinoline derivatives synthesized with methoxy and substituted 8-amino groups, pamaquine was the first introduced into medicine. During World War II the search for more potent and less toxic 8-aminoquinoline antimalarials led to the selection of primaquine. This compound, in contrast with other antimalarials, acts on tissue stages (exoerythrocytic) of plasmodia in the liver to prevent and cure relapsing malaria. The striking hemolysis that may follow primaquine therapy led directly to the landmark discovery of G6PD deficiency, the first genetic disorder associated with an enzyme (Carson *et al.*, 1956) (see Chapter 4). Hemolysis remains notoriously identified with primaquine therapy, and there is a pressing need for alternatives to this important drug. 8-Aminoquinoline shows promise but needs more evaluation (Kain and Jong, 2003; Wiesner *et al.*, 2003b). The chemical structure of primaquine is shown in Figure 39–3.

Antimalarial Actions. Primaquine destroys primary and latent hepatic stages of *P. vivax* and *P. ovale* and thus has great clinical value for preventing relapses of *P. vivax* or *P. ovale* malaria. The drug will not treat ongoing attacks of malaria, even though it displays some activity against the erythrocytic stages. The 8-aminoquinolines exert a marked gametocidal effect against all four species of plasmodia that infect humans, especially *P. falciparum*. Some strains of *P. vivax* exhibit partial resistance to the action of primaquine (Smoak *et al.*, 1997), which makes it imperative that strict adherence to drug regimen be maintained and that other liver-stage antimalarials be developed.

Mechanism of Antimalarial Action. Little is known about the antimalarial action of the 8-aminoquinolines. Primaquine may be converted to electrophiles that act as oxidation–reduction mediators (see below). Such activity could contribute to antimalarial effects by generating reactive oxygen species or by interfering with electron transport in the parasite (Bates *et al.*, 1990).

Absorption, Fate, and Excretion. Primaquine causes marked hypotension after parenteral administration and therefore is given only by the oral route. Absorption from the gastrointestinal tract

is nearly complete. After a single dose, the plasma concentration reaches a maximum within 3 hours and then falls with an apparent elimination half-life of 6 hours. The apparent volume of distribution is several times that of total-body water. Primaquine is metabolized rapidly (Brueckner *et al.*, 2001); only a small fraction of an administered dose is excreted as the parent drug. Many oxidative metabolites of primaquine have been observed, but 8-(3-carboxyl-1-methylpropylamino)-6-methoxyquinoline is the major metabolite in human plasma. After a single dose, this metabolite reaches concentrations more than ten times those of primaquine; it is eliminated more slowly and accumulates with multiple doses.

Therapeutic Uses. Primaquine is used primarily for the terminal prophylaxis and radical cure of *P. vivax* and *P. ovale* (relapsing) malarias because of its high activity against the latent tissue forms of these plasmodial species. The compound is given together with a blood schizontocide, usually chloroquine, to eradicate erythrocytic stages of these plasmodia and reduce the possibility of emerging drug resistance. For terminal prophylaxis, primaquine regimens are initiated shortly before or immediately after the patient leaves an endemic area (Table 39–1). Radical cure of *P. vivax* or *P. ovale* malaria can be achieved if the drug is given either during the long-term latent period of infection or during an acute attack. Limited studies also have shown efficacy in prevention of *P. falciparum* and *P. vivax* malaria when primaquine is taken prophylactically (Taylor and White, 2004). The drug generally is well tolerated when taken for up to 1 year.

Toxicity and Side Effects. Primaquine is fairly innocuous when given to most Caucasians in the usual therapeutic doses. Primaquine can cause mild-to-moderate abdominal distress in some individuals; these symptoms often are alleviated by taking the drug at mealtime. Mild anemia, cyanosis (methemoglobinemia), and leukocytosis are less common. High doses (60 to 240 mg daily) accentuate the abdominal symptoms and cause methemoglobinemia in most subjects. Methemoglobinemia can occur even with usual doses of primaquine and can be severe in individuals with congenital deficiency of nicotinamide adenine dinucleotide (NADH) methemoglobin reductase (Coleman and Coleman, 1996). Chloroquine and dapsone may be synergistic with primaquine in producing methemoglobinemia in these patients. Granulocytopenia and agranulocytosis are rare complications of therapy and usually are associated with overdosage. Also rare are hypertension, arrhythmias, and symptoms referable to the CNS.

Therapeutic or higher doses of primaquine may cause acute hemolysis and hemolytic anemia in humans with G6PD deficiency (Taylor and White, 2004). This X-linked condition, primarily owing to amino acid substitutions in the G6PD enzyme, affects more than 200 million people worldwide. More than 400 genetic variants have been identified that are associated with variable responses to oxidative stress. About 11% of African-Americans have the A– variant of G6PD, which makes them vulnerable to hemolysis caused by oxidant drugs such as primaquine. Sensitivity of erythrocytes to pri-

maquine can be even more severe in some Caucasian ethnic groups, including Sardinians, Sephardic Jews, Greeks, and Iranians. These populations have a G6PD variant in which two amino acid substitutions impair both enzyme stability and activity. Because primaquine sensitivity is inherited by a gene on the X chromosome, hemolysis often is of intermediate severity in heterozygous females who have two populations of red cells, one normal and the other deficient in G6PD. Owing to “variable penetrance,” such females may be affected less frequently than predicted. Primaquine is the prototype of more than 50 drugs, including antimalarial sulfonamides and other substances known to cause hemolysis in susceptible individuals with G6PD deficiency (*see* Chapter 4).

Precautions and Contraindications. Patients should be tested for G6PD deficiency before they receive primaquine. Primaquine has been used cautiously in subjects with the A– form of G6PD deficiency, although benefits of treatment may not necessarily outweigh the risks. The drug should not be used in patients with more severe deficiency. The CDC recommend use only when a normal G6PD level has been documented. If a daily dose of more than 30 mg primaquine base (more than 15 mg in possibly sensitive patients) is given, repeated blood counts and at least gross examination of the urine for hemoglobin should be undertaken. Primaquine should not be used in pregnant women and can be used only in lactating mothers whose infants have a normal G6PD level.

Primaquine is contraindicated for acutely ill patients suffering from systemic disease characterized by a tendency to granulocytopenia; very active forms of rheumatoid arthritis and lupus erythematosus are examples of such conditions. Primaquine should not be given to patients receiving other potentially hemolytic drugs or agents capable of depressing the myeloid elements of the bone marrow.

Other Quinolines and Related Antimalarials

A number of quinolines and structurally related antimalarials are available outside the United States or are in development. Amodiaquine is a congener of chloroquine (Figure 39–3) that is no longer recommended in the United States for chemoprophylaxis of *P. falciparum* malaria because its use is associated with hepatic toxicity and agranulocytosis. It is inexpensive and has substantial activity in chloroquine-resistant strains; its use in endemic areas with few alternatives is being debated and reevaluated (Olliaro and Musano, 2003). *Isoquine* is an isomer of amodiaquine that may yield fewer toxic metabolites and is being assessed (Olliaro and Taylor, 2003). Pyronaridine is a Mannich-base antimalarial that is structurally related to amodiaquine (Figure 39–3). This compound, developed by the Chinese in the 1970s, was shown to be well tolerated and effective against *P. falciparum* and *P. vivax* malarias. However, it cannot be recommended for routine use at this time because of a lack of standardized dosage regimens and because its possible long-term toxicity has yet to be evaluated adequately (Winstanley, 2001). This drug currently is being developed in combination with artesunate (Olliaro and Taylor, 2003). *Piper-aquine* is a bisquinoline (shown in Figure 39–3) that has been used extensively in Asia. It has activity against chloroquine-resistant parasites and currently is being assessed as a combination with dihydroartemisinin (Ridley, 2002; Tran *et al.*, 2004). Halofantrine (HALFAN) is a phenanthrene methanol antimalarial drug (Figure 39–3) with blood schizontocidal properties similar to those of the

quinoline antimalarials. This compound was developed originally to treat acute malarial attacks caused by drug-resistant strains of *P. falciparum*. Because halofantrine displays erratic bioavailability, potentially lethal cardiotoxicity, and extensive cross-resistance with mefloquine, its use generally is not recommended. Details of the history, pharmacology, and toxicology of halofantrine are presented in the ninth edition of this book. Lumefantrine is a drug with structural similarities to mefloquine and halofantrine (Figure 39–3). It is marketed in combination with artemether (CO-ARTEM) for treatment of malaria (Ridley, 2002). It appears to be effective and well tolerated, but experience is limited.

SULFONAMIDES AND SULFONES

Shortly after their introduction into therapeutics, the sulfonamides were found to have antimalarial activity, a property investigated extensively during World War II. The sulfones also were shown to be effective; the first trial of dapsone was against *P. falciparum* in 1943. The sulfonamides are used together with pyrimethamine and often in addition to quinine to treat chloroquine-resistant *P. falciparum* malaria, especially in parts of Africa. The sulfonamides and sulfones are slow-acting blood schizontocides that are more active against *P. falciparum* than *P. vivax*. As *p*-aminobenzoate analogs that competitively inhibit the dihydropteroate synthase of *P. falciparum*, the sulfonamides are used together with an inhibitor of parasite dihydrofolate reductase to enhance their antiparasitodal action. The synergistic “antifolate” combination of sulfadoxine, a long-acting sulfonamide, with pyrimethamine (FANSIDAR) is used to treat malarial attacks in parts of Africa. The sulfone dapsone given with the biguanide chlorproguanil also has been effective for therapy of chloroquine-resistant *P. falciparum* malaria.

The future of the antimalarial antifolates appears bleak unless they are used together with more effective, rapidly acting drugs, *e.g.*, an artemisinin derivative. Long-term use of pyrimethamine–sulfadoxine, for example, is no longer recommended for prophylaxis of *P. falciparum* malaria because of potentially serious toxicity from the sulfonamide (Bjorkman and Phillips-Howard, 1991) (*see* Diaminopyrimidines, above, and Chapter 43). Moreover, resistance of *P. falciparum* to the antifolates is prevalent and develops rapidly on exposure to these agents, rendering them ineffective in many parts of the world. Mutations that cause amino acid substitutions at several different loci in the dihydropteroate synthase of *P. falciparum* confer resistance to sulfadoxine and raise the K_i values for other sulfonamides and dapsone as well. These and other mutations that accumulate during exposure to sulfonamides, together with dihydrofolate reductase mutations associated with pyrimethamine and cycloguanil resistance, can severely compromise therapy of *P. falciparum* malaria with antifolate combinations (Sibley *et al.*, 2001).

TETRACYCLINES

The tetracyclines are slow-acting blood schizontocides that are used alone for short-term prophylaxis in areas with chloroquine and mefloquine resistance. Tetracyclines are particularly useful for the treatment of the acute malarial attack owing to multidrug-resistant strains of *P. falciparum* that also show partial resistance to quinine. Their relative slowness of action makes them ineffective as single agents for malaria treatment. As an adjunct to quinine or quinidine, they are quite useful therapy (*see* Quinine, above). Several tetracyclines appear equivalent, but *tetracycline* or *doxycycline* usually is recommended. Clindamycin is an alternative. Tetracyclines have shown marked activity against primary tissue schizonts of chloroquine-resistant *P. falciparum*. Doxycycline is used alone by travelers for short-term prophylaxis of multidrug-resistant strains. Dosage regimens for tetracyclines and doxycycline are listed in Tables 39–1 and 39–2. Because of their adverse effects on bones and teeth, tetracyclines should not be given to pregnant women or children younger than 8 years of age. Photosensitivity reactions or drug-induced superinfections may mandate discontinuation of therapy or prophylaxis with these agents (*see* Chapter 46).

PRINCIPLES AND GUIDELINES FOR PROPHYLAXIS AND CHEMOTHERAPY OF MALARIA

Pharmacological control of malaria poses a difficult challenge because *P. falciparum*, which causes nearly all the deaths from human malaria, has become progressively more resistant to available antimalarial drugs. Fortunately, chloroquine still is effective against malarials caused by *P. ovale*, *P. malariae*, most strains of *P. vivax*, and chloroquine-sensitive strains of *P. falciparum* found in some geographic areas. However, chloroquine-resistant strains of *P. falciparum* now prevail in all endemic areas except Mexico, Central America west of the Panama Canal Zone, the Caribbean, and parts of South America and the Middle East (Figure 39–4). Except for parts of Africa, extensive geographic overlap also exists between chloroquine resistance and resistance to pyrimethamine–sulfadoxine, an inexpensive combination of antifolate drugs used widely for the treatment of *P. falciparum* malaria. Multidrug-resistant *P. falciparum* malaria, especially prevalent and severe in Southeast Asia and Oceania, now is well estab-

lished in South America and threatens Africa. These infections may not respond adequately even to mefloquine or quinine.

Genetic studies indicate that isolates of *P. falciparum* from patients in highly endemic areas contain many parasite clones with different drug-resistance phenotypes (Druihe *et al.*, 1998). A patient with severe malaria may have 10^{12} parasites, so it is easy to understand how single point mutations conferring resistance can arise in virtually every patient and double mutations can arise occasionally. Compounding the situation, parasites that already have developed drug-resistant traits might be even more prone to acquiring resistance to new unrelated antimalarial agents by a hypermutation mechanism (Rathod *et al.*, 1997). Therefore, drugs or drug combinations that are to be successful must not be susceptible to single-point-mutation resistance. Intense chloroquine use for decades preceded development of resistance to this agent likely because multiple mutations were necessary to confer resistance. Resistance also can be promoted by free radicals generated by atovaquone treatment in the mitochondria of the parasite; this is thought to promote development of resistance to this drug (*see* Atovaquone, above). Pharmacokinetics also can be a determinant in the generation of resistance. Drugs with a long half-life are more likely to select out resistant parasites (White, 2004). On a population level, the fitness of resistant parasites is an important parameter—if mutation causes a reduced ability to survive or grow, the parasites are less likely to spread. On the other side, in the case of antifolates, treatment actually induces gametocytogenesis, which promotes propagation and may explain the sweep of particular resistance alleles across Africa. These considerations strongly suggest using regimens consisting of two or more agents to treat drug-resistant *P. falciparum* malaria (White, 1999, 2004). Promising examples of such regimens include artemisinin combination treatments (ACT) (*see* Artemisinin, above) and proguanil together with atovaquone. Current recommendations for drugs and dosing regimens for the prophylaxis and therapy of malaria in nonimmune individuals are shown in Tables 39–1 and 39–2. These will change and should serve only as general guidelines to be modified appropriately according to the status and habitat of the patient; the geographic origin, species, and drug-resistance profile of infecting parasites; and the agents used locally for malaria control.

The following section presents an overview of the chemoprophylaxis and chemotherapy of malaria. For more details about individual drugs and their clinical applications, the reader should consult the text and references, especially Thompson and colleagues (2003), Kain and Jong (2003), and Suh and colleagues (2004) for prophylaxis and treatment; Taylor and White (2004) for toxicity; and Stauffer and Fischer (2003) for treatment of children. The latest information about malaria risk areas and prophylaxis is available from the CDC (www.cdc.gov/travel/travel). Consultation and emergency advice about treatment are available 24 hours a day from the duty officer, Division of Parasitic Diseases, CDC.

Importantly, *drugs should not replace simple, inexpensive measures for malaria prevention*. Individuals

visiting malarious areas should take appropriate steps to prevent mosquito bites. Avoiding exposure to mosquitoes at dusk and dawn, usually times of maximal feeding, is one such measure. Others include wearing long-sleeved dark clothes, using insect repellents containing at least 30% *N,N'*-diethylmetatoluamide (DEET) (Fradin and Day, 2002), and sleeping in well-screened rooms or under bed nets impregnated with a pyrethrin insecticide such as permethrin (Kain and Jong, 2003).

A number of regimens are available for malaria chemoprophylaxis. In general, dosing should be started before exposure, ideally before the traveler leaves home, to establish therapeutic blood levels and to detect early signs or symptoms of intolerance so that the regimen can be modified before departure. As described earlier, the duration of postexposure dosing is dictated by the spectrum of drug action (Figure 39–2). In those few areas where chloroquine-sensitive strains of *P. falciparum* are found, chloroquine still is suitable for prophylaxis. It also remains the drug of choice for prophylaxis and control of infections due to *P. vivax*, *P. ovale*, and *P. malariae*. In areas where chloroquine-resistant malaria is endemic, mefloquine and atovaquone–proguanil are the regimens of choice for prophylaxis. There is more experience with mefloquine and more evidence for its efficacy against *P. vivax*, which is a consideration in areas where this species coexists with *P. falciparum*. However, there are more contraindications to the use of mefloquine and perhaps more toxicity (*see* Mefloquine, above). Doxycycline is an alternative chemoprophylactic agent. In cases where mefloquine, atovaquone–proguanil, and doxycycline all are contraindicated, primaquine is a possibility for prophylaxis. Primaquine, like atovaquone–proguanil, is active against liver stages and can be discontinued shortly after leaving the endemic area. Attempts at radical cure of *P. vivax* malaria with primaquine should be delayed until the patient leaves an endemic area.

A malarial attack should be viewed as a medical emergency, especially for vulnerable populations such as non-immune travelers, pregnant women, and young children. Treatment with a rapidly acting blood schizontocide must be instituted promptly if *P. falciparum* malaria is suspected from a travel history and clinical findings. One should not wait for a definitive parasitological diagnosis in such patients because their clinical status may deteriorate rapidly. Moreover, the clinical presentation may be atypical, and thick blood smears may fail to reveal plasmodia in early stages of this infection. Chloroquine is the drug of choice for *P. vivax*, *P. ovale*, *P. malariae*, and chloro-

quine-sensitive strains of *P. falciparum*. The oral route of administration is used whenever possible, but chloroquine can be given intramuscularly or even intravenously if suitable precautions are taken, although quinine and quinidine usually are the parenteral drugs of choice (see above). Within 48 to 72 hours of initiating therapy, patients should show marked clinical improvement and a substantial decrease in parasitemia as monitored by daily thick blood smears. Lack of such a response or failure to clear parasites from the blood by 7 days is indicative of drug resistance. If chloroquine-resistant *P. falciparum* malaria is suspected, either from the travel history or from lack of response to chloroquine, the preferred treatment is quinine. For multidrug-resistant *P. falciparum* malaria, quinine is given together with other effective but slower-acting blood schizontocides such as antifolates or tetracyclines (Table 39–2) (see above). Again, the oral route of drug administration is preferred, but intravenous preparations should be given until oral medication can be taken. For parenteral therapy in the U.S., quinidine gluconate must be substituted for quinine dihydrochloride, which is no longer available. Exchange transfusion may be of additional value in severe *P. falciparum* malaria with high parasitemia (Miller *et al.*, 1989).

Attacks of malaria may recur during or after a course of anti-malarial chemotherapy, even in the absence of reinfection. Recurrent attacks caused by *P. vivax*, *P. ovale*, or *P. malariae* usually are well controlled by another course of chloroquine combined with or followed by a course of primaquine in the case of *P. vivax* or *P. ovale*. Some patients with *P. vivax* infection may require more than one course of primaquine to effect a radical cure. Recrudescence of *P. falciparum* malarial attacks or parasitemia after appropriate treatment with chloroquine usually denotes infection with chloroquine-resistant plasmodia (for clinical classification of drug resistance, see Bruce-Chwatt *et al.*, 1986). Quinine together with a slower-acting drug such as doxycycline in Southeast Asia or with antifolate antimalarials (e.g., pyrimethamine-sulfadoxine) in Africa has combated this problem successfully (Table 39–2). However, the 7-day course of treatment that often is required, the toxic doses of quinine needed to overcome increasingly drug-resistant parasites, and poor patient compliance compromise the utility of these regimens. Mefloquine is a good alternative to quinine for geographical areas where resistance is lacking, but mefloquine cannot be given parenterally. Moreover, toxic doses of mefloquine may be needed to eradicate parasites that exhibit *in vitro* cross-resistance to quinine. Especially promising compounds for treatment of multidrug-resistant *P. falciparum* malaria are the artemisinin compounds. As the most rapidly acting and potent blood schizontocides known, these endoperoxides markedly reduce parasite burden in a single life cycle and, when used to initiate therapy, make ideal partners for other drugs such as quinolines or antifolates. Parasite resistance has not been seen to date probably because of their rapid action and very short half-lives (see above). Success against multidrug-resistant *P. falciparum* malaria also has been achieved with atovaquone-proguanil.

However, this combination is relatively expensive, and treatment failure owing to resistance already is being reported (see Atovaquone, above).

Malarial infection, especially with *P. falciparum*, is a severe threat to children and pregnant women. With appropriate adjustments and safety precautions, the treatment of children generally is the same as for adults. However, tetracyclines should not be given except in an emergency to children younger than 8 years of age, and atovaquone-proguanil has been approved only for children weighing more than 11 kg. Pregnant women should be urged not to travel to endemic areas if possible. While chloroquine and proguanil may be used during pregnancy, safety documentation is not as complete as would be desired. Antifolates, tetracyclines, the artemisinins, atovaquone, and primaquine should be avoided. Quinine and quinidine can be used with appropriate caution given to the frequently accompanying hypoglycemia. Mefloquine can be used if necessary, but safety data are not quite reassuring.

In lactating mothers, treatment with most compounds is acceptable, but use of atovaquone-proguanil is not recommended. Also, the infant must be tested and found to have a normal G6PD level before using primaquine. For prophylaxis in long-term travelers (Hughes *et al.*, 2003), chloroquine is safe at the doses used, but some recommend yearly retinal examinations. Mefloquine and doxycycline are well tolerated. Atovaquone-proguanil has been studied for up to 20 weeks but probably is acceptable for years based on experience with the individual components.

NEW TARGETS

Genome analysis has suggested a number of new targets, many of which are shared with bacteria and/or plants but not mammals. The apicoplast, a specialized organelle of algal origin, appears to be important for lipid and heme biosynthesis (Ralph *et al.*, 2004). It is a major focus of current drug-development efforts. Furthest along is an inhibitor of apicoplast DoxP isoprenoid biosynthesis, fosmidomycin (Wiesner *et al.*, 2003a). This agent, developed as an antibacterial drug, has shown efficacy in combination with clindamycin against *P. falciparum* malaria in limited trials. Inhibition of phospholipid metabolism, proteases involved in hemoglobin degradation, and protein prenylation also are being studied actively, among other pathways (see Rosenthal *et al.*, 2002; Ridley, 2002).

CLINICAL SUMMARY

Agents available in the United States as antimalarials include quinolines, atovaquone, diaminopyrimidines, sulfa drugs, and tetracyclines. Long-acting quinolines such as chloroquine and mefloquine are used for prophylaxis and treatment, although resistance to chloroquine now is widespread, whereas toxicity and increasing resistance limit mefloquine's utility. Short-acting quinolines such as quinine and quinidine are important for the treatment of severe and drug-resistant malaria. Primaquine is a quinoline with activity against the latent hepatic phase of some malaria parasites and is used for radical cure of these infections. Atovaquone is a hydroxynaphthoquinone that is useful for prophylaxis and treatment when combined with proguanil (MALARONE). Diaminopyrimidines are used in combination with sulfa drugs (pyrimethamine-sulfadoxine, FANSIDAR) in therapy of chloroquine-resistant malaria or with atovaquone (as above). Tetracyclines can be used for treatment as an adjunct to other agents such as quinine or as a prophylaxis in regions where multidrug resistance occurs. The artemisinins, currently not approved for use in the United States, are a group of potent antimalarials that are used in combination treatments for drug-resistant malaria infections. Many promising combinations are being explored.

CHEMOTHERAPY OF PROTOZOAL INFECTIONS

Amebiasis, Giardiasis, Trichomoniasis, Trypanosomiasis, Leishmaniasis, and Other Protozoal Infections

Margaret A. Phillips and Samuel L. Stanley, Jr.

Humans host a wide variety of protozoal parasites that can be transmitted by insect vectors, directly from other mammalian reservoirs or from one person to another. Because protozoa multiply rapidly in their hosts and effective vaccines are unavailable, chemotherapy has been the only practical way to both treat infected individuals and reduce transmission. The immune system plays a crucial role in protecting against the pathological consequences of protozoal infections. Thus, opportunistic infections with protozoa are prominent in infants, individuals with cancer, transplant recipients, those receiving immunosuppressive drugs or extensive antibiotic therapy, and persons with advanced human immunodeficiency virus (HIV) infection. Treatment of protozoal infections in immunocompromised individuals is especially difficult, and the outcome is often unsatisfactory.

Most antiprotozoal drugs have been in use for years despite major advances in bioscience relevant to parasite biology, host defenses, and mechanisms of disease. Satisfactory agents for treating important protozoal infections such as African trypanosomiasis (sleeping sickness) and chronic Chagas' disease still are lacking. Many effective antiprotozoal drugs are toxic at therapeutic doses, a problem exacerbated by increasing drug resistance. Development of drug resistance also poses a serious threat to better-tolerated antiprotozoal agents in current use. Unfortunately, many of these diseases afflict the poor in developing countries, and there is little economic incentive for pharmaceutical companies to develop new antiparasitic drugs. In fact, there are only a few new agents available, and one, *nitazoxanide*,

represents the first drug developed and approved specifically for protozoal infections (other than malaria) in a decade. Scientists and physicians working in this field must be creative and have turned to drugs developed originally for other indications (e.g., *amphotericin* and *miltefosine* for leishmaniasis), to investigational drugs made available directly from the Centers for Disease Control and Prevention (CDC), or to agents developed for veterinary use to discover new antiparasitic therapies.

This chapter briefly describes important human protozoal infections other than malaria and the drugs used to treat them.

INTRODUCTION TO PROTOZOAL INFECTIONS OF HUMAN BEINGS

Amebiasis. Amebiasis affects about 10% of the world's population, causing invasive disease in about 50 million people and death in about 100,000 of these annually. In the United States, amebiasis is seen most commonly in the states that border Mexico and among individuals living in poverty, crowded conditions, and areas with poor sanitation. Two morphologically identical but genetically distinct species of *Entamoeba* (i.e., *E. histolytica* and *E. dispar*) have been isolated from infected persons. While the proportions vary worldwide, *E. dispar* accounts for approximately 90% of human infections, with *E. histolytica* responsible for only 10%. However, only *E. histolytica* is capable of causing disease and thus requires treatment. The two organisms can be differentiated by antigen-detection enzyme-linked immunosorbent assays (ELISAs) or by polymerase chain reaction (PCR)-based diagnostics. Humans are the only known hosts for these protozoa, which are transmitted

almost exclusively by the fecal–oral route. Ingested *E. histolytica* cysts from contaminated food or water survive acid gastric contents and transform into *trophozoites* that reside in the large intestine. The outcome of *E. histolytica* infection is variable. Many individuals remain asymptomatic but excrete the infectious cyst form, making them a source for further infections. In other individuals, *E. histolytica* trophozoites invade into the colonic mucosa with resulting colitis and bloody diarrhea (amebic dysentery). In a smaller proportion of patients, *E. histolytica* trophozoites invade through the colonic mucosa, reach the portal circulation, and travel to the liver, where they establish an amebic liver abscess.

The cornerstone of therapy for amebiasis is the nitroimidazole compound *metronidazole* or its analogs *tinidazole* and *ornidazole*. Metronidazole and tinidazole are the only nitroimidazoles available in the United States and are the drugs of choice for the treatment of amebic colitis, amebic liver abscess, and any other extraintestinal form of amebiasis. Other agents, such as dehydroemetine and chloroquine, are now used rarely in the treatment of amebic colitis or amebic liver abscess and are reserved for only very unusual cases where metronidazole is contraindicated. Because metronidazole is so well absorbed in the gut, levels may not be therapeutic in the colonic lumen, and it is less effective against cysts. Hence patients with amebiasis (amebic colitis or amebic liver abscess) also should receive a luminal agent to eradicate any *E. histolytica* trophozoites residing within the gut lumen. Luminal agents are also used to treat asymptomatic individuals found to be infected with *E. histolytica*. The nonabsorbed aminoglycoside *paromomycin* and the 8-hydroxyquinoline compound *iodoquinol* are two effective luminal agents. *Diloxanide furoate*, previously considered the luminal agent of choice for amebiasis, is no longer available in the United States. Nitazoxanide (ALINIA), a drug approved in the United States for the treatment of cryptosporidiosis and giardiasis, is also active against *E. histolytica*.

Giardiasis. Giardiasis, caused by the flagellated protozoan *Giardia intestinalis*, is prevalent worldwide and is the most commonly reported intestinal protozoal infection in the United States (Farthing, 1996). Infection results from ingestion of the cyst form of the parasite, which is found in fecally contaminated water or food. *Giardia* is a zoonosis, and cysts shed from animals or from infected humans can contaminate recreational and drinking water supplies. *Giardia* was the most common cause of waterborne outbreaks of diarrhea in the United States between 1978 and 1991 (Lengerich *et al.*, 1994). Human-to-human transmission *via* the fecal–oral route is especially common among children in day-care centers and nurseries, as well as among institutionalized individuals and male homosexuals.

Infection with *Giardia* results in one of three syndromes: an asymptomatic carrier state, acute self-limited diarrhea, or chronic diarrhea. Asymptomatic infection is most common; these individuals excrete *Giardia* cysts and serve as a source for new infections. Most adults with symptomatic infection will develop an acute self-limited illness with watery, foul-smelling stools, abdominal distension, and flatus. However, a significant proportion of these individuals go on to develop a chronic diarrhea syndrome (>2 weeks of illness) with signs of malabsorption (steatorrhea) and weight loss.

The diagnosis of giardiasis is made by identification of cysts or trophozoites in fecal specimens or of trophozoites in duodenal contents. Chemotherapy with a 5-day course of metronidazole usually is successful, although therapy may have to be repeated or

prolonged in some instances. A single dose of tinidazole (TINDAMAX) probably is superior to metronidazole for the treatment of giardiasis. The nonabsorbed aminoglycoside paromomycin has been used to treat pregnant women to avoid any possible mutagenic effects of the other drugs. Nitazoxanide, *N*-(nitrothiazolyl) *salicylamide*, and tinidazole were approved recently for the treatment of giardiasis in immune-competent children younger than 12 years of age. They join *furazolidone* as the only drugs currently approved by the Food and Drug Administration (FDA) for the treatment of giardiasis.

Trichomoniasis. Trichomoniasis is caused by the flagellated protozoan *Trichomonas vaginalis*. This organism inhabits the genitourinary tract of the human host, where it causes vaginitis in women and, uncommonly, urethritis in men. Trichomoniasis is a sexually transmitted disease, with more than 200 million people infected worldwide and at least 3 million women infected in the United States annually. Infection with *Trichomonas* has been associated with an increased risk of acquiring HIV infection.

Only *trophozoite* forms of *T. vaginalis* have been identified in infected secretions. Metronidazole remains the drug of choice for the treatment of trichomoniasis. However, treatment failures owing to metronidazole-resistant organisms are becoming more frequent (Dunne *et al.*, 2003). Tinidazole, another nitroimidazole that was approved recently by the FDA, appears to be better tolerated than metronidazole and has been used successfully at higher doses to treat metronidazole-resistant *T. vaginalis* (Sobel *et al.*, 2001). Nitazoxanide shows activity against *T. vaginalis* *in vitro* but has not undergone clinical trials and is not licensed for the treatment of trichomoniasis.

Toxoplasmosis. Toxoplasmosis is a cosmopolitan zoonotic infection caused by the obligate intracellular protozoan *Toxoplasma gondii* (Montoya and Liesenfeld, 2004). Although cats and other feline species are the natural hosts, tissue cysts (*bradyzoites*) have been recovered from all mammalian species examined. The four most common routes of infection in humans are (1) ingestion of undercooked meat containing tissue cysts; (2) ingestion of vegetable matter contaminated with soil containing infective *oocysts*; (3) direct oral contact with feces of cats shedding *oocysts*; and (4) transplacental fetal infection with *tachyzoites* from acutely infected mothers.

Primary infection with *T. gondii* produces clinical symptoms in about 10% of immunocompetent individuals. The acute illness is usually self-limiting, and treatment rarely is required. Individuals who are immunocompromised, however, are at risk of developing toxoplasmic encephalitis from reactivation of tissue cysts deposited in the brain. The vast majority of cases of toxoplasmic encephalitis are seen in patients with AIDS, in whom the disease is fatal if it is not recognized and treated appropriately. Clinical manifestations of congenital toxoplasmosis vary widely, but chorioretinitis, which may present decades after perinatal exposure, is the most commonly recognized finding. The primary treatment for toxoplasmic encephalitis consists of the antifolates *pyrimethamine* and *sulfadiazine* along with *folinic acid* (LEUCOVORIN). However, therapy must be discontinued in about 40% of cases because of toxicity owing primarily to the sulfa compound. In this instance, *clindamycin* can be substituted for sulfadiazine without loss of efficacy. Alternative regimens combining *azithromycin*, *clarithromycin*, *atovaquone*, or *dapsone* with either *trimethoprim-sulfamethoxazole* or pyrimethamine and folinic acid are less toxic but also less effective than the combination of pyrimethamine and sulfadiazine.

Spiramycin, which concentrates in placental tissue, is used for the treatment of acute acquired toxoplasmosis in pregnancy to prevent transmission to the fetus. If fetal infection is detected, the combination of pyrimethamine, sulfadiazine, and folinic acid is administered to the mother (only after the first 12 to 14 weeks of pregnancy) and to the newborn in the postnatal period.

Cryptosporidiosis. Cryptosporidia are coccidian protozoan parasites that can cause diarrhea in a number of animal species, including humans (Ramirez *et al.*, 2004). Their taxonomy is evolving, but *Cryptosporidium parvum* and the newly named *C. hominis* appear to account for almost all infections in humans. Infectious oocysts in feces may be spread either by direct human-to-human contact or by contaminated water supplies, the latter being recognized as an established route of epidemic infection. Groups at risk include travelers, children in day-care facilities, male homosexuals, animal handlers, veterinarians, and other healthcare personnel. Immunocompromised individuals are especially vulnerable. After ingestion, the mature oocyte is digested, releasing *sporozoites* that invade host epithelial cells, penetrating the cell membrane but not actually entering the cytoplasm. In most individuals, infection is self-limited. However, in AIDS patients and other immunocompromised individuals, the severity of voluminous, secretory diarrhea may require hospitalization and supportive therapy to prevent severe electrolyte imbalance and dehydration.

The most effective therapy for cryptosporidiosis in AIDS patients is restoration of their immune function through highly active antiretroviral therapy (HAART) (*see* Chapter 50). *Nitazoxanide* has shown activity in treating cryptosporidiosis in immunocompetent children and is possibly effective in immunocompetent adults as well (Rossignol *et al.*, 2001). Its efficacy in children and adults with HIV infection and AIDS is not clearly established, and it appears that the lower their CD4 count, the less likely a patient is to respond to nitazoxanide (Rossignol *et al.*, 1998; Bailey and Erramouspe, 2004). Nevertheless, it is currently the only drug approved for the treatment of cryptosporidiosis in the United States. *Paromomycin* or the combination of paromomycin and *azithromycin* has been used to treat cryptosporidiosis in AIDS patients, but in a randomized, controlled trial, paromomycin alone was no more effective than placebo for this indication (Hewitt *et al.*, 2000).

Trypanosomiasis. African trypanosomiasis, or “sleeping sickness,” is caused by subspecies of the hemoflagellate *Trypanosoma brucei* that are transmitted by bloodsucking tsetse flies of the genus *Glossinia*. Largely restricted to Central Africa, it causes serious human illness and also threatens livestock (*nagana*), leading to protein malnutrition. In humans, the infection is fatal unless treated. Owing to strict surveillance, vector control, and early therapy, the prevalence of African sleeping sickness declined to its nadir in the early 1960s. However, relaxation of these measures, together with massive population displacement and breakdowns in societal infrastructure owing to armed conflict, led to a resurgence of this disease in the 1990s (Welburn and Odiit, 2002; Abel *et al.*, 2004; Kennedy, 2004). An estimated 300,000 to 500,000 Africans carry the infection, and over 60 million people are at risk for the disease. It is extremely rare in travelers returning to the United States and can be difficult to diagnose in its more chronic form (Lejon *et al.*, 2003). The parasite is entirely extracellular, and early human infection is characterized by the finding of replicating parasites in the bloodstream without

central nervous system (CNS) involvement (stage 1). Symptoms of early-stage disease include febrile illness, lymphadenopathy, splenomegaly, and occasional myocarditis that result from systemic dissemination of the parasites. Stage 2 disease is characterized by CNS involvement. There are two types of African trypanosomiasis, the East African (Rhodesian) and West African (Gambian), caused by *T. brucei rhodesiense* and *T. brucei gambiense*, respectively. *T. brucei rhodesiense* produces a progressive and rapidly fatal form of disease marked by early involvement of the CNS and terminal cardiac failure; *T. brucei gambiense* causes illness that is characterized by later involvement of the CNS and a more long-term course that progresses to the classical symptoms of sleeping sickness over months to years. Neurological symptoms include confusion, poor coordination, sensory deficits, disruption of the sleep cycle, and eventual progression into coma and death.

There are four drugs used for the treatment of sleeping sickness, and only one, *eflornithine*, has been developed since the 1950s (Fries and Fairlamb, 2003; Fairlamb, 2003; Legros *et al.*, 2002; Bouteille *et al.*, 2003). Standard therapy for early-stage disease is *pentamidine* for *T. brucei gambiense* and suramin for *T. brucei rhodesiense*. These agents are not effective against late-stage disease, and the standard treatment of the CNS phase is *melarsoprol*, which is a highly toxic agent that causes a fatal reactive encephalopathy in about 2% to 10% of treated patients. Moreover, resistance to this agent is leading to increasing numbers of treatment failures (Maser *et al.*, 2003). All three compounds must be given parenterally over long periods (Pépin and Milord, 1994). Eflornithine, which was developed originally as an anticancer agent, offers the only alternative for the treatment of late-stage disease. This compound is an irreversible inhibitor of ornithine decarboxylase, a key enzyme in polyamine metabolism. It has shown marked efficacy against both early and late stages of human *T. brucei gambiense* infection (Pépin and Milord, 1994; Fries and Fairlamb, 2003; Burri and Brun, 2003). It notably has significantly fewer side effects than melarsoprol, and it has been shown to be effective in patients who have failed melarsoprol therapy. However, this agent is expensive and difficult to administer, leading to availability problems that have restricted its use. Further, it is ineffective as monotherapy for infections of *T. brucei rhodesiense* (*see* below). Although *T. brucei* offers a variety of attractive molecular targets for selective pharmacological intervention, few have been turned to practical advantage despite their promise in experimental systems and animal models (Wang, 1995; Fries and Fairlamb, 2003; Fairlamb, 2003).

American trypanosomiasis, or *Chagas' disease*, a zoonotic infection caused by *Trypanosoma cruzi*, affects about 18 to 20 million people from Mexico to Argentina and Chile (Urbina and Docambo, 2003; Rodrigues-Coura and deCastro; Fairlamb, 2003), where the chronic form of the disease in adults is a major cause of cardiomyopathy, megaesophagus, megacolon, and death. Blood-sucking triatomid bugs infesting poor rural dwellings most commonly transmit this infection to young children; transplacental transmission also may occur in endemic areas.

Reactivation of disease also may occur in patients who are immunosuppressed after organ transplantation or because of infection (*e.g.*, AIDS, leukemia, and other neoplasias). Occurrences of *T. cruzi* infection in transplant patients or through blood transfusions have been reported in the United States, where up to 300,000 immigrants are estimated to carry the disease. Acute infection is evidenced by a raised tender skin nodule (*chagoma*)

at the site of inoculation; other signs may be absent or range from fever, adenitis, skin rash, and hepatosplenomegaly to, albeit rarely, acute myocarditis and death. Invading metacyclic *trypomastigotes* penetrate host cells, especially macrophages, where they proliferate as *amastigotes*. The latter then differentiate into trypomastigotes that enter the bloodstream. Circulating trypomastigotes do not multiply until they invade other cells or are ingested by an insect vector during a blood meal. After recovery from the acute infection that lasts a few weeks to months, individuals usually remain asymptomatic for years despite sporadic parasitemia. During this period, their blood can transmit the parasites to transfusion recipients and accidentally to laboratory workers. An increasing fraction of adults develops overt chronic disease of the heart and gastrointestinal tract as they age. Progressive destruction of myocardial cells and neurons of the myenteric plexus results from the special tropism of *T. cruzi* for muscle cells. Whether an undefined autoimmune response also contributes to the pathogenesis of Chagas' disease is controversial, especially because recent studies with improved techniques indicate the presence of *T. cruzi* at sites of cardiac lesions. However, immunological defenses, especially cell-mediated immunity, do play a role in modulating the course of disease. Two nitroheterocyclic drugs, *nifurtimox* (available under an investigational new drug protocol from the CDC drug service) and *benznidazole* are used to treat this infection. Both agents suppress parasitemia and can cure the acute phase of Chagas' disease in 60% to 80% of cases. Their value in treating the chronic infection, however, is controversial. Several studies demonstrate that treatment can result in parasitological cure even in advanced cases, and importantly, even when patients remain positive for parasites by PCR and serological testing, treatment with these two drugs can reduce clinical symptoms. The recommendations of the Pan American Health Organization and the World Health Organization (WHO) are that patients with either acute- or recent chronic-phase disease should be treated. For patients with late chronic-phase disease (>10 years), parasitological cure is less likely, and there is no consensus on how to manage these patients. Both drugs are toxic and must be taken for long periods. Field isolates vary with respect to their susceptibility to nifurtimox and benznidazole. Moreover, resistance to both compounds can be induced in the laboratory. While both drugs can generate intracellular free radicals, their mechanisms of action and resistance are not well understood. Clearly, new drugs with better potency against parasites in the chronic phase and with reduced toxicities are needed. A number of triazole antifungal agents that inhibit sterol biosynthesis have been shown to have good activity against *T. cruzi* in animal models, and inhibitors of a cysteine protease (cruzipain) are currently being evaluated for the treatment of Chagas' disease by the Institute for One World Health. In the absence of new drugs, however, alternative measures such as improved vector control and housing accommodations have been used to reduce the transmission of Chagas' disease substantially in Brazil, Chile, and Venezuela (World Health Organization, 1999).

Leishmaniasis. Leishmaniasis is a complex vector-borne zoonosis caused by about 20 different species of obligate intramacrophage protozoa of the genus *Leishmania* (Croft and Coombs, 2003; Fairlamb, 2003; Meyerhoff, 1999). Small mammals and canines generally serve as reservoirs for these pathogens, which can be transmitted to humans by the bites of some 30 different species of female phlebotomine sandflies. Various forms of leishmaniasis

affect people in southern Europe and many tropical and subtropical regions throughout the world. Flagellated extracellular free *promastigotes*, regurgitated by feeding flies, enter the host, where they attach to and become phagocytized by tissue macrophages. There they transform into *amastigotes*, which reside and multiply within phagolysosomes until the cell bursts. Released amastigotes then propagate the infection by invading more macrophages. Amastigotes taken up by feeding sandflies transform back into promastigotes, thereby completing the transformation cycle. The particular localized or systemic disease syndrome caused by *Leishmania* depends on the species or subspecies of infecting parasite, the distribution of infected macrophages, and especially the host's immune response. In increasing order of systemic involvement and potential clinical severity, major syndromes of human leishmaniasis have been classified into *cutaneous*, *mucocutaneous*, *diffuse cutaneous*, and *visceral (kala azar)* forms. Leishmaniasis increasingly is becoming recognized as an AIDS-associated opportunistic infection (Berman, 1997).

The classification, clinical features, course, and chemotherapy of the various human leishmaniasis syndromes have been reviewed recently, in addition to the biochemistry and immunology of the parasite and host germane to chemotherapy (Herwaldt, 1999; Croft and Coombs, 2003). Cutaneous forms of leishmaniasis generally are self-limiting, with cures occurring within 3 to 18 months after infection. However, this form of the disease can leave disfiguring scars. The mucocutaneous, diffuse cutaneous, and visceral forms of the disease do not resolve without therapy. Visceral leishmaniasis caused by *L. donovani* is fatal unless treated. The list of current drugs useful for the treatment of all forms of leishmaniasis has been described recently in several reviews (Berman, 2003; Croft and Coombs, 2003; Fries and Fairlamb, 2003). The classic therapy for all species of *Leishmania* is *pentavalent antimony*; however, increasing resistance to this compound has been encountered. Liposomal *amphotericin B* is a highly effective agent for visceral leishmaniasis, and it is currently the drug of choice for antimony-resistant disease, although the high cost has been a barrier to its clinical use (see Chapter 48). Importantly, treatment of leishmania is currently undergoing major changes owing to the success of the first orally active agent, *miltefosine*, in clinical trials (Sundar *et al.*, 2002; Jha *et al.*, 1999). Miltefosine was approved in India for the treatment of visceral leishmaniasis in 1992. The drug also appears to have promise for the treatment of the cutaneous disease and for the treatment of dogs, which serve as an important animal reservoir of the disease. Paromomycin and pentamidine both have been used with success as parenteral agents for visceral disease, although the usefulness of pentamidine has been limited by toxicity. Topical formulations of paromomycin, recently combined with *gentamicin*, have also shown effectiveness against cutaneous disease in studies conducted by the Walter Reed Institute of Research.

Other Protozoal Infections. Just a few of the many less common protozoal infections of humans are highlighted here.

Babesiosis, caused by either *Babesia microcoti* or *B. divergens*, is a tick-borne zoonosis that superficially resembles malaria in that the parasites invade erythrocytes, producing a febrile illness, hemolysis, and hemoglobinuria. This infection usually is mild and self-limiting but can be severe or even fatal in asplenic or severely immunocompromised individuals. Currently recommended therapy is with a combination of *clindamycin* and *quinine*, but a combination of azithromycin and atovaquone was found to be as effective in

treating adults with babesiosis and was associated with fewer adverse effects (Krause *et al.*, 2000).

Balantidiasis, caused by the ciliated protozoan *Balantidium coli*, is an infection of the large intestine that may be confused with amebiasis. Unlike amebiasis, however, this infection usually responds to tetracycline therapy.

Isoospora belli, a coccidian parasite, causes diarrhea in AIDS patients, and responds to treatment with trimethoprim-sulfamethoxazole. *Cyclospora cayentanensis*, another coccidian parasite, causes self-limited diarrhea in normal hosts and can cause prolonged diarrhea in individuals with AIDS. It too is susceptible to trimethoprim-sulfamethoxazole. Microsporidia are spore-forming unicellular eukaryotic fungal parasites that can cause a number of disease syndromes, including diarrhea in immunocompromised individuals. Infections with microsporidia of the *Encephalitozoon* genus, including *E. hellum*, *E. intestinalis*, and *E. cuniculi*, have been treated successfully with albendazole, a derivative of benzimidazole and inhibitor of β -tubulin polymerization (Gross, 2003) (see Chapter 41). Immunocompromised individuals with intestinal microsporidiosis owing to *E. bienewisi* (which does not respond as well to albendazole) have been treated successfully with the antibiotic fumagillin (Molina *et al.*, 2002).

AMPHOTERICIN

The pharmacology, formulation, and toxicology of amphotericin are presented in Chapter 48. Only those features of the drug pertinent to its use in leishmaniasis are described here.

Antiprotozoal Effects. In 1997, the FDA approved liposomal amphotericin B (AMBISOME) for the treatment of visceral leishmaniasis. Amphotericin is a highly effective antileishmanial agent that cures nearly 100% of the cases of visceral leishmaniasis in clinical studies, and it has become the drug of choice for antimonial-resistant cases (Berman, 2003; Fries and Fairlamb, 2003). The drug has not been useful against cutaneous or mucosal leishmaniasis, which likely has its basis in pharmacokinetic considerations. The lipid preparations of the drug have reduced toxicity, but the cost of the drug and the difficulty of administration remain a problem in endemic regions.

The mechanism of action of amphotericin against leishmania is similar to the basis for the drug's antifungal activities (see Chapter 48). Amphotericin complexes with ergosterol precursors in the cell membrane, forming pores that allow ions to enter the cell. Leishmania has similar sterol composition to fungal pathogens, and the drug binds to these sterols preferentially over the host cholesterol. No significant resistance to the drug has been encountered after nearly 30 years of use as an antifungal agent.

Therapeutic Uses. The recommended dose for the treatment of visceral leishmaniasis is 3 mg/kg per day intravenously for days 1 to 5, 14, and 21, with the dose being increased to 4 mg/kg and extended to days 1 to 5, 10, 17, 24, 31, and 38 for immunosuppressed patients (Fairlamb, 2003). Shorter courses of the drug have been tested with good efficacy and provide a potential alternative with lower cost. Cure rates of 93% and 89% were found for 5-

day dosing of 7.5 and 3.75 mg/kg, respectively, and a single injection of 5 mg/kg cured 91% of patients in a 46-person trial (Berman, 2003).

CHLOROQUINE

The pharmacology and toxicology of chloroquine are presented in Chapter 39. Only those features of the drug pertinent to its use in amebiasis are described here.

Chloroquine is directly toxic to *E. histolytica* trophozoites and is highly concentrated within the liver, making it an effective therapy for amebic liver abscess. However, it is not as effective as metronidazole and should be used to treat amebic liver abscess only when metronidazole or another nitroimidazole compound is either contraindicated or not available. Chloroquine is not effective against intestinal amebiasis because it is absorbed in the small bowel and attains low concentrations in the colonic lumen and wall. Anyone receiving chloroquine for the treatment of amebic liver abscess also should receive a luminal agent (paromomycin or iodoquinol) to eliminate *E. histolytica* intestinal colonization.

The conventional course of treatment with chloroquine phosphate for extraintestinal amebiasis in adults is 1 g/day for 2 days, followed by 500 mg/day for at least 2 to 3 weeks. Because of the low toxicity of this drug, this dose can be increased or the schedule can be repeated if necessary.

DILOXANIDE FUROATE

Diloxanide furoate (FURAMIDE) is the furoate ester of diloxanide, a derivative of dichloroacetamide. Diloxanide furoate is a very effective luminal agent for the treatment of *E. histolytica* infection but is no longer available in the United States. The reader is referred to the 10th edition of this book for further details on this agent.

EFLORNITHINE

History. Eflornithine (α -difluoromethylornithine, DFMO, ORNIDYL) is an irreversible catalytic (suicide) inhibitor of ornithine decarboxylase, the enzyme that catalyzes the first and rate-limiting step in the biosynthesis of polyamines (Marton and Pegg, 1995; Igarashi and Kashiwagi, 2000; Seiler, 2003). The polyamines—putrescine, spermidine, and in mammals, spermine—are required for cell division and for normal cell differentiation. In trypanosomes, spermidine additionally is required for the synthesis of trypanothione, which is a conjugate of spermidine and glutathione that replaces many of the functions of glutathione in the parasite cell (Fries and Fairlamb, 2003; Fairlamb, 2003). Both in animal models and *in vitro*, eflornithine arrests the growth of several types of tumor cells, providing the basis for its clinical evaluation as an antitumor agent (Seiler, 2003). The discovery that eflornithine cured rodent infections with *T. brucei* first focused attention on protozoal polyamine biosynthesis as a potential target for chemotherapeutic attack (Bacchi *et al.*, 1980). Eflornithine currently is used to treat West African (Gambian) trypanosomiasis caused by *T. brucei gambiense* (Fries and Fairlamb, 2003; Fairlamb, 2003; Pépin and Milord,

1994; Mpia and Pépin, 2002; Burri and Brun, 2003). The drug usually is curative even for late CNS stages of infection resistant to arsenical trypanocides. In contrast, this compound is largely ineffective for East African trypanosomiasis, and its high cost, coupled with production shortages and the difficult treatment regimen, had limited its application in the field (Burri and Brun, 2003). However, recent studies have sparked renewed interest in the potential of eflornithine as both a chemopreventive agent for people at high risk for various types of epithelial cancers (Meyskens and Gerner, 1999) and for its use to reduce facial hair in woman (Wickware, 2002). The marketing of the compound for this latter use has enabled a stable supply of the drug to be provided to the WHO through 2006. Eflornithine is no longer available for systemic use in the United States but may be available for treatment of Gambian trypanosomiasis by special request from the WHO. The chemical structure of eflornithine is:

Antitrypanosomal Effects. The effects of eflornithine have been evaluated both on drug-susceptible and drug-resistant *T. brucei* *in vitro* and in infections with these parasites in rodent models (Fries and Fairlamb, 2003; Fairlamb, 2003). Eflornithine is a cytostatic agent that has multiple biochemical effects on trypanosomes, all of which are a consequence of polyamine depletion. The polyamine putrescine is depleted to undetectable levels, whereas both spermidine and trypanothine levels are reduced by 25% to 50%, and methionine metabolism is altered. Depletion of the polyamines, or of trypanothione, would be expected to be lethal to the cells based on genetic studies that have disrupted the biosynthetic genes in the pathway. As a consequence, macromolecular biosynthesis is depressed, and the parasites transform from the long, slender dividing forms into the short, stumpy nonreplicating forms. These latter parasites are unable to synthesize variable cell surface glycoprotein and eventually are cleared by the immune system.

The molecular mechanism of eflornithine action clearly has been established to be inhibition of ornithine decarboxylase, whereas the mechanisms of selective toxicity are still debated (Fries and Fairlamb, 2003; Fairlamb, 2003; Wang, 1997). Eflornithine irreversibly inhibits both mammalian and trypanosomal ornithine decarboxylases, thereby preventing the synthesis of putrescine, a precursor of polyamines needed for cell division. Eflornithine inactivates the enzyme through covalent labeling of an active-site cysteine residue, and an X-ray structure of the *T. brucei* enzyme bound to the drug has been reported (Grishin *et al.*, 1999). A number of studies demonstrate conclusively that ornithine decarboxylase is the target of eflornithine action that leads to cell death. Mutant bloodstream trypanosomes lacking ornithine decarboxylase or wild-type trypanosomes treated with eflornithine cannot replicate, and mice inoculated with these null parasites become resistant to infection by wild-type parasites (Li *et al.*, 1998; Mutomba *et al.*, 1999). The

product of the ornithine decarboxylase reaction, putrescine, rescues the growth deficit in both the mutant parasites and eflornithine-treated cells. The null mutant parasites grown with putrescine are not affected by eflornithine, demonstrating the selectivity of the drug for the target enzyme.

The mechanisms of selective toxicity between the host and parasite, or between the different species of *T. brucei*, are less clear (Wang, 1995; Fries and Fairlamb, 2003). The parasite and human enzymes are equally susceptible to inhibition by eflornithine; however, the mammalian enzyme is turned over rapidly, whereas the parasite enzyme is stable, and this difference likely plays a role in the selective toxicity. In addition, mammalian cells may be able to replenish polyamine pools through uptake of extracellular polyamines, whereas the slender bloodstream forms of human trypanosomes divide within human blood, which contains only very low levels of these essential compounds. Further, the parasites lack efficient transport mechanisms.

T. brucei rhodesiense cells are less sensitive to eflornithine inhibition than *T. brucei gambiense* cells, and studies *in vitro* suggest that the effective doses are increased by 10 to 20 times in the refractory cells (Matovu *et al.*, 2001). The molecular basis for the higher dose requirement in *T. brucei rhodesiense* is still poorly understood; however, it has been postulated to involve differences both in enzyme stability and in the metabolism of *S*-adenosylmethionine compared with the sensitive *T. brucei gambiense* cell lines (Fries and Fairlamb, 2003).

Absorption, Fate, and Excretion. Eflornithine is given by either the intravenous or the oral route; its bioavailability after oral administration is about 54%. Peak plasma levels are achieved about 4 hours after an oral dose, and the elimination half-life averages about 200 minutes. The drug does not bind to plasma proteins but is well distributed and penetrates into the cerebrospinal fluid (CSF). The latter property is especially important in late-stage African trypanosomiasis, where CSF:plasma ratios exceeding 0.9 have been reported. Over 80% of eflornithine is cleared by the kidney largely in unchanged form. There is some evidence that eflornithine displays dose-dependent pharmacokinetics at the highest doses used clinically (Burri and Brun, 2003).

Therapeutic Uses. Experience with the use of eflornithine for the treatment of West African trypanosomiasis owing to *T. brucei gambiense* has been well summarized (Van Nieuwenhove, 1992; Pépin *et al.*, 2000; Mpia and Pépin, 2002). Most patients reported had advanced disease with CNS complications, and many had received arsenicals prior to treatment with eflornithine. The preferred regimen for adult patients was found to be 100 mg/kg given intravenously every 6 hours for 14 days. Virtually all patients improved on this regimen unless they were extremely ill, and the WHO reported improvement rates exceeding 90% in late-stage patients. Clinical trials have been conducted on a 7-day course, which was found to be effective for relapsing cases. A higher risk of treatment failure overall was found in patients who were stuporous on admission or were older (Pépin *et al.*, 2000). Children younger than 12 years of age required higher doses of

eflornithine, probably because they clear the drug more rapidly than do adults and because the drug does not reach the CNS as well. To avoid early convulsions, which could be more frequent in children receiving higher doses, a regimen using the current intravenous dosage (400 mg/kg per day) in the first few days, followed by an increase for the second part of therapy, has been proposed (Milord *et al.*, 1993). A recent study combining eflornithine with melarsoprol suggests that the drugs may act synergistically (Mpia and Pépin, 2002); however, the potential for improving treatment by combining eflornithine with other antitrypanosomal agents remains unexplored.

Equal doses of eflornithine were less effective when given by the oral route probably because of limited bioavailability. The problem cannot be overcome simply by increasing the oral dose because of ensuing osmotic diarrhea.

The WHO is currently revisiting this question and plans to initiate clinical trials to assess efficacy of oral treatment regimens (Legros *et al.*, 2002). Eflornithine has proven to be less successful for treating AIDS patients with West African trypanosomiasis, presumably because host defenses play a critical role in clearing drug-treated *T. brucei gambiense* from the bloodstream. Even high doses of eflornithine failed to improve East African trypanosomiasis owing to *T. brucei rhodesiense*, consistent with the relatively short half-life and high activity of ornithine decarboxylase in these parasites.

Toxicity and Side Effects. Eflornithine causes severe adverse effects in treated patients (Burri and Brun, 2003; Van Nieuwenhove, 1992); however, they are generally reversible on withdrawal of the drug. Anemia (48%), diarrhea (39%), and leukopenia (27%) are the most common complications in patients receiving intravenous medication. Diarrhea is both dose-related and dose-limiting, especially after oral administration of the drug. Convulsions occur early in about 7% of treated patients, but they do not appear to recur despite continuation of therapy. Other complications—such as thrombocytopenia, alopecia, vomiting, abdominal pain, dizziness, fever, anorexia, and headache—occur in less than 10% of treated patients. Reversible hearing loss can occur after prolonged therapy with oral doses. While this has been a problem in the use of eflornithine for cancer chemotherapy, hearing loss has not been observed during the treatment of sleeping sickness.

Therapeutic doses of eflornithine are large and require coadministration of substantial volumes of intravenous fluid. This can pose practical limitations in remote settings and cause fluid overload in susceptible patients.

EMETINE AND DEHYDROEMETINE

The use of emetine, an alkaloid derived from *ipecac* (“Brazil root”), as a direct-acting systemic amebicide dates from the early part of the twentieth century. Dehydroemetine (MEBADIN) has similar pharmacological properties but is considered to be less toxic. Although both drugs were once used widely to treat severe invasive intestinal amebiasis and extraintestinal amebiasis, they have been replaced by metronidazole, which is as effective and far safer. Thus, emetine and dehydroemetine should not be used unless metronidazole is contraindicated. In the United States, dehydroemetine is available under an investigational new drug protocol from the CDC drug service. Details of the pharmacology and toxicology of emetine and dehydroemetine are presented in the fifth and earlier editions of this book.

FUMAGILLIN

Fumagillin (FUMIDIL B, others) is an acyclic polyene macrolide produced by the fungus *Aspergillus fumigatus*. Its structure is shown below:

Both fumagillin and its synthetic analog *TNP-470* are toxic to microsporidia, and fumagillin is used widely to treat the microsporidian *Nosema apis*, a pathogen of honey bees. Fumagillin has some activity against *E. histolytica* and was tested as a drug for amebiasis more than five decades ago. Both fumagillin and *TNP-470* also inhibit angiogenesis and suppress tumor growth, and *TNP-470* is undergoing clinical trials as an anticancer agent (*see* Chapter 51). Human methionine–aminopeptidase-2 has been identified as the target for fumagillin’s antitumor activity, and a gene encoding methionine–aminopeptidase-2 has been found in the genome of the microsporidian parasite *E. cuniculi*. Fumagillin is used topically to treat keratoconjunctivitis caused by *E. hellem* at a dose of 3 to 10 mg/ml in a balanced salt suspension. For the treatment of intestinal microsporidiosis caused by *E. bienersi*, fumagillin was used at a dose of 20 mg orally three times daily for 2 weeks (Molina *et al.*, 2002). Adverse effects of fumagillin may include abdominal cramps, nausea, vomiting, and diarrhea. Reversible thrombocytopenia and neutropenia also have been reported (Molina *et al.*, 2002). Fumagillin has not been approved for the systemic treatment of microsporidia infection in the United States.

8-HYDROXYQUINOLINES

The halogenated 8-hydroxyquinolines *iodoquinol* (diiodohydroxyquin) and *clioquinol* (iodochlorhydroxyquin) have been used as luminal agents to eliminate intestinal colonization with *E. histolytica*. Iodoquinol (YODOXIN) is the safer of the two agents and

is the only one available for use as an oral agent in the United States. When used at appropriate doses (never to exceed 2 g/day and duration of therapy not greater than 20 days in adults), adverse effects are unusual. However, the use of these drugs, especially at doses exceeding 2 g/day, for long periods is associated with significant risk. The most important toxic reaction, which has been ascribed primarily to clioquinol, is subacute myelo-optic neuropathy. This disease is a myelitis-like illness that was first described in epidemic form (thousands of afflicted patients) in Japan; only sporadic cases have been reported elsewhere, but the actual prevalence is undoubtedly higher. Peripheral neuropathy is a less severe manifestation of neurotoxicity owing to these drugs. Administration of iodoquinol in high doses to children with chronic diarrhea has been associated with optic atrophy and permanent loss of vision. Because of its superior adverse-event profile, paromomycin is preferred by many authorities as the luminal agent used to treat amebiasis; however, iodoquinol is a reasonable alternative. Iodoquinol is used in combination with metronidazole to treat individuals with amebic colitis or amebic liver abscess but may be used as a single agent for asymptomatic individuals found to be infected with *E. histolytica*. For adults, the recommended dose of iodoquinol is 650 mg orally three times daily for 20 days, whereas children receive 10 mg/kg of body weight orally three times a day (not to exceed 2 g/day) for 20 days.

The pharmacology and toxicology of the 8-hydroxyquinolines are described in greater detail in the fifth and earlier editions of this book.

MELARSOPROL

History. In 1949, Friedheim demonstrated that melarsoprol, the dimercaptopropanol derivative of melarsen oxide, was effective in the treatment of late-stage trypanosomiasis. It was considerably safer than other trypanocides available at the time. Despite the fact that it causes an often fatal encephalopathy in 2% to 10% of the patients, it has remained a first-line drug in the treatment of late (CNS) stages of both West and East African trypanosomiasis. The continued use of melarsoprol in the field is indicative of the paucity of alternative therapies for the disease.

Chemistry and Preparation. Melarsoprol has the following chemical structure:

MELARSOPROL

Melarsoprol (Mel B; ARSOBAL), consisting of two stereoisomers in a 3:1 ratio (Ericsson *et al.*, 1997), is insoluble in water and is supplied as a 3.6% (w/v) solution in propylene glycol for intravenous administration. It is available in the United States only from the CDC.

Antiprotozoal Effects. Melarsoprol has many wide-ranging nonspecific effects on both the trypanosome and host cells (Fries and Fairlamb, 2003). Melarsoprol is a prodrug and is metabolized rapidly (half-life of 30 minutes) to melarsen oxide, the active form of the drug. Arsenoxides react avidly and reversibly with vicinal sulfhydryl groups, including those of proteins, and thereby inactivate a great number and variety of enzymes. The same nonspecific mechanisms by which melarsoprol is lethal to parasites are probably responsible for its toxicity to host tissues. However, susceptible African trypanosomes actively concentrate melarsoprol *via* an unusual purine transporter, which may account for the small level of selective toxicity that is achieved (de Koning, 2001; Fairlamb, 2003).

The basis for the trypanocidal action of melarsoprol is not understood, probably owing to its high reactivity with many biomolecules. Disruption of energy metabolism by inhibition of glycolytic enzyme was long thought to explain its trypanocidal activity. Other evidence suggests, however, that this is not a primary effect. Melarsoprol reacts with trypanothione, the spermidine–glutathione adduct that substitutes for glutathione in these parasites. Binding of melarsoprol to trypanothione results in formation of melarsen oxide–trypanothione adduct (Mel T), a compound that is a potent competitive inhibitor of trypanothione reductase, the enzyme responsible for maintaining trypanothione in its reduced form.

Both the sequestering of trypanothione and the inhibition of trypanothione reductase would be expected to have lethal consequences to the cell. However, critical evidence directly linking melarsoprol's action on the trypanothione system to parasite death is still lacking (Fries and Fairlamb, 2003; Fairlamb, 2003).

The number of treatment failures owing to increasing resistance of trypanosomes to melarsoprol has risen sharply in recent years. Failure rates as high as 27% in Uganda and Angola have been reported (Burri and Keiser, 2001; Welburn and Odiit, 2002). *In vitro* analysis of field isolates indicates that resistant strains are tenfold less sensitive to the drug than sensitive strains (Brun *et al.*, 2001; Matovu *et al.*, 2001).

Resistance to melarsoprol is likely to involve transport defects, although the situation is complicated by evidence for multiple transport mechanisms of the drug (de Koning, 1991; Maser *et al.*, 2003; Bray *et al.*, 2003). The best-characterized transporter is an unusual adenine–adenosine transporter termed the *P2 transporter* that has activity on melarsoprol as well as pentamidine and *berenil*. Cross-resistance between these compounds is observed frequently. Point mutations in this transporter are found in melarsoprol-resistant field isolates. However, null mutant cell lines that lack this transporter were resistant to *berenil* but had only twofold resistance to melarsoprol and pentamidine. The evidence for at least one additional common transporter for these drugs is strong; however, it remains to be identified and characterized.

Absorption, Fate, and Excretion. Melarsoprol is always administered intravenously. A small but therapeutically significant amount of the drug enters the CSF and has a lethal effect on trypanosomes infecting the CNS. The compound is excreted rapidly, with 70% to 80% of the arsenic appearing in the feces (Pépin and Milord, 1994).

Therapeutic Uses. Melarsoprol is the only effective drug available for treatment of the late meningoencephalitic stage of East African (Rhodesian) trypanosomiasis. It is also effective in the early hemolymphatic stage of these infections, but because of its toxicity, it is reserved for therapy of late-stage infections. However, treatment of East African trypanosomiasis with melarsoprol is initiated soon after the diagnosis is made because CNS involvement occurs early in this aggressive infection. Melarsoprol is not used for prophylaxis of trypanosomiasis because of its toxicity and rapid elimination.

The pattern of resistance to melarsoprol therapy differs between the two subspecies of *T. brucei*. Patients infected with *T. brucei rhodesiense* who relapse after a course of melarsoprol usually respond to a second course of the drug. In contrast, patients infected with *T. brucei gambiense* who are not cured with melarsoprol rarely benefit from repeated treatment with this drug. Such patients often respond well to eflornithine (Pépin and Milord, 1994; Burri and Brun, 2003; Mpia and Pépin, 2002). Additionally, men have a higher relapse rate than women (Pépin *et al.*, 2002).

Treatment schedules with melarsoprol were derived empirically more than 40 years ago, and they have not changed appreciably since (Bouteille *et al.*, 2003). Melarsoprol is administered by slow intravenous injection, with care to avoid leakage into the surrounding tissues because the drug is intensely irritating. Therapeutic regimens are complex, and because melarsoprol has such a narrow therapeutic window, no standardized protocol is in use (*i.e.*, low doses risk therapeutic failure, whereas higher doses can cause reactive encephalopathy in 4% to 10% of treated patients). A typical course of treatment is three 3- to 4-day courses of 2 to 3.6 mg/kg with 7-day intervals between courses. Lesser doses should be given to children and debilitated patients. A continuous 10-day course of 2.2 mg/kg per day also has been shown to be effective, and it is likely that a short-course schedule will become the field standard. The shorter-course therapy has not reduced the incidence of encephalopathy, but it has the advantage of easier administration, and in an area where hospitalization is difficult, this is particularly important. Unless contraindicated, cotreatment with glucocorticoids should be initiated to decrease the incidence of reactive encephalopathy. Clinical trials have demonstrated that melarsoprol has strong synergistic effects with eflornithine, and the possibility to reduce toxicity by drug combinations is an active area of study that requires follow-up trials (Mpia and Pépin, 2002).

Toxicity and Side Effects. Toxicity is common during treatment with melarsoprol (Pépin and Milord, 1994; Welburn and Odiit, 2002; Burri and Brun, 2003; Kennedy, 2004). A febrile reaction often occurs soon after drug injection, especially if parasitemia is high. The most serious complications involve the nervous system. A reactive encephalopathy occurs in about 5% to

10% of patients, leading to fatality, on average, in about half of these. Encephalopathy, when it occurs, typically develops between the two courses of therapy. It is more common in East African than in West African trypanosomiasis and is more likely to develop in patients whose CSF contains many cells and trypanosomes (Pépin *et al.*, 1995). Manifestations include convulsions associated with acute cerebral edema, rapidly progressive coma, and acute nonlethal mental disturbances without neurological signs. Its cause is unknown, but it may represent an immune reaction elicited by the rapid release of trypanosomal antigens from dying parasites rather than by a direct toxic effect of the drug. Concurrent administration of *prednisolone* reduces the frequency of reactive encephalopathy and also can be used to control hypersensitivity reactions that occur most often during the second or subsequent courses of melarsoprol therapy. Peripheral neuropathy, noted in about 10% of patients receiving melarsoprol, probably is due to a direct toxic effect of the drug. Hypertension and myocardial damage are not uncommon, although shock is rare. Albuminuria occurs frequently, and occasionally the appearance of numerous casts in the urine or evidence of hepatic disturbances may necessitate modification of treatment. Vomiting and abdominal colic also are common, but their incidence can be reduced by injecting melarsoprol slowly into the supine, fasting patient. The patient should remain in bed and not eat for several hours after the injection is given.

Precautions and Contraindications. Melarsoprol should be given only to patients under hospital supervision so that the dosage regimen may be modified if necessary. It is most important that the initial dosage be based on clinical assessment of the general condition of the patient rather than on body weight. Initiation of therapy during a febrile episode has been associated with an increased incidence of reactive encephalopathy. Administration of melarsoprol to leprosy patients may precipitate erythema nodosum. Use of the drug is contraindicated during epidemics of influenza. Severe hemolytic reactions have been reported in patients with deficiency of glucose-6-phosphate dehydrogenase. Pregnancy is not a contraindication for treatment with melarsoprol.

METRONIDAZOLE

History. Isolation of the antibiotic *azomycin* (2-nitro-imidazole) from a streptomycete by Maeda and collaborators in 1953 and demonstra-

tion of its trichomonocidal properties by Horie in 1956 led to the chemical synthesis and biological testing of many nitroimidazoles. One compound, 1-(β -hydroxyethyl)-2-methyl-5-nitroimidazole, now called *metronidazole* (FLAGYL, others), had especially high activity *in vitro* and *in vivo* against the anaerobic protozoa *T. vaginalis* and *E. histolytica*. In 1960, Durel and associates reported that oral doses of the drug imparted trichomonocidal activity to semen and urine and that high cure rates could be obtained in both male and female patients with trichomoniasis. Later studies revealed that metronidazole had extremely useful clinical activity against a variety of anaerobic pathogens that included both gram-negative and gram-positive bacteria and the protozoan *G. lamblia* (Freeman *et al.*, 1997) (see below). Other clinically effective 5-nitroimidazoles closely related in structure and activity to metronidazole are available outside the United States. These include tinidazole (TINDAMAX, FASIGYN, others), *secnidazole* (SECZOL-DS, others), and ornidazole (TIBERAL, others). Among these, only tinidazole is available in the United States. Benzimidazole (ROCHAGAN) is another 5-nitroimidazole derivative that is unusual in that it is effective in acute Chagas' disease. Metronidazole has the following chemical structure:

Antiparasitic and Antimicrobial Effects. Metronidazole and related nitroimidazoles are active *in vitro* against a wide variety of anaerobic protozoal parasites and anaerobic bacteria (Freeman *et al.*, 1997). The compound is directly trichomonocidal. Sensitive isolates of *T. vaginalis* are killed by less than 0.05 $\mu\text{g}/\text{ml}$ of the drug under anaerobic conditions; higher concentrations are required when 1% oxygen is present or to affect isolates from patients who display poor therapeutic responses to metronidazole. The drug also has potent amebicidal activity against *E. histolytica*. Trophozoites of *G. lamblia* are affected by metronidazole at concentrations of 1 to 50 $\mu\text{g}/\text{ml}$ *in vitro*. *In vitro* studies on drug-sensitive and drug-resistant protozoan parasites indicate that the nitro group at the 5 position of metronidazole is essential for activity and that substitutions at the 2 position of the imidazole ring that enhance the resonance conjugation of the chemical structure increase antiprotozoal activity (Upcroft *et al.*, 1999).

In contrast, substitution of an acyl group at the 2 position ablates such conjugation and reduces antiprotozoal activity (Upcroft *et al.*, 1999).

Metronidazole manifests antibacterial activity against all anaerobic cocci and both anaerobic gram-negative bacilli, including *Bacteroides* spp., and anaerobic spore-forming gram-positive bacilli. Nonsporulating gram-positive bacilli often are resistant, as are aerobic and facultatively anaerobic bacteria.

Metronidazole is clinically effective in trichomoniasis, amebiasis, and giardiasis, as well as in a variety of infections caused by obligate anaerobic bacteria, including *Bacteroides*, *Clostridium*, and microaerophilic bacteria such as *Helicobacter* and *Campylobacter* spp. Metronidazole may facilitate extraction of adult guinea worms in dracunculiasis even though it has no direct effect on the parasite (see Chapter 41).

Mechanism of Action and Resistance. Metronidazole is a prodrug; it requires reductive activation of the nitro group by susceptible organisms. Its selective toxicity toward anaerobic and microaerophilic pathogens such as the amitochondriate protozoa *T. vaginalis*, *E. histolytica*, and *G. lamblia* and various anaerobic bacteria derives from their energy metabolism, which differs from that of aerobic cells (Land and Johnson, 1997; Samuelson, 1999; Upcroft and Upcroft, 1999). These organisms, unlike their aerobic counterparts, contain electron transport components such as ferredoxins, small Fe-S proteins that have a sufficiently negative redox potential to donate electrons to metronidazole. The single electron transfer forms a highly reactive nitro radical anion that kills susceptible organisms by radical-mediated mechanisms that target DNA and possibly other vital biomolecules. Metronidazole is catalytically recycled; loss of the active metabolite's electron regenerates the parent compound. Increasing levels of O_2 inhibit metronidazole-induced cytotoxicity because O_2 competes with metronidazole for electrons generated by energy metabolism. Thus, O_2 can both decrease reductive activation of metronidazole and increase recycling of the activated drug. Anaerobic or microaerophilic organisms susceptible to metronidazole derive energy from the oxidative fermentation of ketoacids such as pyruvate. Pyruvate decarboxylation, catalyzed by pyruvate:ferredoxin oxidoreductase (PFOR), produces electrons that reduce ferredoxin, which, in turn, catalytically donates its electrons to biological electron acceptors or to metronidazole.

Clinical resistance to metronidazole is well documented for *T. vaginalis*, *G. lamblia*, and a variety of anaerobic and microaerophilic bacteria but has yet to be shown for *E. histolytica*. Resistant strains of *T. vaginalis* derived from nonresponsive patients have shown two major types of abnormalities when tested under aerobic conditions. The first correlates with impaired oxygen-scavenging capabilities, leading to higher local O_2 concentrations, decreased activation of metronidazole, and futile recycling of the activated drug (Yarlett *et al.*, 1986) (see above). The second type is associated with lowered levels of PFOR and ferredoxin, the latter owing to reduced transcription of the ferredoxin gene (Quon *et al.*, 1992). That PFOR and ferredoxin are not completely absent may explain why infections with such strains usually respond to higher doses of metronidazole or more prolonged therapy (Johnson, 1993). Studies on metronidazole-resistant isolates of *G. intestinalis* indicate that similar mechanisms may be operating, with PFOR levels reduced fivefold compared with susceptible strains (Upcroft and Upcroft, 2001). Metronidazole resistance has not been found in clinical isolates of *E. histolytica* but has been induced *in vitro* by culturing trophozoites in gradually increasing concentrations of the drug. Interestingly, while some decrease in PFOR levels was reported, metronidazole resistance was mediated primarily by increased expression of superoxide dismutase and peroxiredoxin in amebic trophozoites (Wassmann *et al.*, 1999; Samarawickrema

et al., 1997). Resistance of anaerobic bacteria to metronidazole is being recognized increasingly and has important clinical consequences. In the case of *Bacteroides* spp., metronidazole resistance has been linked to a family of nitroimidazole (*nim*) resistance genes, *nimA*, *-B*, *-C*, *-D*, *-E*, and *-F*, that can be encoded chromosomally or episomally (Gal and Brazier, 2004). The exact mechanisms underlying resistance are not known, but *nim* genes appear to encode a nitroimidazole reductase capable of converting a 5-nitroimidazole to a 5-aminoimidazole, thus stopping the formation of the reactive nitroso group responsible for microbial killing. Metronidazole has been used widely for the treatment of the microaerophilic organism *Helicobacter pylori*, the major cause of ulcer disease and gastritis worldwide. However, *Helicobacter* can develop resistance to metronidazole rapidly. Multiple mechanisms probably are operating, but there are data associating loss-of-function mutations in an oxygen-independent NADPH nitroreductase (*rdxA* gene) with resistance to metronidazole (Mendz and Mègeaud, 2002).

Absorption, Fate, and Excretion. The pharmacokinetic properties of metronidazole and its two major metabolites have been investigated intensively (Lamp *et al.*, 1999). Preparations of metronidazole are available for oral, intravenous, intravaginal, and topical administration. The drug usually is absorbed completely and promptly after oral intake, reaching concentrations in plasma of 8 to 13 $\mu\text{g/ml}$ within 0.25 to 4 hours after a single 500-mg dose. (Mean effective concentrations of the compound are 8 $\mu\text{g/ml}$ or less for most susceptible protozoa and bacteria.) A linear relationship between dose and plasma concentration pertains for doses of 200 to 2000 mg. Repeated doses every 6 to 8 hours result in some accumulation of the drug; systemic clearance exhibits dose dependence. The half-life of metronidazole in plasma is about 8 hours, and its volume of distribution is approximately that of total-body water. Less than 20% of the drug is bound to plasma proteins. With the exception of the placenta, metronidazole penetrates well into body tissues and fluids, including vaginal secretions, seminal fluid, saliva, and breast milk. Therapeutic concentrations also are achieved in CSF.

After an oral dose, over 75% of labeled metronidazole is eliminated in the urine largely as metabolites; only about 10% is recovered as unchanged drug. The liver is the main site of metabolism, and this accounts for over 50% of the systemic clearance of metronidazole. The two principal metabolites result from oxidation of side chains, a hydroxy derivative and an acid. The hydroxy metabolite has a longer half-life (about 12 hours) and contains nearly 50% of the antitrichomonal activity of metronidazole. Formation of glucuronides also is observed. Small quantities of reduced metabolites, including ring-cleavage products, are formed by the gut flora. The urine of some patients may be reddish brown owing to the presence of unidentified pigments derived from the drug. Oxidative metabolism of metronidazole is induced by *phenobarbital*, *prednisone*, *rifampin*, and possibly *ethanol*. *Cimetidine* appears to inhibit hepatic metabolism of the drug.

Therapeutic Uses. The uses of metronidazole for anti-protozoal therapy have been reviewed extensively (Freeman *et al.*, 1997; Johnson, 1993; Stanley, 2003; Nash, 2001). Metronidazole cures genital infections with *T. vaginalis* in both females and males in more

than 90% of cases. The preferred treatment regimen is 2 g metronidazole as a single oral dose for both males and females. For patients who cannot tolerate a single 2-g dose, an alternative regimen is a 250-mg dose given three times daily or a 375-mg dose given twice daily for 7 days. When repeated courses or higher doses of the drug are required for uncured or recurrent infections, it is recommended that intervals of 4 to 6 weeks elapse between courses. In such cases, leukocyte counts should be carried out before, during, and after each course of treatment.

Treatment failures owing to the presence of metronidazole-resistant strains of *T. vaginalis* are becoming increasingly common. Most of these cases can be treated successfully by giving a second 2-g dose to both patient and sexual partner. In addition to oral therapy, the use of a topical gel containing 0.75% metronidazole or a 500- to 1000-mg vaginal suppository will increase the local concentration of drug and may be beneficial in refractory cases (Heine and McGregor, 1993).

Metronidazole is an effective amebicide and is the agent of choice for the treatment of all symptomatic forms of amebiasis, including amebic colitis and amebic liver abscess. The recommended dose is 500 to 750 mg metronidazole taken orally three times daily for 7 to 10 days. The daily dose for children is 35 to 50 mg/kg given in three divided doses for 7 to 10 days.

While standard recommendations are for 7 to 10 days' duration of therapy, amebic liver abscess has been treated successfully by short courses (2.4 g daily as a single oral dose for 2 days) of metronidazole or tinidazole (Stanley, 2003). *E. histolytica* persist in most patients who recover from acute amebiasis after metronidazole therapy, so it is recommended that all such individuals also be treated with a luminal amebicide.

Although effective for the therapy of giardiasis, metronidazole has yet to be approved for treatment of this infection in the United States. Favorable responses have been noted with doses similar to or lower than those used for trichomoniasis; the usual regimen is 250 mg given three times daily for 5 days for adults and 15 mg/kg given three times a day for 5 days for children. A daily dose of 2 g for 3 days also has been used successfully.

Metronidazole is a relatively inexpensive, highly versatile drug with clinical efficacy against a broad spectrum of anaerobic and microaerophilic bacteria. It is used for the treatment of serious infections owing to susceptible anaerobic bacteria, including *Bacteroides*, *Clostridium*, *Fusobacterium*, *Peptococcus*, *Peptostreptococcus*, *Eubacterium*, and *Helicobacter*. The drug is also given in combination with other antimicrobial agents to treat polymicrobial infections with aerobic and anaerobic bacteria. Metronidazole achieves clinically effective levels in bones, joints, and the CNS. Metronidazole can be given intravenously when oral administration is not possible. A loading dose of 15 mg/kg is followed 6 hours later by a maintenance dose of 7.5 mg/kg every 6 hours, usually for 7 to 10 days. Metronidazole is used as a component of prophylaxis of postoperative mixed bacterial infections (Song and Glenny, 1998) and is used as a single agent to treat bacterial vaginosis. It is used in combination with other antibiotics and a proton pump inhibitor in regimens to treat infection with *H. pylori* (Suerbaum and Michetti, 2002) (*see* Chapter 36).

Metronidazole is being used increasingly as primary therapy for *Clostridium difficile* infection, the major cause of pseudomembranous colitis. Given at doses of 250 to 500 mg orally three times daily for 7 to 14 days (or even longer), metronidazole is an effective and cost-saving alternative to oral *vancomycin* therapy. Finally, metronidazole is used in the treatment of patients with Crohn's disease who have perianal fistulas, and it can help control colonic (but not small bowel) Crohn's disease. However, high doses (750 mg three times daily) for prolonged periods may be necessary, and neurotoxicity may be limiting (Podolsky, 2002). Metronidazole and other nitroimidazoles can sensitize hypoxic tumor cells to the effects of ionizing radiation, but these drugs are not used clinically for this purpose.

Toxicity, Contraindications, and Drug Interactions.

The toxicity of metronidazole has been reviewed (Raether and Hanel, 2003). Side effects only rarely are severe enough to discontinue therapy. The most common are headache, nausea, dry mouth, and a metallic taste. Vomiting, diarrhea, and abdominal distress are experienced occasionally. Furry tongue, glossitis, and stomatitis occurring during therapy may be associated with an exacerbation of candidiasis. Dizziness, vertigo, and very rarely, encephalopathy, convulsions, incoordination, and ataxia are neurotoxic effects that warrant discontinuation of metronidazole. The drug also should be withdrawn if numbness or paresthesias of the extremities occur. Reversal of serious sensory neuropathies may be slow or incomplete. Urticaria, flushing, and pruritus are indicative of drug sensitivity that can require withdrawal of metronidazole. Metronidazole is a rare cause of Stevens-Johnson syndrome (toxic epidermal necrolysis), but a recent report described a high rate of this syndrome among individuals receiving high doses of metronidazole and concurrent therapy with the antihelminthic *mebendazole* (Chen *et al.*, 2003).

Dysuria, cystitis, and a sense of pelvic pressure also have been reported. Metronidazole has a well-documented disulfiram-like effect, and some patients will experience abdominal distress, vomiting, flushing, or headache if they drink alcoholic beverages during or within 3 days of therapy with this drug. Patients should be cautioned to avoid consuming alcohol during metronidazole treatment even though the risk of a severe reaction is low. By the same token, metronidazole and *disulfiram* or any disulfiram-like drug should not be taken together because confusional and psychotic states may occur. Although related chemicals have caused blood dyscrasias, only a temporary neutropenia, reversible after discontinuation of therapy, occurs with metronidazole.

Metronidazole should be used with caution in patients with active disease of the CNS because of its potential neurotoxicity. The drug also may precipitate

CNS signs of *lithium* toxicity in patients receiving high doses of lithium. Plasma levels of metronidazole can be elevated by drugs such as cimetidine that inhibit hepatic microsomal metabolism. Moreover, metronidazole can prolong the prothrombin time of patients receiving therapy with *coumadin* anticoagulants. The dosage of metronidazole should be reduced in patients with severe hepatic disease.

Given in high doses for prolonged periods, metronidazole is carcinogenic in rodents; it also is mutagenic in bacteria (Raether and Hanel, 2003). Mutagenic activity is associated with metronidazole and several of its metabolites found in the urine of patients treated with therapeutic doses of the drug. However, there is no evidence that therapeutic doses of metronidazole pose any significant increased risk of cancer to human patients. There is conflicting evidence about the teratogenicity of metronidazole in animals. While metronidazole has been taken during all stages of pregnancy with no apparent adverse effects, its use during the first trimester generally is not advised.

MILTEFOSINE

History. Miltefosine (IMPAVIDO) is an alkylphosphocholine (APC) analog that was developed originally as an anticancer agent. Its antiprotozoal activity was discovered in the 1980s during the time that it was being evaluated for cancer chemotherapy. In 1992 it was approved in India as the first orally active treatment available for visceral leishmaniasis. It has been highly curative against the parasite in the studies conducted to date, and it is hoped that this compound will revolutionize the treatment of this fatal disease (Croft and Combs, 2003; Berman, 2003). Studies also suggest that it is effective against the cutaneous forms of the disease (Soto *et al.*, 2004). Miltefosine has the following chemical structure:

Antiprotozoal Effects. *In vitro* analysis of a large number of alkylglycerophosphoethanolamines (AGPEs), alkylglycerophosphocholines (AGPCs), and APCs, originally developed as anticancer agents, demonstrated that a number of these compounds had potent antileishmanial activity against cultured promastigote or amastigote parasites (Croft *et al.*, 2003). Of the APCs, miltefosine demonstrated the best activity against both stages of parasites. The potency of miltefosine varies for different

Leishmania spp., with *L. donovani* being the most sensitive (ED₅₀ values of 1.2 to 5 μM against amastigotes) and *L. major* being the least sensitive (ED₅₀ values of 8 to 40 μM against amastigotes). Several phospholipid analogs also had good potency against cultured *T. cruzi* parasites, whereas they were relatively inactive against *T. brucei*. *In vivo*, miltefosine had the best activities of the tested APCs, and by 5 days of treatment with 20 mg/kg orally, it gave greater than 95% suppression of *L. donovani* and *L. infantum* amastigotes in the affected organs of mice. It also had good activity when administered as a 6% ointment to skin lesions of *L. mexicana* or *L. major* on BALB/c mice.

In phase II human studies against visceral leishmaniasis, 95% to 98% cure rates were observed with a 100 mg/day oral dose for 28 to 42 days (Croft *et al.*, 2003). Phase III studies of drug efficacy in India on larger numbers of patients continued to demonstrate a greater than 95% rate of parasitological cure, and the drug is effective against antimonial-resistant cases and in immunocompromised patients (Sundar *et al.*, 2002; Jha *et al.*, 1999). These studies have led to the conclusion that oral miltefosine is a safe and effective treatment for visceral leishmaniasis. Further analyses of efficacy in regions of the world other than India, however, are needed. Recent studies of oral miltefosine also have shown greater than 95% efficacy against cutaneous leishmaniasis (Soto *et al.*, 2004). Miltefosine is the first orally available therapy for leishmaniasis and may revolutionize the treatment of this disease.

The mechanism of action of miltefosine is not yet understood. Potential targets in mammalian cells include protein kinase C; phosphatidylcholine biosynthesis, where miltefosine inhibits CTP:phosphocholine-cytidyltransferase; and sphingomyelin biosynthesis, where increased levels of cellular ceramide may trigger apoptosis (Croft *et al.*, 2003). *Leishmania* studies suggest the drug may alter ether-lipid metabolism, cell signaling, or glycosylphosphatidylinositol anchor biosynthesis. A transporter for miltefosine has been cloned recently by functional rescue of a laboratory-generated resistant strain of *L. donovani* (Perez-Victoria *et al.*, 2003). The transporter is a P-type ATPase that belongs to the aminophospholipid translocase subfamily, and the basis for the drug resistance appears to be point mutation in the transporter leading to decreased drug uptake.

Absorption, Fate, and Excretion. Miltefosine is well absorbed orally and distributed throughout the human body. Plasma concentrations are proportional to the dose, and maximum serum concentrations for dosing of 50 to 150 mg/kg per day were 20 to 80 μg/ml with a half-life of 6 to 8 days. No differences between sexes or between adults and children were observed in the pharmacokinetic parameters.

Therapeutic Uses. Oral miltefosine is registered for use in India for the treatment of visceral leishmaniasis in adults at a dose of 100 mg/kg daily (for patients weighing more than 25 kg) for 28 days. A similar dosing schedule has shown efficacy against cutaneous disease. Efficacy and tolerance in children also have been

assessed on a limited number of patients; children should be administered 2.5 mg/kg per day. The compound cannot be given intravenously because it has hemolytic activity.

Toxicity and Side Effects. Vomiting and diarrhea have been reported as frequent side effects in up to 60% of the patients. Elevations in hepatic transaminases and serum creatinine also have been reported. These effects are typically mild and resolve quickly. They are generally reversible once the drug is withdrawn. The drug is contraindicated in pregnant women. Women should receive a negative pregnancy test prior to treatment, and birth control is required during and for at least 2 months after treatment. In rats, a possible effect on male fertility was noted; clinical trials to assess this risk in humans are ongoing. However, early studies have not indicated that male fertility problems detected in animal models will be observed in humans.

NIFURTIMOX

History. Nitrofurans and nitroimidazole analogs were shown to be effective in experimental infections with American trypanosomiasis caused by *T. cruzi*. Of these, nifurtimox and benznidazole were introduced in the late 1970s and are currently used clinically to treat the disease. Nifurtimox (Bayer 2502, LAMPIT), which is a nitrofurans analog, is no longer available commercially but can be obtained in the United States from the CDC. Benznidazole (Roche 7-1051, ROCHAGAN), which is a nitroimidazole analog, can only be obtained from the manufacturer.

Antiprotozoal Effects. Nifurtimox and benznidazole are trypanocidal against both the trypomastigote and amastigote forms of *T. cruzi*. Nifurtimox also has activity against *T. brucei* and can be curative against both early- and late-stage disease (Pépin *et al.*, 1995). Further evaluation of its potential for use alone or in combination with suramin or melarsoprol for this disease is ongoing at the WHO.

The trypanocidal action of nifurtimox derives from its ability to undergo activation by partial reduction to nitro radical anions. Transfer of electrons from the activated drug then regenerates the native nitrofurans and forms superoxide radical anions and other reactive oxygen species such as hydrogen peroxide and hydroxyl radical (Fairlamb, 2003). Reaction of free radicals with cellular macromolecules results in cellular damage that includes lipid peroxidation and membrane injury, enzyme inactivation, and damage to DNA. Nifurtimox also may produce

damage to mammalian tissues by formation of radicals and redox cycling. The mechanism of action of benznidazole also requires a one-electron transfer that occurs in the cell. The generated nitro anion radicals then form covalent attachments to macromolecules leading to cellular damage that kills the parasites (Fries and Fairlamb, 2003; Urbina and Docampo, 2003).

Absorption, Fate, and Excretion. Nifurtimox is well absorbed after oral administration, with peak plasma levels observed after about 3.5 hours (Paulos *et al.*, 1989). Despite this, only low concentrations of the drug (10 to 20 μM) are present in plasma, and less than 0.5% of the dose is excreted in urine. The elimination half-life is only about 3 hours. High concentrations of several unidentified metabolites are found, however, and nifurtimox clearly undergoes rapid biotransformation, probably *via* a presystemic first-pass effect. Whether the metabolites have any trypanocidal activity is unknown.

Therapeutic Uses. Nifurtimox and benznidazole are employed in the treatment of American trypanosomiasis (Chagas' disease) caused by *T. cruzi* (Urbina and Docampo, 2003; Rodreques-Coura and de Castro, 2002; Fries and Fairlamb, 2003). However, because of toxicity issues, benznidazole is the preferred treatment. Both drugs markedly reduce the parasitemia, morbidity, and mortality of acute Chagas' disease, with parasitological cures being obtained in 80% of these cases. Parasitological cure is defined by a negative result in polymerase chain reaction (PCR) and serological tests for the parasite. In the chronic form of the disease, parasitological cures are still possible in up to 50% of the patients, although the drug is less effective than in the acute stage. However, even in the absence of a complete parasitological cure, treatment of chronic infections also reduces the clinical symptoms of the disease. Treatment with nifurtimox or benznidazole has no effect on irreversible organ lesions. While a component of tissue destruction may be autoimmune in nature, the continued presence of parasites in the infected organs of patients with chronic disease argues that Chagas' disease should be treated as a parasitic disease. The clinical response of the acute illness to drug therapy varies with geographical region; parasite strains present in Argentina, southern Brazil, Chile, and Venezuela appear to be more susceptible than those in central Brazil. Despite these uncertainties, treatment of all seropositive individuals is recommended and should be initiated as soon as possible, although many physicians still are uncomfortable treating the chronic stage of the disease because of the toxicity. Therapy with nifurtimox or benznidazole should start promptly after exposure for persons at risk of *T. cruzi* infection from laboratory accidents or from blood transfusions.

Both drugs are given orally. For nifurtimox, adults with acute infection should receive 8 to 10 mg/kg per day in four divided doses for 90 to 120 days. Children 1 to 10 years of age with acute Chagas' disease should receive 15 to 20 mg/kg per day in four divided doses for 90 days; for individuals 11 to 16 years old, the daily dose is 12.5 to 15 mg/kg given according to the same schedule. For benznidazole, the recommended treatment is 5 to 7 mg/kg per day in two divided doses for 30 to 90 days, with children up to 12 years receiving 10 mg/kg per day. Gastric upset and weight loss can occur during treatment. If the latter occurs, dosage should be reduced. The ingestion of alcohol should be avoided during treatment because the incidence of side effects may increase.

Toxicity and Side Effects. Children tolerate nifurtimox and benznidazole better than do adults. Nonetheless, drug-related side effects are common. They range from hypersensitivity reactions—such as dermatitis, fever, icterus, pulmonary infiltrates, and anaphylaxis—to dose- and age-dependent complications primarily referable to the gastrointestinal tract and both the peripheral and central nervous systems (Brenner, 1979). Nausea and vomiting are common, as are myalgia and weakness. Peripheral neuropathy and gastrointestinal symptoms are especially common after prolonged treatment; the latter complication may lead to weight loss and preclude further therapy. Headache, psychic disturbances, paresthesias, polyneuritis, and CNS excitability are less frequent. Leukopenia and decreased sperm counts also have been reported. Because of the seriousness of Chagas' disease and the lack of superior drugs, there are few absolute contraindications to the use of these drugs.

NITAZOXANIDE

History. Nitazoxanide (*N*-[nitrothiazoly] salicylamide, ALINA) is an oral synthetic broad-spectrum antiparasitic agent that was synthesized originally in the 1980s based on the structure of the anthelmintic *niclosamide* (see Chapter 41). It was found initially to have activity against tapeworms (Rossignol and Maisonneuve, 1984); subsequent *in vitro* studies suggested that it was effective against a number of intestinal helminths and protozoans. Following several controlled clinical trials in children with diarrhea, nitazoxanide received FDA approval in 2002 for the treatment of cryptosporidiosis and giardiasis in children.

Chemistry. Nitazoxanide has the following chemical structure:

Antimicrobial Effects. Nitazoxanide and its active metabolite, tizoxanide (desacetyl-nitazoxanide), inhibit the growth of sporozoites and oocytes of *C. parvum* and inhibit the growth of the trophozoites of *G. intestinalis*, *E. histolytica*, and *T. vaginalis* *in vitro* (Adagu *et al.*, 2002). Activity against other protozoans, including *Blastocystis hominis*, *Isospora belli*, and *Cyclospora cayetanensis* also has been reported. Nitazoxanide also demonstrated activity against the intestinal helminths: *Hymenolepis nana*, *Trichuris trichura*, *Ascaris lumbricoides*, *Enterobius vermicularis*, *Ancylostoma duodenale*, *Strongyloides stercoralis*, and the liver fluke *Fasciola hepatica*. Effects against some anaerobic or microaerophilic bacteria, including *Clostridium* spp. and *H. pylori*, also have been reported.

Mechanism of Action and Resistance. While the exact mechanisms remain unclear, nitazoxanide appears to interfere with the PFOR enzyme-dependent electron-transfer reaction. This reaction is essential in anaerobic metabolism. Nitazoxanide does not appear to produce DNA mutations, suggesting that its mode of action is different from that of the nitroimidazoles (*e.g.*, metronidazole). No resistance to nitazoxanide in infectious agents previously known to be susceptible to the drug has yet been reported.

Absorption, Fate, and Excretion. Following oral administration, nitazoxanide is hydrolyzed rapidly to its active metabolite tizoxanide, which undergoes conjugation primarily to tizoxanide glucuronide. Bioavailability after an oral dose is excellent, and maximum plasma concentrations of the metabolites are detected within 1 to 4 hours of administration of the parent compound. Tizoxanide is greater than 99.9% bound to plasma proteins. Tizoxanide is excreted in the urine, bile, and feces, whereas tizoxanide glucuronide is excreted in the urine and bile. The pharmacokinetics of nitazoxanide in individuals with impaired hepatic or renal function have not been studied.

Therapeutic Uses. In the United States, nitazoxanide is currently available only as an oral suspension. It is approved for the treatment of *G. intestinalis* infection in children under the age of 12 (therapeutic efficacy of 85% to 90% for clinical response) and for the treatment of diarrhea in children under 12 caused by cryptosporidiosis (therapeutic efficacy ranging from 56% to 88% for clinical response) (Amadi *et al.*, 2002; Rossignol *et al.*, 2001). The efficacy of nitazoxanide in children (or adults) with cryptosporidiosis infection and AIDS has not been clearly established. For children between the ages of 12 and 47 months, the recommended dose is 100 mg nitazoxanide every 12 hours for 3 days; for children between 4 and 11 years of age, the dose is 200 mg nitazoxanide every 12 hours for 3 days. A 500-mg tablet, suitable for adult dosing (every 12 hours), is not yet available in the United States.

Nitazoxanide has been used as a single agent to treat mixed infections with intestinal parasites (protozoa and helminths) in several trials. Effective parasite clearance (based on negative follow-up fecal samples) after nitazoxanide treatment was shown for *G. intestinalis*, *E. histolytica/E. dispar*, *B. hominis*, *C. parvum*, *C. cayetanensis*, *I. belli*, *H. nana*, *T. trichura*, *A. lumbricoides*, and *E. vermicularis* (Diaz *et al.*, 2003; Romero-Cabello *et al.*, 1997), although

more than one course of therapy was required in some cases. Nitazoxanide may have some efficacy against *Fasciola hepatica* infections (Favennec *et al.*, 2003), and has been used to treat infections with *G. intestinalis* that is resistant to metronidazole and albendazole (Abboud *et al.*, 2001).

Toxicity and Side Effects. To date, adverse effects appear to be rare with nitazoxanide. Abdominal pain, diarrhea, vomiting, and headache have been reported, but rates were no different from those in patients receiving placebo. A greenish tint to the urine is seen in most individuals taking nitazoxanide. Nitazoxanide is considered a category B agent for use in pregnancy based on animal teratogenicity and fertility studies, but there is no clinical experience with its use in pregnant women or nursing mothers.

PAROMOMYCIN

Paromomycin (aminosidine, HUMATIN) is an aminoglycoside of the neomycin/kanamycin family (*see* Chapter 45) that is used as an oral agent to treat *E. histolytica* infection. Paromomycin also has been used orally to treat cryptosporidiosis and giardiasis. A topical formulation has been used to treat trichomoniasis, and parenteral administration has been used for visceral leishmaniasis. The structure of paromomycin is:

Paromomycin shares the same mechanism of action as neomycin and kanamycin (binding to the 30S ribosomal subunit) and has the same spectrum of antibacterial activity. Paromomycin is available only for oral use in the United States. Following oral administration, 100% of the drug is recovered in the feces, and even in cases of compromised gut integrity, there is little evidence for clinically significant absorption of paromomycin. *Parenteral administration carries the same risks of nephrotoxicity and ototoxicity seen with other aminoglycosides.*

Paromomycin has become the drug of choice for treating intestinal colonization with *E. histolytica*. It is used in combination with metronidazole to treat amebic colitis and amebic liver abscess and can be used as a single agent for asymptomatic individuals found to have *E. histolytica* intestinal colonization. Recommended dosing for adults and children is 25 to 35 mg/kg per day orally in three divided doses. Adverse effects are rare with oral usage but include abdominal pain and cramping, epigastric pain, nausea and vomiting, steatorrhea, and diarrhea. Rarely, rash and headache have been reported. Paromomycin has been used to treat cryptosporidiosis in AIDS

patients both as a single agent (oral doses of 500 mg three times daily or 1 g orally twice daily for 14 to 28 days followed by 500 mg orally twice daily) and in combination with azithromycin (paromomycin 1 g orally twice daily plus azithromycin 600 mg orally once daily for 4 weeks, followed by paromomycin alone for 8 weeks). While still recommended by some authorities, in a randomized, controlled trial, paromomycin was no more effective than placebo in treating individuals with cryptosporidiosis and AIDS (Hewitt *et al.*, 2000). Paromomycin has been advocated as a treatment for giardiasis in pregnant women, especially during the first trimester, when metronidazole is contraindicated and as an alternative agent for metronidazole-resistant isolates of *G. intestinalis*. While there is limited clinical experience, response rates of 55% to 90% have been reported (Gardner and Hill, 2001). Dosing in adults is 500 mg orally three times daily for 10 days, whereas children have been treated with 25 to 30 mg/kg per day in three divided oral doses. Paromomycin formulated as a 6.25% cream has been used to treat vaginal trichomoniasis in patients who had failed metronidazole therapy or could not receive metronidazole. Some cures have been reported, but vulvovaginal ulcerations and pain have complicated treatment (Nyrjely *et al.*, 1998).

Paromomycin as a topical formulation containing 15% paromomycin in combination with either a patented base from Walter Reed Army Institute of Research or 12% *methylbenzoniium chloride* has shown variable efficacy in clinical trials for the treatment of cutaneous leishmaniasis (Berman, 2003). Paromomycin has been administered parenterally (doses of 16 to 18 mg/kg per day) alone or in combination with antimony to treat visceral leishmaniasis. In one study, cure rates of 89% with paromomycin alone were reported, and cure rates of 94% were seen with combination therapy. These results compared favorably with the cure rate for antimony alone (69% in this study) in an endemic area where antimony resistance is common (Thakur *et al.*, 2000).

PENTAMIDINE

History. Pentamidine is a positively charged aromatic diamine that was discovered in 1937 as a fortuitous consequence of the search for hypoglycemic compounds that might compromise parasite energy metabolism. Of the compounds tested, three were found to possess outstanding activity: *stilbamidine*, pentamidine, and *promamidine*. Pentamidine was the most useful clinically because of its relative stability, lower toxicity, and ease of administration. Pentamidine is a broad-spectrum agent with activity against several species of pathogenic protozoa and some fungi. Alone or in combination with suramin, pentamidine is used for the treatment of early-stage *T. brucei gambiense* infection (Docampo and Moreno, 2003; Nok, 2003). Pentamidine is an alternative agent for the treatment of antimony-resistant visceral leishmaniasis, although the availability of newer, less toxic agents, (*e.g.*, liposomal preparations of amphotericin and miltefosine) may decrease its use (Berman, 2003). Pentamidine is also used as an alternative agent for the treatment and prophylaxis of pneumocystis pneumonia caused by the ascomycetous fungus *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*) (Thomas and Limper, 2004). *T. brucei rhodesiense* is refractory to treatment by pentamidine for unexplained reasons. *Diminazene* (BERENIL) is a related diamidine that is used as an inexpensive alternative to pentamidine for the treatment of early African trypanoso-

miasis in some endemic areas despite the fact that it is *approved for veterinary use only*.

Chemistry. Pentamidine has the following chemical structure:

Pentamidine as the di-isethionate salt is marketed for injection (PENTAM 300) or for use as an aerosol (NEBUPENT). One milligram of pentamidine base is equivalent to 1.74 mg of the pentamidine isethionate. The di-isethionate salt is highly water soluble; however, solutions should be used promptly after preparation because pentamidine is unstable in solution.

Antiprotozoal and Antifungal Effects. The positively charged aromatic diamidines are toxic to a number of different protozoa yet show rather marked selectivity of action. They are effective for the treatment of *T. brucei gambiense* sleeping sickness but not *T. brucei rhodesiense* or *T. cruzi* infections. Additionally, they are useful for the treatment of antimony-resistant leishmania infections.

The diamidines also are fungicidal. Activity *in vitro* against *Blastomyces dermatitidis* led to the successful therapeutic trial of these drugs in systemic blastomycoses. The use of amphotericin B, however, has reduced the value of the diamidines in the treatment of this disease. At near-therapeutic levels, pentamidine kills nonreplicating forms of *P. jiroveci* in culture (Pifer *et al.*, 1983), but other evidence suggests that pentamidine exerts a biostatic rather than biocidal effect (Vöhringer and Arastéh, 1993).

Mechanism of Action and Resistance. The mechanism of action of the diamidines is unknown. The dicationic compounds appear to display multiple effects on any given parasite and act by disparate mechanisms in different parasites (Wang, 1995; Fairlamb, 2003). In *T. brucei*, for example, the diamidines are concentrated *via* an energy-dependent high-affinity uptake system to millimolar concentrations in cells; this selective uptake is essential to their efficacy. The best-characterized diamidine transporter is the same purine (P2) adenine and adenosine transporter used by the melamine-based arsenicals, which explains the cross-resistance to diamidines exhibited by certain arsenical-resistant strains of *T. brucei* generated in the laboratory (Fairlamb, 2003; de Koning, 2001; Maser *et al.*, 2003; Bray *et al.*, 2003). However, it is becoming increasingly clear that multiple transporters are responsible for pentamidine uptake, and this may account for the fact that little resistance to this drug is observed in field isolates despite years of use as a prophylactic agent. Although failure to concentrate diamidines is the usual cause of pentamidine resistance *in vitro*, other mechanisms also may be involved (Fairlamb, 2003).

The positively charged hydrophobic diamidines may exert their trypanocidal effects by reacting with a variety of negatively

charged intracellular targets such as membrane phospholipids, enzymes, RNA, and DNA. Indeed, ribosomal aggregation, inhibition of DNA and protein synthesis, and inhibition of several enzymes—along with seeming loss of trypanosomal kinetoplast DNA—all have been reported (Fairlamb, 2003). The loss of kinetoplast DNA may be mediated through inhibition of topoisomerase II, a hypothesis that is supported by recent studies using interference RNA to knock down levels of the protein. This latter effect cannot account for the broad antimicrobial activity of the drug and thus cannot fully explain its mechanism of action. Inhibition of *S*-adenosyl-L-methionine decarboxylase *in vitro* suggested that pentamidine might interfere with polyamine biosynthesis; however, polyamine levels are not affected in intact cells, suggesting that inhibition of this enzyme plays no role in the toxicity of the drug (Fairlamb, 2003). Inhibition of a plasma Ca^{2+} , Mg^{2+} -ATPase also has been reported (Fairlamb, 2003).

In *Leishmania*, pentamidine accumulates within the mitochondria, and disintegration of the kinetoplast and collapse of the mitochondrial membrane potential are early effects of the drug. An important role for mitochondria as the target for pentamidine's antileishmanial activities is also suggested by studies of pentamidine-resistant parasites, where resistance was not associated with decreased drug uptake into the parasite but linked to decreased concentrations of the drug within mitochondria (Bray *et al.*, 2003).

Absorption, Fate, and Excretion. The pharmacokinetics and biodeposition of pentamidine isethionate have been studied most extensively in AIDS patients with *P. jiroveci* infections (Vöhringer and Arastéh, 1993); information from patients with Gambian trypanosomiasis is more limited (Pépin and Milord, 1994; Bronner *et al.*, 1995; Bouteille *et al.*, 2003). Pentamidine isethionate is fairly well absorbed from parenteral sites of administration. Following a single intravenous dose, the drug disappears from plasma with an apparent half-life of several minutes to a few hours and maximum plasma concentrations after intramuscular injection occurring at 1 hour. The half-life of elimination is very slow, lasting from weeks to months, and the drug is 70% bound to plasma proteins. This highly charged compound is poorly absorbed orally and does not cross the blood-brain barrier, explaining why it is ineffective against late-stage trypanosomiasis.

After multiple parenteral doses, the liver, kidney, adrenal, and spleen contain the highest concentrations of drug, whereas only traces are found in the brain (Donnelly *et al.*, 1988). The lungs contain intermediate but therapeutic concentrations after five daily doses of 4 mg/kg. Inhalation of pentamidine aerosols is used for prophylaxis of *Pneumocystis* pneumonia; delivery of drug by this route results in little systemic absorption and decreased toxicity compared with intravenous administration in both adults and children (Leoung *et al.*, 1990; Hand *et al.*, 1994). The actual dose delivered to the lungs depends on both the size of particles generated by the nebulizer and the patient's ventilatory patterns.

Therapeutic Uses. Pentamidine isethionate usually is given by intramuscular injection or by slow intravenous infusion over 60 minutes in single doses of 1.7 to 4.5 mg/kg per day for a series of 10 days. However, alternative dosing schedules are common, and the coadministration

of suramin on alternate days provides an alternative means of treating *T. brucei gambiense* infections (Pépin and Milord, 1994). Because of failure to penetrate the CNS, pentamidine is not used to treat *T. brucei rhodesiense*, which affects the brain early in the course of infection. The drug is also ineffective in *T. brucei gambiense* infections once the CNS is involved.

Pentamidine has been used successfully in courses of 12 to 15 intramuscular doses of 2 to 4 mg/kg either daily or every other day to treat visceral leishmaniasis (kala azar caused by *L. donovani*). This compound provides an alternative to antimonials or lipid formulations of amphotericin B for patients who cannot tolerate the latter agents. Pentamidine isethionate given as four intramuscular doses of 3 mg/kg every other day has enjoyed some success in the treatment of cutaneous leishmaniasis (Oriental sore caused by *L. tropica*) but is not used routinely to treat this infection (Berman, 1997).

Pentamidine is one of several drugs or drug combinations used to treat or prevent *Pneumocystis* infection. *Pneumocystis* pneumonia (PCP) is a major cause of mortality in individuals with HIV infection and AIDS and can occur in patients who are immunosuppressed by other mechanisms (*e.g.*, high-dose corticosteroids or underlying malignancy). The availability of highly active antiretroviral therapy (HAART) has reduced the number of cases of PCP significantly within the United States and Europe and greatly reduced the number of individuals requiring prophylaxis for PCP. Trimethoprim-sulfamethoxazole is the drug of choice for the treatment and prevention of PCP (*see* Chapter 43). Pentamidine is reserved for two indications. Pentamidine given intravenously as a 4 mg/kg single daily dose for 21 days is used to treat severe PCP in individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not candidates for alternative agents such as atovaquone or the combination of clindamycin and *primaquine*. Pentamidine has been recommended as a "salvage" agent for individuals with PCP who failed to respond to initial therapy (usually trimethoprim-sulfamethoxazole), but a meta-analysis suggested that pentamidine is less effective than other therapies (specifically the combination of clindamycin and primaquine or atovaquone) for this indication (Smego *et al.*, 2001). Pentamidine administered as an aerosol preparation is used for the prevention of PCP in at-risk individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not deemed candidates for either dapsone (alone or in combination with pyrimethamine) or atovaquone. Candidates for PCP prophylaxis are individuals with HIV infection and a CD4 count of less than 200/mm³ and individuals with HIV infection and persistent unexplained fever or oropharyngeal candidiasis. Secondary prophylaxis is recommended for everyone with a documented PCP episode. For prophylaxis, pentamidine isethionate is given monthly as a 300-mg dose in a 5% to 10% nebulized solution over 30 to 45 minutes. While the monthly dosage regimen is convenient, aerosolized pentamidine has several disadvantages, including its failure to treat any extrapulmonary sites of *Pneumocystis*, the lack of efficacy against any other potential opportunistic pathogens (compared with trimethoprim-sulfamethoxazole), and a slightly increased risk for pneumothorax. Long-term aerosolized pentamidine prophylaxis (5 years or more) has not been associated with the

development of any pulmonary disease (Obaji *et al.*, 2003). For individuals who receive HAART and develop CD4 counts persistently above 200/mm³ for 3 months, primary or secondary PCP prophylaxis can be stopped.

Toxicity and Side Effects. Pentamidine is a toxic agent, and approximately 50% of individuals receiving the drug at recommended doses (4 mg/kg per day) will show some adverse effect. Intravenous administration of pentamidine may be associated with hypotension, tachycardia, and headache. These effects are probably secondary to the ability of pentamidine to bind imidazoline receptors (*see* Chapter 10) and can be ameliorated by slowing the rate of the intravenous infusion (Wood *et al.*, 1998). As noted earlier, the diamidines were designed originally for use as hypoglycemics, and pentamidine retains that property. Hypoglycemia, which can be life threatening, may occur at any time during pentamidine treatment, even weeks into therapy. Careful monitoring of blood sugar is key. Paradoxically, pancreatitis, hyperglycemia, and the development of insulin-dependent diabetes have been seen in some patients. Pentamidine is nephrotoxic (almost 25% of treated patients will show signs of renal dysfunction), and if the serum creatinine concentration rises more than 1.0 to 2.0 mg/dl, it may be necessary to withhold the drug temporarily or change to an alternative agent. Individuals developing pentamidine-induced renal dysfunction are at higher risk for hypoglycemia. Other adverse effects include skin rashes, thrombophlebitis, anemia, neutropenia, and elevation of hepatic enzymes. Intramuscular administration of pentamidine, while effective, is associated with the development of sterile abscesses at the injection site, which can become infected secondarily. For this reason, most authorities recommend intravenous administration. Aerosolized pentamidine is associated with few adverse events.

QUINACRINE

Quinacrine is an acridine derivative used widely during World War II as an antimalarial agent. Although it has been replaced by newer and safer antimalarial drugs (*see* Chapter 39), *quinacrine hydrochloride* is very effective against *G. lamblia*, producing cure rates of at least 90%. However, quinacrine is no longer available in the United States. For a description of the pharmacology and toxicology of quinacrine, consult the fifth and earlier editions of this book.

SODIUM STIBOGLUCONATE

History. Antimonial compounds were introduced in 1945 and have been used for therapy of leishmaniasis and other protozoal

infections (Berman, 2003; Fairlamb, 2003; Croft and Coombs, 2003). The first trivalent antimonial compound used to treat cutaneous leishmaniasis and kala azar was *antimony potassium tartrate* (tartar emetic), which was both toxic and difficult to administer. Tartar emetic and other trivalent arsenicals eventually were replaced by pentavalent antimonial derivatives of phenylstibonic acid. An early member of this family of compounds was *sodium stibogluconate* (sodium antimony gluconate, PENTOSTAM). This drug is used widely today and, together with *meglumine antimonate* (GLUCANTIME), a pentavalent antimonial compound preferred in French-speaking countries, has been the mainstay of the treatment of leishmaniasis. However, increasing resistance to antimonials has reduced their efficacy, and both lipid-based amphotericin and miltefosine are being used increasingly in their place (Fries and Fairlamb, 2003; Croft and Coombs, 2003; Berman, 2003).

Chemistry. Sodium stibogluconate has the following chemical structure:

Clinical formulations of sodium stibogluconate actually consist of multiple uncharacterized molecular forms, some of which have higher molecular masses than the compound shown (Fairlamb, 2003). Typical preparations contain 30% to 34% pentavalent antimony by weight as well as *m*-chlorocresol added as a preservative. In the United States, sodium stibogluconate is no longer available.

Antiprotozoal Effects and Drug Resistance. The mechanism of the antileishmanial action of sodium stibogluconate remains an active area of research, and recent studies have provided interesting new insights. These studies support the old hypothesis that relatively nontoxic pentavalent antimonials act as prodrugs. These compounds are reduced to the more toxic Sb³⁺ species that kill amastigotes within the phagolysosomes of macrophages. This reduction preferentially occurs in the intracellular amastigote stage, and recently an enzyme, As⁵⁺ reductase, was characterized that is able to reduce Sb⁵⁺ to the active Sb³⁺ form. Furthermore, the overexpression of this enzyme in promastigotes increased their sensitivity to the drugs (Zhou *et al.*, 2004). Classically, it was thought that the antiparasitic effects of antimonials occurred through inhibition of glucose catabolism and fatty acid oxidation; however, recent studies strongly suggest that the drugs operate by interfering with the trypanothione redox system. In drug-sensitive cell lines, Sb³⁺ induces a rapid

efflux of trypanothione and glutathione from the cells, and it also inhibits trypanothione reductase, thereby causing a significant loss of thiol reduction potential in the cells (Wyllie *et al.*, 2004). This hypothesis is further supported by the observation that laboratory-generated resistance to antimonials leads to overexpression of glutathione and polyamine biosynthetic enzymes, resulting in increased trypanothione levels, which conjugate to the drug. Elevated levels of ABC transporters, which are involved in the efflux of these conjugates, also were observed (Croft, 2001).

Absorption, Fate, and Excretion. The pentavalent antimonials attain much higher concentrations in plasma than do the trivalent compounds. Consequently, most of a single dose of sodium stibogluconate is excreted in the urine within 24 hours. Its pharmacokinetic behavior is similar whether the drug is given intravenously or intramuscularly; it is not active orally (Pamplin *et al.*, 1981; Chulay *et al.*, 1988). The agent is absorbed rapidly, distributed in an apparent volume of about 0.22 L/kg, and eliminated in two phases. The first has a short half-life of about 2 hours, and the second is much slower ($t_{1/2} = 33$ to 76 hours). The prolonged terminal elimination phase may reflect conversion of the pentavalent antimonial (Sb^{5+}) to the more toxic trivalent (Sb^{3+}) form that is concentrated and slowly released from tissues. Indeed, about 20% of the plasma antimony is present in the trivalent form after pentavalent antimonial administration. Sequestration of antimony in macrophages also may contribute to the prolonged antileishmanial effect after plasma antimony levels have dropped below the minimal inhibitory concentration observed *in vitro*.

Therapeutic Uses. The changing use of sodium stibogluconate, meglumine antimonate, and other agents for the chemotherapy of leishmaniasis has been reviewed extensively (Berman, 2003; Croft and Coombs, 2003; Fries and Fairlamb, 2003). Sodium stibogluconate is given parenterally, with the dosage regimen individualized depending on the local responsiveness of a particular form of leishmaniasis to this compound. The standard course is 20 mg/kg per day for 20 days for cutaneous disease and for 28 days for visceral disease. Prolonged dosage schedules with maximally tolerated doses are now needed for successful therapy of visceral, mucosal, and some cutaneous forms of leishmaniasis, in part to overcome increasing clinical resistance to antimonial drugs. Even high-dose regimens may no longer produce satisfactory results. Increased resistance has greatly compromised the effectiveness of these drugs, and treatment failure rates of as high as 60% have been observed in parts of India. This is in contrast to previous cure rates of 85% to 90% for both visceral and cutaneous disease. Amphotericin B is the recommended alternative for treatment of either visceral leishmaniasis (kala azar) in India or mucosal leishmaniasis in general,

although the newly approved orally active compound miltefosine is likely to see much wider use in the coming years.

Children usually tolerate the drug well, and the dose per kilogram is the same as that given to adults. Patients who respond favorably show clinical improvement within 1 to 2 weeks of initiation of therapy. The drug may be given on alternate days or for longer intervals if unfavorable reactions occur in especially debilitated individuals. Patients infected with HIV present a challenge because they usually relapse after successful initial therapy with either pentavalent antimonials or amphotericin B.

Toxicity and Side Effects. The toxicity of the pentavalent antimonials is best evaluated in patients without systemic disease, *i.e.*, visceral leishmaniasis. In general, high-dose regimens of sodium stibogluconate are fairly well tolerated; toxic reactions usually are reversible, and most subside despite continued therapy. Effects noted most commonly include pain at the injection site after intramuscular administration; chemical pancreatitis in nearly all patients; elevation of serum hepatic transaminase levels; bone marrow suppression manifested by decreased red cell, white cell, and platelet counts in the blood; muscle and joint pain; weakness and malaise; headache; nausea and abdominal pain; and skin rashes. Changes in the electrocardiogram that include T-wave flattening and inversion and prolongation of the QT interval found in patients with systemic disease are uncommon in other forms of leishmaniasis (Navin *et al.*, 1992; Berman, 1997; Sundar *et al.*, 1998). Reversible polyneuropathy has been reported. Hemolytic anemia and renal damage are rare manifestations of antimonial toxicity, as are shock and sudden death.

SURAMIN

History. Based on the trypanocidal activity of the dyes *trypan red*, *trypan blue*, and *afridol violet*, research in Germany resulted in the introduction of suramin into therapy in 1920. Today, the drug is used primarily for treatment of African trypanosomiasis; it has no clinical utility against American trypanosomiasis. Although suramin is effective in clearing adult filariae in *onchocerciasis*, it has been replaced by *ivermectin* for the treatment of this condition (*see* Chapter 41). Suramin is a potent inhibitor of retroviral reverse transcriptase *in vitro*, but it is ineffective in HIV infection. Drug-associated adrenal insufficiency, along with the antiproliferative activity of suramin, stimulated the experimental use of high doses, alone or with other compounds, for the therapy of adrenocortical hyperfunction, adrenocortical carcinoma, and a variety of

other metastatic tumors (Voogd *et al.*, 1993; Frommel, 1997). The antiparasitic and antineoplastic properties of suramin, along with its clinical uses and limitations, have been the topic of numerous reviews (Voogd *et al.*, 1993; Pépin and Milord, 1994; Barrett and Barrett, 2000).

Chemistry and Preparation. *Suramin sodium* (BAYER 205, formerly GERMANIN, others) has the following chemical structure:

The drug is soluble in water, but solutions deteriorate quickly in air; only freshly prepared solutions should be used. In the United States, suramin is available only from the CDC.

Antiparasitic Effects. Suramin is a relatively slowly acting trypanocide (>6 hours *in vitro*) with high clinical activity against both *T. brucei gambiense* and *T. brucei rhodesiense* and an unknown mechanism of action (Fairlamb, 2003; Bouteille, 2003). Selective toxicity is likely to result from the ability of the parasite to take up the drug by receptor-mediated endocytosis of the protein-bound drug, with low-density lipoproteins being the most important interacting proteins for this event (Fries and Fairlamb, 2003). Suramin reacts reversibly with a variety of biomolecules *in vitro*, inhibiting many trypanosomal and mammalian enzymes and receptors unrelated to its antiparasitic effects, including purinergic and AMPA receptors (Fairlamb, 2003; Suzuki *et al.*, 2004). Compartmentation protects many vital molecules, such as the glycolytic enzymes inside trypanosomal glycosomes, from suramin because this compound does not cross membrane barriers by passive diffusion. However, the chemical structure of suramin may confer transport specificity because removal of its two methyl groups results in the loss of trypanocidal activity *in vivo* but not *in vitro* (Morty *et al.*, 1998). Suramin-treated trypanosomes exhibit damage to intracellular membrane structures other than lysosomes, but whether or not this relates to the drug's primary action is unknown. Inhibition of a trypanosomal cytosolic serine oligopeptidase may account for at least part of the activity of suramin, but it is also a potent inhibitor of dihydrofolate reductase, thymidine kinase, and several of the glycolytic enzymes. The synergism that has been observed between eflornithine and suramin also has led to speculation that it may inhibit polyamine biosynthesis (Fries and Fair-

lamb, 2003). No clear consensus for the mechanism of action has emerged, and the lack of any significant field resistance points to multiple potential targets.

Suramin is the only microfilaricide used clinically, albeit rarely now, for the treatment of human onchocerciasis. This compound displays delayed but prolonged filaricidal activity against both adult male and female worms and lesser but significant activity against microfilariae. Its mechanism of action against *Onchocerca volvulus* is unknown (Voogd *et al.*, 1993).

Absorption, Fate, and Excretion. Because it is not absorbed after oral intake, suramin is given intravenously to avoid local inflammation and necrosis associated with subcutaneous or intramuscular injections. After its administration, the drug displays complex pharmacokinetics with marked interindividual variability. The concentration in plasma falls fairly rapidly after a few hours, but the drug is 99.7% serum bound and has a terminal elimination half-life of about 90 days. Suramin is not appreciably metabolized, and renal clearance accounts for elimination of about 80% of the compound from the body. This large polar anion does not enter cells readily, and tissue concentrations are uniformly lower than those in plasma. In experimental animals, however, the kidneys contain considerably more suramin than do other organs. Such retention may account for the fairly frequent occurrence of albuminuria following injection of the drug in human beings. Very little suramin penetrates the CSF, consistent with its lack of efficacy once the CNS has been invaded by trypanosomes. The dose-dependent prolonged persistence of suramin in the circulation explains why the drug has been used for prophylaxis of African trypanosomiasis.

Therapeutic Uses. Suramin is used to treat African trypanosomiasis but is of no value in South American trypanosomiasis caused by *T. cruzi*. It is used as the first-line therapy for early-stage *T. brucei rhodesiense* infection and as an alternative to pentamidine for early-stage *T. brucei gambiense*. Because no drug resistance has been observed after over 80 years of use, it is also an ideal drug for prophylaxis.

Because only small amounts of the drug enter the brain, suramin is used primarily to treat early stages (before CNS involvement) of African trypanosomiasis (Pépin and Milord, 1994). For therapy of early West African infections, this drug is more effective when given by intravenous regimens that also include intramuscular injections of pentamidine. In contrast, suramin alone appears superior for therapy of early East African disease. Suramin will clear the hemolymphatic system of trypanosomes even in late-stage disease, so it is often administered before initiating melarsoprol to reduce the risk of reactive encephalopathy associated with the administration of that arsenical (*see above*). In animal models, suramin has been found to display synergism with other trypanocides, including eflornithine. However, suramin-

eflornithine therapy has been disappointing against late-stage human *T. brucei rhodesiense* infection (Clerinx *et al.*, 1998).

Suramin is given by slow intravenous injection as a 10% aqueous solution. Treatment of active African trypanosomiasis should not be started until 24 hours after diagnostic lumbar puncture to ensure no CNS involvement, and caution is required if the patient has onchocerciasis (river blindness) because of the potential for eliciting a Mazzotti reaction (*i.e.*, pruritic rash, fever, malaise, lymph node swelling, eosinophilia, arthralgias, tachycardia, hypotension, and possibly permanent blindness). The normal single dose for adults with *T. brucei rhodesiense* infection is 1 g. It is advisable to employ a test dose of 200 mg initially to detect sensitivity, after which the normal dose is given on days 1, 3, 7, 14, and 21. The pediatric dose is 20 mg/kg, given according to the same schedule. Patients in poor condition should be treated with lower doses during the first week. When suramin and pentamidine are used to treat early-stage *T. brucei gambiense* infection, Pépin and Milord (1994) recommend suramin (20 mg/kg, up to a maximum of 1 g) given intravenously on days 1 and 13 and pentamidine isethionate (4 mg/kg) given intramuscularly on days 1, 3, 5, 13, 15, and 17. However, suramin and pentamidine may lose their advantage over pentamidine alone for the treatment of Gambian trypanosomiasis if there is even minimal evidence of CNS involvement (Pépin and Khonde, 1996). Patients who relapse after suramin therapy should be treated with melarsoprol (Pépin and Milord, 1994).

Suramin is effective for the prophylaxis of African trypanosomiasis. Chemoprophylaxis is not recommended for travelers on occasional brief visits to endemic areas because the risk of serious drug toxicity outweighs the risk of acquiring the disease (*see below*). For chemoprophylaxis, the single dose of 1 g is repeated weekly for 5 or 6 weeks.

Toxicity and Side Effects. Suramin can cause a variety of untoward reactions that vary in intensity and frequency and tend to be more severe in debilitated patients. Fortunately, the most serious immediate reaction consisting of nausea, vomiting, shock, and loss of consciousness is rare (about 1 in 2000 patients). Malaise, nausea, and fatigue are also common immediate reactions. Parasite destruction may cause febrile episodes and skin hypersensitivity rashes that are reduced by pretreatment with glucocorticoids; concomitant onchocerciasis optimally should be treated first with ivermectin to minimize these reactions (*see Chapter 41*). The most common problem encountered after several doses of suramin is renal toxicity, manifested by albuminuria, and delayed neurological complications, including headache, metallic taste, paresthesias, and peripheral neuropathy. These complications usually disappear spontaneously despite continued therapy. At higher doses over long periods of treatment used for cancer chemotherapy, suramin-induced coagulopathy is the most common toxicity observed, whereas development of a severe polyradiculoneuropathy is the most serious complication (Voogd *et al.*, 1993). Other, less prevalent reac-

tions include vomiting, diarrhea, stomatitis, chills, abdominal pain, and edema. Laboratory abnormalities noted in 12% to 26% of patients with AIDS include leukopenia and occasional agranulocytosis, thrombocytopenia, proteinuria, and elevations of plasma creatinine, transaminases, and bilirubin, which are reversible. Unexpected findings in patients with AIDS include adrenal insufficiency and vortex keratopathy.

Precautions and Contraindications. Patients receiving suramin should be followed closely. Therapy should not be continued in patients who show intolerance to initial doses, and the drug should be employed with great caution in individuals with renal insufficiency. Moderate albuminuria is common during control of the acute phase, but persisting, heavy albuminuria calls for caution as well as modification of the treatment schedule. If casts appear, treatment with suramin should be discontinued. The occurrence of palmar-plantar hyperesthesia may presage peripheral neuritis.

CHEMOTHERAPY OF HELMINTH INFECTIONS

Alex Loukas and Peter J. Hotez

Infections with helminths, or parasitic worms, affect more than two billion people worldwide. In regions of rural poverty in the tropics, where prevalence is greatest, simultaneous infection with more than one type of helminth is common. The relative incidence of common helminthic infections in humans worldwide is illustrated in Figure 41–1.

Primarily as a result of stepped-up advocacy by the World Health Organization (WHO), the World Bank, and smaller nongovernmental organizations such as the London-based Partnership for Child Development (PCD), there is increasing appreciation for the impact of helminth infections on the health and education of school-aged children (Savioli *et al.*, 2002). These organizations have promoted the periodic and frequent use of anthelmintic drugs in schools as a means to control morbidity caused by soil-transmitted helminths and schistosomes in developing countries. In addition, there is interest in eliminating arthropod-borne helminth infections by interrupting their transmission through the widespread use of anthelmintics. Control programs using anthelmintics could become the world's largest health programs (Horton, 2003).

Worms pathogenic for humans are Metazoa, classified into roundworms (nematodes) and two types of flatworms, flukes (trematodes) and tapeworms (cestodes). These biologically diverse eukaryotes vary with respect to life cycle, bodily structure, development, physiology, localization within the host, and susceptibility to chemotherapy. Immature forms invade humans *via* the skin or gastrointestinal tract and evolve into well-differentiated adult worms with characteristic tissue distributions. With few exceptions, such as *Strongyloides* and *Echinococcus*, these organisms cannot com-

plete their life cycle and replicate themselves within the human host. Therefore, the extent of exposure to these parasites dictates the severity of infection, and reduction in the number of adult organisms by chemotherapy is sustained unless reinfection occurs. The prevalence of parasitic helminths typically displays a negative binomial distribution within an infected population such that relatively few persons carry heavy parasite burdens. Without treatment, those individuals are most likely to become ill and to perpetuate infection within their community.

Anthelmintics are drugs that act either locally to expel worms from the gastrointestinal tract or systemically to eradicate adult helminths or developmental forms that invade organs and tissues. Due to discovery and development of anthelmintics, particularly for veterinary applications, physicians now have effective, and in some cases broad-spectrum, agents that will cure or control most human infections caused by either flukes or intestinal helminths. But cysticercosis, echinococcosis, filariasis, and trichinosis are examples of systemic infections caused by tissue-dwelling helminths that at best respond only partially to currently available drugs. Because metazoan parasites generally are long-lived and have relatively complex life cycles, acquired resistance to anthelmintics in humans has yet to become a major factor limiting clinical efficacy. However, based on extensive use of anthelmintics, such as the benzimidazoles in veterinary medicine, the potential for drug resistance among helminths in humans cannot be discounted.

This chapter first describes the recommended chemotherapy for common human infections caused by helminths and then discusses the properties of specific anthelmintics.

Figure 41-1. Relative incidence of helminth infections worldwide.

TREATMENT OF HELMINTH INFECTIONS

Nematodes (Roundworms)

The major nematode parasites of humans include the soil-transmitted helminths (STHs; sometimes referred to as “geohelminths”) and the filarial nematodes.

The major STH infections, which include ascariasis, trichuriasis, and hookworm infection, are among the most prevalent infections in developing countries. Because STH worm burdens are higher in school-aged children than in any other single group, the WHO and the PCD advocate using schools and schoolteachers to administer broad-spectrum anthelmintics on a periodic and frequent basis. The most widely used agents employed for reducing morbidity are the benzimidazole anthelmintics (BZAs), either *albendazole* (ALBENZA and ZENTEL) or *mebendazole* (VERMOX) (see Table 41-1). A single dose of a BZA reduces worm burdens and subsequently improves host iron and hemoglobin status, physical growth, cognition, educational achievement, and school absenteeism, as well as having a positive influence on the entire community, namely through a reduction in the spread of ascariasis and trichuriasis (Bundy *et al.*, 1990; Savioli *et al.*, 2002; Hotez *et al.*, 2004a; Hotez *et al.*, 2005). In 2001, the World Health Assembly adopted a resolution urging that by 2010 member states should regularly administer anthelmintics to

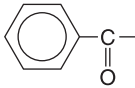

75% of all school-age children at risk for morbidity (World Health Organization, 2002). Concerns with this recommendation include: (1) the sheer scope of the undertaking (Horton, 2003); (2) the high rates of posttreatment STH reinfection that occur in areas of high transmission (Albonico *et al.*, 1995); (3) the possibility that widespread treatment will lead to the emergence of BZA drug resistance (Albonico, 2003; Albonico *et al.*, 2003); and (4) the observation that focusing exclusively on school-aged children would miss populations that are vulnerable to hookworm infection, such as preschool children and women of reproductive age (Brooker *et al.*, 2004; Hotez *et al.*, 2004a).

In addition to targeting STH infections among school-aged children, there is an ongoing attempt to employ anthelmintics that eliminate lymphatic filariasis (LF) and onchocerciasis (river blindness) over the next 10 to 20 years (Molyneux and Zagaria, 2002; Molyneux *et al.*, 2003). The term *elimination* refers to the reduction of disease incidence to zero or close to zero, with a requirement for ongoing control efforts (Hotez *et al.*, 2004b). The major goal for LF and onchocerciasis elimination is to interrupt arthropod-borne transmission by administering combination therapy with either *diethylcarbamazine* and *albendazole* (in LF-endemic regions such as India and Egypt), or *ivermectin* and *albendazole* (in LF regions where onchocerciasis and/or loiasis are co-endemic). These drugs target the microfilarial stages of the parasite, which circulate in blood and are taken up by arthropod vectors where further parasite development takes place. Both control programs rely heavily on the generosity of major drug companies that donate ivermectin and albendazole (Molyneux *et al.*, 2003; Burnham and Mebrahtu, 2004).

***Ascaris lumbricoides* and *Toxocara canis*.** *Ascaris lumbricoides*, known as the “roundworm,” parasitizes an estimated 1.2 billion people worldwide (de Silva *et al.*, 2003). Ascariasis may affect from 70% to 90% of persons in some tropical regions, but it also is seen in temperate climates. People become infected by ingesting food or soil contaminated with embryonated *A. lumbricoides* eggs. The highest ascaris worm burdens occur in school-aged children in whom the parasite can cause intestinal obstruction or hepatobiliary ascariasis (Crompton, 2001).

More effective, less toxic compounds largely have replaced the older ascaricides. *Mebendazole*, *pyrantel pamoate* (ANTIMINTH, others), and *albendazole* are preferred agents. *Piperazine* also is effective but is used less often because of occasional neurotoxicity and hypersensitivity reactions. Cure with any of these drugs can be achieved in nearly 100% of cases, and all infected persons should be treated. *Mebendazole* and *albendazole* are preferred for therapy of asymptomatic to moderate ascariasis. Both of these benzimidazoles are ascaricidal and have a broad spectrum of activity against mixed

Table 41–1

—NHCO ₂ CH ₃	CH ₃ CH ₂ CH ₂ S—	Albendazole

infections with other gastrointestinal nematodes. Albendazole is useful against infections with some systemic nematodes and some cestodes as well. Both compounds should be used with caution to treat heavy *Ascaris* infections, alone or with hookworms. In rare instances, hyperactive ascarids may migrate to unusual loci and cause serious complications such as appendicitis, occlusion of the common bile duct, intestinal obstruction, and intestinal perforation with peritonitis. Therapy with nonascaricidal agents such as pyrantel is preferred by some clinicians for heavy *Ascaris* infections because this agent paralyzes the worms prior to their expulsion. Surgery still may be required despite the use of these agents. Pyrantel is considered safe for use during pregnancy, whereas the BZAs should be avoided during the first trimester (see below). Pyrantel and albendazole are considered “investigational” drugs for treatment of ascariasis in the United States, even though they are approved for other indications.

Toxocariasis, a zoonotic infection caused by the canine ascarid *Toxocara canis*, is a common helminthiasis in North America and Europe. Possibly, it has displaced pinworm as the most common helminthic infection in the United States (Sharghi *et al.*, 2000). The three major syndromes caused by *T. canis* infection are visceral larva migrans (VLM), ocular larva migrans (OLM), and covert toxocariasis (CT). CT has been postulated to represent an underappreciated cause of asthma and seizures (Sharghi *et al.*, 2000; Sharghi *et al.*, 2001). The specific treatment of VLM is reserved for patients with severe, persistent, or progressive symptoms (Hotez *et al.*, 2005). Albendazole is the drug of choice. In contrast, the role of anthelmintic drugs for the treatment of OLM and CT is controversial. In the case of the former, surgical management often is indicated, sometimes accompanied by systemic or topical steroids (Sabrosa and de Souza, 2001).

Hookworm. *Necator americanus*, *Ancylostoma duodenale*. These closely related hookworm species infect 740 million people in developing countries (de Silva *et al.*, 2003). *N. americanus* is the predominant hookworm worldwide, especially in the Americas, sub-Saharan

Africa, South China, and Southeast Asia, whereas *A. duodenale* is focally endemic in Egypt, and parts of northern India and China. Infection also occurs farther north in unusual but relatively warm settings such as mines and large mountain tunnels, hence the term *miner’s disease* and *tunnel disease*. Hookworm larvae live in the soils and penetrate exposed skin. After reaching the lungs, the larvae migrate to the oral cavity and are swallowed. After attaching to the jejunal mucosa, the derived adult worms feed on host blood. There is a direct correlation between the number of hookworms (hookworm burden) as determined by quantitative fecal egg counts and fecal blood loss. In individuals with low iron reserves, the correlation extends to hookworm burden and degree of iron-deficiency anemia (Hotez *et al.*, 2004a). Unlike heavy *Ascaris* and *Trichuris* infections, which occur predominantly in children, heavy hookworm infections also occur in adults, including women of reproductive age. In some endemic areas, the heaviest hookworm burdens occur exclusively in adult populations.

Although iron supplementation (and transfusion in severe cases) often is helpful in individuals with severe iron-deficiency anemia, the major treatment goal is to remove blood-feeding adult hookworms from the intestines. Albendazole and mebendazole now are agents of first choice against both *A. duodenale* and *N. americanus*, and both benzimidazoles have the advantage of effectiveness against other roundworms when there is multiple infection. When used in a single dose, albendazole is superior to mebendazole at removing adult hookworms from the GI tract. Oral albendazole is the drug of choice for treating *cutaneous larva migrans* or “creeping eruption,” which is due most commonly to skin migration by larvae of the dog hookworm, *A. braziliense*. Oral ivermectin or topical *thiabendazole* also can be used.

***Trichuris trichiura*.** *Trichuris* (whipworm) infection occurs in an estimated 795 million people in developing countries (de Silva *et al.*, 2003). The infection is acquired by ingestion of embryonated eggs. In children, heavy *Trichuris* worm burdens can lead to colitis, *Trichuris* dysentery syndrome, and rectal prolapse (Bundy and Cooper, 1989). Mebendazole and albendazole are considered the safest and most effective agents for treatment of whipworm, alone or together with *Ascaris* and hookworm infections. Pyrantel pamoate is ineffective against *Trichuris*.

***Strongyloides stercoralis*.** *S. stercoralis*, sometimes called the threadworm or dwarf threadworm, is exceptional among helminths because it can replicate and cause cycles of larval reinfection within the human host. The organism infects more than 200 million people worldwide, most frequently in the tropics and other hot, humid locales. In the United States, strongyloidiasis is endemic in the Appalachian region. It also is found in institutionalized individuals living in unsanitary conditions and in immigrants, travelers, and military personnel who lived in endemic areas. Infective larvae in fecally contaminated soil penetrate the skin or mucous membranes, travel to the lungs, and ultimately mature into adult worms in the small intestine, where they reside. Most infected individuals are asymptomatic, while some experience skin rashes and gastrointestinal symptoms. Life-threatening, systemic disease due to massive larval hyperinfection can occur in immunosuppressed persons, even decades after the initial infection. Most deaths caused by parasites in the United States probably are due to *Strongyloides* hyperinfection. Ivermectin is the best drug for treating intestinal strongyloidiasis. Hyperinfection may require prolonged or repeated therapy. Effective benzimidazole com-

pounds, listed in order of decreasing efficacy, are thiabendazole and albendazole. Thiabendazole shows efficacy comparable to that of ivermectin but is far more toxic.

Enterobius vermicularis. *Enterobius*, the pinworm, is one of the most common helminth infections in temperate climates, including the United States. This parasite rarely causes serious complications; pruritus in the perianal and perineal regions, however, can be severe, and scratching may cause secondary infection. In female patients, worms may wander into the genital tract and penetrate into the peritoneal cavity. Salpingitis or even peritonitis may ensue. Because the infection is easily distributed throughout members of a family, a school, or an institution, the physician must decide whether to treat all individuals in close contact with an infected person, and more than one course of therapy may be required.

Pyrantel pamoate, mebendazole, and albendazole are highly effective. Single oral doses of each should be repeated after 2 weeks. When their use is combined with rigid standards of personal hygiene, a very high proportion of cures can be obtained. Treatment is simple and almost devoid of side effects.

Trichinella spiralis. *T. spiralis* is ubiquitous, regardless of climate, and can live outside its hosts. It is found in Canada, Eastern Europe, and now less frequently the United States. The infection results from eating raw or insufficiently cooked flesh of infected animals, especially pigs. When released by acid stomach contents, encysted larvae mature into adult worms in the intestine. Adults then produce infectious larvae that invade tissues, especially skeletal muscle and heart. Severe infection can be fatal, but more typically causes marked muscle pain and cardiac complications. Fortunately, infection is readily preventable. All pork, including pork sausages, should be thoroughly cooked before being eaten. The encysted larvae are killed by exposure to heat of 60°C for 5 minutes.

Albendazole and mebendazole appear to be effective against the intestinal forms of *T. spiralis* that are present early in infection. The efficacy of these agents or any anthelmintic agent on larvae that have migrated to muscle is questionable. Glucocorticoids may be of considerable value in controlling the acute and dangerous manifestations of established infection, although steroids can alter the metabolism of albendazole (see below).

***Wuchereria bancrofti* and *Brugia* Species (Lymphatic Filariasis).** Adult worms that cause human filariasis dwell either in the lymphatic system (*Wuchereria bancrofti*, *Brugia malayi*, *Brugia timori*) or other tissues (*Mansonella* species). Spread by the bites of infected mosquitoes, lymphatic filariasis (LF) affects nearly 120 million people, about 90% of them infected with *W. bancrofti* and most of the rest with *B. malayi*. Of the 120 million infections worldwide, approximately 40 million people in 80 countries have clinical disease (Molyneux and Zagaria, 2002). The major endemic regions are sub-Saharan Africa, the Indian subcontinent, Southeast Asia and the Pacific region, and the tropical regions of the Americas. In LF, host reactions to the adult worms initially cause lymphatic inflammation manifested by fevers, lymphangitis, and lymphadenitis; this can progress to lymphatic obstruction typified by lymphedema, hydrocele, and elephantiasis. A reaction to microfilariae, *tropical pulmonary eosinophilia*, also occurs in some persons. In 1997, the World Health Assembly passed a resolution calling on WHO member states to support the global elimination of LF. This led to the establishment of the Global Program for the Elimination of LF, which recommended that all at-risk individuals be treated once yearly with an

oral two-drug combination (Molyneux and Zagaria, 2002). For most countries, the WHO recommends albendazole and diethylcarbamazine. The exceptions are in many parts of sub-Saharan Africa, where loiasis and onchocerciasis are co-endemic, and in Yemen, where albendazole and ivermectin are the drugs of choice (Molyneux *et al.*, 2003). These drugs clear circulating microfilariae from infected subjects (Molyneux and Zagaria, 2002), thereby reducing the likelihood that mosquitoes will transmit LF to other individuals. To date the number of serious adverse events from LF-control mass chemotherapy programs has been remarkably low and recently was estimated at 1 out of 4.5 million (Molyneux *et al.*, 2003).

Diethylcarbamazine also is the drug of choice for the direct treatment of LF adult worms. However, the effect on the adult worms is variable; best results are achieved in *W. bancrofti* and *B. malayi* infections if chemotherapy is started early, before lymphatic obstruction has occurred. Diethylcarbamazine decreases the incidence of filarial lymphangitis, but it is unclear whether it reverses lymphatic damage or other chronic manifestations of LF. In long-standing elephantiasis, surgical measures are required to improve lymph drainage and remove redundant tissue. Filariasis caused by *Mansonella* species, transmitted largely by midges, is variably responsive to chemotherapy, but does not usually result in serious pathology.

***Loa loa* (loiasis).** Transmitted by deerflies, *L. loa* is a tissue-migrating filarial parasite found in large river regions of Central and West Africa. Adult worms in subcutaneous tissues typically cause episodic “Calabar” swellings and allergic reactions, but also can penetrate the conjunctivae and skin. Rarely, encephalopathy, cardiopathy, or nephropathy occur in association with heavy infection. Diethylcarbamazine currently is the best single drug for the treatment of loiasis, but it is advisable to start with a small initial dose to diminish host reactions that result from destruction of microfilariae. Glucocorticoids often are required to control acute reactions. In rare instances, serious cerebral reactions occur in the treatment of loiasis, probably due to destruction of microfilariae in the brain or cerebral vasculature. If headache is severe and there is other evidence of an adult *L. loa* near the orbit, extra caution for initial dosing is advised. The potential complications of unmonitored diethylcarbamazine treatment of loiasis are the major reason that this agent is not recommended for mass chemoprophylaxis of LF in regions of sub-Saharan Africa where *L. loa* is co-endemic.

***Onchocerca volvulus* (Onchocerciasis or River Blindness).** Transmitted by blackflies near fast-flowing streams and rivers, *O. volvulus* infects about 17 million people in 22 countries in sub-Saharan Africa (Molyneux *et al.*, 2003), and less than 100,000 people in parts of Mexico, Guatemala, and South America. Some cases also occur in Yemen. Inflammatory reactions, primarily to microfilariae rather than adult worms, affect the subcutaneous tissues, lymph nodes, and eyes. Onchocerciasis is a leading cause of infectious blindness worldwide, and results from the cumulative destruction of microfilariae in the eyes, a process that evolves over decades.

Ivermectin is the best single drug for control and treatment of onchocerciasis. Diethylcarbamazine is no longer recommended. Both agents kill only microfilariae of *O. volvulus*, but ivermectin produces far milder systemic reactions and few if any ocular complications. With diethylcarbamazine, such reactions are likely to be severe, particularly in cases in which there are lesions of the eye. Ivermectin treatments clear microfilariae in the tissues, pre-

vent the development of blindness, and interrupt onchocerciasis transmission, a cornerstone of control. Widespread use of ivermectin from 1974 through 2002 through the Mectizan donation plan resulted in the prevention of 600,000 cases of blindness. Since then, the Nongovernmental Development Organizations Group for Onchocerciasis Control (which includes UNICEF, The Carter Center, Lion Clubs, and Helen Keller International, among others) has proposed ivermectin treatment for at least 40 million additional people (www.who.int/pbd/blindness/onchocerciasis). Although *suramin* (see Chapter 40) is lethal to adult *O. volvulus*, treatment with this relatively toxic agent probably is unwarranted. Less toxic macrofilaricides are needed.

***Dracunculus medinensis*.** Known as the guinea, dragon, or Medina worm, this parasite causes dracunculiasis, an infection in decline that is most commonly found in rural Sudan and West Africa. People become infected by drinking water containing copepods that carry infective larvae. After about 1 year, the adult female worms migrate and emerge through the skin, usually of the lower legs or feet.

There is no suitable anthelmintic that acts directly against *D. medinensis*. Traditional treatment for this disabling condition is to draw the live adult female worm out day by day by rolling it onto a small piece of wood. This procedure risks severe infection if rupture occurs. *Metronidazole*, 250 mg given three times a day for 10 days, can provide symptomatic and functional relief by facilitating removal of the worm through indirect suppression of host inflammatory responses. Through the advocacy and work of the Carter Center, strategies such as filtering drinking water and reducing contact of infected individuals with water have markedly reduced the transmission and prevalence of dracunculiasis in most endemic regions.

Cestodes (Flatworms)

***Taenia saginata*.** Humans are the definitive hosts for *Taenia saginata*, known as the beef tapeworm. This most common form of tapeworm usually is detected after passage of proglottids from the intestine. It is cosmopolitan, occurring most commonly in sub-Saharan Africa and the Middle East, where undercooked or raw beef is consumed. Preventable by cooking beef to 60°C for over 5 minutes, this infection rarely produces serious clinical disease, but it must be distinguished from that produced by *Taenia solium*.

Praziquantel is the drug of choice for treatment of infection by *T. saginata*, although *niclosamide* also is used because it is cheap and available. Both are very effective, simple to administer, and comparatively free from side effects. Assessment of cure can be difficult because the worm (segments as well as scolex) usually is passed in a partially digested state. If the parasitological diagnosis is uncertain, praziquantel is the preferred drug because of the danger of cysticercosis (see below).

***Taenia solium*.** *Taenia solium*, or pork tapeworm, also has a cosmopolitan distribution; immigrant populations are a common source of infection in the United States. This cestode causes two types of infection. The intestinal form with adult tapeworms is caused by eating undercooked meat containing cysticerci; this can be prevented by proper cooking of infected meat. *Cysticercosis*, the far more dangerous systemic form that usually coexists with the intestinal form, is caused by invasive larval forms of the parasite (Garcia and Del Brutto, 2000). This infection by parasite eggs usually results either from ingestion of fecally contaminated infectious material, or from eggs liberated from a gravid segment passing upward into the duodenum, where the outer layers are digested. In either case, larvae

gain access to the circulation and tissues exactly as in their cycle in the intermediate host, usually the pig. The seriousness of the resulting disease depends on the particular tissue involved. Invasion of the brain (neurocysticercosis) is common and dangerous. Epilepsy, meningitis, and increased intracranial pressure can develop, depending on the inflammatory reactions to the cysticerci and/or their size and location. Praziquantel is preferred for treatment of intestinal infections with *T. solium*. Albendazole and praziquantel are the drugs of choice for treating cysticercosis, although most studies suggest that albendazole is more effective. Chemotherapy is appropriate only when it is directed at live cysticerci causing pathology; pre-treatment with glucocorticoids is advised strongly in this situation to minimize inflammatory reactions to dying parasites (Evans *et al.*, 1997). Anthelmintic treatment can shrink brain cysts but also can have adverse consequences leading to seizures and hydrocephalus. One trial found that there was insufficient evidence to determine whether cysticidal therapy in neurocysticercosis is associated with beneficial effects (Salinas and Prasad, 2000). Some investigators and physicians advocate use of cysticidal therapy for patients with multiple cysts or viable cysts (as determined by absence of ring enhancement on contrast neuroimaging studies).

***Diphyllobothrium latum*.** *Diphyllobothrium latum*, the fish tapeworm, is found most commonly in rivers and lakes of the northern hemisphere. In North America, the pike is the most common second intermediate host. The eating of inadequately cooked, infested fish introduces the larvae into the human intestine; the larvae can develop into adult worms up to 25 meters long. Most infected individuals are asymptomatic. The most frequent manifestations include abdominal symptoms and weight loss, while megaloblastic anemia develops due to a deficiency of vitamin B₁₂, which is taken up by the parasite. Therapy with praziquantel readily eliminates the worm and ensures hematological remission.

***Hymenolepis nana*.** *Hymenolepis nana*, the dwarf tapeworm, is the smallest and most common tapeworm parasitizing humans. Infection with this cestode is cosmopolitan, more prevalent in tropical than temperate climates, and most common among institutionalized children, including those in the southern United States. *H. nana* is the only cestode that can develop from ovum to mature adult in humans without an intermediate host. Cysticerci develop in the villi of the intestine and then regain access to the intestinal lumen where larvae mature into adults. Treatment therefore must be adapted to this cycle of autoinfection. Praziquantel is effective against *H. nana* infections, but higher doses than those used for other tapeworm infections usually are required. In addition, therapy may have to be repeated. Treatment failure or reinfection is indicated by the appearance of eggs in the stool about 4 weeks after the last dose. Albendazole is partially efficacious against *H. nana*; in 277 cases from 11 studies, 69.5% of patients were cured by albendazole (400 mg daily for 3 days) (Horton, 2000).

***Echinococcus* Species.** Humans serve as one of several intermediate hosts for larval forms of *Echinococcus* species that cause “cystic” (*E. granulosus*) and “alveolar” (*E. multilocularis* and *E. vogeli*) hydatid disease. Dogs are definitive hosts for these tapeworms. Parasite eggs from canine stools are a major worldwide cause of disease in associated livestock (*e.g.*, sheep and goats). *E. granulosus* produces unilocular, slowly growing cysts, most often in liver and lung, whereas *E. multilocularis* creates multilocular invasive cysts, predominantly in the same organs. Removal of the cysts by surgery is the preferred treatment, but leakage from ruptured cysts may spread disease to other organs. Prolonged regimens of albendazole, either alone or as an adjunct to surgery, are reportedly of some ben-

efit. However, some patients are not cured despite multiple courses of therapy. Treatment of infected dogs with praziquantel eradicates adult worms and interrupts transmission of these infections. New treatment methods, such as percutaneous puncture, aspiration, injection of scolicalid agents, and re-aspiration-based techniques, have received much attention, and yield rates of cure and relapse equivalent to those following surgery. Adjunct treatment with BZAs now is considered the cornerstone of the interdisciplinary approach to controlling cystic echinococcosis (Kern, 2003).

Trematodes (Flukes)

Schistosoma haematobium, *Schistosoma mansoni*, *Schistosoma japonicum*. These are the main species of blood flukes that cause human schistosomiasis; less common species are *Schistosoma intercalatum* and *Schistosoma mekongi*. The infection affects about 200 million people, and more than 600 million are considered at risk. Schistosomiasis is widely distributed over the South American continent and certain Caribbean islands (*S. mansoni*), much of Africa and the Arabian Peninsula (*S. mansoni* and *S. haematobium*), and China, the Philippines, and Indonesia (*S. japonicum*). Infected snails act as intermediate hosts for freshwater transmission of the infection, which continues to spread as the development of agricultural and water resources increases. Schistosomiasis, or schistosomal disease, which generally correlates with the intensity of infection, primarily involves the liver, spleen, and gastrointestinal tract (*S. mansoni* and *S. japonicum*) or the lower genitourinary tract (*S. haematobium*). Heavy infections with *S. haematobium* are associated with squamous cell carcinoma of the bladder in some endemic regions. Chronic infections can result in portosystemic shunting due to granuloma formation and periportal fibrosis in the liver.

Praziquantel is the drug of choice for treating all species of schistosomes that infect humans. The drug is safe and effective when given in single or divided oral doses on the same day. These properties make praziquantel especially suitable for population-based chemotherapy. Moreover, repeated chemotherapy with praziquantel is thought to accelerate protective immune responses by increasing exposure to antigens released from dying worms that induce a T-helper type-2 response (Mutapi *et al.*, 1998). Although not effective clinically against *S. haematobium* and *S. japonicum*, oxamniquine is effective for treatment of *S. mansoni* infections, particularly in South America, where the sensitivity of most strains may permit single-dose therapy. However, resistance has been reported, in both the field and the laboratory, and higher doses of the drug are required to treat African strains than to treat Brazilian strains of *S. mansoni*. Metrifonate has been used with considerable success in the treatment of *S. haematobium* infections, but the drug is not effective against *S. mansoni* and *S. japonicum*. Metrifonate is relatively inexpensive and can be used in conjunction with oxamniquine for treatment of mixed infections with *S. haematobium* and *S. mansoni*.

The artemisinin derivative *artemether* (see Chapter 39) shows promise as an anti-schistosomal agent. Artemether targets the larval schistosomula stages of the parasite. Clinical trials confirmed that artemether (oral dose of 6 mg/kg once every 2 to 3 weeks) significantly reduced the incidence and intensity of schistosome infections without adverse reactions. Combined treatment of animals harboring juvenile and adult schistosome worms with artemether and praziquantel resulted in significantly higher worm burden reductions than each drug administered singly (Xiao *et al.*, 2002). There is concern, however, that widespread use of artemether as an anthelmintic may induce drug-resistant malaria in areas where multidrug resistant plasmodia still respond to artemether therapy.

Paragonimus westermani and Other *Paragonimus* Species. Called lung flukes, a number of *Paragonimus* species, of which *P. westermani* is the most common, are pathogenic for humans and carnivores. Found in the Far East and on the African and South American continents, these parasites have two intermediate hosts: snails and crustaceans. Humans become infected by eating raw or undercooked crabs or crayfish. Disease is caused by reactions to adult worms in the lungs and ectopic sites. Although these flukes are rather refractory to praziquantel *in vitro*, the drug is effective when used clinically. *Bithionol* is considered a second-line agent. *Triclabendazole* recently was shown to be efficacious in animals, and when a small number of human patients were treated with 10 mg/kg daily for 3 days, all were cured (Gao *et al.*, 2003).

Clonorchis sinensis, *Opisthorchis viverrini*, *Opisthorchis felineus*. These closely related trematodes exist in the Far East (*C. sinensis*, “the Chinese liver fluke,” and *O. viverrini*) and parts of Eastern Europe (*O. felineus*). Metacercariae released from poorly cooked infected cyprinoid fish mature into adult flukes that inhabit the human biliary system. Heavy infections can cause obstructive liver disease, inflammatory gallbladder pathology associated with cholangiocarcinoma, and obstructive pancreatitis. One-day therapy with praziquantel is highly effective against these parasites.

Fasciola hepatica. Humans are only accidentally infected with *F. hepatica*, the large liver fluke that exists worldwide and primarily affects herbivorous ruminants such as cattle and sheep. Eating contaminated freshwater plants such as watercress initiates the infection. Migratory larvae penetrate the intestine, invade the liver from the peritoneum, and eventually reside in the biliary tract. The acute illness is characterized by fever, urticaria, and abdominal symptoms, whereas chronic infection resembles that caused by other hepatic flukes. However, unlike *O. viverrini*, *F. hepatica* infection is not associated with cholangiocarcinoma. Unlike infections with other flukes, fascioliasis does not usually respond to praziquantel. Previously the recommended drug was bithionol, which may be obtained from the Centers for Disease Control and Prevention Drug Service. However, triclabendazole, given as a single oral dose of 10 mg/kg, or in cases of severe infection 20 mg/kg divided into two doses, now is the drug of choice for human fascioliasis. In the United States, this agent is available only from the manufacturer (Novartis). The cure rate among a cohort of Turkish patients was 78%, and the addition of another course(s) increased this to 90%. No significant side effects were reported (Saba *et al.*, 2004).

Fasciolopsis buski, *Heterophyes heterophyes*, *Metagonimus yokogawai*, *Nanophyetus salmincola*. Obtained by eating contaminated water chestnuts and other caltrops in Southeast Asia, *F. buski* is one of the largest parasites causing human infection. Undercooked fish transmit infection with the other, much smaller gastrointestinal trematodes that are widely distributed geographically. Abdominal symptoms produced by reactions to these flukes usually are mild, but heavy infections with *F. buski* can cause intestinal obstruction and peritonitis. Infections with all the intestinal trematodes respond well to single-day therapy with praziquantel.

ANTHELMINTIC DRUGS

Benzimidazoles (BZAs)

History. The discovery by Brown and coworkers that thiabendazole possessed potent activity against gastrointesti-

nal nematodes sparked development of the BZAs as broad-spectrum anthelmintic agents against parasites of both veterinary and human medical importance. Of the hundreds of derivatives tested, those most therapeutically useful have modifications at the 2 and/or 5 positions of the benzimidazole ring system (Townsend and Wise, 1990). Three compounds, thiabendazole, mebendazole, and albendazole, have been used extensively for the treatment of human helminth infections. The chemical structures of these drugs are shown in Table 41–1.

Thiabendazole, which contains a thiazole at position 2, is active against a wide range of nematodes that infect the GI tract. However, its clinical use against these organisms has declined markedly because of thiabendazole's toxicity relative to that of other equally effective drugs. Mebendazole, the prototype benzimidazole carbamate, was introduced for the treatment of intestinal roundworm infections as a result of research carried out more than 30 years ago. Albendazole is a newer benzimidazole carbamate that is used worldwide, primarily against a variety of intestinal and tissue nematodes, but also against larval forms of certain cestodes (de Silva *et al.*, 1997; Venkatesan, 1998). Albendazole has become the drug of choice for treating cysticercosis (Sotelo and Jung, 1998; Garcia and Del Brutto, 2000) and cystic hydatid disease (Horton, 1997). When used yearly in conjunction with either ivermectin or diethylcarbamazine, single doses of albendazole have shown considerable promise for global control of lymphatic filariasis and related tissue filarial infections (Molyneux and Zagaria, 2002; Molyneux *et al.*, 2003). Albendazole is not effective against *F. hepatica*.

Anthelmintic Action. BZAs produce many biochemical changes in susceptible nematodes including inhibition of mitochondrial fumarate reductase, reduced glucose transport, and uncoupling of oxidative phosphorylation, but their primary action likely is to inhibit microtubule polymerization by binding to β -tubulin (Lacey, 1988; Lacey, 1990; Prichard, 1994). The selective toxicity of these agents results because the BZAs bind parasite β -tubulin with much higher affinity than they do the mammalian protein. Studies on BZA-resistant worms, such as the free-living nematode *Caenorhabditis elegans* (Driscoll *et al.*, 1989) and the sheep nematode *Haemonchus contortus*, have provided insights into the mechanisms of BZA action (Lacey, 1990; Prichard, 1994). In particular, both laboratory-derived and field-isolated strains of benzimidazole-resistant *H. contortus* display reduced high-affinity drug binding to β -tubulin (Lubega and Prichard, 1991) and alterations in β -tubulin isotype gene expression (Kwa *et al.*, 1993; Kwa *et al.*, 1995; Roos, 1997) that correlate with drug resistance. Thus, the two identified mechanisms of drug resistance in nematodes involve both a progressive loss of "susceptible" β -tubulin gene isotypes together with emergence of a "resistant" isotype with a conserved point mutation that encodes a tyrosine instead of a phenylalanine at position 200 of β -tubulin (Roos, 1997; Sangster and Gill, 1999). While this mutation may not be required for BZA resistance in all parasites, *e.g.*, *G. lamblia* (Upcroft *et al.*, 1996), development of novel BZA analogs that target this form of resistance in parasitic nematodes will be challenging because tyrosine also is present at position 200 of human β -tubulin. Although BZA resistance currently is widespread among livestock nematodes, to date there has been no evidence for its emergence among human nematodes. However, the recent observa-

tion that the efficacy of mebendazole can diminish in some settings with frequent and periodic use (Albonico *et al.*, 2003), and the plans for the widespread use of BZAs to control LF caused by STH (Horton, 2003), suggest that global monitoring for downstream BZA resistance could become critically important.

The BZAs, exemplified by mebendazole and albendazole, are versatile anthelmintic agents, particularly against gastrointestinal nematodes, where their action is not dictated by systemic drug concentration. Appropriate doses of mebendazole and albendazole are highly effective in treating the major STH infections (ascariasis, enterobiasis, trichuriasis, and hookworm) as well as less common human nematode infections. These drugs are active against both larval and adult stages of nematodes that cause these infections, and they are ovicidal for *Ascaris* and *Trichuris*. Immobilization and death of susceptible gastrointestinal parasites occur slowly, and their clearance from the GI tract may not be complete until several days after treatment. Accumulating evidence indicates that removal of STHs in children by a single-dose treatment with either albendazole or mebendazole improves their health, as evidenced by posttreatment catch-up growth and improved iron status (Stephenson *et al.*, 1989; Hotez, 2000; Hotez *et al.*, 2005). In addition, BZA treatment of STH infections also produces improvements in childhood intellectual and cognitive development (Drake *et al.*, 2000). These observations have led to advocacy for the implementation of large-scale STH control programs that target school-aged children (Savioli *et al.*, 2002; World Health Organization, 2002). Albendazole is superior to mebendazole in curing hookworm and trichuriasis infections in children (de Silva *et al.*, 1997; de Silva *et al.*, 2003; Bennett and Guyatt, 2000), especially when used as a single dose (Albonico *et al.*, 2003). Moreover, albendazole is more effective than mebendazole against strongyloidiasis (Liu and Weller, 1993), cystic hydatid disease caused by *Echinococcus granulosus* (Horton, 1997; Davis *et al.*, 1989), and neurocysticercosis caused by larval forms of *Taenia solium* (Evans *et al.*, 1997; Garcia and Del Brutto, 2000). The BZAs probably are active against the intestinal stages of *Trichinella spiralis* in humans, but probably do not affect the larval stages in tissues. Albendazole is highly effective against the migrating forms of dog and cat hookworms that cause cutaneous larval migrans, although thiabendazole can be used topically for this purpose. Regimens in which albendazole with either ivermectin or diethylcarbamazine are given as single annual doses show great promise for the elimination of LF (Molyneux and Zagaria, 2002). Such combined therapy has the additional benefit of reducing STH worm burdens in school-aged children (Albonico *et al.*, 1999). Certain microsporidial species that cause intestinal infections in HIV-infected individuals respond partially (*Enterocytozoon bieneusi*) or completely (*Encephalitozoon intestinalis* and related *Encephalitozoon* species) to albendazole; albendazole's sulfoxide metabolite appears to be especially effective against these parasites *in vitro* (Katiyar and Edlind, 1997). Albendazole also has some efficacy against anaerobic protozoa such as *Trichomonas vaginalis* and *Giardia lamblia* (Ottesen *et al.*, 1999). While BZAs have antifungal activity, their clinical use against human mycoses is limited.

Absorption, Fate, and Excretion. BZAs have only limited solubility in water; minor differences in solubility consequently have a major effect on absorption.

Thiabendazole is absorbed rapidly after oral ingestion and reaches peak concentrations in plasma after about 1 hour. Most

of the drug is excreted in the urine within 24 hours as 5-hydroxythiabendazole, conjugated either as the glucuronide or the sulfate. In contrast, tablet formulations of mebendazole are poorly and erratically absorbed, and concentrations of the drug in plasma are low and do not reflect the dosage taken. The low systemic bioavailability (22%) of mebendazole results from a combination of poor absorption and rapid first-pass hepatic metabolism. Co-administration of *cimetidine* will increase plasma levels of mebendazole, possibly due to inhibition of first-pass CYP-mediated metabolism (Dayan, 2003). Mebendazole is about 95% bound to plasma proteins and is extensively metabolized. The major metabolites, methyl-5-(α -hydroxybenzyl)-2-benzimidazole carbamate and 2-amino-5-benzoylbenzimidazole, have lower rates of clearance than does mebendazole. Mebendazole, rather than its metabolites, appears to be the active drug form (Gottschall *et al.*, 1990). Conjugates of mebendazole and its metabolites have been found in bile, but little unchanged mebendazole appears in the urine.

Albendazole is variably and erratically absorbed after oral administration; absorption is enhanced by the presence of fatty foods and possibly by bile salts. A fatty meal or eating enhances absorption by up to fivefold in humans (Dayan, 2003). After a 400-mg oral dose, albendazole cannot be detected in plasma, because the drug is rapidly metabolized in the liver and possibly in the intestine, to albendazole sulfoxide, which has potent anthelmintic activity (Marriner *et al.*, 1986; Moroni *et al.*, 1995; Redondo *et al.*, 1999). Both the (+) and (–) enantiomers of albendazole sulfoxide are formed, but the (+) enantiomer reaches much higher peak plasma concentrations in humans and is cleared much more slowly than the (–) form (Delatour *et al.*, 1991; Marques *et al.*, 1999). Total sulfoxide attains peak plasma concentrations of about 300 ng/ml, but with wide interindividual variation. Albendazole sulfoxide is about 70% bound to plasma proteins and has a highly variable plasma half-life ranging from about 4 to 15 hours (Delatour *et al.*, 1991; Jung *et al.*, 1992; Marques *et al.*, 1999). It is well distributed into various tissues including hydatid cysts, where it reaches a concentration of about one-fifth that in plasma (Marriner *et al.*, 1986; Morris *et al.*, 1987). This probably explains why albendazole is more effective than mebendazole for treating hydatid cyst disease, and possibly other tissue-dwelling helminths. Formation of albendazole sulfoxide is catalyzed by both microsomal flavin monooxygenase and CYP isoforms in the liver and possibly also in the intestine (Redondo *et al.*, 1999). Hepatic flavin monooxygenase activity appears associated with (+) albendazole sulfoxide formation, whereas CYPs preferentially produce the (–) sulfoxide metabolite (Delatour *et al.*, 1991). Both sulfoxide derivatives are oxidized further to the nonchiral sulfone metabolite of albendazole, which is pharmacologically inactive; this reaction favors the (–) sulfoxide and probably becomes rate limiting in determining the clearance and plasma half-life of the bioactive (+) sulfoxide metabolite (Delatour *et al.*, 1991). Induction of enzymes involved in sulfone formation from the (+) sulfoxide could account for some of the wide variation noted in plasma half-lives of albendazole sulfoxide. Indeed, in animal models, BZAs can induce their own metabolism (Gleizes *et al.*, 1991). Albendazole metabolites are excreted mainly in the urine.

Therapeutic Uses. The introduction of thiabendazole (MINTEZOL) was a major advance in the therapy of cuta-

neous larva migrans (creeping eruption) and *Strongyloides stercoralis* infection. The majority of patients experience marked relief of symptoms of creeping eruption, and a high percentage of cures are achieved after topical treatment with 15% thiabendazole in a water-soluble cream base applied to the affected area two or three times per day for 5 days (Davies *et al.*, 1993). A common regimen for therapy of strongyloidiasis is 25 mg/kg of thiabendazole given twice daily after meals for 2 days; the total daily dose should not exceed 3 g. This schedule should be extended for 5 to 7 days for treatment of disseminated strongyloidiasis or until the parasites have been eliminated. As a first-line drug for the treatment of strongyloidiasis, thiabendazole has been largely replaced by ivermectin (*see* “Ivermectin,” below). Thiabendazole given at a dosage of 25 mg/kg twice daily for 7 days may produce some benefit for early trichinosis, but has no effect on migrating or muscle-stage larvae. Thiabendazole also is effective in gastrointestinal nematode infections, but because of its toxicity, it should no longer be used for those infections.

Mebendazole is highly effective against gastrointestinal nematode infections and is particularly valuable for the treatment of mixed infections. Mebendazole always is taken orally, and the same dosage schedule applies to adults and children more than 2 years of age. For treatment of enterobiasis, a single 100-mg tablet is taken; a second should be given after 2 weeks. For control of ascariasis, trichuriasis, or hookworm infections, the recommended regimen is 100 mg of mebendazole taken in the morning and evening for 3 consecutive days (or a single 500-mg tablet administered once). If the patient is not cured 3 weeks after treatment, a second course should be given. The 3-day mebendazole regimen is more effective than single doses of either mebendazole (500 mg) or albendazole (400 mg), which also have been used successfully to control these mixed infections. A single dose of albendazole appears superior to a single dose of mebendazole against hookworms (de Silva *et al.*, 1997; Bennett and Guyatt, 2000). A single dose of mebendazole achieves a cure rate against hookworm of only 21% (Bennett and Guyatt, 2000). Moreover, the efficacy of mebendazole against hookworm may diminish with frequent and repeated use (Albonico *et al.*, 2003), which may reflect emerging BZA drug resistance.

Infections with *Capillaria philippinensis* are also resistant to treatment with mebendazole, and a 10-day treatment regimen with albendazole (400 mg/day) is considered the drug of choice, although 400 mg/day of mebendazole given in two divided doses for at least 20 days produced

few relapses in patients with relapses after thiabendazole (Cross, 1992). Mebendazole has been used to treat cystic hydatid disease, although surgery should be performed first, and chemotherapy with albendazole now is considered to be superior (Horton, 1997).

Like mebendazole, albendazole provides safe and highly effective therapy against infections with gastrointestinal nematodes, including mixed infections of *Ascaris*, *Trichuris*, and hookworms. For treatment of STH infections (enterobiasis, ascariasis, trichuriasis, and hookworm), albendazole is taken as a single oral 400-mg dose by adults and children more than 2 years of age. In children between the ages of 12 and 24 months, the WHO recommends a reduced dose of 200 mg. Cure rates for light to moderate *Ascaris* infections typically are more than 97%, although heavy infections may require therapy for 2 to 3 days. A 400-mg dose of albendazole appears to be superior to a 500-mg dose of mebendazole for curing hookworm infections and reducing egg counts (Sacko *et al.*, 1999; Bennett and Guyatt, 2000). At a dose of 400 mg daily for 3 days, albendazole exhibits highly variable efficacy against strongyloidiasis; both thiabendazole and ivermectin are more effective in treating this infection.

Albendazole is the drug of choice for treating cystic hydatid disease due to *Echinococcus granulosus*. While the drug provides only a modest cure rate when used alone, it produces superior results when used before and after either surgery to remove cysts or aspiration/injection of cysts with protoscolicidal agents (Horton, 1997; Schantz, 1999). A typical dosage regimen for adults is 400 mg given twice a day (for children 15 mg/kg per day with a maximum of 800 mg) for 1 to 6 months. This regimen often is used as adjunctive therapy for either surgical resection or percutaneous drainage. While still the best drug available, albendazole appears to be just marginally effective against alveolar echinococcosis caused by *E. multilocularis* (Venkatesan, 1998); therefore surgical intervention is usually required.

Albendazole also is the preferred treatment of neurocysticercosis caused by larval forms of *Taenia solium* (Evans *et al.*, 1997; Sotelo and Jung, 1998; Garcia and Del Brutto, 2000). The recommended dosage is 400 mg given twice a day for adults for 8 to 30 days, depending on the number, type, and location of the cysts. For children, the dose is 15 mg/kg per day (maximum 800 mg) in two doses for 8 to 30 days. For both adults and children, the course can be repeated as necessary, as long as liver and bone marrow toxicities are monitored. Glucocorticoids are usually given for several days before initiating albendazole therapy to reduce the incidence of side effects

resulting from inflammatory reactions to dead and dying cysticerci. Such pretreatment also increases plasma levels of albendazole sulfoxide. Therapy with either albendazole or praziquantel should include consultation with a neurologist and/or neurosurgeon regarding anticonvulsant therapy, the possible development of complications of arachnoiditis, vasculitis, or cerebral edema, and the need for surgical intervention should obstructive hydrocephalus occur. Albendazole, 400 mg per day, also has shown efficacy for therapy of microsporidial intestinal infections in patients with AIDS.

Albendazole has been combined with either diethylcarbamazine or ivermectin in programs directed toward controlling LF (Ottesen *et al.*, 1999; Molyneux and Zagaria, 2002). By annual dosing with combination therapy for 4 to 6 years, the strategy is to maintain the microfilaremia at such low levels that transmission cannot occur. The period of therapy is estimated to correspond to the duration of fecundity of adult worms. Albendazole is given with diethylcarbamazine to control LF in most parts of the world. However, to avoid serious reactions to dying microfilariae, the albendazole/ivermectin combination is recommended in locations where filariasis coexists with either onchocerciasis or loiasis. Recently, the benefits of adding albendazole to either diethylcarbamazine or ivermectin for LF control were evaluated (Addiss *et al.*, 2004). It was concluded that there currently is insufficient reliable research to confirm or refute whether adding albendazole has an effect on LF.

Toxicity, Side Effects, Precautions, and Contraindications. Overall, the BZAs have excellent safety profiles. To date millions of children have been treated in mass deworming chemotherapy programs. Overall, the incidence of side effects, primarily mild GI symptoms, occurs in only 1% of treated children (Urbani and Albonico, 2003).

The clinical utility of thiabendazole in adults is compromised by its toxicity. Side effects frequently encountered with therapeutic doses include anorexia, nausea, vomiting, and dizziness. Less frequently, diarrhea, fatigue, drowsiness, giddiness, or headache occur. Occasional fever, rashes, erythema multiforme, hallucinations, sensory disturbances, and Stevens-Johnson syndrome have been reported. Angioedema, shock, tinnitus, convulsions, and intrahepatic cholestasis are rare complications of therapy. Some patients excrete a metabolite that imparts an odor to the urine much like that occurring after ingestion of asparagus. Crystalluria without hematuria has been reported on occasion; it promptly subsides with discontinuation of therapy. Transient leukopenia has been noted in a few patients on thiabendazole therapy. There are no absolute contraindications to the use of thiabendazole. Because CNS side effects occur

frequently, activities requiring mental alertness should be avoided during therapy. Thiabendazole has hepatotoxic potential and should be used with caution in patients with hepatic disease or decreased hepatic function. The effects of thiabendazole in pregnant women have not been studied adequately, so it should be used in pregnancy only when the potential benefit justifies the risk.

Unlike thiabendazole, mebendazole does not cause significant systemic toxicity in routine clinical use, even in the presence of anemia and malnutrition. This probably reflects its low systemic bioavailability. Transient symptoms of abdominal pain, distention, and diarrhea have occurred in cases of massive infestation and expulsion of gastrointestinal worms. Rare side effects in patients treated with high doses of mebendazole include allergic reactions, alopecia, reversible neutropenia, agranulocytosis, and hypospermia. Reversible elevation of serum transaminases is not uncommon in this population. Mebendazole treatment may be associated with occipital seizures (Wilmshurst and Robb, 1998). Mebendazole is a potent embryotoxin and teratogen in laboratory animals; effects may occur in pregnant rats at single oral doses as low as 10 mg/kg. Thus, despite a lack of evidence for teratogenicity in humans, it generally is advised that mebendazole not be given to pregnant women or to children less than 2 years of age (*see* below for exceptions and further explanation). It also should not be used in patients who have experienced allergic reactions to the agent.

Like mebendazole, albendazole produces few side effects when used for short-term therapy of gastrointestinal helminthiasis, even in patients with heavy worm burdens. Transient mild GI symptoms (epigastric pain, diarrhea, nausea, and vomiting) occur in approximately 1% of treated individuals. Dizziness, and headache occur on occasion. In school-age mass treatments, the incidence of side effects with albendazole is very low (Horton, 2000). Allergic phenomena rarely occur (edema 7/10,000; rashes 2/10,000; and urticaria 1/10,000) but these usually resolve after 48 hours. In children with asymptomatic trichuriasis, albendazole reportedly impaired growth in children with low levels of infection (Forrester *et al.*, 1998); to date, this observation has not been confirmed.

Even in long-term therapy of cystic hydatid disease and neurocysticercosis, albendazole is well tolerated by most patients. The most common side effect is an increase in serum aminotransferase activity; rarely jaundice or chemical cholestasis may be noted, but enzyme activities return to normal after therapy is completed. A recent pharmacoepidemiologic analysis concluded that long-term treatment of echinococcosis or cysticercosis with high-dose albendazole accounted for most of the adverse drug reactions attributed to anthelmintic therapy (Bagheri *et al.*, 2004). Therefore, liver function tests should be monitored during protracted albendazole therapy, and the drug is not recommended for patients with cirrhosis (Davis *et al.*, 1989). Especially if not pretreated with glucocorticoids, some patients with neurocysticercosis may experience serious neurological sequelae that depend on the location of inflamed cysts with dying cysticerci. Other side effects during extended therapy include gastrointestinal pain, severe headaches, fever, fatigue, loss of hair, leukopenia, and thrombocytopenia. Albendazole is teratogenic and embryotoxic in animals and it should not be given to pregnant women. The safety of albendazole in children less than 2 years of age has not been established.

The BZAs as a group display remarkably few clinically significant interactions with other drugs. The most ver-

satile member of this family, albendazole, probably induces its own metabolism, and plasma levels of its sulfoxide metabolites can be increased by coadministration of glucocorticoids and possibly praziquantel. Caution is advised when using high doses of albendazole together with general inhibitors of hepatic CYPs. As indicated above, coadministration of cimetidine can increase the bioavailability of mebendazole.

Use in Pregnancy. Because of the ongoing and anticipated widespread use of BZAs in global control programs for both STH and filarial infections, there is a high level of interest about their use in young children and in the second and third trimesters of pregnancy.

As indicated above, both albendazole and mebendazole are embryotoxic and teratogenic in pregnant rats, and are not generally recommended for use in pregnancy (Hotez *et al.*, 2005). However, in postmarketing surveys on women who inadvertently consumed mebendazole during the first trimester, the incidence of spontaneous abortion and malformations did not exceed that of the general population; comparable studies with albendazole are not available. A review of the risk of congenital abnormalities from BZAs concluded that their use during pregnancy was not associated with an increased risk of major congenital defects; nonetheless, it is recommended that treatment should be avoided during the first trimester of pregnancy (Urbani and Albonico, 2003). Because hookworm occurs in an estimated 44 million pregnant women in developing countries (Bundy *et al.*, 1995), some of whom develop iron-deficiency anemia leading to adverse pregnancy outcomes, BZA treatment would be beneficial during the second and third trimesters of pregnancy (World Health Organization, 2002). There is no evidence that maternal BZA therapy presents a risk to breast-fed infants (Urbani and Albonico, 2003).

Use in Young Children. The BZAs have not been extensively studied in children under 2 years of age. The WHO convened an informal consultation on the use of BZAs in young children in 2002 and concluded that they may be used to treat children past the first year of life if the risks from adverse consequences caused by STHs are justified (Montresor *et al.*, 2003). The WHO recommends a reduced dose of 200 mg of albendazole in children between the ages of 12 and 24 months.

Diethylcarbamazine. Diethylcarbamazine is a first-line agent for control and treatment of lymphatic filariasis and for therapy of tropical pulmonary eosinophilia caused by *Wuchereria bancrofti* and *Brugia malayi* (Ottesen and Ramachandran, 1995). Although this agent is partially effective against onchocerciasis and loiasis,

it can cause serious reactions to affected microfilariae in both infections. For this reason, ivermectin has replaced diethylcarbamazine for therapy of onchocerciasis. Despite its toxicity, diethylcarbamazine remains the best drug available to treat loiasis. Annual single doses of both diethylcarbamazine and albendazole show considerable promise for the control of lymphatic filariasis in geographic regions where onchocerciasis and loiasis are not endemic (Molyneux and Zagaria, 2002; Molyneux *et al.*, 2003).

Chemistry. Diethylcarbamazine (HETRAZAN) is formulated as the water-soluble citrate salt containing 51% by weight of the active base. Because the compound is tasteless, odorless, and stable to heat, it also can be taken in the form of fortified table salt containing 0.2% to 0.4% by weight of the base. The drug is available outside the United States. In the United States it can be obtained from the CDC. Diethylcarbamazine has the following chemical structure:

Anthelmintic Action. Microfilarial forms of susceptible filarial species are most affected by diethylcarbamazine, which elicits rapid disappearance of these developmental forms of *W. bancrofti*, *B. malayi*, and *L. loa* from human blood. The drug causes microfilariae of *O. volvulus* to disappear from skin but does not kill microfilariae in nodules that contain the adult (female) worms. It does not affect the microfilariae of *W. bancrofti* in a hydrocele, despite penetration into the fluid. The mechanism of action of diethylcarbamazine on susceptible microfilariae is not well understood, but the drug appears to exert a direct effect on *W. bancrofti* microfilariae by causing organelle damage and apoptosis (Peixoto *et al.*, 2004). There is evidence that diethylcarbamazine kills worms of adult *L. loa* and probably adult *W. bancrofti* and *B. malayi* as well. However, it has little action against adult *O. volvulus*. The mechanism of filaricidal action of diethylcarbamazine against adult worms is unknown. Some studies suggest that diethylcarbamazine compromises intracellular processing and transport of certain macromolecules to the plasma membrane (Spiro *et al.*, 1986). The drug also may affect specific immune and inflammatory responses of the host by undefined mechanisms (Mackenzie and Kron, 1985; Martin *et al.*, 1997).

Absorption, Fate, and Excretion. Diethylcarbamazine is absorbed rapidly from the gastrointestinal tract. Peak plasma levels occur within 1 to 2 hours after a single oral dose, and the plasma half-life varies from 2 to 10 hours, depending on the urinary pH. Metabolism is both rapid and extensive. A major metabolite, diethylcarbamazine-*N*-oxide, is bioactive. Diethylcarbamazine is excreted by both urinary and extraurinary routes; more than 50% of

an oral dose appears in acidic urine as the unchanged drug, but this value is decreased when the urine is alkaline. Indeed, alkalinizing the urine can elevate plasma levels, prolong the plasma half-life, and increase both the therapeutic effect and toxicity of diethylcarbamazine (Awadzi *et al.*, 1986). Therefore, dosage reduction may be required for people with renal dysfunction or sustained alkaline urine.

Therapeutic Uses. Dosages of diethylcarbamazine citrate used to prevent or treat filarial infections have evolved empirically and vary according to local experience. Recommended regimens differ according to whether the drug is used for population-based chemotherapy, control of filarial disease, or prophylaxis against infection.

***W. bancrofti*, *B. malayi*, and *B. timori*.** The standard regimen for the treatment of LF traditionally has been a 12-day, 72-mg/kg (6 mg/kg per day) course of diethylcarbamazine. In the United States, it is common practice to administer small test doses of 50 to 100 mg (1 to 2 mg/kg for children) over a 3-day period prior to beginning the 12-day regimen. However, a single dose of 6 mg/kg had comparable macrofilaricidal and microfilaricidal efficacy to the standard regimen (Addiss and Dreyer, 2000). Single-dose therapy may be repeated every 6 to 12 months, as necessary.

Although diethylcarbamazine does not usually reverse existing lymphatic damage, the early treatment of asymptomatic individuals may prevent new lymphatic damage. In men, the effect of the drug can be monitored by scrotal ultrasound approximately 2 to 4 weeks following treatment. Repeat treatment sometimes is recommended if microfilariae remain in the circulation or if adult worms remain on the ultrasound (Addiss and Dreyer, 2000). Expanded use of ultrasound also has facilitated the identification of infected individuals who are microfilaria-negative on blood examination. These individuals also benefit from diethylcarbamazine treatment. During acute episodes of lymphangitis, treatment with diethylcarbamazine is not recommended until acute symptoms subside (Addiss and Dreyer, 2000).

Supportive treatment is critical for the successful management of LF. This includes prevention of secondary bacterial infections through attention to hygiene, wearing shoes to prevent foot injury, and avoidance of lymphostasis through exercise and limb elevation (Addiss and Dreyer, 2000). Attention to hygiene, prevention of secondary bacterial infections, and physiotherapy sometimes can reverse elephantiasis and lymphedema of the leg.

For mass treatment with the objective of reducing microfilaria to subinfective levels for mosquitoes, the introduction of diethylcarbamazine into table salt (0.2% to 0.4% by weight of the base) has markedly reduced the prevalence, severity, and transmission of lymphatic filariasis in many endemic areas (Gelband, 1994). A major advance was the discovery that diethylcarbamazine given annually as a single oral dose of 6 mg/kg was most effective in reducing microfilariaemia when coadministered with either albendazole (400 mg) or ivermectin (0.2 to 0.4 mg/kg) (Ottesen *et al.*, 1999). Adverse reactions to microfilarial destruction, greater after the oral diethylcarbamazine tablet than the table salt preparation, usually are well tolerated. However, mass chemotherapy with diethylcarbamazine should *not* be used in regions where onchocerciasis or loiasis coexist because, even in the table salt formulation, the drug may induce severe reactions related to parasite burden in these infections.

Ovolvulus and Lloa. Diethylcarbamazine is contraindicated for the treatment of onchocerciasis because it causes severe reactions related to microfilarial destruction, including worsening ocular lesions (*see* below). For purposes of LF control, use of diethylcarbamazine is considered contraindicated in areas where onchocerciasis is endemic (Molyneux *et al.*, 2003). Such reactions are far less severe in response to ivermectin, the preferred drug for this infection. Despite its drawbacks, diethylcarbamazine remains the best available drug for therapy of loiasis. Treatment is initiated with test doses of 50 mg (1 mg/kg in children) daily for 2 to 3 days, escalating to maximally tolerated daily doses of 9 mg/kg in three doses for a total of 2 to 3 weeks.

Low test doses are used, often accompanied by pretreatment with glucocorticoids or antihistamines, to minimize reactions to dying microfilariae and adult worms; these reactions consist of severe allergic reactions, and occasionally meningoencephalitis and coma from invasion of the CNS by microfilariae. Repeated courses of diethylcarbamazine treatment, separated by 3 to 4 weeks, may be required to cure loiasis. Ivermectin is not a good alternative to diethylcarbamazine for treatment of loiasis, but albendazole may prove to be useful in patients who either fail therapy with diethylcarbamazine or who cannot tolerate the drug (Klion *et al.*, 1999).

Diethylcarbamazine is clinically effective against microfilariae and adult worms of *Dipetalonema streptocerca*, but filariasis due to *Mansonella perstans*, *M. ozzardi*, or *Dirofilaria immitis* responds minimally to this agent. Diethylcarbamazine is no longer recommended as a first-line drug for the treatment of toxocariasis.

Toxicity and Side Effects. Below a daily dose of 8 to 10 mg/kg, direct toxic reactions to diethylcarbamazine are rarely severe and usually disappear within a few days despite continuation of therapy. These reactions include anorexia, nausea, headache, and at high doses, vomiting. Major adverse

effects result directly or indirectly from the host response to destruction of parasites, primarily microfilariae.

Reactions typically are most severe in patients heavily infected with *O. volvulus*, less serious in *B. malayi* or *L. loa* infections, and mild in bancroftian filariasis, but the drug occasionally induces retinal hemorrhages and severe encephalopathy in patients heavily infected with *L. loa*. In patients with onchocerciasis, the *Mazzotti reaction* typically occurs within a few hours after the first dose and includes intense itching, enlargement and tenderness of the lymph nodes, and sometimes a papular rash, fever, tachycardia, arthralgias, and headache. This reaction persists for 3 to 7 days and then subsides, after which high doses sometimes can be tolerated. Ocular complications include limbitis, punctate keratitis, uveitis, and atrophy of the retinal pigment epithelium (Rivas-Alcala *et al.*, 1981; Dominguez-Vazquez *et al.*, 1983). In patients with bancroftian or brugian filariasis, nodular swellings may occur along the course of the lymphatics, and there often is an accompanying lymphadenitis. This reaction also subsides within a few days. Almost all patients receiving therapy exhibit a leukocytosis, first evident on the second day, reaching its peak on the fourth or fifth day, and gradually subsiding over a period of a few weeks. Reversible proteinuria may occur, and the eosinophilia so frequently observed in patients with filariasis can be intensified by therapy with diethylcarbamazine. Delayed reactions to more mature dying filarial forms include lymphangitis, swelling and lymphoid abscesses in bancroftian and brugian filariasis, and small skin wheals in loiasis. Diethylcarbamazine appears to be safe for use during pregnancy.

Precautions and Contraindications. Population-based chemotherapy with diethylcarbamazine should be avoided in areas where onchocerciasis or loiasis is endemic, although the drug can be used to protect foreign travelers from these infections. Pretreatment with glucocorticoids and antihistamines often is undertaken to minimize indirect reactions to diethylcarbamazine that result from dying microfilariae. Dosage reduction must be considered for patients with impaired renal function or persistent alkaline urine.

Doxycycline

The discovery that filarial parasites, including *W. bancrofti* and *O. volvulus*, harbor bacterial symbionts of the genus *Wolbachia* has led to efforts to examine the effect of antibiotics for treating filarial infections (Taylor and Hoerauf, 2001). For instance, a 6-week regimen of doxycycline (100 mg daily) was found to result in sterility of adult female *Onchocerca* worms (Hoerauf *et al.*, 2000). Studies using shorter treatment courses and alternative antibiotics including rifampicin are in progress. It will be of interest to determine whether anti-*Wolbachia* therapy exerts an antimacrophilicidal effect, or whether this approach could be applied to mass-treatment strategies (Molyneux *et al.*, 2003).

Ivermectin

History. In the mid-1970s, surveys of natural products revealed that a fermentation broth of the soil actinomycete *Streptomyces avermitilis* ameliorated infection with *Nem-*

atospiroides dubius in mice. Isolation of the anthelmintic components from cultures of this organism led to discovery of the avermectins, a novel class of 16-membered lactones (Campbell, 1989). Ivermectin (MECTIZAN; STROMECTION; 22,23-dihydroavermectin B_{1a}) is a semisynthetic analog of avermectin B_{1a} (abamectin), an insecticide developed for crop management. Ivermectin now is used extensively to control and treat a broad spectrum of infections caused by parasitic nematodes (roundworms) and arthropods (insects, ticks, and mites) that plague livestock and domestic animals (Campbell and Benz, 1984; Campbell, 1993). In 1996, the FDA approved the use of ivermectin in humans for treatment of onchocerciasis, the filarial infection responsible for river blindness, and for therapy of intestinal strongyloidiasis. Ivermectin taken as a single oral dose every 6 to 12 months continues to serve as the mainstay of major programs to control onchocerciasis. In addition, annual oral doses of ivermectin, either taken alone or specifically when taken together with annual oral doses of albendazole, markedly reduce microfilaria in lymphatic filariasis due to *W. bancrofti* or *B. malayi* (Ottesen *et al.*, 1999; Plaisier *et al.*, 2000; Molyneux and Zagaria, 2002; Molyneux *et al.*, 2003) (see “Benzimidazoles,” above). Currently The Global Alliance to Eliminate Lymphatic Filariasis advocates diethylcarbamazine (6 mg/kg) plus albendazole (400 mg) (www.filariasis.org). The two-drug regimen now is featured in programs to control LF and is preferred in regions where LF coexists with either onchocerciasis or loiasis. Ivermectin is the drug of choice against intestinal strongyloidiasis and is effective against several other human infections caused by intestinal nematodes (Naquira *et al.*, 1989; Gann *et al.*, 1994; de Silva *et al.*, 1997). The agent also has been used successfully against human scabies and head lice.

Chemistry. The milbemycins are macrocyclic lactone analogs of the avermectins. Some of these compounds have antiparasitic activity similar to that of the avermectins and probably act by similar mechanisms (Fisher and Mrozik, 1992; Arena *et al.*, 1995).

The chemical structure of ivermectin is shown below.

Antiparasitic Activity and Resistance. Several reviews have focused on the antiparasitic action of and resistance to the avermectins and related milbemycins (Cully *et al.*, 1996; Sangster, 1996; Martin *et al.*, 1997; Sangster and Gill, 1999). Ivermectin is effective and highly potent against at least some developmental stages of many parasitic nematodes and insects that affect animals and humans. The drug immobilizes affected organisms by inducing a tonic paralysis of the musculature. Studies of *Caenorhabditis elegans* indicate that avermectins induce paralysis via a group of glutamate-gated Cl⁻ channels found only in invertebrates. There is close correlation among activation and potentiation by avermectins and milbemycin D of glutamate-sensitive Cl⁻ current, nematocidal activity, and membrane binding affinity (Arena *et al.*, 1995; Cully *et al.*, 1996). Moreover, glutamate-gated Cl⁻ channels are expressed in the pharyngeal muscle cells of these worms, consistent with the marked and potent inhibitory effect of avermectins on the feeding behavior of the organisms (Sangster and Gill, 1999). Therefore, ivermectin probably binds to glutamate-activated Cl⁻ channels found in nematode nerve or muscle cells, which causes hyperpolarization by increasing permeability of chloride ions through the cell membrane; this results in paralysis of the parasite (Ikeda, 2003). The basis for resistance or relative unresponsiveness to avermectin action shown by different nematodes, especially those species parasitizing livestock, is complex. Several different avermectin-“resistant” developmental and physiological phenotypes have been described, but definitive relationships among these phenotypes and native avermectin receptor subtypes, locations, numbers, and binding affinities require clarification (Sangster and Gill, 1999; Hejmadi *et al.*, 2000). Alterations in genes encoding ATP-dependent P-glycoprotein transporters that bind avermectins and in those encoding putative components of the glutamate-gated Cl⁻ channel have been associated with the development of resistance in *Haemonchus contortus* (Xu *et al.*, 1998; Blackhall *et al.*, 1998). A large increase in low-affinity glutamate binding has been detected in ivermectin-resistant nematodes, but how this relates to drug resistance is unclear (Hejmadi *et al.*, 2000). Glutamate-gated Cl⁻ channels probably are one site of ivermectin action in insects and crustaceans, too (Duce and Scott, 1985; Scott and Duce, 1985; Zufall *et al.*, 1989). Avermectins also bind with high affinity to γ -aminobutyric acid (GABA)-gated and other ligand-gated Cl⁻ channels in nematodes such as *Ascaris* and in insects, but the physiological consequences are less well defined. Lack of high-affinity avermectin receptors in cestodes and trematodes may explain why these helminths are not sensitive to ivermectin (Shoop *et al.*, 1995). Avermectins also interact with GABA receptors in mammalian brain, but their affinity for invertebrate receptors is about one hundredfold higher (Schaeffer and Haines, 1989).

In humans infected with *O. volvulus*, ivermectin causes a rapid, marked decrease in microfilarial counts in the skin and ocular tissues that lasts for 6 to 12 months (Greene *et al.*, 1987; Newland *et al.*, 1988). The drug has little discernible effect on adult parasites, even at doses as high as 800 μ g/kg (Molyneux *et al.*, 2003), but affects developing larvae and blocks egress of microfilariae from the uterus of adult female worms (Awadzi *et al.*, 1985; Court *et al.*, 1985). By reducing microfilariae in the skin, ivermectin decreases transmission to the *Simulium* black fly vector (Cupp *et al.*, 1986; Cupp *et al.*, 1989). Regular treatment with ivermectin also has been conjectured to act prophylactically against the development of *Onchocerca* infection (Molyneux *et al.*, 2003).

Ivermectin also is effective against microfilaria but not against adult worms of *W. bancrofti*, *B. malayi*, *L. loa*, and *M. ozzardi* (de Silva *et al.*, 1997). The drug exhibits excellent efficacy in humans against *Ascaris lumbricoides*, *Strongyloides stercoralis*, and cutaneous larva migrans. Other gastrointestinal nematodes are either partially affected (*Trichuris trichura* and *Enterobius vermicularis*) or unresponsive (*Necator americanus* and *Ancylostoma duodenale*) (Naquira *et al.*, 1989; de Silva *et al.*, 1997).

Absorption, Fate, and Excretion. In humans, peak levels of ivermectin in plasma are achieved within 4 to 5 hours after oral administration. The long terminal half-life of about 57 hours in adults primarily reflects a low systemic clearance (about 1 to 2 liters/hour) and a large apparent volume of distribution (*see* Appendix II). Ivermectin is about 93% bound to plasma proteins (Klotz *et al.*, 1990). The drug is extensively converted by hepatic CYP3A4 to at least 10 metabolites, mostly hydroxylated and demethylated derivatives (Zeng *et al.*, 1998). Virtually no ivermectin appears in human urine in either unchanged or conjugated form (Krishna and Klotz, 1993). In animals, ivermectin is recovered in feces, nearly all as unchanged drug, and the highest tissue concentrations occur in liver and fat. Extremely low levels are found in brain, even though ivermectin would be expected to penetrate the blood–brain barrier on the basis of its lipid solubility. Studies in transgenic mice suggest that a P-glycoprotein efflux pump in the blood–brain barrier prevents ivermectin from entering the CNS (Schinkel *et al.*, 1994). This and the limited affinity of ivermectin for CNS receptors may explain the paucity of CNS side effects and the relative safety of this drug in humans.

Therapeutic Uses. Onchocerciasis. Single oral doses of ivermectin (150 $\mu\text{g}/\text{kg}$) given every 6 to 12 months are considered effective, safe, and practical for reducing the number of circulating microfilariae in adults and children 5 years of age or older (Goa *et al.*, 1991). Widespread use of ivermectin therefore has become a mainstay of onchocerciasis control programs in the Americas and in sub-Saharan Africa. Equally important, such therapy results in reversal of lymphadenopathy and acute inflammatory changes in ocular tissues and arrests the development of further ocular pathology due to microfilariae. Marked reduction of microfilariae in the skin and ocular tissues is noted within a few days and lasts for 6 to 12 months; the dose then should be repeated. Cure is not attained, because ivermectin has little effect on adult *O. volvulus*. Ivermectin has been used since 1987 as the mainstay for onchocerciasis control programs in all 34 countries in Africa and in the Middle

East and Latin America, where the disease is endemic. Nearly 20 million people have received at least one dose of the drug, and many have received 6 to 9 doses (Dull and Meredith, 1998). Since 1991, the Onchocerciasis Elimination Programme in the Americas (OEPA) has been highly effective in reducing transmission in the endemic nations of the Americas, Brazil, Colombia, Ecuador, Guatemala, Mexico, and Venezuela through biannual treatment with ivermectin (Molyneux *et al.*, 2003). Through the African Programme for Onchocerciasis Control, there is an interest in extending biannual ivermectin coverage to the endemic regions of sub-Saharan Africa. Annual doses of the drug are quite safe and substantially reduce transmission of this infection (Brown, 1998; Boatin *et al.*, 1998). How long such therapy should continue still is unknown.

The possibility that high-dose ivermectin could be used as an agent against the adult stage worms (macrofilaricide) has been investigated (Molyneux *et al.*, 2003). However, the high-dose regimens appear to offer no benefit over standard doses, and they are accompanied by unexpected side effects of mild visual changes (Molyneux *et al.*, 2003).

Lymphatic Filariasis. Initial studies indicated that single annual doses of ivermectin (400 $\mu\text{g}/\text{kg}$) are both effective and safe for mass chemotherapy of infections with *W. bancrofti* and *B. malayi* (Ottesen and Ramachandran, 1995). Ivermectin is as effective as diethylcarbamazine for controlling lymphatic filariasis, and unlike the latter agent, can be used in regions where onchocerciasis, loiasis, or both infections are endemic. Although ivermectin as a single agent can reduce *W. bancrofti* microfilaremia, the duration of treatment required to eliminate LF at 65% coverage presumably would be longer than 6 years (Molyneux *et al.*, 2003). More recent evidence indicates that a single annual dose of ivermectin (200 $\mu\text{g}/\text{kg}$) and a single annual dose of albendazole (400 mg) are even more effective in controlling lymphatic filariasis than either drug alone (www.filariasis.org). The duration of treatment is for at least 5 years based on the estimated fecundity of the adult worms. This dual-drug regimen also reduces infections with intestinal nematodes. Facilitated by corporate donation of ivermectin and albendazole, the drug combination now serves as the treatment standard for mass chemotherapy and control of lymphatic filariasis (Ottesen *et al.*, 1999) (*see* “Benzimidazoles,” above).

Infections with Intestinal Nematodes. The finding that a single dose of 150 to 200 $\mu\text{g}/\text{kg}$ of ivermectin can cure human strongyloidiasis is encouraging, especially because

this drug also is effective against coexisting ascariasis, trichuriasis, and enterobiasis (Naquira *et al.*, 1989). A single dose of 100 $\mu\text{g}/\text{kg}$ of ivermectin is as effective as traditional treatment of intestinal strongyloidiasis with thiabendazole, and less toxic (Gann *et al.*, 1994; Keiser and Nutman, 2004). In a Phase III trial in Japan, 49 of 50 *S. stercoralis*-infected patients were cured after they received 200 $\mu\text{g}/\text{kg}$ of ivermectin orally twice at an interval of 2 weeks (Ikeda, 2003). In *Strongyloides* hyperinfection syndrome, ivermectin has been used successfully, including cases that were unresponsive to thiabendazole (Keiser and Nutman, 2004).

Other Indications. Although ivermectin has activity against microfilaria but not against adult worms of *L. loa* and *M. ozzardi*, it is not used clinically to treat infections with these parasites. Taken as a single 200- $\mu\text{g}/\text{kg}$ oral dose, ivermectin is a first-line drug for treatment of cutaneous larva migrans caused by dog or cat hookworms. Similar doses also are safe and highly effective against human head lice and scabies, the latter even in HIV-infected individuals (de Silva *et al.*, 1997).

Toxicity, Side Effects, and Precautions. Ivermectin is well tolerated by uninfected humans and other mammals. In animals, signs of CNS toxicity, including lethargy, ataxia, mydriasis, tremors, and eventually death, occur only at very high doses; dogs, particularly collie breeds, are especially vulnerable (Campbell and Benz, 1984). In infected humans, ivermectin toxicity nearly always results from Mazzotti-like reactions to dying microfilariae; the intensity and nature of these reactions relate to the microfilarial burden and the duration and type of filarial infection.

After treatment of *O. volvulus* infections with ivermectin, these side effects usually are limited to mild itching and swollen, tender lymph nodes, which arise in 5% to 35% of people, last just a few days, and are relieved by aspirin and antihistamines (Goa *et al.*, 1991). Rarely, more severe reactions occur that include high fever, tachycardia, hypotension, prostration, dizziness, headache, myalgia, arthralgia, diarrhea, and facial and peripheral edema; these may respond to glucocorticoid therapy. Ivermectin induces milder side effects than does diethylcarbamazine, and unlike the latter, seldom exacerbates ocular lesions in onchocerciasis. The drug can cause rare but serious side effects including marked disability and encephalopathies in patients coinfecting with heavy burdens of *L. loa* microfilaria (Gardon *et al.*, 1997). *Loa* encephalopathy is associated with ivermectin treatment of individuals with *Loa* microfilariaemia levels $\geq 30,000$ microfilariae per milliliter of blood (Molyneux *et al.*, 2003). Most of the cases of *Loa* encephalopathy in association with ivermectin chemotherapy have been recorded in the central province of Cameroon (Molyneux *et al.*, 2003). There is little evidence that ivermectin is teratogenic or carcinogenic.

Because of its effects on GABA receptors in the CNS, ivermectin is contraindicated in conditions asso-

ciated with an impaired blood-brain barrier (*e.g.*, African trypanosomiasis and meningitis). Caution also is advised about coadministration of ivermectin with other agents that depress CNS activity. A recent analysis of the experience of epileptics who received ivermectin indicated that such individuals should not be excluded from onchocerciasis treatment programs (Twum-Danso, 2004). Possible adverse interactions of ivermectin with other drugs that are extensively metabolized by hepatic CYP3A4 have yet to be evaluated. Ivermectin is not approved for use in children less than 5 years old or in pregnant women, but both populations undoubtedly have been exposed to the drug in mass treatment programs. Lactating women taking the drug secrete low levels in their milk; the consequences for nursing infants are unknown.

Metrifonate

Metrifonate (trichlorfon; BILARCIL) is an organophosphorus compound used first as an insecticide and later as an anthelmintic, especially for treatment of schistosomiasis haematobium. Metrifonate has the following chemical structure:

Metrifonate is a prodrug; at physiological pH, it is converted nonenzymatically to dichlorvos (2,2-dichlorovinyl dimethyl phosphate, DDVP), a potent cholinesterase inhibitor (Hinz *et al.*, 1996). However, inhibition of cholinesterase alone is unlikely to explain the antischistosomal properties of metrifonate (Bloom, 1981). *In vitro*, dichlorvos is about equally potent as an inhibitor of both *S. mansoni* and *S. haematobium* acetylcholinesterases, yet metrifonate is effective clinically only against infections with *S. haematobium*. The molecular basis for this species-selective effect is not understood. More complete information on the pharmacology and therapeutic uses of metrifonate can be found in the 10th edition of this book.

Niclosamide

Niclosamide (NICLOCIDE), a halogenated salicylanilide derivative, was introduced in the 1960s for human use as a taeniocide. This compound was considered as a second-choice drug to praziquantel for treating human intestinal infections with *Taenia saginata*, *Diphyllobothrium latum*, *Hymenolepis nana*, and most other cestodes because it was cheap, effective, and readily available in many parts of the world. However, therapy with niclosamide poses a risk to people infected with *T. solium*, because ova released from drug-damaged gravid worms develop into larvae that can cause cysticercosis, a dangerous infection that responds poorly to chemotherapy. Niclosamide is no longer approved for use in the United States. More complete information on the pharmacology and therapeutic uses of niclosamide can be found in the ninth edition of this book.

Oxamniquine

Oxamniquine (VANSIL) is a 2-aminomethyltetrahydroquinoline derivative that is used as a second-choice drug to praziquantel for the treatment of schistosomiasis. Most strains of *S. mansoni* are highly susceptible to oxamniquine, but *S. haematobium* and *S. japonicum* are virtually unaffected by therapeutic doses. Because of a low incidence of mild side effects together with normally high efficacy after a single oral dose, oxamniquine continues to be used in *S. mansoni* control programs, especially in South America. More details on the pharmacology and therapeutic uses of oxamniquine can be found in the ninth edition of this book.

Piperazine

The discovery of the anthelmintic properties of piperazine usually is credited to Fayard (1949), but these first were observed by Boismare, a Rouen pharmacist whose recipe is quoted in Fayard's thesis. A large number of substituted piperazine derivatives exhibit anthelmintic activity, but apart from diethylcarbamazine, none has found a place in human therapeutics. Piperazine, a cyclic secondary amine, has the following chemical structure:

Piperazine is highly effective against *Ascaris lumbricoides* and *Enterobius vermicularis*. The predominant effect of piperazine on *Ascaris* is a flaccid paralysis that results in expulsion of the worm by peristalsis. Affected worms recover if incubated in drug-free medium. Piperazine acts as a GABA-receptor agonist. By increasing chloride ion conductance of *Ascaris* muscle membrane, the drug produces hyperpolarization and reduced excitability that leads to muscle relaxation and flaccid paralysis (Martin, 1985). The basis for its selectivity of action is not clear, but studies like those done on ivermectin (Arena *et al.*, 1995) could help resolve this issue. More complete information on the pharmacology and therapeutic uses of piperazine may be found in the 10th edition of this book.

Praziquantel

History. Praziquantel (BILTRICIDE, DISTOCIDE) is a pyrazinoisoquinoline derivative developed after this class of compounds was discovered to have anthelmintic activity in 1972. In animals and humans, infections with many different cestodes and trematodes respond favorably to this agent, whereas nematodes generally are unaffected (Symposium, 1981; Andrews, 1985). Treatment with praziquantel of patients coinfecting with schistosomes and hookworms reduced hookworm prevalence and infection intensities (egg counts) significantly (Utzinger *et al.*, 2002). Praziquantel has the following chemical structure:

The (–) isomer is responsible for most of the drug's anthelmintic activity.

Anthelmintic Action. After rapid and reversible uptake, praziquantel has two major effects on adult schistosomes. At the lowest effective concentrations, it causes increased muscular activity, followed by contraction and spastic paralysis. Affected worms detach from blood vessel walls, resulting in a rapid shift from the mesenteric veins to the liver. At slightly higher therapeutic concentrations, praziquantel causes tegumental damage, which exposes a number of tegumental antigens (Redman *et al.*, 1996). Comparisons of stage-specific susceptibility of *S. mansoni* to praziquantel *in vitro* and *in vivo* indicate that the clinical efficacy of this drug correlates better with tegumental action (Xiao *et al.*, 1985). Studies in laboratory animals have shown that praziquantel is less effective against *S. mansoni* and *S. japonicum* in immunosuppressed mice (Fallon *et al.*, 1996). Whether or not host immune status is important for clinical efficacy of praziquantel in humans is not known.

The tegument of schistosomes seems to be the primary site of action of praziquantel. The drug causes an influx of Ca^{2+} across the tegument, and the effect is blocked in Ca^{2+} -free medium. A number of praziquantel-sensitive sites have been suggested as possible targets, but the precise molecular mechanism of action remains elusive (Redman *et al.*, 1996). Praziquantel also produces a variety of biochemical changes, but most appear to be secondary to its primary tegumental action (Andrews, 1985). Nearly all available information about the action of praziquantel has come from studies on schistosomes. Although it generally is assumed that the anthelmintic action of praziquantel against other trematodes and cestodes is the same as for schistosomes, direct evidence is lacking.

Absorption, Fate, and Excretion. Praziquantel is readily absorbed after oral administration, so that maximal levels in human plasma occur in 1 to 2 hours. The pharmacokinetics of praziquantel are dose-related. Extensive first-pass metabolism to many inactive hydroxylated and conjugated products limits the bioavailability of this drug and results in plasma concentrations of metabolites at least one hundredfold higher than that of praziquantel. The drug is about 80% bound to plasma proteins. Its plasma half-life is 0.8 to 3 hours, depending on the dose, compared with 4 to 6 hours for its metabolites, but this may be prolonged in patients with severe liver disease, including those with hepatosplenic schistosomiasis. About 70% of an oral dose of praziquantel is recovered as metabolites in the urine within 24 hours; most of the remainder is metabolized in the liver and eliminated in the bile.

Therapeutic Uses. Praziquantel is approved in the United States only for therapy of schistosomiasis and liver fluke infections, but elsewhere, this remarkably versatile and safe drug also is used to treat infections with many other trematodes and cestodes. Praziquantel should be stored at temperatures below 30°C and swallowed with water without chewing because of its bitter taste.

Praziquantel is the drug of choice for treating schistosomiasis caused by all *Schistosoma* species that infect humans. Although dosage regimens vary, a single oral dose of 40 mg/kg or three doses of 20 mg/kg each, given 4 to 6 hours apart, generally produce cure rates of 70% to 95% and consistently high reductions (over 85%) in egg counts. Tablets of 600 mg currently are available from generic manufacturers; on average, treatment of a school-aged child in Africa requires 2.5 tablets (World Health Organization, 2002).

The absence of weighing scales in Africa and elsewhere in developing countries led to the innovative development of “tablet poles” to determine dosing. Tablet poles operate by measuring height to the nearest centimeter and then determining five height intervals that correspond to 1.5, 2, 2.5, 3, and 4 tablets of praziquantel (World Health Organization, 2002 and www.who.int/wormcontrol). In China, 200-mg tablets typically are used and the number of tablets is modified accordingly. A 600-mg/5-ml praziquantel syrup is available in Egypt (World Health Organization, 2002).

Strains of *S. mansoni* and *S. japonicum* resistant to praziquantel have been selected in laboratory studies (Fallon *et al.*, 1996). Moreover, decreased clinical efficacy of praziquantel against infections with *S. mansoni* has been reported in two human populations, one in a focal area of high transmission in northern Senegal (van Lieshout *et al.*, 1999) and the other in Egypt, where 1% to 2% of patients were not cured after two or three treatments with praziquantel (Ismail *et al.*, 1999). However, praziquantel-tolerant or -resistant schistosome strains currently do not limit its clinical usefulness (Fallon *et al.*, 1996).

Three doses of 25 mg/kg taken 4 to 8 hours apart on the same day result in high rates of cure for infections with either the liver flukes *Clonorchis sinensis* and *Opisthorchis viverrini*, or the intestinal flukes *Fasciolopsis buski*, *Heterophyes heterophyes*, and *Metagonimus yokogawai*. The same three-dose regimen used for 2 days is highly effective against infections with the lung fluke, *Paragonimus westermani*. Infections with *Fasciola hepatica* are unresponsive to high doses, even though praziquantel penetrates this trematode. The reason for the insensitivity of *F. hepatica* to praziquantel is unknown.

Low doses of praziquantel can be used successfully to treat intestinal infections with adult cestodes, for example, a single oral dose of 25 mg/kg for *Hymenolepis nana* and 10 to 20 mg/kg for *Diphyllobothrium latum*, *Taenia saginata*, or *T. solium*. Retreatment after 7 to 10 days is advisable for individuals heavily infected with *H. nana*. While albendazole is preferred for therapy of human cysticercosis, the tissue infection with intermediate cyst larvae of *T. solium*, prolonged high-dose therapy with praziquantel remains an alternative treatment (Evans *et al.*, 1997). Neither the “cystic” nor “alveolar” hydatid diseases caused by larval stages of *Echinococcus*

tapeworms respond to praziquantel; here, too, albendazole is effective (Horton, 1997; Schantz, 1999).

Toxicity, Precautions, and Interactions. Abdominal discomfort, particularly pain and nausea, diarrhea, headache, dizziness, and drowsiness may occur shortly after taking praziquantel; these direct effects are transient and dose-related. Indirect effects such as fever, pruritus, urticaria, rashes, arthralgia, and myalgia are noted occasionally. Such side effects and increases in eosinophilia often relate to parasite burden. In neurocysticercosis, inflammatory reactions to praziquantel may produce meningismus, seizures, mental changes, and cerebrospinal fluid pleocytosis. These effects usually are delayed in onset, last 2 to 3 days, and respond to appropriate symptomatic therapy such as analgesics and anticonvulsants.

Praziquantel is considered safe in children over 4 years of age, who probably tolerate the drug better than do adults. Low levels of the drug appear in the maternal milk, but there is no evidence that this compound is mutagenic or carcinogenic. High doses of praziquantel increase abortion rates in rats, but a retrospective study showed that treatment of pregnant women in Sudan resulted in no significant differences between treated and untreated women in the rates of abortion or preterm deliveries. Moreover, no congenital abnormalities were noted by clinical examination in any of the babies born to either group (Adam *et al.*, 2004).

The bioavailability of praziquantel is reduced by inducers of hepatic CYPs such as carbamazepine and phenobarbital; predictably, coadministration of the CYP inhibitor cimetidine has the opposite effect (Bittencourt *et al.*, 1992; Dachman *et al.*, 1994). Dexamethasone reduces the bioavailability of praziquantel, but the mechanism is not understood. Under certain conditions, praziquantel may increase the bioavailability of albendazole (Homeida *et al.*, 1994).

Praziquantel is contraindicated in ocular cysticercosis because the host response can irreversibly damage the eye. Shortly after taking the drug, driving, operating machinery, and other tasks requiring mental alertness should be avoided. The half-life of praziquantel can be prolonged in patients with severe hepatic disease; dosage adjustment in such patients may be required (Mandour *et al.*, 1990).

Pyrantel Pamoate

Pyrantel pamoate first was introduced into veterinary practice as a broad-spectrum anthelmintic directed against

pinworm, roundworm, and hookworm infections. Its effectiveness and lack of toxicity led to its trial against related intestinal helminths in humans. *Oxantel pamoate*, an *m*-oxyphenol analog of pyrantel, is effective for single-dose treatment of trichuriasis. Pyrantel is employed as the pamoate salt and has the following chemical structure:

Anthelmintic Action. Pyrantel and its analogs are depolarizing neuromuscular blocking agents. They open nonselective cation channels and induce marked, persistent activation of nicotinic acetylcholine receptors, which results in spastic paralysis of the worm (Robertson *et al.*, 1994). Pyrantel also inhibits cholinesterases. It causes a slowly developing contracture of isolated preparations of *Ascaris* at 1% of the concentration of acetylcholine required to produce the same effect. In single muscle cells of this helminth, pyrantel causes depolarization and increased spike-discharge frequency, accompanied by increases in tension. Pyrantel is effective against hookworm, pinworm, and roundworm; unlike its analog oxantel, it is ineffective against *Trichuris trichiura*.

Absorption, Fate, and Excretion. Pyrantel pamoate is poorly absorbed from the gastrointestinal tract, a property that contributes to its selective action on gastrointestinal nematodes. Less than 15% is excreted in the urine as parent drug and metabolites. The major proportion of an administered dose is recovered in the feces.

Therapeutic Uses. Pyrantel pamoate is an alternative to mebendazole in the treatment of ascariasis and enterobiasis. High cure rates have been achieved after a single oral dose of 11 mg/kg, to a maximum of 1 g. Pyrantel also is effective against hookworm infections caused by *Ancylostoma duodenale* and *Necator americanus*, although repeated doses are needed to cure heavy infections by *N. americanus*. The drug should be used in combination with oxantel for mixed infections with *T. trichiura*. In the case of pinworm, it is wise to repeat the treatment after an interval of 2 weeks. In the United States, pyrantel is sold as an over-the-counter pinworm treatment (PIN-X).

Precautions. When given parenterally, pyrantel can produce complete neuromuscular blockade in animals; only very large oral doses produce toxic effects. Transient and mild GI symptoms occasionally are observed in humans, as are headache, dizziness, rash, and fever. Pyrantel pamoate has not been studied in pregnant women. Thus, its use in pregnant patients and children less than 2 years of age is not recommended. Because pyrantel pamoate and piperazine are mutually antagonistic with respect to their neuromuscular effects on parasites, they should not be used together.

SECTION VIII

Chemotherapy of Microbial Diseases

CHAPTER

42

GENERAL PRINCIPLES OF ANTIMICROBIAL THERAPY

Henry F. Chambers

Antimicrobial agents are among the most commonly used and misused of all drugs. The inevitable consequence of the widespread use of antimicrobial agents has been the emergence of antibiotic-resistant pathogens, fueling an ever-increasing need for new drugs. However, the pace of antimicrobial drug development has slowed dramatically, with only a handful of new agents, few of which are novel, being introduced into clinical practice each year. Reducing inappropriate antibiotic use is thought to be the best way to control resistance. Although awareness of the consequences of antibiotic misuse is increasing, overprescribing remains widespread, driven largely by patient demand, time pressure on clinicians, and diagnostic uncertainty. If the gains in the treatment of infectious diseases are to be preserved, clinicians must be wiser and more selective in the use of antimicrobial agents.

This chapter reviews the general classes of antimicrobial drugs, their mechanisms of action, and mechanisms of bacterial resistance. It also discusses principles for the selection of an appropriate antibiotic, the use of antibiotic combinations, and the role of chemoprophylaxis. This chapter offers a philosophical and a practical approach to the appropriate use of antimicrobial agents and discusses the factors that influence the outcome of such treatment. Also emphasized is the frequent misuse of antimicrobial agents owing to lack of identification of the responsible microor-

ganism, which can lead to superinfection or drug resistance. The pharmacological properties and uses of individual classes of antimicrobials are discussed in Chapters 43 through 50.

Definition and Characteristics. In the strictest sense, antibiotics are antibacterial substances produced by various species of microorganisms (bacteria, fungi, and actinomycetes) that suppress the growth of other microorganisms. Common usage often extends the term *antibiotics* to include synthetic antimicrobial agents, such as *sulfonamides* and *quinolones*. Antibiotics differ markedly in physical, chemical, and pharmacological properties, in antimicrobial spectra, and in mechanisms of action. Knowledge of molecular mechanisms of bacterial replication has greatly facilitated rational development of compounds that can interfere with their replication.

Classification and Mechanism of Action. Antimicrobial agents are classified based on chemical structure and proposed mechanism of action, as follows: (1) agents that inhibit synthesis of bacterial cell walls, including the β -lactam class (*e.g.*, penicillins, cephalosporins, and carbapenems) and dissimilar agents such as *cycloserine*, *vancomycin*, and *bacitracin*; (2) agents that act directly on the cell membrane of the microorganism, increasing permeability and leading to leakage of intracellular compounds, including detergents such as *polymyxin*; polyene antifungal agents (*e.g.*, *nystatin* and *amphotericin B*) which bind to cell-wall sterols; and

the lipopeptide daptomycin (Carpenter and Chambers, 2004); (3) agents that disrupt function of 30S or 50S ribosomal subunits to reversibly inhibit protein synthesis, which generally are bacteriostatic (*e.g.*, *chloramphenicol*, the *tetracyclines*, *erythromycin*, *clindamycin*, *streptogramins*, and *linezolid*); (4) agents that bind to the 30S ribosomal subunit and alter protein synthesis, which generally are bactericidal (*e.g.*, the *aminoglycosides*); (5) agents that affect bacterial nucleic acid metabolism, such as the rifamycins (*e.g.*, *rifampin* and *rifabutin*), which inhibit RNA polymerase, and the quinolones, which inhibit topoisomerases; and (6) the antimetabolites, including *trimethoprim* and the *sulfonamides*, which block essential enzymes of folate metabolism. There are several classes of antiviral agents, including: (1) nucleic acid analogs, such as *acyclovir* or *ganciclovir*, which selectively inhibit viral DNA polymerase, and *zidovudine* or *lamivudine*, which inhibit HIV reverse transcriptase; (2) non-nucleoside HIV reverse transcriptase inhibitors, such as *nevirapine* or *efavirenz*; (3) inhibitors of other essential viral enzymes, *e.g.*, inhibitors of HIV protease or influenza neuraminidase; and (4) fusion inhibitors such as enfuvirtide. Additional categories likely will emerge as more complex mechanisms are elucidated. The precise mechanism of action of some antimicrobial agents still is unknown.

Factors That Determine the Susceptibility and Resistance of Microorganisms to Antimicrobial Agents.

Successful antimicrobial therapy of an infection ultimately depends on the concentration of antibiotic at the site of infection. This concentration must be sufficient to inhibit growth of the offending microorganism. If host defenses are intact and active, a minimum inhibitory effect, such as that provided by *bacteriostatic* agents (*i.e.*, agents that interfere with growth or replication of the microorganism but do not kill it) may be sufficient. On the other hand, if host defenses are impaired, antibiotic-mediated killing (*i.e.*, a *bactericidal* effect) may be required to eradicate the infection. The concentration of drug at the site of infection not only must inhibit the organism but also must remain below the level that is toxic to human cells. If this can be achieved, the microorganism is considered susceptible to the antibiotic. If an inhibitory or bactericidal concentration exceeds that which can be achieved safely *in vivo*, then the microorganism is considered resistant to that drug.

The achievable serum concentration for an antibiotic guides selection of the breakpoint for designating a microorganism as either susceptible or resistant by *in vitro* susceptibility testing. However, the concentration at the site of infection may be considerably lower than

achievable serum concentrations (*e.g.*, vitreous fluid of the eye or cerebrospinal fluid). Local factors (*e.g.*, low pH, high protein concentration, and anaerobic conditions) also may impair drug activity. Thus, the drug may be only marginally effective or ineffective in such cases even though standardized *in vitro* tests would likely report the microorganism as “sensitive.” Conversely, concentrations of drug in urine may be much higher than those in plasma. Microorganisms that might otherwise be considered “resistant” may be eradicated when infection is limited to the urinary tract.

Bacterial Resistance to Antimicrobial Agents. The recent emergence of antibiotic resistance in bacterial pathogens, both nosocomially and in the community, is a very serious development that threatens the end of the antibiotic era. Today, more than 70% of the bacteria associated with hospital-acquired infections in the United States are resistant to one or more of the drugs previously used to treat them. Penicillin-resistant strains of pneumococci account for 50% or more of isolates in some European countries, and the proportion of such strains is rising in the United States. The worldwide emergence of *Haemophilus* and gonococci that produce β -lactamase is a major therapeutic problem. *Methicillin*-resistant strains of *Staphylococcus aureus* are endemic in hospitals and are isolated increasingly from community-acquired infections (Naimi *et al.*, 2003; Vandenesch *et al.*, 2003). Multiple-drug-resistant strains of *S. aureus* with intermediate susceptibility to antibiotics and high-level resistance to vancomycin have been reported (Hiramatsu *et al.*, 1997; Smith *et al.*, 1999; Weigel *et al.*, 2003). There now are strains of enterococci, *Pseudomonas*, and *Enterobacter* that are resistant to all available antibiotics. Epidemics of multiple-drug-resistant strains of *Mycobacterium tuberculosis* have been reported in the United States.

The rampant spread of antibiotic resistance mandates a more responsible approach to antibiotic use. The Centers for Disease Control and Prevention has outlined a series of steps to prevent or diminish antimicrobial resistance. Important components include appropriate use of vaccination, judicious use and proper attention to indwelling catheters, early involvement of infectious disease experts, choosing antibiotic therapy based on local patterns of susceptibilities of organisms, proper antiseptic technique to ensure infection rather than contamination, appropriate use of prophylactic antibiotics in surgical procedures, infection control procedures to isolate the pathogen, and strict compliance to hand hygiene (Anonymous, 2002a, 2002b).

For an antibiotic to be effective, it must reach its target in an active form, bind to the target, and interfere with its function. Accordingly, bacterial resistance to an antimicrobial agent is attributable to three general mechanisms: (1) The drug does not reach its target, (2) the drug is not active, or (3) the target is altered (Davies, 1994; Spratt, 1994; Li and Nikaido, 2004).

The outer membrane of gram-negative bacteria is a permeable barrier that excludes large polar molecules from entering the cell. Small polar molecules, including many antibiotics, enter the cell through protein channels called *porins*. Absence of, mutation in, or loss of a favored porin channel can slow the rate of drug entry into a cell or prevent entry altogether, effectively reducing drug concentration at the target site. If the target is intracellular and the drug requires active transport across the cell membrane, a mutation or phenotypic change that shuts down this transport mechanism can confer resistance. For example, *gentamicin*, which targets the ribosome, is actively transported across the cell membrane using energy provided by the membrane electrochemical gradient. This gradient is generated by respiratory enzymes that couple electron transport and oxidative phosphorylation. A mutation in an enzyme in this pathway or anaerobic conditions (oxygen is the terminal electron acceptor of this pathway, and its absence reduces the membrane potential energy) slows entry of gentamicin into the cell, resulting in resistance. Bacteria also have efflux pumps that can transport drugs out of the cell. Resistance to numerous drugs, including tetracycline, chloramphenicol, fluoroquinolones, macrolides, and β -lactam antibiotics, is mediated by an efflux pump mechanism (Li and Nikaido, 2004). Figure 42–1 depicts the multiple membrane and periplasm components that reduce the intracellular concentrations of β -lactam antibiotics and cause resistance.

Drug inactivation is the second general mechanism of drug resistance. Bacterial resistance to aminoglycosides and to β -lactam antibiotics usually is due to production of an aminoglycoside-modifying enzyme or β -lactamase, respectively. A variation of this mechanism is failure of the bacterial cell to activate a prodrug. This is the basis of the most common type of resistance to *isoniazid* in *M. tuberculosis* (Bertrand *et al.*, 2004).

The third general mechanism of drug resistance is target alteration. This may be due to mutation of the natural target (*e.g.*, fluoroquinolone resistance), target modification (*e.g.*, ribosomal protection type of resistance to macrolides and tetracyclines), or acquisition of a resistant form of the native, susceptible target (*e.g.*, staphylococcal

Figure 42–1. Model depicting the interaction among components mediating resistance to β -lactam antibiotics in *Pseudomonas aeruginosa*. (Courtesy of Hiroshi Nikaido.)

Most β -lactam antibiotics are hydrophilic and must cross the outer membrane barrier of the cell *via* outer membrane protein (Omp) channels, or porins. The channel has size and charge selectivity such that some Omps slow or block transit of the drug. If an Omp permitting drug entry is altered by mutation, is missing, or is deleted, then drug entry is slowed or prevented. β -Lactamase concentrated between the inner and outer membranes in the periplasmic space constitutes an enzymatic barrier that works in concert with the porin permeability barrier. If the antibiotic is a good substrate for β -lactamase, it will be destroyed rapidly even if the outer membrane is relatively permeable to the drug. If the rate of drug entry is slow, then a relatively inefficient β -lactamase with a slow turnover rate can hydrolyze just enough drug that an effective concentration cannot be achieved. If the target (PBP, penicillin-binding protein) has low binding affinity for the drug or is altered, then the minimum concentration for inhibition is elevated, further contributing to resistance. Finally, β -lactam antibiotics (and other polar antibiotics) that enter the cell and avoid β -lactamase destruction can be taken up by an efflux transporter system (*e.g.*, MexA, MexB, and OprF) and pumped across the outer membrane, further reducing the intracellular concentration of active drug.

methicillin resistance caused by production of a low-affinity penicillin-binding protein) (Nakajima, 1999; Hooper, 2002; Lim and Strynadka, 2002).

Drug resistance may be acquired by mutation and selection, with passage of the trait *vertically* to daughter cells. For mutation and selection to be successful in generating resistance, the mutation cannot be lethal and should not appreciably alter virulence. For the trait to be passed on, the original mutant or its progeny also must disseminate and replicate; otherwise, the mutation will be

lost until it is “rediscovered” by some other mutant arising from within a wild-type population.

Drug resistance more commonly is acquired by *horizontal transfer* of resistance determinants from a donor cell, often of another bacterial species, by transduction, transformation, or conjugation. Resistance acquired by horizontal transfer can disseminate rapidly and widely either by clonal spread of the resistant strain or by subsequent transfers to other susceptible recipient strains. For example, the plasmid-encoded staphylococcal β -lactamase gene is distributed widely among many unrelated strains, including enterococci (Murray, 1992). Plasmid-encoded class A β -lactamases of gram-negative bacteria also have spread widely to *Escherichia coli*, *Neisseria gonorrhoeae*, and *Haemophilus* spp. Horizontal transfer of resistance offers several advantages over mutation-selection. Lethal mutation of an essential gene is avoided; the level of resistance often is higher than that produced by mutation, which tends to yield incremental changes; the gene, which still can be transmitted vertically, can be mobilized and rapidly amplified within a population by transfer to susceptible cells; and the resistance gene can be eliminated when it no longer offers a selective advantage.

Mutation-Selection. Mutation and antibiotic selection of the resistant mutant are the molecular basis for resistance to *streptomycin* (ribosomal mutation), quinolones (gyrase or topoisomerase IV gene mutation), rifampin (RNA polymerase gene mutation), and linezolid (ribosomal RNA mutation). This mechanism underlies all drug resistance in *M. tuberculosis* (Riska *et al.*, 2000). Mutations may occur in the gene encoding (1) the target protein, altering its structure so that it no longer binds the drug; (2) a protein involved in drug transport; (3) a protein important for drug activation or inactivation, in the case of extended-spectrum β -lactamases (Bush, 2001); or (4) in a regulatory gene or promoter affecting expression of the target, a transport protein, or an inactivating enzyme. Mutations are not caused by drug exposure *per se*. They are random events that confer a survival advantage when drug is present. However, certain drugs that induce the bacterial SOS system of DNA repair proteins that accommodate potentially lethal stress (*e.g.*, fluoroquinolones) may facilitate resistance gene transfer or increase the mutation frequency by induction of error-prone polymerases (Goodman, 2002; Chopra *et al.*, 2003; Beaber *et al.*, 2004). Any large population of antibiotic-susceptible bacteria is likely to contain rare mutants that are only slightly less susceptible than the parent. Through sequential acquisition of more mutations, clinically significant resistance may emerge. High-level resistance of *E. coli* to fluoroquinolones is due to such an accumulation of multiple stepwise mutations. In some instances, a single-step mutation results in a high degree of resistance. For example, a point mutation within the drug-binding domain in the β subunit of bacterial RNA polymerase confers high-level resistance to rifampin.

Horizontal Gene Transfer. Horizontal transfer of resistance genes is greatly facilitated by and is largely dependent on mobile genetic elements. The role of plasmids and transducing phages as carriers of resistance genes and transfer elements is discussed in more detail

below. Other mobile elements, transposable elements, integrons, and gene cassettes also participate in the process. Transposable elements are of three general types: insertion sequences, transposons, and transposable phages; two of these, insertion sequences and transposons, are important for resistance. *Insertion sequences* (Mahillon and Chandler, 1998) are short segments of DNA encoding enzymatic functions (*e.g.*, transposase and resolvase) for site-specific recombination with inverted repeat sequences at either end. They can copy themselves and insert themselves into the chromosome or a plasmid. Insertion sequences do not encode resistance, but they function as sites for integration of other resistance-encoding elements, *e.g.*, plasmids or transposons.

Transposons are basically insertion sequences that also code for other functions, one of which can be drug resistance. Since transposons move between chromosome and plasmid, the resistance gene can hitchhike its way onto a transferable element out of the host and into a recipient. Transposons are mobile elements that excise and integrate in the bacterial genomic or plasmid DNA (*i.e.*, from plasmid to plasmid, from plasmid to chromosome, or from chromosome to plasmid).

Integrons (Fluit and Schmitz, 2004) are not formally mobile and do not copy themselves, but they encode an integrase and provide a specific site into which mobile gene cassettes integrate. *Gene cassettes* encode resistance determinants, usually lacking a promoter, with a downstream repeat sequence. The integrase recognizes this repeat sequence and directs insertion of the cassette into position behind a strong promoter that is present on the integron. Integrons may be located within transposons or in plasmids, and therefore may be mobilizable, or located on the chromosome.

Another type of gene cassette, *SCCmec* (Staphylococcal Chromosomal Cassette), has been described in methicillin-resistant strains of staphylococci (Katayama, *et al.*, 2000). The methicillin resistance gene *mecA* is located within this cassette along with recombinase genes. The recombinases both excise and integrate the cassette element, which exists as a circular intermediate that is not self-replicating, into a very specific site in the staphylococcal chromosome. How this element is transferred and the role of excision-mobilization in this process are not known.

Transduction. Transduction is acquisition of bacterial DNA from a phage (a virus that propagates in bacteria) that has incorporated DNA from a previous host bacterium within its outer protein coat. If the DNA includes a gene for drug resistance, the newly infected bacterial cell may acquire resistance. Transduction is particularly important in the transfer of antibiotic resistance among strains of *S. aureus*.

Transformation. Transformation is the uptake and incorporation into the host genome by homologous recombination of free DNA released into the environment by other bacterial cells. Transformation is the molecular basis of penicillin resistance in pneumococci and *Neisseria* (Spratt, 1994). Penicillin-resistant pneumococci produce altered penicillin-binding proteins (PBPs) that have low-affinity binding of penicillin. Nucleotide sequence analysis of the genes encoding these altered PBPs indicates that they are mosaics in which blocks of foreign DNA from a closely related species of streptococcus have been imported and incorporated into the resident PBP gene.

Conjugation. Conjugation is gene transfer by direct cell-to-cell contact through a sex pilus or bridge. This complex and fascinating mechanism for the spread of antibiotic resistance is extremely important because multiple resistance genes can be transferred in a single event. The transferable genetic material consists of two dif-

ferent sets of plasmid-encoded genes that may be on the same or different plasmids. One set encodes the actual resistance; the second encodes genes necessary for the bacterial conjugation process.

Conjugative plasmids tend to be rather large (50 kilobases or more). They combine elements of plasmid DNA rolling-circle replication (only a single strand is transferred, and it replicates in the host) with a type IV bacterial secretion system. Plasmid transfer requires an origin of transfer demarcating the site within the plasmid where transfer will occur, DNA replicating enzymes, and coupling proteins that direct the DNA across two cell membranes on its way from the host into the recipient. Genes encoding the resistance determinants may be located on transposons.

Conjugation with genetic exchange between nonpathogenic and pathogenic microorganisms probably occurs in the GI tracts of human beings and animals. The efficiency of transfer is low; however, antibiotics can exert a powerful selective pressure to allow emergence of the resistant strain. Genetic transfer by conjugation is common among gram-negative bacilli, and resistance is conferred on a susceptible cell as a single event. Enterococci also contain a broad range of host-range conjugative plasmids that are involved in the transfer and spread of resistance genes among gram-positive organisms. Vancomycin resistance in enterococci is mediated by a conjugative plasmid (Arthur and Courvalin, 1993; Murray, 2000). Vancomycin resistance in *S. aureus* is due to conjugative transfer of vanA-type vancomycin resistance genes encoded on a transposon from *Enterococcus faecalis* donor into a methicillin-resistant strain of *S. aureus* with subsequent integration of the transposon into a resident staphylococcal conjugative plasmid (Weigel *et al.*, 2003).

Selection of an Antimicrobial Agent

Optimal and judicious selection of antimicrobial agents for the therapy of infectious diseases requires clinical judgment and detailed knowledge of pharmacological and microbiological factors. Antibiotics have three general uses: empirical therapy, definitive therapy, and prophylactic or preventive therapy. When used as empirical, or initial, therapy, the antibiotic should cover all the likely pathogens because the infecting organism(s) has not yet been defined. Either combination therapy or, preferably, treatment with a single broad-spectrum agent may be employed. However, once the infecting microorganism is identified, definitive antimicrobial therapy should be instituted with a narrow-spectrum, low-toxicity agent to complete the course of treatment. Failure to document the bacterial etiology so that a narrow-spectrum agent can be used and failure to narrow the spectrum when an organism has been identified are two common ways in which antibiotics are misused.

The first consideration in selecting an antimicrobial agent is whether it is even indicated. *The reflex action to associate fever with treatable infections and prescribe antimicrobial therapy without further evaluation is irrational and potentially dangerous.* The diagnosis may be masked if therapy is started and appropriate cultures are not obtained. Antibiotics are potentially toxic, and anti-

microbial agents promote selection of resistant microorganisms. Of course, definitive identification of a bacterial infection before treatment is initiated often is not possible. In the absence of a clear indication, antibiotics often may be used if disease is severe and if it seems likely that withholding therapy will result in failure to manage a potentially serious or life-threatening infection.

Initiation of optimal empirical antibiotic therapy requires knowledge of the most likely infecting microorganisms and their susceptibilities to antimicrobial drugs. Selection of an antibiotic regimen should rely on the clinical presentation, which may suggest the specific microorganism, and knowledge of the microorganisms most likely to cause specific infections in a given host. In addition, simple and rapid laboratory techniques are available for the examination of infected tissues. The most valuable and time-tested method for immediate identification of bacteria is examination of the infected secretion or body fluid with Gram's stain. Such tests help to narrow the list of potential pathogens and permit more rational selection of initial antibiotic therapy. However, in many situations, identification of the morphology of the infecting organism is not adequate to arrive at a specific bacteriological diagnosis, and the selection of a single narrow-spectrum antibiotic may be inappropriate, particularly if the infection is life threatening. Broad antimicrobial coverage is then indicated, pending isolation and identification of the microorganism. *Whenever the clinician is faced with initiating therapy on a presumptive bacteriological diagnosis, cultures of the presumed site of infection and blood, if bacteremia is a possibility, should be taken prior to the institution of drug therapy.* For definitive therapy, the regimen should be changed to a more specific and narrow-spectrum antimicrobial agent once an organism has been isolated and results of susceptibility tests are known.

Testing for Microbial Sensitivity to Antimicrobial Agents. Bacterial strains, even from the same species, may vary widely in sensitivity to antibiotics. Information about the antimicrobial susceptibility of the infecting microorganism is important for appropriate drug selection. Several tests are available for determination of bacterial sensitivity to antimicrobial agents. The most commonly used are disk-diffusion tests, agar- or broth-dilution tests, and automated test systems.

The disk-diffusion technique provides only qualitative or semi-quantitative information on antimicrobial susceptibility. The test is performed by applying commercially available filter-paper disks impregnated with a specific amount of the drug onto an agar surface, over which a culture of the microorganism has been streaked. After 18 to 24 hours of incubation, the size of the clear zone of inhi-

bition around the disk is measured. The diameter of the zone depends on the activity of the drug against the test strain. Standardized values for zone sizes for each bacterial species and each antibiotic permit classification of the clinical isolate as resistant, intermediate, or susceptible.

Dilution tests employ antibiotics in serially diluted concentrations in solid agar or broth medium containing a culture of the test microorganism. The lowest concentration of the agent that prevents visible growth after 18 to 24 hours of incubation is known as the *minimal inhibitory concentration* (MIC).

Automated systems also use a broth-dilution method. The optical density of a broth culture of the clinical isolate incubated in the presence of drug is determined. If the density of the culture exceeds a threshold optical density, then growth has occurred at that concentration of drug. The MIC is the concentration at which the optical density remains below the threshold.

Pharmacokinetic Factors. *In vitro* activity, although critical, is only a guide as to whether an antibiotic is likely to be effective for an infection. Successful therapy also depends on achieving a drug concentration that is sufficient to inhibit or kill bacteria at the site of the infection without harming the patient. To accomplish this therapeutic goal, several pharmacokinetic and host factors must be evaluated.

The location of the infection to a large extent may dictate the choice of drug and the route of administration. The minimal drug concentration achieved at the infected site should be approximately equal to the MIC for the infecting organism, although in most instances it is advisable to achieve multiples of this concentration if possible. However, there is evidence to suggest that even subinhibitory concentrations of antibiotics may enhance phagocytosis (Nosanchuk *et al.*, 1999) and may be effective. Although this may explain why some infections are cured even when inhibitory concentrations are not achieved, it should be the aim of antimicrobial therapy to produce antibacterial concentrations of drug at the site of infection during the dosing interval. This can be achieved only if the pharmacokinetic and pharmacodynamic principles presented in Chapter 1 are understood and employed.

Access of antibiotics to sites of infection depends on multiple factors. If the infection is in the cerebrospinal fluid (CSF), the drug must pass the blood–brain barrier. Antimicrobial agents that are polar at physiological pH generally penetrate poorly; some, such as *penicillin G*, are actively transported out of the CSF by an anion transport mechanism in the choroid plexus. The concentrations of penicillins and cephalosporins in the CSF usually are only 0.5% to 5% of steady-state concentrations determined simultaneously in plasma. However, the integrity of the blood–brain barrier is diminished during active bacterial infection; tight junctions in cerebral capillaries open, leading to a marked increase in the penetration of even polar

drugs (Quagliarello and Scheld, 1997). As the infection is eradicated and the inflammatory reaction subsides, penetration returns to normal. Since this may occur while viable microorganisms persist in the CSF, drug dosage should not be reduced as the patient improves.

Penetration of drugs into sites of infection almost always depends on passive diffusion. The rate of penetration is thus proportional to the concentration of free drug in the plasma or extracellular fluid. Drugs that are extensively bound to protein thus may not penetrate to the same extent as those bound to a lesser extent. Drugs that are highly protein bound also may have reduced activity because only the unbound fraction of drug is free to interact with its target.

Traditionally, the dose and dosing frequency of antibiotics have been selected to achieve antibacterial activity at the site of infection for most of the dosing interval. However, controversy exists as to whether the therapeutic effect achieved from relatively constant antibacterial activity is superior to that from high peak concentrations followed by periods of subinhibitory activity. To a certain extent, this depends on whether a drug exhibits concentration- or time-dependent growth inhibition (Craig, 1998). The activity of β -lactam antibiotics, for example, is primarily time-dependent, whereas that of aminoglycosides is concentration-dependent. Activity also may depend on the specific organism and the site of infection. Studies in animals with meningitis suggest that pulse dosing (intermittent administration) of β -lactam antibiotics may be more efficacious than continuous exposure (Täuber *et al.*, 1989), but constant activity apparently is superior in other experimental infections. Experimental data suggest that aminoglycosides are at least as efficacious and less toxic when given in a single, large daily dose than when given more frequently (Barclay *et al.*, 1999). Studies in patients also suggest that continuous administration of aminoglycosides may cause unnecessary toxicity.

Knowledge of the status of the individual patient's renal and hepatic function also is essential, especially when excessive plasma or tissue concentrations of the drugs may cause serious toxicity. Most antimicrobial agents and their metabolites are eliminated primarily by the kidneys. Nomograms are available to facilitate adjustment of dosage of many such agents in patients with renal insufficiency. These are discussed in the chapters dealing with the individual drugs and in Appendix II. One must be particularly careful when using aminoglycosides, vancomycin, or *flucytosine* in patients with impaired renal function because these drugs are eliminated exclusively by renal mechanisms, and their toxicity correlates with their concentration in plasma and tissue. If renal toxicity

of a drug that is cleared by the kidney occurs and care is not exercised, a vicious cycle may ensue. For drugs that are metabolized or excreted by the liver (*e.g.*, erythromycin, chloramphenicol, metronidazole, and clindamycin), dosages may have to be reduced in patients with hepatic disease.

Route of Administration. The discussion of choice of routes of administration that appears in Chapter 1 obviously applies to antimicrobial agents. While oral administration is preferred whenever possible, parenteral administration of antibiotics usually is recommended in seriously ill patients in whom predictable concentrations of drug must be achieved. Specific factors that govern the choice of route of administration for individual agents are discussed in the chapters that follow.

Host Factors. Innate host factors can be the prime determinants not only of the type of drug selected but also of its dosage, route of administration, risk and nature of untoward effects, and therapeutic effectiveness.

Host Defense Mechanisms. A critical determinant of the therapeutic effectiveness of antimicrobial agents is the functional state of host defense mechanisms. Both humoral and cellular immunity are important. Inadequacy of type, quality, and quantity of the immunoglobulins; alteration of the cellular immune system; or a qualitative or quantitative defect in phagocytic cells may result in therapeutic failure despite the use of otherwise appropriate and effective drugs. In the immunocompetent host, merely halting multiplication of the microorganisms with a bacteriostatic agent frequently is sufficient to cure the infection. If host defenses are impaired, bacteriostatic activity may be inadequate, and a bactericidal agent may be required for cure. Examples include bacterial endocarditis, where phagocytic cells are absent from the infected site; bacterial meningitis, where phagocytic cells are ineffective because of lack of opsonins in CSF; and disseminated bacterial infections in neutropenic patients, where the total mass of phagocytic cells is reduced. Patients with acquired immune deficiency syndrome (AIDS) have impaired cellular immune responses, and therapy for various opportunistic infections in these patients often is suppressive but not curative. For example, most AIDS patients with bacteremia owing to *Salmonella* will respond to conventional therapy, but this infection may relapse even after prolonged treatment (Gordon *et al.*, 2002). Similarly, treatment of disseminated atypical mycobacterial infection is recommended as long as CD4 counts are below 100 cells/ μ l (Kaplan *et al.*, 2002).

Local Factors. Cure of an infection with antibiotics depends on an understanding of how local factors at the

site of infection affect the antimicrobial activity of the drug. Antimicrobial activity may be reduced significantly in pus, which contains phagocytes, cellular debris, and proteins that can bind drugs or create conditions unfavorable to drug action (Konig *et al.*, 1998). Low pH, characteristic of the fluid in abscesses and in other confined infected sites (pleural space, CSF, and urine), and anaerobic conditions can reduce the antimicrobial activity of some agents markedly, particularly the aminoglycosides. In addition, penetration of antimicrobial agents into infected areas such as abscess cavities can be impaired because the vascular supply is reduced. Successful therapy of abscesses usually requires drainage.

The presence of a foreign body in an infected site markedly reduces the likelihood of successful antimicrobial therapy. Prosthetic material (*e.g.*, prosthetic cardiac valves, prosthetic joints, pacemakers, vascular grafts, and various vascular and CNS shunts) promotes formation of a bacterial biofilm that impairs phagocytosis (Leid *et al.*, 2002). Conditions within the biofilm, where bacterial densities often are high, slow bacterial growth. Because rapidly growing cells are more susceptible to antibiotics than slowly growing or stationary cells, antimicrobial activity is reduced, favoring bacterial persistence (Lewis, 2001). Infections associated with foreign bodies thus are characterized by frequent relapses and failure, even with long-term, high-dose antibiotic therapy. Successful therapy usually requires removal of the foreign material.

Intracellular pathogens, *e.g.*, *Salmonella*, *Brucella*, *Toxoplasma*, *Listeria*, and *M. tuberculosis*, are protected from the action of antimicrobial agents that penetrate into cells poorly. Certain antibiotics—*e.g.*, fluoroquinolones, isoniazid, trimethoprim–sulfamethoxazole, and rifampin—penetrate cells well and can achieve intracellular concentrations that inhibit or kill pathogens residing within cells.

Age. The age of the patient is an important determinant of antimicrobial drug pharmacokinetics. Mechanisms of elimination, especially renal excretion and hepatic biotransformation, are poorly developed in the newborn, especially the premature infant. Failure to make adjustments for such differences can have disastrous consequences (*e.g.*, see discussion of the gray-baby syndrome, caused by chloramphenicol, in Chapter 46). Elderly patients clear drugs eliminated by the kidneys less well because of reduced creatinine clearance. They also may metabolize drugs less rapidly, predisposing them to elevated and potentially toxic concentrations of drugs when compared with younger patients. Elderly patients therefore are more likely to suffer toxicity at otherwise safe concentrations of drugs, as is the case for aminoglycoside ototoxicity.

Developmental factors also may determine the type of untoward response to a drug. Tetracyclines bind avidly to developing teeth and bones, and their use in young children can result in retardation of bone growth and discoloration or hypoplasia of tooth enamel.

Fluoroquinolones accumulate in the cartilage of developing bone, affecting its growth. Kernicterus may follow the use of sulfonamides in newborn infants because this class of drugs competes effectively with bilirubin for binding sites on plasma albumin. Achlorhydria in young children and in the elderly or antacid therapy may alter absorption of orally administered antimicrobial agents (e.g., increased absorption of penicillin G and decreased absorption of *ketoconazole* and *itraconazole*).

Genetic Factors. Certain genetic or metabolic abnormalities must be considered when prescribing antibiotics. A number of drugs (e.g., sulfonamides, *nitrofurantoin*, chloramphenicol, and *nalidixic acid*) may produce acute hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency. Patients who acetylate isoniazid rapidly may have subtherapeutic concentrations of the drug in plasma.

Pregnancy. Pregnancy may impose an increased risk of reaction to antimicrobial agents for both mother and fetus. Hearing loss in the child has been associated with administration of streptomycin to the mother during pregnancy. Tetracyclines can affect the bones and teeth of the fetus. Pregnant women receiving tetracycline may develop fatal acute fatty necrosis of the liver, pancreatitis, and associated renal damage. Pregnancy also may affect the pharmacokinetics of various antibiotics.

The lactating female can pass antimicrobial agents to her nursing child. Both *nalidixic acid* and the sulfonamides in breast milk have been associated with hemolysis in children with glucose-6-phosphate dehydrogenase deficiency. In addition, sulfonamides, even in the small amounts received from breast milk, may predispose the nursing child to kernicterus.

Drug Allergy. Antibiotics, especially β -lactams, are notorious for provoking allergic reactions. Patients with a history of atopy seem particularly susceptible to the development of these reactions. Sulfonamides, trimethoprim, *nitrofurantoin*, and erythromycin also have been associated with hypersensitivity reactions, especially rash. A history of anaphylaxis (immediate hypersensitivity reaction) or hives and laryngeal edema (accelerated reaction) precludes use of the drug in all but extreme, life-threatening situations. Skin testing, particularly of the penicillins, may be of value in predicting life-threatening reactions. Antimicrobial agents, like other drugs, can cause drug fever, which can be mistaken for a sign of continued infection.

Comorbid Conditions. Patients predisposed to seizures are at risk for localized or major motor seizures while taking high doses of penicillin G. This neurotoxicity of penicillin and other β -lactam antibiotics correlates with high concentrations of drug in the CSF and typically occurs in patients with impaired renal function who are given large doses of the drugs. Isoniazid causes a peripheral neuropathy that is preventable and reversible by administration of *pyridoxine*. Diabetics and HIV-infected patients, who are prone to neuropathy because of their underlying diseases, and alcoholics, who often are malnourished, are particularly predisposed. Oncology and HIV-infected patients often have bone marrow suppression, which makes them particularly susceptible to hematologic side effects of antibiotics. Patients with myasthenia gravis or other neuromuscular problems are susceptible to the neuromuscular blocking effect of the aminoglycosides.

Therapy with Combined Antimicrobial Agents

The simultaneous use of two or more antimicrobial agents is recommended in specifically defined situations based on pharmacological rationale. However, selection of an

appropriate combination requires an understanding of the potential for interaction between the antimicrobial agents. Interactions may affect either the microorganism or the patient. Antimicrobial agents acting at different targets may enhance or impair overall antimicrobial activity. A combination of drugs also may have additive or superadditive toxicities. For example, vancomycin given alone usually has minimal nephrotoxicity. However, when vancomycin is given with an aminoglycoside, the toxicity of the aminoglycoside is increased (Rybak *et al.*, 1999).

Methods of Testing Antimicrobial Activity of Drug Combinations.

Two methods are used to measure antimicrobial activity of drug combinations. The first employs serial twofold dilutions of antibiotics in broth inoculated with a standard number of the test microorganism in a checkerboard array so that a large number of antibiotic concentrations in different proportions can be tested simultaneously (Figure 42–2). The concentrations of each drug, singly and in combination, that prevent visible growth are determined after an 18- to 24-hour incubation. *Synergism* is defined as inhibition of growth by a combination of drugs at concentrations less than or equal to 25% of the MIC of each drug acting alone. This implies that one drug is affecting the microorganism in such a way that it becomes more sensitive to the inhibitory effect of the other. If one-half the inhibitory concentration of each drug is required to produce inhibition, the result is called *additive* [fractional inhibitory concentration (FIC) index = 1] (Figure 42–2), suggesting that the two drugs are working independently of each other. If more than one-half the MIC of each drug is necessary to produce the inhibitory effect, the drugs are said to be *antagonistic* (FIC index >1). When the drugs are tested for a variety of proportionate drug concentrations, as with the checkerboard technique, an isobologram may be constructed (Figure 42–2). Synergism is shown by a concave curve, the additive effect by a straight line, and antagonism by a convex curve. Since the endpoint is growth inhibition, not killing, synergism by this method may not indicate enhanced bactericidal effect.

The second method for evaluating drug combinations is the time–kill curve, which assays bactericidal activity. Identical cultures are incubated simultaneously with antibiotics added singly or in combination. Quantitative subcultures are taken over time to determine the number of bacteria remaining. If a combination of antibiotics is more bactericidal than either drug alone, typically defined as at least a hundredfold reduction in the inoculum for the combination compared with the most active single agent, the result is termed *synergism*. If the combination kills

Figure 42-2. Effect of combinations of two antimicrobial agents to inhibit bacterial growth. The effects are expressed as isobols and fractional inhibitory concentration (FIC) indices. Based on the minimum inhibitory concentration (MIC), the FIC index is equal to the sum of the values of FIC for the individual drugs:

$$\text{FIC index} = \frac{(\text{MIC of A with B})}{(\text{MIC of A alone})} + \frac{(\text{MIC of B with A})}{(\text{MIC of B alone})}$$

Points on concave isobols (FIC index < 1) are indicative of synergistic interaction between the two agents, and points on convex isobols (FIC index > 1) represent antagonism. The nature of the interaction is adequately revealed by testing combinations lying along the black dashed line (marked +). See text for further explanation.

fewer bacteria than the most active drug alone, *antagonism* is said to occur. If the combination kills the same number of bacteria or results in less than a hundredfold reduction in the inoculum compared with the most active single drug, the result is called *indifference*.

Bacteriostatic antibiotics (e.g., tetracyclines, erythromycin, and chloramphenicol) frequently antagonize the action of bactericidal drugs (e.g., β -lactam antibiotics, vancomycin, and aminoglycosides) because bacteriostatic antibiotics inhibit cell division and protein synthesis, which are required for the bactericidal effect of most bactericidal agents. Bactericidal drugs in combination tend to be additive or synergistic. For example, an inhibitor of cell wall synthesis and an aminoglycoside are synergistic against many bacterial species. Rifampin combinations appear to be an exception to this general rule. Although it is bactericidal, rifampin inhibits protein synthesis, which may account for its indifferent or antagonistic effect *in vitro* when combined with other bactericidal antibiotics.

The clinical relevance of this phenomenon is not clear because rifampin combinations are effective clinically.

Indications for the Clinical Use of Combinations of Antimicrobial Agents. Use of a combination of antimicrobial agents may be justified (1) for empirical therapy of an infection in which the cause is unknown, (2) for treatment of polymicrobial infections, (3) to enhance antimicrobial activity (*i.e.*, synergism) for a specific infection, or (4) to prevent emergence of resistance.

Empirical Therapy of Severe Infections in Which a Cause Is Unknown. Empirical therapy of infection probably is the most common reason for using a combination of antibiotics. Knowledge of the type(s) of infection(s), the microbiology, and the spectrum of activity of the several potentially useful antimicrobial agents is essential for selection of a rational and effective regimen (Anonymous, 2001). Severe illness and less certainty as to the particular infection or the causative agent may mandate broad coverage initially. More than one agent may be required to ensure that the regimen includes an agent that is active against the potential pathogens. For example, in the treatment of community-acquired pneumonia, a macrolide is used for atypical organisms such as *Mycoplasma*, and *cefuroxime* is used for pneumococci and gram-negative pathogens. Prolonged administration of empirical broad-spectrum coverage or multiple antibiotics, however, should be avoided; it often is unnecessary (*e.g.*, when the infection is caused by a single pathogen or no infection is documented) and unnecessarily expensive. Moreover, toxicity, superinfection, and selection of multiple-drug-resistant microorganisms may result. Inappropriately broad coverage often is continued because adequate cultures were not obtained prior to the initiation of therapy or because of the misconception that a broad-spectrum regimen is superior to a narrow-spectrum regimen. Although reluctance to change antimicrobial agents is understandable when a favorable clinical response has occurred, *the goal should be to use the most selectively active drug that produces the fewest adverse effects, which includes adverse effects on host normal flora.*

Treatment of Polymicrobial Infections. Treatment of intra-abdominal, hepatic, and brain abscesses and some genital tract infections may require the use of a drug combination to eradicate these typically mixed aerobic–anaerobic infections. These and other mixed infections may be caused by two or more microorganisms that are sufficiently different in antimicrobial susceptibility such that no single agent can provide the required coverage.

Enhancement of Antibacterial Activity in the Treatment of Specific Infections. Antimicrobial agents administered together may produce a synergistic effect. Syner-

gistic combinations of antimicrobial agents have been shown to be better than single-agent therapy in relatively few infections.

Perhaps the best-documented example of the utility of a synergistic combination of antimicrobial agents is in the treatment of enterococcal endocarditis (Wilson *et al.*, 1995). *In vitro*, penicillin alone is bacteriostatic against enterococci, whereas a combination of penicillin and streptomycin or gentamicin is bactericidal. Treatment of enterococcal endocarditis with penicillin alone frequently results in relapses, whereas combination therapy is curative.

The combination of penicillin and streptomycin or gentamicin also is synergistic *in vitro* against strains of *viridans* streptococci. This combination eradicates bacteria from infected valvular vegetations more rapidly than does penicillin alone in animal models. A 2-week course of treatment with the combination is just as effective as a 4-week penicillin-only regimen for patients with streptococcal endocarditis. β -Lactam antibiotic-aminoglycoside combinations have been recommended in the therapy of infections with *Pseudomonas aeruginosa*. *In vitro*, an antipseudomonal β -lactam plus an aminoglycoside is synergistic against most strains of *P. aeruginosa*. This combination is more active than either drug alone in animal models. Some but not all clinical studies suggest that outcome is improved when a β -lactam plus an aminoglycoside combination is used for serious pseudomonal infections (Paul *et al.*, 2004; Hilf *et al.*, 1989; Leibovici *et al.*, 1997). Combination therapy has been advocated for the treatment of infections caused by other gram-negative rods. However, the benefits of using a drug combination over a single, effective agent remain largely unproven (Barriere, 1992; Rybak and McGrath, 1996).

The combination of a sulfonamide and an inhibitor of dihydrofolate reductase, such as trimethoprim, is synergistic owing to the blocking of sequential steps in microbial folate synthesis. A fixed combination of sulfamethoxazole and trimethoprim, which is active against organisms that may be resistant to sulfonamides alone, is effective for the treatment of urinary tract infections, *Pneumocystis* pneumonia, typhoid fever, shigellosis, and certain infections owing to ampicillin-resistant *Haemophilus influenzae*.

The combination of flucytosine and amphotericin B is synergistic against *Cryptococcus neoformans* *in vitro* and in animal models of infection. This combination also has been shown to sterilize the CSF more rapidly than amphotericin B alone in AIDS patients with cryptococcal meningitis (van der Horst *et al.*, 1997).

Prevention of the Emergence of Resistant Microorganisms. The theoretical basis for combination therapy of tuberculosis is to prevent the emergence of resistant mutants that might result from monotherapy. For example, if the frequency of mutation for the acquisition of resistance to one drug is 10^{-7} and that for a second drug is 10^{-6} , the probability of two simultaneous, independent mutations in a single cell is the product of the two frequencies, 10^{-13} . The number of organisms that would have to be present for such a mutant to occur is several orders of magnitude greater than that likely to be encountered clinically. The concomitant use of two or more active agents vastly improves cure rates by preventing the development of resistance. Other examples supporting the

concept of combination therapy include infections that are treated with rifampin, such as staphylococcal osteomyelitis or prosthetic valve endocarditis (Zimmerli *et al.*, 1998), in which a second agent is added to prevent emergence of rifampin-resistant mutants, and combination therapy of *Helicobacter pylori* infection (Taylor *et al.*, 1997). Other than for these specific examples, few data document that drug combinations improve outcome by preventing the emergence of resistance.

Disadvantages of Combinations of Antimicrobial Agents. Disadvantages of antimicrobial combinations include increased risk of toxicity from two or more agents, selection of multiple-drug-resistant microorganisms, eradication of normal host flora with subsequent superinfection, and increased cost to the patient. Although antagonism of one antibiotic by another has been a frequent observation *in vitro*, well-documented clinical examples of this phenomenon are relatively rare. The most notable of these involves the therapy of pneumococcal meningitis. Lepper and Dowling reported in 1951 that the fatality rate among patients with pneumococcal meningitis who were treated with penicillin alone was 21%, whereas patients treated with a combination of penicillin and *chlortetracycline* had a fatality rate of 79%. Nonetheless, because the addition of a bacteriostatic drug to a bactericidal drug frequently results in a bacteriostatic effect, antagonism between antibiotics probably is relatively unimportant when host defenses are adequate. On the other hand, if achieving a bactericidal effect is critical for cure of the infection (*e.g.*, meningitis, endocarditis, and gram-negative infections in neutropenic patients), such antibiotic antagonism could adversely affect outcome.

The Prophylaxis of Infection with Antimicrobial Agents

Chemoprophylaxis is highly effective in some clinical settings. In others, it accounts for some of the most flagrant misuses of antimicrobials, is totally without value, and may be deleterious. Use of antimicrobial compounds to prevent infections remains controversial in numerous situations. *In general, if a single, effective, nontoxic drug is used to prevent infection by a specific microorganism or to eradicate an early infection, then chemoprophylaxis frequently is successful. On the other hand, if the aim of prophylaxis is to prevent colonization or infection by any or all microorganisms present in the environment of a patient, then prophylaxis often fails.*

Prophylaxis may be used to protect healthy persons from acquisition of or invasion by specific microorgan-

isms to which they are exposed. Successful examples of this practice include rifampin administration to prevent meningococcal meningitis in people who are in close contact with a case, prevention of gonorrhea or syphilis after contact with an infected person, and the intermittent use of trimethoprim–sulfamethoxazole to prevent recurrent urinary tract infections usually caused by *E. coli*.

Antimicrobial prophylaxis, often with an oral fluoroquinolone, is used to prevent a variety of infections in patients undergoing organ transplantation or receiving cancer chemotherapy. Although specific infections often can be prevented, superinfections with opportunistic fungal pathogens or multiple-drug-resistant bacteria can be a problem. Moreover, the infection rate may be lowered without changing overall outcomes. Prophylaxis is recommended for primary and secondary prevention of opportunistic infections in AIDS patients whose CD4 counts are below certain thresholds, *e.g.*, less than 200 cells/ μ l for the prevention of *Pneumocystis* pneumonia and less than 50 cells/ μ l for prevention of atypical mycobacterial infection (Kaplan *et al.*, 2002).

Chemoprophylaxis is recommended for patients with valvular or other structural lesions of the heart predisposing to endocarditis who are undergoing dental, surgical, or other procedures that produce a high incidence of bacteremia (Dajani *et al.*, 1997). Clinical data suggesting that dental procedures have a minimal, if indeed any, role in causing endocarditis (Strom *et al.*, 1998) have challenged some of the recommendations for chemoprophylaxis, but the recommendations nevertheless remain the standard of care. A procedure that injures a mucous membrane where there are large numbers of bacteria (such as in the oropharyngeal or gastrointestinal tract) will produce transient bacteremia. Streptococci from the mouth, enterococci from the gastrointestinal or genitourinary tract, and staphylococci from the skin commonly enter the bloodstream and may adhere to an abnormal or damaged valve surface, producing endocarditis. Chemoprophylaxis is directed against these microorganisms. Therapy, generally as a single dose, should begin 1 hour before the procedure for oral drugs and 30 minutes for parental drugs. Criteria have been established for the selection of specific drugs and patients who should receive chemoprophylaxis for various procedures (Table 42–1).

The most extensive and probably best-studied use of chemoprophylaxis is to prevent wound infections after various surgical procedures (Bratzler and Houck, 2004) (Table 42–1). Wound infection results when a critical number of bacteria are present in the wound at the time of closure. Several factors determine the size of this critical inoculum, including virulence of the bacteria, the pres-

ence of devitalized or poorly vascularized tissue, the presence of a foreign body, and the status of the host. Antimicrobial agents directed against the invading microorganisms may reduce the number of viable bacteria below the critical level and thus prevent infection.

Several factors are important for the effective and judicious use of antibiotics for surgical prophylaxis. First, antimicrobial activity must be present at the wound site at the time of its closure. Thus the drug should be given preoperatively (1 hour before incision) and perhaps intraoperatively for prolonged procedures to ensure that therapeutic levels are maintained during the entire procedure. Second, the antibiotic must be active against the most likely contaminating microorganisms. Thus cephalosporins are used commonly in this form of chemoprophylaxis. Third, prolonged administration of drugs after the surgical procedure is unwarranted and potentially harmful. No data suggest that the incidence of wound infections is lower if antimicrobial treatment is continued after the day of surgery (Bratzler and Houck, 2004). Use beyond 24 hours not only is unnecessary but also leads to the development of more resistant flora and superinfections caused by antibiotic-resistant strains. Chemoprophylaxis should be limited to operative procedures for which there are data supporting its use. A number of studies indicate that it can be justified in dirty or contaminated surgical procedures (*e.g.*, resection of the colon), where the incidence of wound infections is high. These include less than 10% of all surgical procedures. In clean surgical procedures, which account for approximately 75% of the total, the expected incidence of wound infection is less than 5%, and antibiotics should not be used routinely. When the surgery involves insertion of a prosthetic implant (*e.g.*, prosthetic valve, vascular graft, prosthetic joint), cardiac surgery, or neurosurgical procedures, the complications of infection are so drastic that most authorities currently agree to chemoprophylaxis with these indications. Of course, the use of systemic antibiotics for chemoprophylaxis during surgical procedures does not reduce the need for sterile and skilled surgical technique.

Superinfections

All individuals who receive therapeutic doses of antibiotics undergo alterations in the normal microbial population of the intestinal, upper respiratory, and genitourinary tracts; as a result, some develop *superinfection*, defined as the appearance of bacteriological and clinical evidence of a new infection during the chemotherapy of a primary one. This phenomenon is relatively common and potentially very dangerous because the microorganisms respon-

Table 42-1

Guidelines for Prophylactic Antibiotics in Surgical Procedures

Antibiotics should be administered 30 to 60 minutes prior to incision and may need to be readministered to maintain effective serum drug concentrations during prolonged procedures. A single preoperative antibiotic dose is usually sufficient prophylaxis. Continuation of antibiotics for up to 24 hours may be considered in some cases (for example, contaminated cases, surgery of long duration, implantation of prosthetic material).

NATURE OF SURGERY	PROBABLE PATHOGEN(S)	RECOMMENDED DRUG(S) (ADULT DOSAGE)	TIME OF ADMINISTRATION
I. Clean			
A. Thoracic, cardiac, vascular, and orthopedic; neurosurgery	<i>S. aureus</i> *, coagulase-negative staphylococci, gram-negative bacilli, <i>Pseudomonas</i>	Cefazolin (1 g IV) Vancomycin* (1 g IV)	At induction of anesthesia
B. Ophthalmic		Gentamicin or neomycin-gramacidin-polymixin B ophthalmic drops; multiple drugs at intervals for first 24 hours	
II. Clean-Contaminated			
A. Head and neck (potentially entering esophageal lumen)	<i>S. aureus</i> and oral anaerobes	Cefazolin (1 to 2 g IV) or clindamycin (600 mg IV) ± gentamicin (1.5 mg/kg IV)	At induction of anesthesia
B. Abdominal—cholecystectomy and high-risk gastroduodenal or biliary		Cefazolin (1 g IV)	At induction of anesthesia
C. Abdominal—appendectomy		Cefoxitin or cefotetan (1 g IV)	At induction of anesthesia
D. Colorectal Preoperative lavage recommended, plus antimicrobial treatment		Go-LYTELY electrolyte solution (4 liters)	Preoperative day
1. Oral antimicrobial prophylaxis		Erythromycin stearate (1 g PO) <i>or</i> metronidazole (500 mg PO) plus neomycin (1 g PO)	At 1 P.M., 2 P.M., and 11 P.M. on the preoperative day
2. Parenteral antimicrobial prophylaxis	Patients who have not received lavage and oral prophylaxis should receive parenteral antibiotics for ≤24 hours to cover enteric aerobes (including <i>E. coli</i> , <i>Klebsiella</i> spp.) and enteric anaerobes (including <i>B. fragilis</i> , <i>Clostridium</i> spp., anaerobic cocci, and <i>Fusobacterium</i> spp.)	Cefotetan (1 g every 12 hours for 2 doses) Ceftizoxime (1 g every 12 hours for 2 doses) Cefoxitin (1 g every 4 to 8 hours for 3 doses)	

(Continued)

Table 42-1

Guidelines for Prophylactic Antibiotics in Surgical Procedures (Continued)

NATURE OF SURGERY	PROBABLE PATHOGEN(S)	RECOMMENDED DRUG(S) (ADULT DOSAGE)	TIME OF ADMINISTRATION
II. Clean-Contaminated (Continued)			
E. Gynecological			
1. Vaginal or abdominal hysterectomy and high-risk cesarean section (following labor or ruptured membrane only)		Cefazolin (1 g IV)	At induction of anesthesia or postcord clamp
2. High-risk abortion, first trimester		Penicillin G (2 million units IV) <i>or</i> doxycycline (300 mg PO)	
3. High-risk abortion, second trimester		Cefazolin (1 g IV)	
F. Urology		Prophylactic antibiotics have not been shown to reduce the incidence of wound infection after urological procedures. Bacteriuria is the most common postoperative complication; only patients with evidence of infected urine should be treated with antibiotics directed against the specific pathogens isolated.	
III. Trauma-Contaminated Wounds			
A. Extremity	Antimicrobial coverage for Group A streptococci, staphylococci, and <i>Clostridium</i> spp.	Cefazolin (1 g every 8 hours IV) Vancomycin (1 g every 12 hours IV)†	
B. Ruptured viscus—abdomen/bowel injury		Cefotetan (1 g every 12 hours) <i>or</i> ceftizoxime (1 g every 12 hours) <i>or</i> cefoxitin (1 g every 6 hours) <i>or</i> clindamycin (600 mg IV every 8 hours) + gentamicin (1.5 mg/kg IV every 8 hours)† for ≤5 days	
C. Bites (cats and human)	Aerobic and anaerobic streptococci from skin and oral flora. Infection of animal bites additionally may be caused by <i>Pasteurella multocida</i> , which is penicillin-sensitive	Amoxicillin/clavulanate (750/125 mg twice a day for 5 days) <i>or</i> doxycycline 100 mg PO twice a day for 5 days)	

*Recommended for hospitals with a high prevalence of infections caused by methicillin-resistant staphylococci or for serious allergy to β -lactams.†For serious β -lactam allergy. Abbreviations: IV, intravenous administration; PO, oral administration

sible for the new infection can be drug-resistant strains of Enterobacteriaceae, *Pseudomonas*, and *Candida* or other fungi. Superinfection is due to removal of the inhibitory influence of the normal flora, which produce antibacterial substances and also presumably compete for essential nutrients. The broader the antibacterial spectrum and the longer the period of antibiotic treatment, the greater is the alteration in the normal microflora, and the greater is the possibility that a single, typically drug-resistant microorganism will become predominant, invade the host, and produce infection. *The most specific and narrowest spectrum antimicrobial agent should be chosen to treat infections whenever feasible.*

The fact that harmful effects may follow the therapeutic or prophylactic use of anti-infective agents should not discourage the physician from their administration in any situation in which they are definitely indicated. However, the clinician should use restraint in prescribing antimicrobial drugs in instances where evidence of infection is entirely lacking or, at most, only suggestive.

Misuses of Antibiotics

The purpose of this introductory chapter has been to lay the groundwork for the maximally effective use of antimicrobial drugs. Therefore, a brief discussion of the misuse and overuse of antimicrobial agents is in order. Organizations such as the Centers for Disease Control and Prevention have outlined a number of steps to optimize the use of antimicrobial agents and to prevent drug resistance and the transmission of infections (Anonymous, 2002a, 2002b).

Treatment of Nonresponsive Infections. A common misuse of these agents is in infections that have been proved by experimental and clinical observation to be nonresponsive to treatment with antimicrobial agents (Nyquist *et al.*, 1998). Most of the diseases caused by viruses are self-limited and do not respond to any of the currently available anti-infective compounds. Thus, antimicrobial therapy of measles, mumps, and at least 90% of infections of the upper respiratory tract and many GI infections is ineffective and, therefore, useless.

Therapy of Fever of Unknown Origin. Fever of undetermined cause may persist for only a few days to a week or for a longer period. Both of these are treated frequently and inappropriately with empirical antimicrobial agents. Fever of short duration, in the absence of localizing signs, probably is associated with undefined viral infections. Antimicrobial therapy is unnecessary, and resolution of

fever occurs spontaneously within a week or less. Fever persisting for 2 or more weeks, commonly referred to as *fever of unknown origin*, has a variety of causes, of which only about one-quarter are infections (de Kleijn *et al.*, 1997). Some of these infections (*e.g.*, tuberculosis or disseminated fungal infections) may require treatment with antimicrobial agents that are not used commonly for bacterial infections. Others, such as occult abscesses, may require surgical drainage or prolonged courses of pathogen-specific therapy, as in the case of bacterial endocarditis. Inappropriately administered antimicrobial therapy may mask an underlying infection, delay the diagnosis, and by rendering cultures negative, prevent identification of the infectious pathogen. Noninfectious causes, including regional enteritis, lymphoma, renal cell carcinoma, hepatitis, collagen-vascular disorders, and drug fever, do not respond to antimicrobial agents at all. Rather than embarking on a course of empirical antimicrobial therapy for fever of unknown origin, the physician should search for its cause.

Improper Dosage. Dosing errors, which can be the wrong frequency of administration or the use of either an excessive or a subtherapeutic dose, are common. Although antimicrobial drugs are among the safest and least toxic of drugs used in medical practice, excessive amounts can result in significant toxicities, including seizures (*e.g.*, penicillin), vestibular damage (*e.g.*, aminoglycosides), and renal failure (*e.g.*, aminoglycosides), especially in patients with impaired drug excretion or metabolism. The use of too low a dose may result in treatment failure and is most likely to select for microbial resistance.

Inappropriate Reliance on Chemotherapy Alone. Infections complicated by abscess formation, the presence of necrotic tissue, or the presence of a foreign body often cannot be cured by antimicrobial therapy alone. Drainage, débridement, and removal of the foreign body are at least as important as the choice of antimicrobial agent. For example, the patient with pneumonia and empyema often fails to be cured even with administration of large doses of an effective drug unless the infected pleural fluid is drained. The patient with *S. aureus* bacteremia owing to an intravascular device will continue to have fevers and positive blood cultures and is at risk of dying unless the device is removed. As a general rule, when an appreciable quantity of pus, necrotic tissue, or a foreign body is present, the most effective treatment is an antimicrobial agent given in adequate dose plus a properly performed surgical procedure.

Lack of Adequate Bacteriological Information. Antimicrobial therapy administered to hospitalized patients too often is given in the absence of supporting microbiological data. Bacterial cultures and Gram stains of infected material are obtained too infrequently, and the results, when available, often are disregarded in the selection and application of drug therapy. *Frequent use of drug combinations or drugs with the broadest spectra is a cover for diagnostic imprecision.* The agents are selected more likely by habit than for specific indications, and the dosages employed are routine rather than individualized on the basis of the clinical situation, microbiological information, and the pharmacological considerations presented in this and subsequent chapters of this section.

SULFONAMIDES, TRIMETHOPRIM-SULFAMETHOXAZOLE, QUINOLONES, AND AGENTS FOR URINARY TRACT INFECTIONS

William A. Petri, Jr.

SULFONAMIDES

The sulfonamide drugs were the first effective chemotherapeutic agents to be employed systemically for the prevention and cure of bacterial infections in humans. The considerable medical and public health importance of their discovery and their subsequent widespread use were quickly reflected in the sharp decline in morbidity and mortality figures for treatable infectious diseases. The advent of *penicillin* and subsequently of other antibiotics has diminished the usefulness of the sulfonamides, and they presently occupy a relatively small place in the therapeutic armamentarium of the physician. However, the introduction in the mid-1970s of the combination of *trimethoprim* and *sulfamethoxazole* has increased the use of sulfonamides for the prophylaxis and treatment of specific microbial infections.

History. Investigations at the I. G. Farbenindustrie resulted, in 1932, in the patenting of PRONTOSIL and several other azo dyes containing a sulfonamide group. Prompted by the knowledge that synthetic azo dyes had been studied for their action against streptococci, Domagk tested the new compounds and observed that mice with streptococcal and other infections could be protected by PRONTOSIL. In 1933, the first clinical case study was reported by Foerster, who gave PRONTOSIL to a 10-month-old infant with staphylococcal septicemia and obtained a dramatic cure. Little attention was paid elsewhere to these epoch-making advances in chemotherapy until Colebrook and Kenny, as well as Buttle and coworkers, reported their favorable clinical results with PRONTOSIL and its active metabolite, sulfanilamide, in puerperal sepsis and meningococcal infections. These two reports awakened the medical profession to the new field of antibacterial chemotherapy, and experimental and clinical articles soon appeared in profusion. The

development of the carbonic anhydrase inhibitor-type diuretics and the sulfonyleurea hypoglycemic agents followed from observations made with the sulfonamide antibiotics. For discovering the chemotherapeutic value of PRONTOSIL Domagk was awarded the Nobel Prize in Medicine for 1938.

Chemistry. The term *sulfonamide* is employed herein as a generic name for derivatives of *para*-aminobenzenesulfonamide (sulfanilamide); the structural formulas of selected members of this class are shown in Figure 43-1. Most of them are relatively insoluble in water, but their sodium salts are readily soluble. The minimal structural prerequisites for antibacterial action are all embodied in sulfanilamide itself. The $-\text{SO}_2\text{NH}_2$ group is not essential as such, but the important feature is that the sulfur is linked directly to the benzene ring. The *para*- NH_2 group (the N of which has been designated as N4) is essential and can be replaced only by moieties that can be converted *in vivo* to a free amino group. Substitutions made in the amide NH_2 group (the N of which has been designated as N1) have variable effects on antibacterial activity of the molecule. However, substitution of heterocyclic aromatic nuclei at N1 yields highly potent compounds.

Effects on Microbes

Sulfonamides have a wide range of antimicrobial activity against both gram-positive and gram-negative bacteria. However, resistant strains have become common, and the usefulness of these agents has diminished correspondingly. In general, the sulfonamides exert only a bacteriostatic effect, and cellular and humoral defense mechanisms of the host are essential for final eradication of the infection.

Antibacterial Spectrum. Resistance to sulfonamides is increasingly a problem. Microorganisms that may be susceptible *in vitro* to sulfonamides include *Streptococcus pyo-*

Figure 43-1. Structural formulas of selected sulfonamides and para-aminobenzoic acid. The N of the *para*-NH₂ group is designated as N4; that of the amide NH₂, as N1.

genes, Streptococcus pneumoniae, Haemophilus influenzae, Haemophilus ducreyi, Nocardia, Actinomyces, Calymmatobacterium granulomatis, and Chlamydia trachomatis. Minimal inhibitory concentrations (MICs) range from 0.1 µg/ml for *C. trachomatis* to 4 to 64 µg/ml for *Escherichia coli*. Peak plasma drug concentrations achievable *in vivo* are approximately 100 to 200 µg/ml.

Although sulfonamides were used successfully for the management of meningococcal infections for many years, the majority of isolates of *Neisseria meningitidis* of serogroups B and C in the United States and group A isolates from other countries are now resistant. A similar situation prevails with respect to *Shigella*. Strains of *E. coli* isolated from patients with urinary tract infections (community-acquired) often are resistant to sulfonamides, which are no longer the therapy of choice for such infections.

Mechanism of Action. Sulfonamides, structural analogs and competitive antagonists of para-aminobenzoic acid (PABA), prevent normal bacterial utilization of PABA for the synthesis of folic acid (pteroylglutamic acid). More specifically, sulfonamides are competitive inhibitors of dihydropteroate synthase, the bacterial enzyme responsible for the incorporation of PABA into dihydropteroic acid, the immediate precursor of folic acid (Figure 43-2). Sensitive microorganisms are those that must synthesize their own folic acid; bacteria that can use preformed folate are not affected. Bacteriostasis induced by sulfonamides is counteracted by PABA competitively. Sulfonamides do not affect mammalian cells by this mechanism because they require preformed folic acid and cannot synthesize it. Thus, mammalian cells are comparable to sulfonamide-insensitive bacteria that use preformed folate.

Synergists of Sulfonamides. One of the most active agents that exerts a synergistic effect when used with a sulfonamide is trimethoprim (see Bushby and Hitchings, 1968). This compound is a potent and selective competitive inhibitor of microbial dihydrofolate reductase, the enzyme that reduces dihydrofolate to tetrahydrofolate. It is this reduced form of folic acid that is required for one-carbon transfer reactions. The simultaneous administration of a sulfonamide and trimethoprim thus introduces sequential blocks in the pathway by which microorganisms synthesize tetrahydrofolate from precursor molecules (Figure 43-2). The expectation that such a combination would yield synergistic antimicrobial effects has been realized both *in vitro* and *in vivo* (see below).

Figure 43-2. Steps in folate metabolism blocked by sulfonamides and trimethoprim.

Acquired Bacterial Resistance to Sulfonamides. Bacteria resistant to sulfonamides is presumed to originate by random mutation and selection or by transfer of resistance by plasmids (see Chapter 42). Such resistance, once it is maximally developed, usually is persistent and irreversible, particularly when produced *in vivo*. Acquired resistance to sulfonamide usually does not involve cross-resistance to antimicrobial agents of other classes. The *in vivo* acquisition of resistance has little or no effect on either virulence or antigenic characteristics of microorganisms.

Resistance to sulfonamide probably is the consequence of an altered enzymatic constitution of the bacterial cell; the alteration may be characterized by (1) a lower affinity for sulfonamides by dihydropteroate synthase, (2) decreased bacterial permeability or active efflux of the drug, (3) an alternative metabolic pathway for synthesis of an essential metabolite, or (4) an increased production of an essential metabolite or drug antagonist. For example, some resistant staphylococci may synthesize 70 times as much PABA as do the susceptible parent strains. Nevertheless, an increased production of PABA is not a constant finding in sulfonamide-resistant bacteria, and resistant mutants may possess enzymes for folate biosynthesis that are less readily inhibited by sulfonamides. Plasmid-mediated resistance is due to plasmid-encoded drug-resistant dihydropteroate synthetase.

Absorption, Fate, and Excretion

Except for sulfonamides especially designed for their local effects in the bowel (see Chapter 38), this class of drugs is absorbed rapidly from the gastrointestinal tract. Approximately 70% to 100% of an oral dose is absorbed, and sulfonamide can be found in the urine within 30 minutes of ingestion. Peak plasma levels are achieved in 2 to 6 hours, depending on the drug. The small intestine is the major site of absorption, but some of the drug is absorbed from the stomach. Absorption from other sites, such as the vagina, respiratory tract, or abraded skin, is variable and unreliable, but a sufficient amount may enter the body to cause toxic reactions in susceptible persons or to produce sensitization.

All sulfonamides are bound in varying degree to plasma proteins, particularly to albumin. The extent to which this occurs is determined by the hydrophobicity of a particular drug and its pK_a ; at physiological pH, drugs with a high pK_a exhibit a low degree of protein binding, and *vice versa*.

Sulfonamides are distributed throughout all tissues of the body. The diffusible fraction of sulfadiazine is distributed uniformly throughout the total-body water, whereas *sulfisoxazole* is confined largely to the extracellular space. The sulfonamides readily enter pleural, peritoneal, synovial, ocular, and similar body fluids and may reach concentrations therein that are 50% to 80% of the simultaneously determined concentration in blood. Since the protein content of such fluids usually is low, the drug is present in the unbound active form.

After systemic administration of adequate doses, *sulfadiazine* and *sulfisoxazole* attain concentrations in cerebrospinal fluid that may be effective in meningeal infections. At steady state, the concentration ranges between 10% and 80% of that in the blood. However, because of the emergence of sulfonamide-resistant microorganisms, these drugs are used rarely for the treatment of meningitis.

Sulfonamides pass readily through the placenta and reach the fetal circulation. The concentrations attained in the fetal tissues are sufficient to cause both antibacterial and toxic effects.

The sulfonamides undergo metabolic alterations *in vivo*, especially in the liver. The major metabolic derivative is the N4-acetylated sulfonamide. Acetylation, which occurs to a different extent with each agent, is disadvantageous because the resulting products have no antibacterial activity and yet retain the toxic potential of the parent substance.

Sulfonamides are eliminated from the body partly as the unchanged drug and partly as metabolic products. The largest fraction is excreted in the urine, and the half-life of sulfonamides in the body thus depends on renal function. In acid urine, the older sulfonamides are insoluble and may precipitate, forming crystalline deposits that can cause urinary obstruction (see below). Small amounts are eliminated in the feces, bile, milk, and other secretions.

Pharmacological Properties of Individual Sulfonamides

The sulfonamides may be classified into three groups on the basis of the rapidity with which they are absorbed and excreted: (1) agents that are absorbed and excreted rapidly, such as *sulfisoxazole* and *sulfadiazine*; (2) agents that are absorbed very poorly when administered orally and hence are active in the bowel lumen, such as *sulfasalazine*; (3) agents that are used mainly topically, such as *sulfacetamide*, *mafenide*, and *silver sulfadiazine*; and (4) long-acting sulfonamides, such as *sulfadoxine*, that are absorbed rapidly but excreted slowly (Table 43–1).

Rapidly Absorbed and Eliminated Sulfonamides. *Sulfisoxazole.* *Sulfisoxazole* (GANTRISIN, others) is a rapidly absorbed and excreted sulfonamide with excellent antibacterial activity. Since its high solubility eliminates much of the renal toxicity inherent in the use of older sulfonamides, it has essentially replaced the less-soluble agents.

Sulfisoxazole is bound extensively to plasma proteins. Following an oral dose of 2 to 4 g, peak concentrations in plasma of 110 to 250 $\mu\text{g/ml}$ are found in 2 to 4 hours. From 28% to 35% of *sulfisoxazole* in the blood and about 30% in the urine is in the acetylated

Table 43–1
Classes of Sulfonamides

CLASS	SULFONAMIDE	SERUM HALF-LIFE HOURS
Absorbed and excreted rapidly	Sulfisoxazole	5–6
	Sulfamethoxazole	11
	Sulfadiazine	10
Poorly absorbed—active in bowel lumen	Sulfasalazine	—
Topically used	Sulfacetamide	—
	Silver sulfadiazine	—
Long-acting	Sulfadoxine	100–230

form. Approximately 95% of a single dose is excreted by the kidney in 24 hours. Concentrations of the drug in urine thus greatly exceed those in blood and may be bactericidal. The concentration in cerebrospinal fluid averages about a third of that in the blood.

Sulfisoxazole acetyl is tasteless and hence preferred for oral use in children. Sulfisoxazole acetyl is marketed in combination with *erythromycin ethylsuccinate* (PEDIAZOLE, others) for use in children with otitis media. The urine becomes orange-red soon after ingestion of this mixture because of the presence of phenazopyridine, an orange-red dye.

Fewer than 0.1% of patients receiving sulfisoxazole suffer serious toxic reactions. The untoward effects produced by this agent are similar to those which follow the administration of other sulfonamides, as discussed below. Because of its relatively high solubility in the urine as compared with sulfadiazine, sulfisoxazole only infrequently produces hematuria or crystalluria (0.2% to 0.3%). Despite this, patients taking this drug should ingest an adequate quantity of water. Sulfisoxazole and all sulfonamides that are absorbed must be used with caution in patients with impaired renal function. Like all sulfonamides, sulfisoxazole may produce hypersensitivity reactions, some of which are potentially lethal. Sulfisoxazole currently is preferred over other sulfonamides by most clinicians when a rapidly absorbed and rapidly excreted sulfonamide is indicated.

Sulfamethoxazole. Sulfamethoxazole is a close congener of sulfisoxazole, but its rates of enteric absorption and urinary excretion are slower. It is administered orally and employed for both systemic and urinary tract infections. Precautions must be observed to avoid sulfamethoxazole crystalluria because of the high percentage of the acetylated, relatively insoluble form of the drug in the urine. The clinical uses of sulfamethoxazole are the same as those for sulfisoxazole. It also is marketed in fixed-dose combinations with trimethoprim (*see below*).

Sulfadiazine. Sulfadiazine given orally is absorbed rapidly from the GI tract, and peak blood concentrations are reached within 3 to 6 hours after a single dose. Following an oral dose of 3 g, peak concentrations in plasma are 50 $\mu\text{g/ml}$. About 55% of the drug is bound to plasma protein at a concentration of 100 $\mu\text{g/ml}$ when plasma protein levels are normal. Therapeutic concentrations

are attained in cerebrospinal fluid within 4 hours of a single oral dose of 60 mg/kg.

Sulfadiazine is excreted quite readily by the kidney in both the free and acetylated forms, rapidly at first and then more slowly over a period of 2 to 3 days. It can be detected in the urine within 30 minutes of oral ingestion. About 15% to 40% of the excreted sulfadiazine is in acetylated form. This form of the drug is excreted more readily than the free fraction, and the administration of alkali accelerates the renal clearance of both forms by further diminishing their tubular reabsorption.

In adults and children who are being treated with sulfadiazine, every precaution must be taken to ensure fluid intake adequate to produce a urine output of at least 1200 ml in adults and a corresponding quantity in children. If this cannot be accomplished, sodium bicarbonate may be given to reduce the risk of crystalluria.

Poorly Absorbed Sulfonamides. Sulfasalazine (AZULFIDINE) is very poorly absorbed from the GI tract. It is used in the therapy of ulcerative colitis and regional enteritis, but relapses tend to occur in about one-third of patients who experience a satisfactory initial response. *Corticosteroids* are more effective in treating acute attacks, but sulfasalazine is preferred to corticosteroids for the treatment of patients who are mildly or moderately ill with ulcerative colitis (*see Chapter 38*). The drug also is being employed as the first approach to treatment of relatively mild cases of regional enteritis and granulomatous colitis. Sulfasalazine is broken down by intestinal bacteria to *sulfapyridine*, an active sulfonamide that is absorbed and eventually excreted in the urine, and *5-aminosalicylate*, which reaches high levels in the feces. 5-Aminosalicylate is the effective agent in inflammatory bowel disease, whereas sulfapyridine is responsible for most of the toxicity. Toxic reactions include Heinz-body anemia, acute hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency, and agranulocytosis. Nausea, fever, arthralgias, and rashes occur in up to 20% of patients treated with the drug; desensitization has been an effective treatment. Sulfasalazine can cause a reversible infertility in males owing to changes in sperm number and morphology. There is no evidence that the compound alters the intestinal microflora of patients with ulcerative colitis.

Sulfonamides for Topical Use. **Sulfacetamide.** Sulfacetamide is the N1-acetyl-substituted derivative of *sulfanilamide*. Its aqueous solubility (1:140) is approximately 90 times that of sulfadiazine. Solutions of the sodium salt of the drug (ISOPTO-CETAMIDE, others) are employed extensively in the management of ophthalmic infections. Although topical sulfonamide for most purposes is discouraged because of lack of efficacy and a high risk of sensitization, sulfacetamide has certain advantages. Very high aqueous concentrations are not irritating to the eye and are effective against susceptible microorganisms. A 30% solution of the sodium salt has a pH of 7.4, whereas the solutions of sodium salts of other sulfonamides are highly alkaline. The drug penetrates into ocular fluids and tissues in high concentration. Sensitivity reactions to sulfacetamide are rare, but the drug should not be used in patients with known hypersensitivity to sulfonamides.

Silver Sulfadiazine. Silver sulfadiazine (SILVADENE, others) inhibits the growth *in vitro* of nearly all pathogenic bacteria and fungi, including some species resistant to sulfonamides. The compound is used topically to reduce microbial colonization and the incidence of infections of wounds from burns. It should not be used to treat an established deep infection. Silver is released slow-

ly from the preparation in concentrations that are selectively toxic to the microorganisms. However, bacteria may develop resistance to silver sulfadiazine. Although little silver is absorbed, the plasma concentration of sulfadiazine may approach therapeutic levels if a large surface area is involved. Adverse reactions—burning, rash, and itching—are infrequent. Silver sulfadiazine is considered by most authorities to be one of the agents of choice for the prevention of burn infection.

Mafenide. This sulfonamide (α -amino-*p*-toluene-sulfonamide) is marketed as *mafenide acetate* (SULFAMYLON). When applied topically, it is effective for the prevention of colonization of burns by a large variety of gram-negative and gram-positive bacteria. It should not be used in treatment of an established deep infection. Superinfection with *Candida* occasionally may be a problem. The cream is applied once or twice daily to a thickness of 1 to 2 mm over the burned skin. Cleansing of the wound and removal of debris should be carried out before each application of the drug. Therapy is continued until skin grafting is possible. Mafenide is rapidly absorbed systemically and converted to *para*-carboxybenzenesulfonamide. Studies of absorption from the burn surface indicate that peak plasma concentrations are reached in 2 to 4 hours. Adverse effects include intense pain at sites of application, allergic reactions, and loss of fluid by evaporation from the burn surface because occlusive dressings are not used. The drug and its primary metabolite inhibit carbonic anhydrase, and the urine becomes alkaline. Metabolic acidosis with compensatory tachypnea and hyperventilation may ensue; these effects limit the usefulness of mafenide.

Long-Acting Sulfonamides. *Sulfadoxine* (N1-[5,6-dimethoxy-4-pyrimidiny] sulfanilamide) has a particularly long half-life (7 to 9 days). It is used in combination with *pyrimethamine* (500 mg sulfadoxine plus 25 mg pyrimethamine as FANSIDAR) for the prophylaxis and treatment of malaria caused by *mefloquine*-resistant strains of *Plasmodium falciparum* (see Chapter 39). Because of severe and sometimes fatal reactions, including the Stevens-Johnson syndrome, the drug should be used for prophylaxis only where the risk of resistant malaria is high.

Sulfonamide Therapy

The number of conditions for which the sulfonamides are therapeutically useful and constitute drugs of first choice has been reduced sharply by the development of more effective antimicrobial agents and by the gradual increase in the resistance of a number of bacterial species to this class of drugs. However, introduction of the combination of trimethoprim and sulfamethoxazole has revived the use of sulfonamides.

Urinary Tract Infections. Since a significant percentage of urinary tract infections in many parts of the world are caused by sulfonamide-resistant microorganisms, sulfonamides are no longer a therapy of first choice. Trimethoprim–sulfamethoxazole, a quinolone, trimethoprim, *fosfomicin*, or *ampicillin* are the preferred agents. However, sulfisoxazole may be used effectively in areas where the prevalence of resistance is not high or when the organism is known to be sensitive. The usual dosage is 2 to 4 g initially followed by 1 to 2 g, orally four times a day for 5 to 10 days. Patients with acute

pyelonephritis with high fever and other severe constitutional manifestations are at risk of bacteremia and shock and should not be treated with a sulfonamide.

Nocardiosis. Sulfonamides are of value in the treatment of infections due to *Nocardia* spp. A number of instances of complete recovery from the disease after adequate treatment with a sulfonamide have been recorded. Sulfisoxazole or sulfadiazine may be given in dosages of 6 to 8 g daily. Concentrations of sulfonamide in plasma should be 80 to 160 $\mu\text{g/ml}$. This schedule is continued for several months after all manifestations have been controlled. The administration of sulfonamide together with a second antibiotic has been recommended, especially for advanced cases, and ampicillin, erythromycin, and *streptomycin* have been suggested for this purpose. The clinical response and the results of sensitivity testing may be helpful in choosing a companion drug. Notably, there are no clinical data to show that combination therapy is better than therapy with a sulfonamide alone. Trimethoprim–sulfamethoxazole also has been effective, and some authorities consider it to be the drug of choice.

Toxoplasmosis. The combination of *pyrimethamine* and sulfadiazine is the treatment of choice for toxoplasmosis (Montoya and Remington, 2000) (see Chapter 40). Pyrimethamine is given as a loading dose of 75 mg followed by 25 mg orally per day, with sulfadiazine 1 g orally every 6 hours, plus folic acid 10 mg orally each day for at least 3 to 6 weeks. Patients should receive at least 2 L of fluid intake daily to prevent crystalluria during therapy.

Use of Sulfonamides for Prophylaxis. The sulfonamides are as efficacious as oral penicillin in preventing streptococcal infections and recurrences of rheumatic fever among susceptible subjects. Despite the efficacy of sulfonamides for long-term prophylaxis of rheumatic fever, their toxicity and the possibility of infection by drug-resistant streptococci make sulfonamides less desirable than penicillin for this purpose. They should be used, however, without hesitation in patients who are hypersensitive to penicillin. If untoward responses occur, they usually do so during the first 8 weeks of therapy; serious reactions after this time are rare. White blood cell counts should be carried out once weekly during the first 8 weeks.

Untoward Reactions to Sulfonamides

The untoward effects that follow the administration of sulfonamides are numerous and varied; the overall incidence of reactions is about 5%. Certain forms of toxicity may be related to individual differences in sulfonamide metabolism (Shear *et al.*, 1986).

Disturbances of the Urinary Tract. Although the risk of crystalluria was relatively high with the older, less soluble sulfonamides, the incidence of this problem is very low with more soluble agents such as sulfisoxazole. Crystalluria has occurred in dehydrated patients with the acquired immune deficiency syndrome (AIDS) who were receiving sulfadiazine for *Toxoplasma* encephalitis. Fluid intake should be sufficient to ensure a daily urine volume of at least 1200 ml (in adults). Alkalinization of the urine may be desirable if urine volume or pH is unusually low because the solubility of sulfisoxazole increases greatly with slight elevations of pH.

Disorders of the Hematopoietic System. Acute Hemolytic Anemia.

The mechanism of the acute hemolytic anemia produced by sulfonamides is not always readily apparent. In some cases it has been thought to be a sensitization phenomenon. In other instances the hemolysis is related to an erythrocytic deficiency of glucose-6-phosphate dehydrogenase activity. Hemolytic anemia is rare after treatment with sulfadiazine (0.05%); its exact incidence following therapy with sulfisoxazole is unknown.

Agranulocytosis. Agranulocytosis occurs in about 0.1% of patients who receive sulfadiazine; it also can follow the use of other sulfonamides. Although return of granulocytes to normal levels may be delayed for weeks or months after sulfonamide is withdrawn, most patients recover spontaneously with supportive care.

Aplastic Anemia. Complete suppression of bone-marrow activity with profound anemia, granulocytopenia, and thrombocytopenia is an extremely rare occurrence with sulfonamide therapy. It probably results from a direct myelotoxic effect and may be fatal. However, reversible suppression of the bone marrow is quite common in patients with limited bone marrow reserve (*e.g.*, patients with AIDS or those receiving myelosuppressive chemotherapy).

Hypersensitivity Reactions. The incidence of other hypersensitivity reactions to sulfonamides is quite variable. Among the skin and mucous membrane manifestations attributed to sensitization to sulfonamide are morbilliform, scarlatiniform, urticarial, erysipeloid, pemphigoid, purpuric, and petechial rashes, as well as erythema nodosum, erythema multiforme of the Stevens-Johnson type, Behçet's syndrome, exfoliative dermatitis, and photosensitivity. These hypersensitivity reactions occur most often after the first week of therapy but may appear earlier in previously sensitized individuals. Fever, malaise, and pruritus frequently are present simultaneously. The incidence of untoward dermal effects is about 2% with sulfisoxazole, although patients with AIDS manifest a higher frequency of rashes with sulfonamide treatment than do other individuals. A syndrome similar to serum sickness may appear after several days of sulfonamide therapy. Drug fever is a common untoward manifestation of sulfonamide treatment; the incidence approximates 3% with sulfisoxazole.

Focal or diffuse necrosis of the liver owing to direct drug toxicity or sensitization occurs in fewer than 0.1% of patients. Headache, nausea, vomiting, fever, hepatomegaly, jaundice, and laboratory evidence of hepatocellular dysfunction usually appear 3 to 5 days after sulfonamide administration is started, and the syndrome may progress to acute yellow atrophy and death.

Miscellaneous Reactions. Anorexia, nausea, and vomiting occur in 1% to 2% of persons receiving sulfonamides, and these manifestations probably are central in origin. The administration of sulfonamides to newborn infants, especially if premature, may lead to the displacement of bilirubin from plasma albumin. In newborn infants, free bilirubin can become deposited in the basal ganglia and subthalamic nuclei of the brain, causing an encephalopathy called *kernicterus*. Sulfonamides should not be given to pregnant women near term because these drugs pass through the placenta and are secreted in milk.

Drug Interactions. The most important interactions of the sulfonamides involve those with the oral anticoagulants, the sulfonylurea hypoglycemic agents, and the hydantoin anticonvulsants. In each case, sulfonamides can potentiate the effects of the other drug by mechanisms that appear to involve primarily inhibition of metabo-

lism and, possibly, displacement from albumin. Dosage adjustment may be necessary when a sulfonamide is given concurrently.

TRIMETHOPRIM-SULFAMETHOXAZOLE

The introduction of trimethoprim in combination with sulfamethoxazole constitutes an important advance in the development of clinically effective antimicrobial agents and represents the practical application of a theoretical consideration; *i.e.*, if two drugs act on sequential steps in the pathway of an obligate enzymatic reaction in bacteria (Figure 43-2), the result of their combination will be synergistic (*see* Hitchings, 1961). In much of the world the combination is known as *cotrimoxazole*. In addition to its combination with sulfamethoxazole (BACTRIM, SEPTRA, others), trimethoprim also is available as a single-entity preparation (PROLOPRIM, others).

Chemistry. Sulfamethoxazole was discussed earlier in this chapter, and its structural formula is shown in Figure 43-1. The history of trimethoprim, a diaminopyrimidine, is discussed in Chapter 39. Its structural formula is:

TRIMETHOPRIM

Antibacterial Spectrum. The antibacterial spectrum of trimethoprim is similar to that of sulfamethoxazole, although the former drug usually is 20 to 100 times more potent than the latter. Most gram-negative and gram-positive microorganisms are sensitive to trimethoprim, but resistance can develop when the drug is used alone. *Pseudomonas aeruginosa*, *Bacteroides fragilis*, and enterococci usually are resistant. There is significant variation in the susceptibility of Enterobacteriaceae to trimethoprim in different geographical locations because of the spread of resistance mediated by plasmids and transposons.

Efficacy of Trimethoprim-Sulfamethoxazole in Combination. *Chlamydia diphtheriae* and *N. meningitidis* are susceptible to trimethoprim-sulfamethoxazole. Although most *S. pneumoniae* are susceptible, there has been a disturbing increase in resistance (*see* below). From 50% to 95% of strains of *Staphylococcus aureus*, *Staphylococcus epidermidis*, *S. pyogenes*, the *viridans* group of streptococci, *E. coli*, *Proteus mirabilis*, *Proteus morganii*, *Proteus rettgeri*, *Enterobacter* spp., *Salmonella*, *Shigella*, *Pseudomonas pseudomallei*, *Serratia*, and *Alcaligenes* spp. are inhibited. Also sensitive are *Klebsiella* spp., *Brucella abortus*, *Pasteurella*

haemolytica, *Yersinia pseudotuberculosis*, *Yersinia enterocolitica*, and *Nocardia asteroides*. Methicillin-resistant strains of *S. aureus*, although also resistant to trimethoprim or sulfamethoxazole alone, may be susceptible to the combination. A synergistic interaction between the components of the preparation is apparent even when microorganisms are resistant to sulfonamide with or without moderate resistance to trimethoprim. However, a maximal degree of synergism occurs when microorganisms are sensitive to both components. The activity of trimethoprim–sulfamethoxazole *in vitro* depends on the medium in which it is determined; *e.g.*, low concentrations of thymidine almost completely abolish the antibacterial activity.

Mechanism of Action. The antimicrobial activity of the combination of trimethoprim and sulfamethoxazole results from its actions on two steps of the enzymatic pathway for the synthesis of tetrahydrofolic acid. Sulfonamide inhibits the incorporation of *para*-aminobenzoic acid (PABA) into folic acid, and trimethoprim prevents the reduction of dihydrofolate to tetrahydrofolate (Figure 43–2). Tetrahydrofolate is essential for one-carbon transfer reactions, *e.g.*, the synthesis of thymidylate from deoxyuridylate. Selective toxicity for microorganisms is achieved in two ways. Mammalian cells use preformed folates from the diet and do not synthesize the compound. Furthermore, trimethoprim is a highly selective inhibitor of dihydrofolate reductase of lower organisms: About 100,000 times more drug is required to inhibit human reductase than the bacterial enzyme. This relative selectivity is vital because this enzymatic function is essential to all species.

The synergistic interaction between sulfonamide and trimethoprim is predictable from their respective mechanisms. There is an optimal ratio of the concentrations of the two agents for synergism that equals the ratio of the minimal inhibitory concentrations of the drugs acting independently. While this ratio varies for different bacteria, the most effective ratio for the greatest number of microorganisms is 20 parts sulfamethoxazole to 1 part trimethoprim. The combination thus is formulated to achieve a sulfamethoxazole concentration *in vivo* that is 20 times greater than that of trimethoprim. The pharmacokinetic properties of the sulfonamide chosen to be in combination with trimethoprim are critical because relative constancy of the concentrations of the two compounds in the body is desired.

Bacterial Resistance. Bacterial resistance to trimethoprim–sulfamethoxazole is a rapidly increasing problem, although resistance is lower than it is to either of the agents alone. Resistance often is due to the acquisition of a plasmid that codes for an altered dihydrofolate reductase. The development of resistance is a problem for the treatment of many different bacterial infections. In a survey of children with otitis media in Memphis, Tennessee, 29% of isolates were penicillin-resistant, and 25% of these also were resistant to trimethoprim–sulfamethoxazole (Centers for Disease Control and Prevention, 1994a). In another survey, approximately 50% of *Shigella sonnei* isolates from The Netherlands were resistant (Voogd *et al.*, 1992). Emergence of trimethoprim–sulfamethoxazole-resistant *S. aureus* and Enterobacteriaceae is a special problem in AIDS patients receiving the drug for prophylaxis of *Pneumocystis jiroveci* (formerly called *Pneumocystis carinii*) pneumonia (Martin *et al.*, 1999).

Absorption, Distribution, and Excretion. The pharmacokinetic profiles of sulfamethoxazole and trimethoprim

are closely but not perfectly matched to achieve a constant ratio of 20:1 in their concentrations in blood and tissues. The ratio in blood is often greater than 20:1, and that in tissues is frequently less. After a single oral dose of the combined preparation, trimethoprim is absorbed more rapidly than sulfamethoxazole. The concurrent administration of the drugs appears to slow the absorption of sulfamethoxazole. Peak blood concentrations of trimethoprim usually occur by 2 hours in most patients, whereas peak concentrations of sulfamethoxazole occur by 4 hours after a single oral dose. The half-lives of trimethoprim and sulfamethoxazole are approximately 11 and 10 hours, respectively.

When 800 mg sulfamethoxazole is given with 160 mg trimethoprim (the conventional 5:1 ratio) twice daily, the peak concentrations of the drugs in plasma are approximately 40 and 2 $\mu\text{g/ml}$, the optimal ratio. Peak concentrations are similar (46 and 3.4 $\mu\text{g/ml}$) after intravenous infusion of 800 mg sulfamethoxazole and 160 mg trimethoprim over a period of 1 hour.

Trimethoprim is distributed and concentrated rapidly in tissues, and about 40% is bound to plasma protein in the presence of sulfamethoxazole. The volume of distribution of trimethoprim is almost nine times that of sulfamethoxazole. The drug readily enters cerebrospinal fluid and sputum. High concentrations of each component of the mixture also are found in bile. About 65% of sulfamethoxazole is bound to plasma protein.

About 60% of administered trimethoprim and from 25% to 50% of administered sulfamethoxazole are excreted in the urine in 24 hours. Two-thirds of the sulfonamide is unconjugated. Metabolites of trimethoprim also are excreted. The rates of excretion and the concentrations of both compounds in the urine are reduced significantly in patients with uremia.

Therapeutic Uses. Urinary Tract Infections. Treatment of uncomplicated lower urinary tract infections with trimethoprim–sulfamethoxazole often is highly effective for sensitive bacteria. The preparation has been shown to produce a better therapeutic effect than does either of its components given separately when the infecting microorganisms are of the family Enterobacteriaceae. Single-dose therapy (320 mg trimethoprim plus 1600 mg sulfamethoxazole in adults) has been effective in some cases for the treatment of acute uncomplicated urinary tract infections, but a minimum of 3 days of therapy is more likely to be effective (Zinner and Mayer, 2000; Stamm and Hooton, 1993).

The combination appears to have special efficacy in chronic and recurrent infections of the urinary tract. Small doses (200 mg sulfamethoxazole plus 40 mg trimethoprim per day or two to four times these amounts once or twice per week) appear to be effective in reducing the number of recurrent urinary tract infec-

tions in adult females. This effect may be related to the presence of therapeutic concentrations of trimethoprim in vaginal secretions. Enterobacteriaceae surrounding the urethral orifice may be eliminated or markedly reduced in number, thus diminishing the chance of an ascending reinfection. Trimethoprim also is found in therapeutic concentrations in prostatic secretions, and trimethoprim-sulfamethoxazole is often effective for the treatment of bacterial prostatitis.

Bacterial Respiratory Tract Infections. Trimethoprim-sulfamethoxazole is effective for acute exacerbations of chronic bronchitis. Administration of 800 to 1200 mg sulfamethoxazole plus 160 to 240 mg trimethoprim twice a day appears to be effective in decreasing fever, purulence and volume of sputum, and sputum bacterial count. Trimethoprim-sulfamethoxazole should *not* be used to treat streptococcal pharyngitis because it does not eradicate the microorganism. It is effective for acute otitis media in children and acute maxillary sinusitis in adults caused by susceptible strains of *H. influenzae* and *S. pneumoniae*.

Gastrointestinal Infections. The combination is an alternative to fluoroquinolone for treatment of shigellosis because many strains of the causative agent now are resistant to ampicillin; however, resistance to trimethoprim-sulfamethoxazole is increasingly common. It also is a second-line drug (ceftriaxone or a fluoroquinolone is the preferred treatment) for typhoid fever, but resistance is an increasing problem. In adults, trimethoprim-sulfamethoxazole appears to be effective when the dose is 800 mg sulfamethoxazole plus 160 mg trimethoprim every 12 hours for 15 days.

Trimethoprim-sulfamethoxazole appears to be effective in the management of carriers of sensitive strains of *Salmonella typhi* and other *Salmonella* spp. One proposed schedule is the administration of 800 mg sulfamethoxazole plus 160 mg trimethoprim twice a day for 3 months; however, failures have occurred. The presence of chronic disease of the gallbladder may be associated with a high incidence of failure to clear the carrier state. Acute diarrhea owing to sensitive strains of enteropathogenic *E. coli* can be treated or prevented with either trimethoprim or trimethoprim plus sulfamethoxazole (Hill and Pearson, 1988). However, antibiotic treatment (either trimethoprim-sulfamethoxazole or cephalosporin) of diarrheal illness owing to enterohemorrhagic *E. coli* O157:H7 may increase the risk of hemolytic-uremic syndrome, perhaps by increasing the release of Shiga toxin by the bacteria (Wong *et al.*, 2000).

Infection by *Pneumocystis jiroveci*. High-dose therapy (trimethoprim 15 mg/kg per day plus sulfamethoxazole 100 mg/kg per day in three or four divided doses) is effective for this severe infection in patients with AIDS (Thomas and Limper, 2004). This combination compares favorably with pentamidine for treatment of this disease. Adjunctive corticosteroids should be given at the onset of anti-*Pneumocystis* therapy in patients with a P_{O_2} of less than 70 mm Hg or an alveolar-arterial gradient of greater than 35 mm Hg (Lane *et al.*, 1994). However, the incidence of side effects is high for both regimens (Sattler and Remington, 1981; Lane *et al.*, 1994). Lower-dose oral therapy with 800 mg sulfamethoxazole plus 160 mg trimethoprim (given twice daily) has been used successfully in AIDS patients with less severe pneumonia ($P_{O_2} > 60$ mm Hg) (Medina *et al.*, 1990). Prophylaxis with 800 mg sulfamethoxazole and 160 mg trimethoprim once daily or three times a week is effective in preventing pneumonia caused by this organism in patients with AIDS (Schneider *et al.*, 1992; Gallant *et al.*, 1994). Adverse reactions are less frequent with the lower prophylactic doses of trimethoprim-sulfamethoxazole. The most common problems are rash, fever, leukopenia, and hepatitis.

Prophylaxis in Neutropenic Patients. Several studies have demonstrated the effectiveness of low-dose therapy (150 mg/m² of body surface area of trimethoprim and 750 mg/m² of body surface area of sulfamethoxazole) for the prophylaxis of infection by *P. carinii* (see Hughes *et al.*, 1977). In addition, significant protection against sepsis caused by gram-negative bacteria was noted when 800 mg sulfamethoxazole and 160 mg trimethoprim were given twice daily to severely neutropenic patients. The emergence of resistant bacteria may limit the usefulness of trimethoprim-sulfamethoxazole for prophylaxis (Gualtieri *et al.*, 1983).

Miscellaneous Infections. *Nocardia* infections have been treated successfully with the combination, but failures also have been reported. Although a combination of doxycycline and streptomycin or gentamicin now is considered to be the treatment of choice for brucellosis, trimethoprim-sulfamethoxazole may be an effective substitute for the doxycycline combination. Trimethoprim-sulfamethoxazole also has been used successfully in the treatment of Whipple's disease, infection by *Stenotrophomonas maltophilia*, and infection by the intestinal parasites *Cyclospora* and *Isospora*. Wegener's granulomatosis may respond, depending on the stage of the disease. Trimethoprim-sulfamethoxazole also has been used to treat methicillin-resistant strains of *S. aureus*.

Untoward Effects. There is no evidence that trimethoprim-sulfamethoxazole, when given in the recommended doses, induces folate deficiency in normal persons. However, the margin between toxicity for bacteria and that for human beings may be relatively narrow when the cells of the patient are deficient in folate. In such cases, trimethoprim-sulfamethoxazole may cause or precipitate megaloblastosis, leukopenia, or thrombocytopenia. In routine use, the combination appears to exert little toxicity. About 75% of the untoward effects involve the skin. However, trimethoprim-sulfamethoxazole has been reported to cause up to three times as many dermatological reactions as does sulfisoxazole when given alone (5.9% versus 1.7%) (Arndt and Jick, 1976). Exfoliative dermatitis, Stevens-Johnson syndrome, and toxic epidermal necrolysis (Lyell's syndrome) are rare, occurring primarily in older individuals. Nausea and vomiting constitute the bulk of GI reactions; diarrhea is rare. Glossitis and stomatitis are relatively common. Mild and transient jaundice has been noted and appears to have the histological features of allergic cholestatic hepatitis. CNS reactions consist of headache, depression, and hallucinations, manifestations known to be produced by sulfonamides. Hematological reactions, in addition to those just mentioned, are various anemias (including aplastic, hemolytic, and macrocytic), coagulation disorders, granulocytopenia, agranulocytosis, purpura, Henoch-Schönlein purpura, and sulfhemoglobinemia. Permanent impairment of renal function may follow the use of trimethoprim-sulfamethoxazole in patients with renal disease, and a reversible decrease in creatinine clearance has been noted in patients with normal renal function.

Patients with AIDS frequently have hypersensitivity reactions when trimethoprim–sulfamethoxazole is administered (Gordin *et al.*, 1984). These adverse reactions include rash, neutropenia, Stevens-Johnson syndrome, Sweet's syndrome, and pulmonary infiltrates. It may be possible to continue therapy in such patients following rapid oral desensitization (Gluckstein and Ruskin, 1995).

THE QUINOLONES

The first quinolone, *nalidixic acid*, was isolated as a by-product of the synthesis of *chloroquine*. It has been available for the treatment of urinary tract infections for many years. The introduction of fluorinated 4-quinolones, such as *ciprofloxacin* (CIPRO), *moxifloxacin* (AVELOX), and *gatifloxacin* (TEQUIN) represents a particularly important therapeutic advance because these agents have broad antimicrobial activity and are effective after oral administration for the treatment of a wide variety of infectious diseases (Table 43–2). Relatively few side effects appear to accompany the use of these fluoroquinolones, and microbial resistance to their action does not develop rapidly (*see* Andriole, 1993; Hooper, 2000a). Rare and potentially fatal side effects, however, have resulted in the withdrawal from the market of *temafloxacin* (immune hemolytic anemia), *trovafloxacin* (hepatotoxicity), *grepafloxacin* (cardiotoxicity), and *clinafloxacin* (phototoxicity). In all these cases, the side effects were so infrequent as to be missed by prerelease clinical trials and detected only by postmarketing surveillance (Sheehan and Chew, 2003).

Chemistry. The compounds that currently are available for clinical use in the United States are quinolones containing a carboxylic acid moiety at position 3 of the primary ring structure. Many of the newer fluoroquinolones also contain a fluorine substituent at position 6 and a piperazine moiety at position 7 (Table 43–2).

Mechanism of Action. The quinolone antibiotics target bacterial DNA gyrase and topoisomerase IV (Drlica and Zhao, 1997). For many gram-positive bacteria (such as *S. aureus*), topoisomerase IV is the primary activity inhibited by the quinolones. In contrast, for many gram-negative bacteria (such as *E. coli*), DNA gyrase is the primary quinolone target (Hooper, 2000a; Alovero *et al.*, 2000). The individual strands of double-helical DNA must be separated to permit DNA replication or transcription. However, anything that separates the strands results in “overwinding” or excessive positive supercoiling of the DNA in front of the point of separation. To combat this mechanical obstacle, the bacterial enzyme DNA gyrase is responsible for the continuous introduction of negative supercoils into DNA. This is an ATP-dependent reaction requiring that both strands of the DNA be cut to permit passage of a segment of DNA through the break; the break then is resealed.

The DNA gyrase of *E. coli* is composed of two 105,000-dalton A subunits and two 95,000-dalton B subunits encoded by the *gyrA* and *gyrB* genes, respectively. The A subunits, which carry out the strand-cutting function of the gyrase, are the site of action of the quinolones (Figure 43–3). The drugs inhibit gyrase-mediated DNA supercoiling at concentrations that correlate well with those required to inhibit bacterial growth (0.1 to 10 $\mu\text{g/ml}$). Mutations of the gene that encodes the A subunit polypeptide can confer resistance to these drugs (Hooper, 2000a).

Topoisomerase IV also is composed of four subunits encoded by the *parC* and *parE* genes in *E. coli* (Drlica and Zhao, 1997; Hooper, 2000a). Topoisomerase IV separates interlinked (catenated) daughter DNA molecules that are the product of DNA replication. Eukaryotic cells do not contain DNA gyrase. However, they do contain a conceptually and mechanistically similar type II DNA topoisomerase that removes positive supercoils from eukaryotic DNA to prevent its tangling during replication. This enzyme is the target for some antineoplastic agents (*see* Chapter 51). Quinolones inhibit eukaryotic type II topoisomerase only at much higher concentrations (100 to 1000 $\mu\text{g/ml}$) (Mitscher and Ma, 2003).

Antibacterial Spectrum. The fluoroquinolones are potent bactericidal agents against *E. coli* and various species of *Salmonella*, *Shigella*, *Enterobacter*, *Campylobacter*, and *Neisseria* (*see* Eliopoulos and Eliopoulos, 1993). Minimal inhibitory concentrations of the fluoroquinolones for 90% of these strains (MIC_{90}) usually are less than 0.2 $\mu\text{g/ml}$. Ciprofloxacin is more active than *norfloxacin* (NOROXIN) against *P. aeruginosa*; values of MIC_{90} range from 0.5 to 6 $\mu\text{g/ml}$. Fluoroquinolones also have good activity against staphylococci, but not against methicillin-resistant strains ($\text{MIC}_{90} = 0.1$ to 2 $\mu\text{g/ml}$).

Activity against streptococci is limited to a subset of the quinolones, including *levofloxacin* (LEVAQUIN), *gatifloxacin* (TEQUIN), and *moxifloxacin* (AVELOX) (Hooper, 2000a; Eliopoulos and Eliopoulos, 1993). Several intracellular bacteria are inhibited by fluoroquinolones at concentrations that can be achieved in plasma; these include species of *Chlamydia*, *Mycoplasma*, *Legionella*, *Brucella*, and *Mycobacterium* (including *Mycobacterium tuberculosis*) (Leysen *et al.*, 1989; Alangaden and Lerner, 1997). Ciprofloxacin, *ofloxacin* (FLOXIN), and *pefloxacin* have MIC_{90} values from 0.5 to 3 $\mu\text{g/ml}$ for *M. fortuitum*, *M. kansasii*, and *M. tuberculosis*; ofloxacin and pefloxacin are active in animal models of leprosy (Hooper, 2000a). However, clinical experience with these pathogens remains limited.

Several of the new fluoroquinolones have activity against anaerobic bacteria, including *garenoxacin* and *gemifloxacin* (Medical Letter, 2000).

Resistance to quinolones may develop during therapy *via* mutations in the bacterial chromosomal genes encoding DNA gyrase or topoisomerase IV or by active transport of the drug out of the bacteria (Oethinger *et al.*, 2000). No quinolone-modifying or -inactivating activities have been identified in bacteria (Gold and Moellering, 1996). Resistance has increased after the introduction of fluoroquinolones, especially in *Pseudomonas* and staphylococci (Pegues *et al.*, 1998; Peterson *et al.*, 1998). Increasing fluoroquinolone resistance also is being observed in *C. jejuni*, *Salmonella*, *N. gonorrhoeae*, and *S. pneumoniae* (Smith *et al.*, 1999; Centers for Disease Control and Prevention, 1994b; Thornsberry *et al.*, 1997; Mølbak *et al.*, 1999).

As mentioned in Chapter 42, the pharmacokinetic and pharmacodynamic parameters of antimicrobial agents are important in preventing the selection and spread of resistant strains and have led to description of the mutation-prevention concentration, which is the lowest concentration of antimicrobial that prevents selection of resistant bac-

Figure 43–3. Model of the formation of negative DNA supercoils by DNA gyrase. The enzyme binds to two segments of DNA (1), creating a node of positive (+) superhelix. The enzyme then introduces a double-strand break in the DNA and passes the front segment through the break (2). The break is then resealed (3), creating a negative (–) supercoil. Quinolones inhibit the nicking and closing activity of the gyrase and also block the decatenating activity of topoisomerase IV. (Reprinted from Cozzarelli, 1980, with permission.)

teria from high bacterial inocula. β -Lactams are time-dependent agents without significant postantibiotic effects, resulting in bacterial eradication when unbound serum concentrations exceed MICs of these agents against infecting pathogens for more than 40% to 50% of the dosing interval. By contrast, fluoroquinolones are concentration-dependent agents, resulting in bacterial eradication when unbound serum area-under-the-curve-to-MIC ratios exceed 25 to 30. These observations are now being used to assess the roles of current agents, develop new formulations, and assess potency of new antimicrobials.

Absorption, Fate, and Excretion. The quinolones are well absorbed after oral administration and are distributed widely in body tissues. Peak serum levels of the fluoroquinolones are obtained within 1 to 3 hours of an oral dose of 400 mg, with peak levels ranging from 1.1 $\mu\text{g/ml}$ for *sparfloxacin* to 6.4 $\mu\text{g/ml}$ for *levofloxacin*. Relatively low serum levels are reached with norfloxacin and limit its usefulness to the treatment of urinary tract infections. Food does not impair oral absorption but may delay the time to peak serum concentrations. Oral doses in adults are 200 to 400 mg every 12 hours for ofloxacin, 400 mg every 12 hours for norfloxacin and pefloxacin, and 250 to 750 mg every 12 hours for ciprofloxacin. Bioavailability of the fluoroquinolones is greater than 50% for all agents and greater than 95% for several. The serum half-life ranges from 3 to 5 hours for norfloxacin and ciprofloxacin to 20 hours for sparfloxacin. The volume of distribution of quinolones is high, with concentrations of quinolones in urine, kidney, lung and prostate tissue, stool, bile, and macrophages and neutrophils higher than serum levels. Quinolone concentrations in cerebrospinal fluid, bone, and prostatic fluid are lower than in serum. Pefloxacin and ofloxacin levels in ascites fluid are close to serum levels, and ciprofloxacin, ofloxacin, and pefloxacin have been detected in human breast milk.

Most quinolones are cleared predominantly by the kidney, and dosages must be adjusted for renal failure. Exceptions are pefloxacin and moxifloxacin, which are metabolized predominantly by the liver and should not be used in patients with hepatic failure. None of the agents is removed efficiently by peritoneal dialysis or hemodialysis.

Therapeutic Uses. Urinary Tract Infections. Nalidixic acid is useful only for urinary tract infections caused by susceptible microorganisms. The fluoroquinolones are significantly more potent and have a much broader spectrum of antimicrobial activity. Norfloxacin is approved for use in the United States only for urinary tract infections. Comparative clinical trials indicate that the fluoroquinolones are more efficacious than trimethoprim–sulfamethoxazole for the treatment of urinary tract infections (Hooper and Wolfson, 1991; Warren *et al.*, 1999).

Prostatitis. Norfloxacin, ciprofloxacin, and ofloxacin all have been effective in uncontrolled trials for the treatment of prostatitis caused by sensitive bacteria. Fluoroquinolones administered for 4 to 6 weeks appear to be effective in patients not responding to trimethoprim–sulfamethoxazole (Hooper and Wolfson, 1991).

Sexually Transmitted Diseases. The quinolones are contraindicated in pregnancy. Fluoroquinolones lack activity for *Treponema pallidum* but have activity *in vitro* against *N. gonorrhoeae*, *C. trachomatis*, and *H. ducreyi*. For chlamydial urethritis/cervicitis, a 7-day course of ofloxacin or sparfloxacin is an alternative to a 7-day treatment with doxycycline or a single dose of azithromycin; other available quinolones have not been reliably effective. A single oral dose of a fluoroquinolone such as ofloxacin or ciprofloxacin is effective treatment for sensitive strains of *N. gonorrhoeae*, but increasing resistance to fluoroquinolones has led to ceftriaxone being the first-line agent for this infection (Newman *et al.*, 2004). Pelvic inflammatory disease has been treated effectively with a 14-day course of ofloxacin combined with an antibiotic with activity against anaerobes (clindamycin or metronidazole) (Centers for Disease Control and Prevention, 1998). Chancroid (infection by *H. ducreyi*) can be treated with 3 days of ciprofloxacin.

Gastrointestinal and Abdominal Infections. For traveler's diarrhea (frequently caused by enterotoxigenic *E. coli*), the quinolones are equal to trimethoprim–sulfamethoxazole in effectiveness, reducing the duration of loose stools by 1 to 3 days (DuPont and Ericsson, 1993). Norfloxacin, ciprofloxacin, and ofloxacin given for 5 days all have been effective in the treatment of patients with shigellosis, with even shorter courses effective in many cases (Bennish *et al.*, 1992). Norfloxacin is superior to tetracyclines in decreasing the duration of diarrhea in cholera (Bhattacharya *et al.*, 1990). Ciprofloxacin and ofloxacin treatment cures most patients with enteric fever caused by *S. typhi*, as well as bacteremic nontyphoidal infections in AIDS patients, and it clears chronic fecal carriage. Shigellosis is treated effectively with either ciprofloxacin or *azithromycin* (Khan *et al.*, 1997). The *in vitro* ability of the quinolones to induce the Shiga toxin *stx2* gene (the cause of the hemolytic-uremic syndrome) in *E. coli* suggests that the quinolones should not be used for Shiga toxin-producing *E. coli* (Miedouge *et al.*, 2000). Ciprofloxacin and ofloxacin have been less effective in treating episodes of peritonitis occurring in

patients on chronic ambulatory peritoneal dialysis likely owing to the higher MICs for these drugs for the coagulase-negative staphylococci that are a common cause of peritonitis in this setting.

Respiratory Tract Infections. The major limitation to the use of quinolones for the treatment of community-acquired pneumonia and bronchitis had been the poor *in vitro* activity of ciprofloxacin, ofloxacin, and norfloxacin against *S. pneumoniae* and anaerobic bacteria. However, many of the newer fluoroquinolones, including gatifloxacin and moxifloxacin, have excellent activity against *S. pneumoniae*. Initial clinical experience with some of these newer quinolones shows comparable efficacy to β -lactam antibiotics (Aubier *et al.*, 1998; File *et al.*, 1997). The fluoroquinolones have *in vitro* activity against the rest of the commonly recognized respiratory pathogens, including *H. influenzae*, *Moraxella catarrhalis*, *S. aureus*, *M. pneumoniae*, *Chlamydia pneumoniae*, and *Legionella pneumophila*. Either a fluoroquinolone (ciprofloxacin or levofloxacin) or azithromycin is the antibiotic of choice for *L. pneumophila* (Yu, 2000). Fluoroquinolones have been very effective at eradicating both *H. influenzae* and *M. catarrhalis* from sputum. Mild to moderate respiratory exacerbations owing to *P. aeruginosa* in patients with cystic fibrosis have responded to oral fluoroquinolone therapy. Emerging clinical data are demonstrating a clear role for the newer fluoroquinolones as single agents for treatment of community-acquired pneumonia (Hooper, 2000a). However, on the horizon is a decreasing susceptibility of *S. pneumoniae* to fluoroquinolones (Chen *et al.*, 1999; Wortmann and Bennett, 1999).

Bone, Joint, and Soft Tissue Infections. The treatment of chronic osteomyelitis requires prolonged (weeks to months) antimicrobial therapy with agents active against *S. aureus* and gram-negative rods. The fluoroquinolones, by virtue of their oral administration and appropriate antibacterial spectrum for these infections, may be used appropriately in some cases (Gentry and Rodriguez-Gomez, 1991); recommended doses are 500 mg every 12 hours or, if severe, 750 mg twice daily. Bone and joint infections may require treatment for 4 to 6 weeks or more. Dosage should be reduced for patients with severely impaired renal function. Ciprofloxacin should not be given to children or pregnant women. Clinical cures have been as high as 75% in chronic osteomyelitis in which gram-negative rods predominated (Hooper, 2000a). Failures have been associated with the development of resistance in *S. aureus*, *P. aeruginosa*, and *Serratia marcescens*. In diabetic foot infections, which are commonly caused by a mixture of bacteria including gram-negative rods, anaerobes, streptococci, and staphylococci, the fluoroquinolones in combination with an agent with antianaerobic activity are a reasonable choice. Ciprofloxacin as sole therapy is effective in 50% of diabetic foot infections (Peterson *et al.*, 1989).

Other Infections. Ciprofloxacin received wide usage for the prophylaxis of anthrax and has been shown to be effective for the treatment of tularemia (Chocarro *et al.*, 2000; Swartz, 2001). The quinolones may be used as part of multiple-drug regimens for the treatment of multidrug-resistant tuberculosis and for the treatment of atypical mycobacterial infections as well as *M. avium* complex infections in AIDS (*see* Chapter 47). In neutropenic cancer patients with fever, the combination of a quinolone with an *aminoglycoside* is comparable to β -lactam-aminoglycoside combinations; quinolones are less effective when used alone (Meunier *et al.*, 1991). Quinolones, when used as prophylaxis in neutropenic patients, have decreased the incidence of gram-negative rod bacteremias (GIMEMA Infection Program, 1991). Ciprofloxacin plus *amoxicillin-clavulanate* has been shown recently to be effective as an oral empirical therapy for fever in low-risk patients with granulocytopenia secondary to cancer chemotherapy (Kern *et al.*, 1999; Freifeld *et al.*, 1999).

Adverse Effects. Quinolones and fluoroquinolones generally are well tolerated (Mandell, 2003). The most common adverse reactions involve the GI tract, with 3% to 17% of patients reporting mostly mild nausea, vomiting, and/or abdominal discomfort. Diarrhea and antibiotic-associated colitis have been unusual. CNS side effects, predominantly mild headache and dizziness, have been seen in 0.9% to 11% of patients. Rarely, hallucinations, delirium, and seizures have occurred, predominantly in patients who also were receiving *theophylline* or a nonsteroidal antiinflammatory drug. Ciprofloxacin and pefloxacin inhibit the metabolism of theophylline, and toxicity from elevated concentrations of the methylxanthine may occur (Schwartz *et al.*, 1988). Nonsteroidal antiinflammatory drugs may augment displacement of γ -aminobutyric acid (GABA) from its receptors by the quinolones (Halliwell *et al.*, 1993). Rashes, including photosensitivity reactions, also can occur. Achilles tendon rupture or tendinitis has occurred rarely. Renal disease, hemodialysis, and steroid use may be predisposing factors (Mandell, 2003). All these agents can produce arthropathy in several species of immature animals. Traditionally, the use of quinolones in children has been contraindicated for this reason. However, children with cystic fibrosis given ciprofloxacin, norfloxacin, and nalidixic acid have had few, and reversible, joint symptoms (Burkhardt *et al.*, 1997). Therefore, in some cases the benefits may outweigh the risks of quinolone therapy in children.

Leukopenia, eosinophilia, and mild elevations in serum transaminases occur rarely. QT_c interval (QT interval corrected for heart rate) prolongation has been observed with sparfloxacin and to a lesser extent with gatifloxacin and moxifloxacin. Quinolones probably should be used only with caution in patients on class III (*amiodarone*) and class IA (*quinidine, procainamide*) antiarrhythmics (*see* Chapter 34).

ANTISEPTIC AND ANALGESIC AGENTS FOR URINARY TRACT INFECTIONS

The urinary tract antiseptics inhibit the growth of many species of bacteria. They cannot be used to treat systemic infections because effective concentrations are not achieved in plasma with safe doses. However, because they are concentrated in the renal tubules, they can be administered orally to treat infections of the urinary tract. Furthermore, effective antibacterial concentrations reach the renal pelvis and the bladder. Treatment with such drugs can be thought of as local therapy: Only in the kidney and bladder, with the rare exceptions mentioned below, are adequate therapeutic levels achieved (*see* Hooper, 2000b).

Methenamine. *Methenamine* is a urinary tract antiseptic and pro-drug that owes its activity to its capacity to generate formaldehyde.

Chemistry. Methenamine is hexamethylenetetramine (hexamethylenamine). It has the following structure:

METHENAMINE

The compound decomposes in water to generate formaldehyde, according to the following reaction:

At pH 7.4, almost no decomposition occurs; however, the yield of formaldehyde is 6% of the theoretical amount at pH 6 and 20% at pH 5. Thus, acidification of the urine promotes the formaldehyde-dependent antibacterial action. The reaction is fairly slow, and 3 hours are required to reach 90% completion (Strom and Jun, 1993).

Antimicrobial Activity. Nearly all bacteria are sensitive to free formaldehyde at concentrations of about 20 $\mu\text{g}/\text{ml}$. Urea-splitting microorganisms (e.g., *Proteus* spp.) tend to raise the pH of the urine and thus inhibit the release of formaldehyde. Microorganisms do not develop resistance to formaldehyde.

Pharmacology and Toxicology. Methenamine is absorbed orally, but 10% to 30% decomposes in the gastric juice unless the drug is protected by an enteric coating. Because of the ammonia produced, methenamine is contraindicated in hepatic insufficiency. Excretion in the urine is nearly quantitative. When the urine pH is 6 and the daily urine volume is 1000 to 1500 ml, a daily dose of 2 g will yield a concentration of 18 to 60 $\mu\text{g}/\text{ml}$ of formaldehyde; this is more than the MIC for most urinary tract pathogens. Various poorly metabolized acids can be used to acidify the urine. Low pH alone is bacteriostatic, so acidification serves a double function. The acids commonly used are *mandelic acid* and *hippuric acid* (UREX, HIPREX).

Gastrointestinal distress frequently is caused by doses greater than 500 mg four times a day, even with enteric-coated tablets. Painful and frequent micturition, albuminuria, hematuria, and rashes may result from doses of 4 to 8 g/day given for longer than 3 to 4 weeks. Once the urine is sterile, a high dose should be reduced. Because systemic methenamine has low toxicity at the typically used doses, renal insufficiency does not constitute a contraindication to the use of methenamine alone, but the acids given concurrently may be detrimental. Methenamine mandelate is contraindicated in renal insufficiency. Crystalluria from the mandelate moiety can occur. Methenamine combines with sulfamethizole and perhaps other sulfonamides in the urine, which results in mutual antagonism.

Therapeutic Uses and Status. Methenamine is not a primary drug for the treatment of acute urinary tract infections, but it is of value for chronic suppressive treatment (Stamm and Hooton, 1993). The agent is most useful when the causative organism is *E. coli*, but it usually can suppress the common gram-negative offenders and often *S. aureus* and *S. epidermidis* as well. *Enterobacter aerogenes* and *Proteus vulgaris* are usually resistant. Urea-splitting bacteria (mostly *Proteus*) make it difficult to control the urine pH. The physician should strive to keep the pH below 5.5.

Nitrofurantoin. Nitrofurantoin (FURADANTIN, MACROBID, others) is a synthetic nitrofuran that is used for the prevention and treatment of infections of the urinary tract. Its structural formula is:

Antimicrobial Activity. Enzymes capable of reducing nitrofurantoin appear to be crucial for its activation. Highly reactive interme-

diates are formed, and these seem to be responsible for the observed capacity of the drug to damage DNA. Bacteria reduce nitrofurantoin more rapidly than do mammalian cells, and this is thought to account for the selective antimicrobial activity of the compound. Bacteria that are susceptible to the drug rarely become resistant during therapy. Nitrofurantoin is active against many strains of *E. coli* and enterococci. However, most species of *Proteus* and *Pseudomonas* and many species of *Enterobacter* and *Klebsiella* are resistant. Nitrofurantoin is bacteriostatic for most susceptible microorganisms at concentrations of 32 $\mu\text{g}/\text{ml}$ or less and is bactericidal at concentrations of 100 $\mu\text{g}/\text{ml}$ and more. The antibacterial activity is higher in an acidic urine.

Pharmacology and Toxicity. Nitrofurantoin is absorbed rapidly and completely from the GI tract. The macrocrystalline form of the drug is absorbed and excreted more slowly. Antibacterial concentrations are not achieved in plasma following ingestion of recommended doses because the drug is eliminated rapidly. The plasma half-life is 0.3 to 1 hour; about 40% is excreted unchanged into the urine. The average dose of nitrofurantoin yields a concentration in urine of approximately 200 $\mu\text{g}/\text{ml}$. This concentration is soluble at pH >5, but the urine should not be alkalinized because this reduces antimicrobial activity. The rate of excretion is linearly related to the creatinine clearance, so in patients with impaired glomerular function, the efficacy of the drug may be decreased and the systemic toxicity increased. Nitrofurantoin colors the urine brown.

The most common untoward effects are nausea, vomiting, and diarrhea; the macrocrystalline preparation is better tolerated. Various hypersensitivity reactions occur occasionally. These include chills, fever, leukopenia, granulocytopenia, hemolytic anemia [associated with glucose-6-phosphate dehydrogenase deficiency (Gait, 1990)], cholestatic jaundice, and hepatocellular damage. Chronic active hepatitis is an uncommon but serious side effect (Black *et al.*, 1980; Tolman, 1980). Acute pneumonitis with fever, chills, cough, dyspnea, chest pain, pulmonary infiltration, and eosinophilia may occur within hours to days of the initiation of therapy; these symptoms usually resolve quickly after discontinuation of the drug. More insidious subacute reactions also may be noted, and interstitial pulmonary fibrosis can occur in patients taking the drug chronically. This appears to be due to generation of oxygen radicals as a result of redox cycling of the drug in the lung. Elderly patients are especially susceptible to the pulmonary toxicity of nitrofurantoin (see Holmberg *et al.*, 1980). Megaloblastic anemia is rare. Various neurological disorders are observed occasionally. Headache, vertigo, drowsiness, muscular aches, and nystagmus are readily reversible, but severe polyneuropathies with demyelination and degeneration of both sensory and motor nerves have been reported; signs of denervation and muscle atrophy result. Neuropathies are most likely to occur in patients with impaired renal function and in persons on long-continued treatment. Toxic reactive metabolites may contribute to some adverse reactions (Spielberg and Gordon, 1981).

The oral dosage of nitrofurantoin for adults is 50 to 100 mg four times a day with meals and at bedtime. Alternatively, the daily dosage is better expressed as 5 to 7 mg/kg in four divided doses (not to exceed 400 mg). A single 50- to 100-mg dose at bedtime may be sufficient to prevent recurrences. The daily dose for children is 5 to 7 mg/kg but may be as low as 1 mg/kg for long-term therapy (Lohr *et al.*, 1977). A course of therapy should not exceed 14 days, and repeated courses should be separated by rest periods. Pregnant women, individuals with impaired renal function (creatinine clearance < 40 ml/min), and children younger than 1 month of age should not receive nitrofurantoin.

Nitrofurantoin is approved only for the treatment of urinary tract infections caused by microorganisms known to be susceptible to the drug. Currently, bacterial resistance to nitrofurantoin is more frequent than resistance to fluoroquinolones or trimethoprim-sulfamethoxazole, making nitrofurantoin a second-line agent for treatment of urinary tract infections (Stamm and Hooton, 1993). Nitrofurantoin also is not recommended for treatment of pyelonephritis or prostatitis. However, nitrofurantoin is effective for prophylaxis of recurrent urinary tract infections (Brumfitt and Hamilton-Miller, 1995).

Phenazopyridine. *Phenazopyridine hydrochloride* (PYRIDIDIUM, others) is *not* a urinary antiseptic. However, it does have an analgesic action on the urinary tract and alleviates symptoms of dysuria, frequency, burning, and urgency. The usual dose is 200 mg three times daily. The compound is an azo dye, which colors urine orange or red; the patient should be so informed. Gastrointestinal upset is seen in up to 10% of patients and can be reduced by administering the drug with food; overdosage may result in methemoglobinemia. Phenazopyridine has been marketed since 1925 and has had dual prescription/over-the-counter (OTC) marketing status since 1951. As part of their ongoing review of OTC drug products, the FDA is currently in the process of evaluating products containing less than 200 mg phenazopyridine to determine whether these products generally are recognized as safe and effective as urinary analgesics. The outcome of this evaluation will determine the continued availability of OTC phenazopyridine products in the United States. Products containing 200 mg phenazopyridine are sold by prescription, but their long-term availability in the marketplace also may be affected by the FDA's final OTC ruling.

PENICILLINS, CEPHALOSPORINS, AND OTHER β -LACTAM ANTIBIOTICS

William A. Petri, Jr.

The β -lactam antibiotics are useful and frequently prescribed antimicrobial agents that share a common structure and mechanism of action—inhibition of synthesis of the bacterial peptidoglycan cell wall. This class includes penicillins G and V, which are highly active against susceptible gram-positive cocci; penicillinase-resistant penicillins such as nafcillin, which are active against penicillinase-producing *Staphylococcus aureus*; ampicillin and other agents with an improved gram-negative spectrum, especially when combined with a β -lactamase inhibitor; and extended-spectrum penicillins with activity against *Pseudomonas aeruginosa*, such as piperacillin.

The β -lactams also include the cephalosporin antibiotics, which are classified by generation: First-generation agents have excellent gram-positive and modest gram-negative activity; second-generation agents have somewhat better activity against gram-negative organisms and include some agents with antianaerobe activity; third-generation agents have activity against gram-positive organisms and much more activity against the Enterobacteriaceae, with a subset active against *P. aeruginosa*; and fourth-generation agents encompass the antimicrobial spectrum of all the third-generation agents and have increased stability to hydrolysis by inducible chromosomal β -lactamases.

β -Lactamase inhibitors such as clavulanate are used to extend the spectrum of penicillins against β -lactamase-producing organisms. Carbapenems, including imipenem and meropenem, have the broadest antimicrobial spectrum of any antibiotic, whereas the monobactam aztreonam has a gram-negative spectrum resembling that of the aminoglycosides.

Bacterial resistance against the β -lactam antibiotics continues to increase at a dramatic rate. Mechanisms of resistance include not only production of β -lactamases that destroy the antibiotics but also alterations in or acqui-

sition of novel penicillin-binding proteins and decreased entry and/or active efflux of the antibiotic.

THE PENICILLINS

The penicillins constitute one of the most important groups of antibiotics. Although numerous other antimicrobial agents have been produced since the first penicillin became available, these still are used widely, and major antibiotics and new derivatives of the basic penicillin nucleus still are being produced. Many of these have unique advantages such that members of this group of antibiotics are currently the drugs of choice for a large number of infectious diseases.

History. The history of the brilliant research that led to the discovery and development of penicillin is well chronicled. In 1928, while studying *Staphylococcus* variants in the laboratory at St. Mary's Hospital in London, Alexander Fleming observed that a mold contaminating one of his cultures caused the bacteria in its vicinity to undergo lysis. Broth in which the fungus was grown was markedly inhibitory for many microorganisms. Because the mold belonged to the genus *Penicillium*, Fleming named the antibacterial substance *penicillin*.

A decade later, penicillin was developed as a systemic therapeutic agent by the concerted research of a group of investigators at Oxford University headed by Florey, Chain, and Abraham. By May 1940, the crude material then available was found to produce dramatic therapeutic effects when administered parenterally to mice with experimentally produced streptococcal infections. Despite great obstacles to its laboratory production, enough penicillin was accumulated by 1941 to conduct therapeutic trials in several patients desperately ill with staphylococcal and streptococcal infections refractory to all other therapy. At this stage, the crude, amorphous penicillin was only about 10% pure, and it required nearly 100 L of the broth in which the mold had been grown to obtain enough of the antibiotic to treat one patient for 24 hours. Bedpans actually were

Figure 44–1. Structure of penicillins and products of their enzymatic hydrolysis.

used by the Oxford group for growing cultures of *Penicillium notatum*. Case 1 in the 1941 report from Oxford was that of a policeman who was suffering from a severe mixed staphylococcal and streptococcal infection. He was treated with penicillin, some of which had been recovered from the urine of other patients who had been given the drug. It is said that an Oxford professor referred to penicillin as a remarkable substance grown in bedpans and purified by passage through the Oxford Police Force.

A vast research program soon was initiated in the United States. During 1942, 122 million units of penicillin were made available, and the first clinical trials were conducted at Yale University and the Mayo Clinic, with dramatic results. By the spring of 1943, 200 patients had been treated with the drug. The results were so impressive that the surgeon general of the U.S. Army authorized trial of the antibiotic in a military hospital. Soon thereafter, penicillin was adopted throughout the medical services of the U.S. Armed Forces.

The deep-fermentation procedure for the biosynthesis of penicillin marked a crucial advance in the large-scale production of the antibiotic. From a total production of a few hundred million units a month in the early days, the quantity manufactured rose to over 200 trillion units (nearly 150 tons) by 1950. The first marketable penicillin cost several dollars per 100,000 units; today, the same dose costs only a few cents.

Chemistry. The basic structure of the penicillins, as shown in Figure 44–1, consists of a thiazolidine ring (A) connected to a β -lactam ring (B) to which is attached a side chain (R). The penicillin nucleus itself is the chief structural requirement for biological activity; metabolic transformation or chemical alteration of this portion of the molecule causes loss of all significant antibacterial activity. The side chain (Table 44–1) determines many of the antibacterial and pharmacological characteristics of a particular type of penicillin. Several natural penicillins can be produced depending on the chemical composition of the fermentation medium used to culture *Penicillium*. Penicillin G (benzylpenicillin) has the greatest antimicrobial activity of these and is the only natural penicillin used clinically. For penicillin G, the side chain (R in Figure 44–1) is a phenyl-methyl substituent (Table 44–1).

Semisynthetic Penicillins. The discovery that 6-aminopenicillanic acid could be obtained from cultures of *P. chrysogenum* that were depleted of side-chain precursors led to the development of the semisynthetic penicillins. Side chains can be added that alter the susceptibility of

the resulting compounds to inactivating enzymes (β -lactamases) and that change the antibacterial activity and the pharmacological properties of the drug. 6-Aminopenicillanic acid is now produced in large quantities with the aid of an amidase from *P. chrysogenum* (Figure 44–1). This enzyme splits the peptide linkage by which the side chain of penicillin is joined to 6-aminopenicillanic acid. Table 44–1 shows the variety of side chains that have been added to 6-aminopenicillanic acid to produce the medicinal penicillins in current use; the table also summarizes their major therapeutic properties (e.g., absorption following oral administration, resistance to penicillinase, and antimicrobial spectrum).

Unitage of Penicillin. The international unit of penicillin is the specific penicillin activity contained in 0.6 μg of the crystalline sodium salt of penicillin G. One milligram of pure penicillin G sodium thus equals 1667 units; 1.0 mg of pure penicillin G potassium represents 1595 units. The dosage and the antibacterial potency of the semisynthetic penicillins are expressed in terms of weight.

Mechanism of Action of the Penicillins and Cephalosporins. The β -lactam antibiotics can kill susceptible bacteria. Although knowledge of the mechanism of this action is incomplete, numerous researchers have supplied information that allows understanding of the basic phenomenon (see Ghuysen, 1991; Bayles, 2000).

The cell walls of bacteria are essential for their normal growth and development. Peptidoglycan is a heteropolymeric component of the cell wall that provides rigid mechanical stability by virtue of its highly cross-linked latticework structure (Figure 44–2). In gram-positive microorganisms, the cell wall is 50 to 100 molecules thick, but it is only 1 or 2 molecules thick in gram-negative bacteria (Figure 44–3). The peptidoglycan is composed of glycan chains, which are linear strands of two alternating amino sugars (*N*-acetylglucosamine and *N*-acetylmuramic acid) that are cross-linked by peptide chains.

The biosynthesis of the peptidoglycan involves about 30 bacterial enzymes and may be considered in three stages. The first stage, precursor formation, takes place in the cytoplasm. The product, uridine diphosphate (UDP)-acetylmuramyl-pentapeptide, accumulates in cells when subsequent synthetic stages are inhibited. The last reaction in the synthesis of this compound is the addition of a dipeptide, D-alanyl-D-alanine. Synthesis of the dipeptide involves prior racemization of L-alanine and condensation catalyzed by D-alanyl-D-alanine synthetase.

Table 44-1
Chemical Structures and Major Properties of Various Penicillins

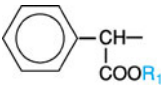

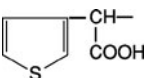

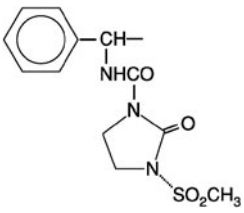

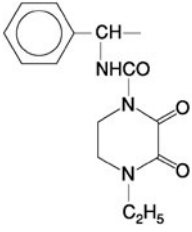

Penicillins are substituted 6-aminopenicillanic acids

MAJOR PROPERTIES

R	NONPROPRIETARY NAME	Absorption after Oral Administration	Resistance to Penicillinase	Useful Antimicrobial Spectrum
	Penicillin G	Variable (poor)	No	<i>Streptococcus</i> species, ** <i>Enterococci</i> , ** <i>Listeria</i> , <i>Neisseria meningitidis</i> , many anaerobes (not <i>Bacteroides fragilis</i>), *** spirochetes, <i>Actinomyces</i> , <i>Erysipelothrix</i> spp., <i>Pasteurella multocida</i> ***
	Penicillin V	Good	No	
	Methicillin	Poor (not given orally)	Yes	Indicated only for non-methicillin-resistant strains of <i>Staphylococcus aureus</i> and <i>Staphylococcus epidermidis</i> . Compared to other penicillins, these penicillinase-resistant penicillins lack activity against <i>Listeria monocytogenes</i> and <i>Enterococcus</i> spp.
	Oxacillin ($R_1 = R_2 = H$)	Good	Yes	
	Cloxacillin ($R_1 = Cl$; $R_2 = H$)			
	Dicloxacillin ($R_1 = R_2 = Cl$)			
	Nafcillin			Variable
	Ampicillin [†] ($R_1 = H$)	Good	No	Extends spectrum of penicillin to include sensitive strains of Enterobacteriaceae *** <i>Escherichia coli</i> , <i>Proteus mirabilis</i> , <i>Salmonella</i> , <i>Shigella</i> , <i>Haemophilus influenzae</i> , *** and <i>Helicobacter pylori</i> . Superior to penicillin for treatment of <i>Listeria monocytogenes</i> and sensitive enterococci. Amoxicillin most active of all oral β -lactams against penicillin-resistant <i>Streptococcus pneumoniae</i>
	Amoxicillin ($R_1 = OH$)	Excellent		

(Continued)

Table 44–1
Chemical Structures and Major Properties of Various Penicillins (Continued)

R	NONPROPRIETARY NAME	MAJOR PROPERTIES		
		Absorption after Oral Administration	Resistance to Penicillinase	Useful Antimicrobial Spectrum
	Carbenicillin (R ₁ = H)	Poor (not given orally)		
	Carbenicillin indanyl (R ₁ = 5-indanol)	Good	No	Less active than ampicillin against <i>Streptococcus</i> species, <i>Enterococcus faecalis</i> , <i>Klebsiella</i> , and <i>Listeria monocytogenes</i> . Activity against <i>Pseudomonas aeruginosa</i> is inferior to that of mezlocillin and piperacillin
	Ticarcillin	Poor (not given orally)	No	
	Mezlocillin	Poor (not given orally)	No	
	Piperacillin	Poor (not given orally)	No	Extends spectrum of ampicillin to include <i>Pseudomonas aeruginosa</i> , [‡] Enterobacteriaceae, ^{***} Bacteroides species ^{***}

^{*}Equivalent to R in Figure 45–1. ^{**}Many strains are resistant due to altered penicillin-binding proteins. ^{***}Many strains are resistant due to production of β -lactamases. [†]There are other congeners of ampicillin; see the text. [‡]Some strains are resistant due to decreased entry or active efflux.

D-Cycloserine is a structural analog of D-alanine and acts as a competitive inhibitor of both the racemase and the synthetase (see Chapter 47).

During reactions of the second stage, UDP-acetylmuramyl-pentapeptide and UDP-acetylglucosamine are linked (with the release of the uridine nucleotides) to form a long polymer.

The third and final stage involves completion of the cross-link. This is accomplished by a transpeptidation reaction that occurs outside the cell membrane. The transpeptidase itself is membrane-bound. The terminal glycine residue of the pentaglycine bridge is linked to the fourth residue of the pentapeptide (D-alanine), releasing the fifth residue (also D-alanine) (Figure 44–2). It is this last step in peptidoglycan synthesis that is inhibited by the β -lactam antibiotics and glycopeptide antibiotics such as *vancomycin* (by a different mechanism than the β -lactams; see Chapter 45). Stereomodels reveal that the conformation of penicillin is very similar to that of D-alanyl-D-alanine. The transpeptidase probably is acylated by penicillin; that is, penicilloyl enzyme apparently is formed, with cleavage of the —CO—N— bond of the β -lactam ring.

Although inhibition of the transpeptidase just described is demonstrably important, there are additional, related targets for the actions of penicillins and cephalosporins; these are collectively termed *penicillin-binding proteins* (PBPs). All bacteria have several such entities; for example, *S. aureus* has four PBPs, whereas *Escherichia coli* has at least seven. The PBPs vary in their affinities for different β -lactam antibiotics, although the interactions eventually become covalent. The higher-molecular-weight PBPs of *E. coli* (PBPs 1a and 1b) include the transpeptidases responsible for synthesis of the peptidoglycan. Other PBPs in *E. coli* include those that are necessary for maintenance of the rodlike shape of the bacterium and for septum formation at division. Inhibition of the transpeptidases causes spheroplast formation and rapid lysis. However, inhibition of the activities of other PBPs may cause delayed lysis (PBP 2) or the production of long, filamentous forms of the bacterium (PBP 3). The lethality of penicillin for bacteria appears to involve both lytic and nonlytic mechanisms. Penicillin's disruption of the balance between PBP-mediated peptidoglycan assem-

Figure 44-2. Action of β -lactam antibiotics in *Staphylococcus aureus*. The bacterial cell wall consists of glycopeptide polymers linked via bridges between amino acid side chains. In *S. aureus*, the bridge is (Gly)₅-D-Ala between lysines. The cross-linking is catalyzed by a transpeptidase, the enzyme that penicillins and cephalosporins inhibit.

bly and murein hydrolase activity results in autolysis. Nonlytic killing by penicillin may involve holin-like proteins in the bacterial membrane that collapse the membrane potential (Bayles, 2000).

Mechanisms of Bacterial Resistance to Penicillins and Cephalosporins. Although all bacteria with cell walls contain PBPs, β -lactam antibiotics cannot kill or even inhibit all bacteria because by various mechanisms bacteria can be resistant to these agents. The microorganism may be intrinsically resistant because of structural differences in the PBPs that are the targets of these drugs. Furthermore, a sensitive strain may acquire resistance of this type by the development of high-molecular-weight PBPs that have decreased affinity for the antibiotic. Because the β -lactam antibiotics inhibit many different PBPs in a single bacterium, the affinity for β -lactam antibiotics of several PBPs must decrease for the organism to be resistant. Altered PBPs with decreased affinity for β -lactam antibiotics are acquired by homologous recombination between PBP genes of different bacterial species. Four of the five high-molecular-weight PBPs of the most highly penicillin-resistant *Streptococcus pneumoniae* isolates have decreased affinity for β -lactam antibiotics as a result of interspecies homologous recombination events (Figure 44-4). In contrast, isolates with high-level resistance to third-generation cephalosporins contain alterations of only two of the five high-molecular-weight PBPs because the other PBPs have inherently low affinity for the third-generation cephalosporins. Penicillin resistance in *Streptococcus sanguis* and other *viridans* streptococci apparently emerged as a result of replacement of its PBPs with resistant PBPs from *S. pneumoniae* (Carratalá *et al.*, 1995). Methicillin-resistant *S. aureus* are resistant *via* acquisition of an additional high-molecular-weight

Figure 44-3. Comparison of the structure and composition of gram-positive and gram-negative cell walls. (Adapted from Tortora *et al.*, 1989, with permission.)

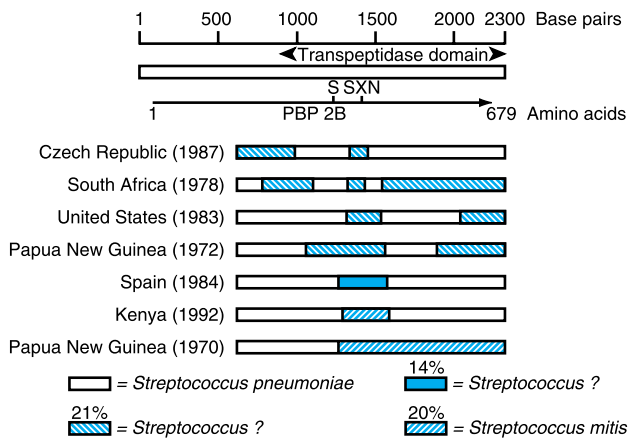

Figure 44-4. Mosaic PBP 2B genes in penicillin-resistant pneumococci. The divergent regions in the PBP 2B genes of seven resistant pneumococci from different countries are shown. These regions have been introduced from at least three sources, one of which appears to be *Streptococcus mitis*. The approximate percent sequence divergence of the divergent regions from the PBP 2B genes of susceptible pneumococci is shown. (Reprinted from Spratt, 1994, with permission.)

PBP (via a transposon from an unknown organism) with a very low affinity for all β -lactam antibiotics. The gene (*MecA*) encoding this new PBP also is present in and responsible for methicillin resistance in the coagulase-negative staphylococci (Spratt, 1994).

Other instances of bacterial resistance to the β -lactam antibiotics are caused by the inability of the agent to penetrate to its site of action (Jacoby, 1994) (Figure 44-5). In

Figure 44-5. Antibiotic efflux pumps of gram-negative bacteria. Multidrug efflux pumps traverse both the inner and outer membranes of gram-negative bacteria. The pumps are composed of a minimum of three proteins and are energized by the proton motive force. Increased expression of these pumps is an important cause of antibiotic resistance. (Reprinted from Nikaido, 1998, with permission.)

gram-positive bacteria, the peptidoglycan polymer is very near the cell surface (Figure 44-3). Some gram-positive bacteria have polysaccharide capsules that are external to the cell wall, but these structures are not a barrier to the diffusion of the β -lactams; the small β -lactam antibiotic molecules can penetrate easily to the outer layer of the cytoplasmic membrane and the PBPs, where the final stages of the synthesis of the peptidoglycan take place. The situation is different with gram-negative bacteria. Their surface structure is more complex, and their inner membrane, which is analogous to the cytoplasmic membrane of gram-positive bacteria, is covered by the outer membrane, lipopolysaccharide, and capsule (Figure 44-3). The outer membrane functions as an impenetrable barrier for some antibiotics (see Nakae, 1986). Some small hydrophilic antibiotics, however, diffuse through aqueous channels in the outer membrane that are formed by proteins called *porins*. Broader-spectrum penicillins, such as ampicillin and amoxicillin, and most of the cephalosporins diffuse through the pores in the *E. coli* outer membrane significantly more rapidly than can penicillin G. The number and size of pores in the outer membrane vary among different gram-negative bacteria. An extreme example is *P. aeruginosa*, which is intrinsically resistant to a wide variety of antibiotics because it lacks the classical high-permeability porins (Nikaido, 1994). Active efflux pumps serve as another mechanism of resistance, removing the antibiotic from its site of action before it can act (Nikaido, 1998) (Figure 44-5). This is an important mechanism of β -lactam resistance in *P. aeruginosa*, *E. coli*, and *Neisseria gonorrhoeae*.

Bacteria also can destroy β -lactam antibiotics enzymatically. β -Lactamases are capable of inactivating certain of these antibiotics and may be present in large quantities (Figures 44-1 and 44-3). Different microorganisms elaborate a number of distinct β -lactamases, although most bacteria produce only one form of the enzyme. The substrate specificities of some of these enzymes are relatively narrow, and these often are described as either penicillinases or cephalosporinases. Other “extended spectrum” enzymes are less discriminant and can hydrolyze a variety of β -lactam antibiotics. β -Lactamases are grouped into four classes: A through D. Class A β -lactamases include the extended-spectrum β -lactamases (ESBLs) and degrade penicillins, some cephalosporins, and, in some instances, carbapenems. Class A and D enzymes are inhibited by the commercially available β -lactamase inhibitors, such as clavulanate and *tazobactam*. Class B β -lactamases are Zn^{2+} -dependent enzymes that destroy all β -lactams except aztreonam, whereas class C β -lactamases are active against cephalosporins. Class D includes cloxacillin-degrading enzymes (Bush, 2001).

In general, gram-positive bacteria produce and secrete a large amount of β -lactamase (Figure 44-3). Most of these

enzymes are penicillinases. The information for staphylococcal penicillinase is encoded in a plasmid, and this may be transferred by bacteriophage to other bacteria. The enzyme is inducible by substrates, and 1% of the dry weight of the bacterium can be penicillinase. In gram-negative bacteria, β -lactamases are found in relatively small amounts but are located in the periplasmic space between the inner and outer cell membranes (Figure 44–3). Since the enzymes of cell wall synthesis are on the outer surface of the inner membrane, these β -lactamases are strategically located for maximal protection of the microbe. β -Lactamases of gram-negative bacteria are encoded either in chromosomes or in plasmids, and they may be constitutive or inducible. The plasmids can be transferred between bacteria by conjugation. These enzymes can hydrolyze penicillins, cephalosporins, or both (see Davies, 1994). However, there is an inconsistent correlation between the susceptibility of an antibiotic to inactivation by β -lactamase and the ability of that antibiotic to kill the microorganism.

Other Factors That Influence the Activity of β -Lactam Antibiotics.

Microorganisms adhering to implanted prosthetic devices (e.g., catheters, artificial joints, prosthetic heart valves, etc.) produce biofilms. Bacteria in biofilms produce extracellular polysaccharides and, in part owing to decreased growth rates, are much less sensitive to antibiotic therapy (Donlan, 2001). The density of the bacterial population and the age of an infection influence the activity of β -lactam antibiotics. The drugs may be several thousand times more potent when tested against small bacterial inocula than when tested against a dense culture. Many factors are involved. Among these are the greater number of relatively resistant microorganisms in a large population, the amount of β -lactamase produced, and the phase of growth of the culture. The clinical significance of this effect of inoculum size is uncertain. The intensity and duration of penicillin therapy needed to abort or cure experimental infections in animals increase with the duration of the infection. The primary reason is that the bacteria are no longer multiplying as rapidly as they do in a fresh infection. These antibiotics are most active against bacteria in the logarithmic phase of growth and have little effect on microorganisms in the stationary phase, when there is no need to synthesize components of the cell wall.

The presence of proteins and other constituents of pus, low pH, or low oxygen tension does not appreciably decrease the ability of β -lactam antibiotics to kill bacteria. However, bacteria that survive inside viable cells of the host generally are protected from the action of the β -lactam antibiotics.

Classification of the Penicillins and Summary of Their Pharmacological Properties

It is useful to classify the penicillins according to their spectra of antimicrobial activity (Table 44–1) (see Chambers, 2000).

1. *Penicillin G* and its close congener *penicillin V* are highly active against sensitive strains of gram-positive cocci, but they are readily hydrolyzed by penicillinase. Thus

they are ineffective against most strains of *S. aureus*.

2. The penicillinase-resistant penicillins [*methicillin* (discontinued in the United States), *nafcillin*, *oxacillin*, *cloxacillin* (not currently marketed in the United States), and *dicloxacillin*] have less potent antimicrobial activity against microorganisms that are sensitive to penicillin G, but they are the agents of first choice for treatment of penicillinase-producing *S. aureus* and *S. epidermidis* that are not methicillin-resistant.
3. *Ampicillin*, *amoxicillin*, and others make up a group of penicillins whose antimicrobial activity is extended to include such gram-negative microorganisms as *Haemophilus influenzae*, *E. coli*, and *Proteus mirabilis*. Frequently these drugs are administered with a β -lactamase inhibitor such as *clavulanate* or *salbactam* to prevent hydrolysis by broad-spectrum β -lactamases that are found with increasing frequency in clinical isolates of these gram-negative bacteria.
4. The antimicrobial activity of *carbenicillin* (discontinued in the United States), its indanyl ester (*carbenicillin indanyl*), and *ticarcillin* is extended to include *Pseudomonas*, *Enterobacter*, and *Proteus* spp. These agents are inferior to ampicillin against gram-positive cocci and *Listeria monocytogenes* and are less active than piperacillin against *Pseudomonas*.
5. *Mezlocillin*, *azlocillin* (both discontinued in the United States), and *piperacillin* have excellent antimicrobial activity against *Pseudomonas*, *Klebsiella*, and certain other gram-negative microorganisms. Piperacillin retains the activity of ampicillin against gram-positive cocci and *L. monocytogenes*.

Although the pharmacological properties of the individual drugs are discussed in detail below, certain generalizations are useful. Following absorption of orally administered penicillins, these agents are distributed widely throughout the body. Therapeutic concentrations of penicillins are achieved readily in tissues and in secretions such as joint fluid, pleural fluid, pericardial fluid, and bile. Penicillins do not penetrate living phagocytic cells to a significant extent, and only low concentrations of these drugs are found in prostatic secretions, brain tissue, and intraocular fluid. Concentrations of penicillins in cerebrospinal fluid (CSF) are variable but are less than 1% of those in plasma when the meninges are normal. When there is inflammation, concentrations in CSF may increase to as much as 5% of the plasma value. Penicillins are eliminated rapidly, particularly by glomerular filtration and renal tubular secretion, such that their half-lives in the body are short; values of 30 to 90 minutes are typical. Concentrations of these drugs in urine thus are high.

Penicillin G and Penicillin V

Antimicrobial Activity. The antimicrobial spectra of penicillin G (*benzylpenicillin*) and penicillin V (the phenoxy-methyl derivative) are very similar for aerobic gram-positive microorganisms. However, penicillin G is 5 to 10 times more active against *Neisseria* spp. that are sensitive to penicillins and against certain anaerobes.

Penicillin G has activity against a variety of species of gram-positive and gram-negative cocci, although many bacteria previously sensitive to the agent are now resistant. Most streptococci (but not enterococci) are very susceptible to the drug; concentrations of less than 0.01 $\mu\text{g/ml}$ usually are effective. However, penicillin-resistant *viridans* streptococci (Carratalá *et al.*, 1995) and *S. pneumoniae* are becoming more common. During 1997, 13.6% of *S. pneumoniae* sterile-site isolates had high-level [minimal inhibitory concentration (MIC) $\geq 2 \mu\text{g/ml}$] and 11.4% of isolates had low-level (MIC $\geq 0.12 \mu\text{g/ml}$) penicillin resistance, for a total of 25% of isolates (Centers for Disease Control and Prevention, 1999, 2002). Penicillin-resistant pneumococci are especially common in pediatric populations, such as children attending day-care centers. Many penicillin-resistant pneumococci also are resistant to third-generation cephalosporins.

Whereas most strains of *S. aureus* were highly sensitive to penicillin G when this agent was first employed therapeutically, more than 90% of strains of staphylococci isolated from individuals inside or outside of hospitals are now resistant to penicillin G. Most strains of *S. epidermidis* also are resistant to penicillin. Unfortunately, penicillinase-producing strains of gonococci that are highly resistant to penicillin G have become widespread. With rare exceptions, meningococci are quite sensitive to penicillin G.

Although the vast majority of strains of *Corynebacterium diphtheriae* are sensitive to penicillin G, some are highly resistant. The presence of chromosomally encoded β -lactamase in *Bacillus anthracis* is the reason that penicillin was not used for prophylaxis of anthrax exposure, although most isolates are susceptible. Most anaerobic microorganisms, including *Clostridium* spp., are highly sensitive. *Bacteroides fragilis* is an exception, displaying resistance to penicillins and cephalosporins by virtue of expressing a broad-spectrum cephalosporinase. Some strains of *Prevotella melaninogenica* also have acquired this trait. *Actinomyces israelii*, *Streptobacillus moniliformis*, *Pasteurella multocida*, and *L. monocytogenes* are inhibited by penicillin G. Most species of *Leptospira* are moderately susceptible to the drug. One of the most exquisitely sensitive microorganisms is *Treponema pallidum*. *Borrelia burgdorferi*, the organism responsible for Lyme disease, also is susceptible. None of the penicillins is effective against amebae, plasmodia, rickettsiae, fungi, or viruses.

Absorption. Oral Administration of Penicillin G.

About one-third of an orally administered dose of penicillin G is absorbed from the intestinal tract under favorable conditions. Gastric juice at pH 2 rapidly destroys the antibiotic. The decrease in gastric acid production with aging accounts for better absorption of penicillin G from the gastrointestinal tract of older individuals. Absorption is rapid, and maximal concentrations in blood are attained in 30 to 60 minutes. The peak value is approximately 0.5

unit/ml (0.3 $\mu\text{g/ml}$) after an oral dose of 400,000 units (about 250 mg) in an adult. Ingestion of food may interfere with enteric absorption of all penicillins, perhaps by adsorption of the antibiotic onto food particles. Thus oral penicillin G should be administered at least 30 minutes before a meal or 2 hours after. Despite the convenience of oral administration of penicillin G, this route should be used only in infections in which clinical experience has proven its efficacy.

Oral Administration of Penicillin V. The virtue of penicillin V in comparison with penicillin G is that it is more stable in an acidic medium and therefore is better absorbed from the gastrointestinal tract. On an equivalent oral-dose basis, penicillin V (K⁺ salt; VEETIDS) yields plasma concentrations two to five times greater than those provided by penicillin G. The peak concentration in the blood of an adult after an oral dose of 500 mg is nearly 3 $\mu\text{g/ml}$. Once absorbed, penicillin V is distributed in the body and excreted by the kidney in a manner similar to that of penicillin G.

Parenteral Administration of Penicillin G. After intramuscular injection, peak concentrations in plasma are reached within 15 to 30 minutes. This value declines rapidly because the half-life of penicillin G is 30 minutes.

Many means for prolonging the sojourn of the antibiotic in the body and thereby reducing the frequency of injections have been explored. *Probenecid* blocks renal tubular secretion of penicillin, but it is used rarely for this purpose (*see below*). More commonly, repository preparations of penicillin G are employed. The two such compounds currently favored are *penicillin G procaine* (WYCILLIN, others) and *penicillin G benzathine* (BICILLIN L-A, PERMAPEN). Such agents release penicillin G slowly from the area in which they are injected and produce relatively low but persistent concentrations of antibiotic in the blood.

Penicillin G procaine suspension is an aqueous preparation of the crystalline salt that is only 0.4% soluble in water. Procaine combines with penicillin mole for mole; a dose of 300,000 units thus contains approximately 120 mg procaine. When large doses of penicillin G procaine are given (*e.g.*, 4.8 million units), procaine may reach toxic concentrations in the plasma. If the patient is believed to be hypersensitive to procaine, 0.1 ml of 1% solution of procaine should be injected intradermally as a test. The anesthetic effect of the procaine accounts in part for the fact that injections of penicillin G procaine are virtually painless.

The injection of 300,000 units of penicillin G procaine produces a peak concentration in plasma of about 0.9 $\mu\text{g/ml}$ within 1 to 3 hours; after 24 hours, the concentration is reduced to 0.1 $\mu\text{g/ml}$, and by 48 hours it has fallen to 0.03 $\mu\text{g/ml}$. A larger dose (600,000 units) yields somewhat higher values that are maintained for as long as 4 to 5 days.

Penicillin G benzathine suspension is the aqueous suspension of the salt obtained by the combination of 1 mol of an ammonium base

and 2 mol of penicillin G to yield *N,N'*-dibenzylethylenediamine dipenicillin G. The salt itself is only 0.02% soluble in water. The long persistence of penicillin in the blood after a suitable intramuscular dose reduces cost, need for repeated injections, and local trauma. The local anesthetic effect of penicillin G benzathine is comparable with that of penicillin G procaine.

Penicillin G benzathine is absorbed very slowly from intramuscular depots and produces the longest duration of detectable antibiotic of all the available repository penicillins. For example, in adults, a dose of 1.2 million units given intramuscularly produces a concentration in plasma of 0.09 $\mu\text{g/ml}$ on the first, 0.02 $\mu\text{g/ml}$ on the fourteenth, and 0.002 $\mu\text{g/ml}$ on the thirty-second day after injection. The average duration of demonstrable antimicrobial activity in the plasma is about 26 days.

Distribution. Penicillin G is distributed widely throughout the body, but the concentrations in various fluids and tissues differ widely. Its apparent volume of distribution is about 0.35 L/kg. Approximately 60% of the penicillin G in plasma is reversibly bound to albumin. Significant amounts appear in liver, bile, kidney, semen, joint fluid, lymph, and intestine.

While probenecid markedly decreases the tubular secretion of the penicillins, this is not the only factor responsible for the elevated plasma concentrations of the antibiotic that follow its administration. Probenecid also produces a significant decrease in the apparent volume of distribution of the penicillins.

Cerebrospinal Fluid. Penicillin does not readily enter the CSF when the meninges are normal. However, when the meninges are acutely inflamed, penicillin penetrates into the CSF more easily. Although the concentrations attained vary and are unpredictable, they are usually in the range of 5% of the value in plasma and are therapeutically effective against susceptible microorganisms.

Penicillin and other organic acids are secreted rapidly from the CSF into the bloodstream by an active transport process. Probenecid competitively inhibits this transport and thus elevates the concentration of penicillin in CSF. In uremia, other organic acids accumulate in the CSF and compete with penicillin for secretion; the drug occasionally reaches toxic concentrations in the brain and can produce convulsions.

Excretion. Under normal conditions, penicillin G is eliminated rapidly from the body mainly by the kidney but in small part in the bile and by other routes. Approximately 60% to 90% of an intramuscular dose of penicillin G in aqueous solution is eliminated in the urine, largely within the first hour after injection. The remainder is metabolized to penicilloic acid. The half-life for elimination of penicillin G is about 30 minutes in normal adults. Approximately 10% of the drug is eliminated by glomeru-

lar filtration and 90% by tubular secretion. Renal clearance approximates the total renal plasma flow. The maximal tubular secretory capacity for penicillin in the normal adult male is about 3 million units (1.8 g) per hour.

Clearance values are considerably lower in neonates and infants because of incomplete development of renal function; as a result, after doses proportionate to surface area, the persistence of penicillin in the blood is several times as long in premature infants as in children and adults. The half-life of the antibiotic in children younger than 1 week of age is 3 hours; by 14 days of age it is 1.4 hours. After renal function is fully established in young children, the rate of renal excretion of penicillin G is considerably more rapid than in adults.

Anuria increases the half-life of penicillin G from a normal value of 0.5 hour to about 10 hours. When renal function is impaired, 7% to 10% of the antibiotic may be inactivated each hour by the liver. Patients with renal shutdown who require high-dose therapy with penicillin can be treated adequately with 3 million units of aqueous penicillin G followed by 1.5 million units every 8 to 12 hours. The dose of the drug must be readjusted during dialysis and the period of progressive recovery of renal function. If, in addition to renal failure, hepatic insufficiency also is present, the half-life will be prolonged even further.

Therapeutic Uses. Pneumococcal Infections. Penicillin G remains the agent of choice for the management of infections caused by sensitive strains of *S. pneumoniae*. However, strains of pneumococci resistant to usual doses of penicillin G are being isolated more frequently in several countries, including the United States (see Centers for Disease Control and Prevention, 1999; Fiore *et al.*, 2000).

Pneumococcal Pneumonia. Until it is highly likely or established that the infecting isolate of pneumococcus is penicillin-sensitive, pneumococcal pneumonia should be treated with a third-generation cephalosporin or with 20 million to 24 million units of penicillin G daily by constant intravenous infusion. If the organism is sensitive to penicillin, then the dose can be reduced (Medical Letter, 2004). For parenteral therapy of sensitive isolates of pneumococci, penicillin G or penicillin G procaine is favored. Although oral treatment with 500 mg penicillin V given every 6 hours for treatment of pneumonia owing to penicillin-sensitive isolates has been used with success in this disease, it cannot be recommended for routine initial use because of the existence of resistance. Therapy should be continued for 7 to 10 days, including 3 to 5 days after the patient's temperature has returned to normal.

Pneumococcal Meningitis. Until it is established that the infecting pneumococcus is penicillin-sensitive, pneumococcal meningitis should be treated with a combination of vancomycin and a third-generation cephalosporin (John, 1994; Catalan *et al.*, 1994). *Dexamethasone* given at the same time as antibiotics was associated with an improved outcome (de Gans and van de Beek, 2002). Prior to the appearance of penicillin resistance, penicillin treatment reduced the death rate in this disease from nearly 100% to about 25%. The recommended therapy is 20 million to 24 million units of penicillin G daily by constant intravenous infusion or divided into boluses given every 2 to 3 hours. The usual duration of therapy is 14 days.

Streptococcal Infections. *Streptococcal Pharyngitis (Including Scarlet Fever).* This is the most common disease produced by *S. pyogenes* (group A β -hemolytic streptococcus). Penicillin-resistant isolates have yet to be observed for *S. pyogenes* (Tomasz, 1986). The preferred oral therapy is with penicillin V, 500 mg every 6 hours for 10 days. Equally good results are produced by the administration of 600,000 units of penicillin G procaine intramuscularly once daily for 10 days or by a single injection of 1.2 million units of penicillin G benzathine. Parenteral therapy is preferred if there are questions of patient compliance. Penicillin therapy of streptococcal pharyngitis reduces the risk of subsequent acute rheumatic fever; however, current evidence suggests that the incidence of glomerulonephritis that follows streptococcal infections is not reduced to a significant degree by treatment with penicillin.

Streptococcal Toxic Shock and Necrotizing Fasciitis. These are life-threatening infections associated with toxin production and are treated optimally with penicillin plus *clindamycin* (to decrease toxin synthesis) (Bisno and Stephens, 1996).

Streptococcal Pneumonia, Arthritis, Meningitis, and Endocarditis. While uncommon, these conditions should be treated with penicillin G when they are caused by *S. pyogenes*; daily doses of 12 million to 20 million units are administered intravenously for 2 to 4 weeks. Such treatment of endocarditis should be continued for a full 4 weeks.

Infections Caused by Other Streptococci. The *viridans* streptococci are the most common cause of infectious endocarditis. These are nongroupable β -hemolytic microorganisms that are increasingly resistant to penicillin G (MIC >0.1 $\mu\text{g/ml}$). Since enterococci also may be β -hemolytic, and certain other β -hemolytic strains may be relatively resistant to penicillin, it is important to determine quantitative microbial sensitivities to penicillin G in patients with endocarditis. Patients with penicillin-sensitive *viridans* group streptococcal endocarditis can be treated successfully with 1.2 million units of procaine penicillin G given four times daily for 2 weeks or with daily doses of 12 million to 20 million units of intravenous penicillin G for 2 weeks, both regimens in combination with *streptomycin* 500 mg intramuscularly every 12 hours or *gentamicin* 1 mg/kg every 8 hours. Some physicians prefer a 4-week course of treatment with penicillin G alone.

Enterococcal endocarditis is one of the few diseases treated optimally with two antibiotics. The recommended therapy for penicillin- and aminoglycoside-sensitive enterococcal endocarditis is 20 million units of penicillin G or 12 g ampicillin daily administered intravenously in combination with a low dose of gentamicin. Therapy usually should be continued for 6 weeks, but selected patients with a short duration of illness (<3 months) have been treated successfully in 4 weeks (Wilson *et al.*, 1984).

Infections with Anaerobes. Many anaerobic infections are caused by mixtures of microorganisms. Most are sensitive to penicillin G. An exception is the *B. fragilis* group, in which up to 75% of strains may be resistant to high concentrations of this antibiotic. Pulmonary and periodontal infections (with the exception of β -lactamase-producing *Prevotella melaninogenica*) usually respond well to penicillin G, although a multicenter study indicated that clindamycin is more effective than penicillin for therapy of lung abscess (Levison *et al.*, 1983). Mild-to-moderate infections at these sites may be treated with oral medication (either penicillin G or penicillin V 400,000 units four times daily). More severe infections should be treated with 12 million to 20 million units of penicillin G intravenously. Brain abscesses also frequently contain several species of anaerobes, and most authorities prefer to treat such disease with high

doses of penicillin G (20 million units per day) plus *metronidazole* or *chloramphenicol*. Some physicians add a third-generation cephalosporin for activity against aerobic gram-negative bacilli.

Staphylococcal Infections. The vast majority of staphylococcal infections are caused by microorganisms that produce penicillinase. A patient with a staphylococcal infection who requires treatment with an antibiotic should receive one of the penicillinase-resistant penicillins—*e.g.*, nafcillin or oxacillin (Swartz, 2004).

So-called methicillin-resistant staphylococci are resistant to penicillin G, all the penicillinase-resistant penicillins, and the cephalosporins. Isolates occasionally may appear to be sensitive to various cephalosporins *in vitro*, but resistant populations arise during therapy and lead to failure (Chambers *et al.*, 1984). Vancomycin, *linezolid*, *quinupristin-dalfopristin*, and *daptomycin* are active for infections caused by these bacteria, although reduced susceptibility to vancomycin has been observed (Centers for Disease Control and Prevention, 2004).

Meningococcal Infections. Penicillin G remains the drug of choice for meningococcal disease. Patients should be treated with high doses of penicillin given intravenously, as described for pneumococcal meningitis. Penicillin-resistant strains of *N. meningitidis* have been reported in Britain and Spain but are infrequent at present. In 1997, 97% of *N. meningitidis* isolates analyzed from the United States were penicillin-sensitive (Rosenstein *et al.*, 2000). The occurrence of penicillin-resistant strains should be considered in patients who are slow to respond to treatment (Sprott *et al.*, 1988, Mendelman *et al.*, 1988). It should be remembered that penicillin G does not eliminate the meningococcal carrier state, and its administration thus is ineffective as a prophylactic measure.

Gonococcal Infections. Gonococci gradually have become more resistant to penicillin G, and penicillins are no longer the therapy of choice, unless it is known that gonococcal strains in a particular geographical area are susceptible. Uncomplicated gonococcal urethritis is the most common infection, and a single intramuscular injection of 250 mg *ceftriaxone* is the recommended treatment (Sparling and Handsfield, 2000).

Gonococcal arthritis, disseminated gonococcal infections with skin lesions, and gonococemia should be treated with ceftriaxone 1 g daily given either intramuscularly or intravenously for 7 to 10 days. Ophthalmia neonatorum also should be treated with ceftriaxone for 7 to 10 days (25 to 50 mg/kg per day intramuscularly or intravenously).

Syphilis. Therapy of syphilis with penicillin G is highly effective. Primary, secondary, and latent syphilis of less than 1 year's duration may be treated with penicillin G procaine (2.4 million units per day intramuscularly) plus probenecid (1.0 g/day orally) for 10 days or with 1 to 3 weekly intramuscular doses of 2.4 million units of penicillin G benzathine (three doses in patients with HIV infection). Patients with late latent syphilis, neurosyphilis, or cardiovascular syphilis may be treated with a variety of regimens. Since the latter two conditions are potentially lethal and their progression can be halted (but not reversed), intensive therapy with 20 million units of penicillin G daily for 10 days is recommended. Since there are no proven alternatives for treating syphilis in pregnant women, penicillin-allergic individuals must be acutely desensitized to prevent anaphylaxis (Centers for Disease Control and Prevention, 2002).

Infants with congenital syphilis discovered at birth or during the postnatal period should be treated for at least 10 days with 50,000 units/kg daily of aqueous penicillin G in two divided doses or 50,000 units/kg of procaine penicillin G in a single daily dose (Tramont, 2000).

Most patients (70% to 90%) with secondary syphilis develop the Jarisch-Herxheimer reaction. This also may be seen in patients with other forms of syphilis. Several hours after the first injection of penicillin, chills, fever, headache, myalgias, and arthralgias may develop. The syphilitic cutaneous lesions may become more prominent, edematous, and brilliant in color. Manifestations usually persist for a few hours, and the rash begins to fade within 48 hours. It does not recur with the second or subsequent injections of penicillin. This reaction is thought to be due to release of spirochetal antigens with subsequent host reactions to the products. *Aspirin* gives symptomatic relief, and therapy with penicillin should not be discontinued.

Actinomycosis. Penicillin G is the agent of choice for the treatment of all forms of actinomycosis. The dose should be 12 million to 20 million units of penicillin G intravenously per day for 6 weeks. Some physicians continue therapy for 2 to 3 months with oral penicillin V (500 mg four times daily). Surgical drainage or excision of the lesion may be necessary before cure is accomplished.

Diphtheria. There is no evidence that penicillin or any other antibiotic alters the incidence of complications or the outcome of diphtheria; specific antitoxin is the only effective treatment. However, penicillin G eliminates the carrier state. The parenteral administration of 2 to 3 million units per day in divided doses for 10 to 12 days eliminates the diphtheria bacilli from the pharynx and other sites in practically 100% of patients. A single daily injection of penicillin G procaine for the same period produces comparable results.

Anthrax. Strains of *Bacillus anthracis* resistant to penicillin have been recovered from human infections. When penicillin G is used, the dose should be 12 million to 20 million units per day.

Clostridial Infections. Penicillin G is the agent of choice for gas gangrene; the dose is in the range of 12 million to 20 million units per day given parenterally. Adequate débridement of the infected areas is essential. Antimicrobial drugs probably have no effect on the ultimate outcome of tetanus. Débridement and administration of human tetanus immune globulin may be indicated. Penicillin is administered, however, to eradicate the vegetative forms of the bacteria that may persist.

Fusospirochetal Infections. Gingivostomatitis, produced by the synergistic action of *Leptotrichia buccalis* and spirochetes that are present in the mouth, is readily treatable with penicillin. For simple "trench mouth," 500 mg penicillin V given every 6 hours for several days is usually sufficient to clear the disease.

Rat-Bite Fever. The two microorganisms responsible for this infection, *Spirillum minor* in the Orient and *Streptobacillus moniliformis* in America and Europe, are sensitive to penicillin G, the therapeutic agent of choice. Since most cases due to *Streptobacillus* are complicated by bacteremia and, in many instances, by metastatic infections, especially of the synovia and endocardium, the dose should be large; a daily dose of 12 million to 15 million units given parenterally for 3 to 4 weeks has been recommended.

Listeria Infections. Ampicillin (with gentamicin for immunosuppressed patients with meningitis) and penicillin G are the drugs of choice in the management of infections owing to *L. monocytogenes*. The recommended dose of ampicillin is 1 to 2 g intravenously every 4 hours. The recommended dose of penicillin G is 15 million to 20 million units parenterally per day for at least 2 weeks. When endocarditis is the problem, the dose is the same, but the duration of treatment should be no less than 4 weeks.

Lyme Disease. Although a tetracycline is the usual drug of choice for early disease, amoxicillin is effective; the dose is 500 mg three times daily for 21 days. Severe disease is treated with a third-

generation cephalosporin or 20 million units of intravenous penicillin G daily for 14 days.

Erysipeloid. The causative agent of this disease, *Erysipelothrix rhusiopathiae*, is sensitive to penicillin. The uncomplicated infection responds well to a single injection of 1.2 million units of penicillin G benzathine. When endocarditis is present, penicillin G, 12 million to 20 million units per day, has been found to be effective; therapy should be continued for 4 to 6 weeks.

Pasteurella multocoda. *Pasteurella multocoda* is the cause of wound infections after a cat or dog bite. It is uniformly susceptible to penicillin G and ampicillin and resistant to penicillinase-resistant penicillins and first-generation cephalosporins (Goldstein *et al.*, 1988). When the infection causes meningitis, a third-generation cephalosporin is preferred because the MICs are slightly lower than for penicillin.

Prophylactic Uses of the Penicillins. The demonstrated effectiveness of penicillin in eradicating microorganisms was followed quickly and quite naturally by attempts to prove that it also was effective in preventing infection in susceptible hosts. As a result, the antibiotic has been administered in almost every situation in which a risk of bacterial invasion has been present. As prophylaxis has been investigated under controlled conditions, it has become clear that penicillin is highly effective in some situations, useless and potentially dangerous in others, and of questionable value in still others (*see* Chapter 42).

Streptococcal Infections. The administration of penicillin to individuals exposed to *S. pyogenes* affords protection from infection. The oral ingestion of 200,000 units of penicillin G or penicillin V twice a day or a single injection of 1.2 million units of penicillin G benzathine is effective. Indications for this type of prophylaxis include outbreaks of streptococcal disease in closed populations, such as boarding schools or military bases. Patients with extensive deep burns are at high risk of severe wound infections with *S. pyogenes*; "low dose" prophylaxis for several days appears to be effective in reducing the incidence of this complication.

Recurrences of Rheumatic Fever. The oral administration of 200,000 units of penicillin G or penicillin V every 12 hours produces a striking decrease in the incidence of recurrences of rheumatic fever in susceptible individuals. Because of the difficulties of compliance, parenteral administration is preferable, especially in children. The intramuscular injection of 1.2 million units of penicillin G benzathine once a month yields excellent results. In cases of hypersensitivity to penicillin, sulfisoxazole or sulfadiazine, 1 g twice a day for adults, also is effective; for children weighing under 27 kg, the dose is halved. Prophylaxis must be continued throughout the year. The duration of such treatment is an unsettled question. It has been suggested that prophylaxis should be continued for life because instances of acute rheumatic fever have been observed in the fifth and sixth decades. However, the necessity for such prolonged prophylaxis has not been established and may be unnecessary for certain young adults judged to be at low risk for recurrence (Berrios *et al.*, 1993).

Syphilis. Prophylaxis for a contact with syphilis consists of a course of therapy as described for primary syphilis. A serological test for syphilis should be performed at monthly intervals for at least 4 months thereafter.

Surgical Procedures in Patients with Valvular Heart Disease.

About 25% of cases of subacute bacterial endocarditis follow dental extractions. This observation, together with the fact that up to 80% of persons who have teeth removed experience a transient bacteremia, emphasizes the potential importance of chemoprophylaxis for those who have congenital or acquired valvular heart disease of any type and need to undergo dental procedures. Since transient bacterial invasion of the bloodstream occurs occasionally after surgical procedures (e.g., tonsillectomy and genitourinary and gastrointestinal procedures) and during childbirth, these, too, are indications for prophylaxis in patients with valvular heart disease. Whether the incidence of bacterial endocarditis actually is altered by this type of chemoprophylaxis remains to be determined.

Detailed recommendations for adults and children with valvular heart disease have been formulated (see Dajani *et al.*, 1997; Durack, 2000).

The Penicillinase-Resistant Penicillins

The penicillins described in this section are resistant to hydrolysis by staphylococcal penicillinase. Their appropriate use should be restricted to the treatment of infections that are known or suspected to be caused by staphylococci that elaborate the enzyme—which now includes the vast majority of strains of this bacterium that are encountered clinically. These drugs are much less active than is penicillin G against other penicillin-sensitive microorganisms, including non-penicillinase-producing staphylococci.

The role of the penicillinase-resistant penicillins as the agents of choice for most staphylococcal disease is changing with the increasing incidence of isolates of so-called methicillin-resistant microorganisms. As commonly used, this term denotes resistance of these bacteria to all the penicillinase-resistant penicillins and cephalosporins. Hospital-acquired strains usually are resistant to the aminoglycosides, tetracyclines, *erythromycin*, and *clindamycin* as well. *Vancomycin* is considered the drug of choice for such infections. Some physicians use a combination of *vancomycin* and *rifampin*, especially for life-threatening infections and those involving foreign bodies. Community-acquired methicillin-resistant strains are less likely to be resistant to other classes of antibiotics with the exception of macrolides (Okuma *et al.*, 2002). Methicillin-resistant *S. aureus* contains an additional high-molecular-weight PBP with a very low affinity for β -lactam antibiotics (Spratt, 1994). From 40% to 60% of strains of *S. epidermidis* also are resistant to the penicillinase-resistant penicillins by the same mechanism. As with methicillin-resistant *S. aureus*, these strains may appear to be susceptible to cephalosporins on disk-sensitivity testing, but there usually is a significant population of microbes that is resistant to cephalosporins and that emerges during such therapy. *Vancomycin* also is the drug of choice for serious infection caused by methicillin-

resistant *S. epidermidis*; *rifampin* is given concurrently when a foreign body is involved.

The Isoxazolyl Penicillins: Oxacillin, Cloxacillin, and Dicloxacillin. These three congeneric semisynthetic penicillins are similar pharmacologically and thus conveniently are considered together. Their structural formulas are shown in Table 44–1. All are relatively stable in an acidic medium and are absorbed adequately after oral administration. All are markedly resistant to cleavage by penicillinase. These drugs are not substitutes for penicillin G in the treatment of diseases amenable to it, and they are not active against enterococci or *Listeria*. Furthermore, because of variability in intestinal absorption, oral administration is not a substitute for the parenteral route in the treatment of serious staphylococcal infections that require a penicillin unaffected by penicillinase.

Pharmacological Properties. The isoxazolyl penicillins are potent inhibitors of the growth of most penicillinase-producing staphylococci. This is their valid clinical use. Dicloxacillin is the most active, and many strains of *S. aureus* are inhibited by concentrations of 0.05 to 0.8 $\mu\text{g/ml}$. Comparable values for cloxacillin and oxacillin are 0.1 to 3 and 0.4 to 6 $\mu\text{g/ml}$, respectively. These differences may have little practical significance, however, because dosages (see below) are adjusted accordingly. These agents are, in general, less effective against microorganisms susceptible to penicillin G, and they are not useful against gram-negative bacteria.

These agents are absorbed rapidly but incompletely (30% to 80%) from the gastrointestinal tract. Absorption of the drugs is more efficient when they are taken on an empty stomach; preferably they are administered 1 hour before or 2 hours after meals to ensure better absorption. Peak concentrations in plasma are attained by 1 hour and approximately 5 to 10 $\mu\text{g/ml}$ after the ingestion of 1 g oxacillin. Slightly higher concentrations are achieved after the administration of 1 g cloxacillin, whereas the same oral dose of dicloxacillin yields peak plasma concentrations of 15 $\mu\text{g/ml}$. There is little evidence that these differences are of clinical significance. All these congeners are bound to plasma albumin to a great extent (approximately 90% to 95%); none is removed from the circulation to a significant degree by hemodialysis.

The isoxazolyl penicillins are excreted rapidly by the kidney. Normally, about one-half of any of these drugs is excreted in the urine in the first 6 hours after a conventional oral dose. There also is significant hepatic elimination of these agents in the bile. The half-lives for all are between 30 and 60 minutes. Intervals between doses of oxacillin, cloxacillin, and dicloxacillin do not have to be altered for patients with renal failure. The above-noted differences in plasma concentrations produced by the isoxazolyl penicillins are related mainly to differences in rate of urinary excretion and degree of resistance to degradation in the liver.

Nafcillin. This semisynthetic penicillin is highly resistant to penicillinase and has proven effective against infections caused by penicillinase-producing strains of *S. aureus*. Its structural formula is shown in Table 44–1.

Pharmacological Properties. Nafcillin is slightly more active than oxacillin against penicillin G-resistant *S. aureus* (most strains are inhibited by 0.06 to 2 $\mu\text{g/ml}$). While it is the most active of the

penicillinase-resistant penicillins against other microorganisms, it is not as potent as penicillin G.

Nafcillin is variably inactivated in the acidic medium of the gastric contents. Its oral absorption is irregular regardless of whether the drug is taken with meals or on an empty stomach; injectable preparations therefore should be used. The peak plasma concentration is about 8 $\mu\text{g/ml}$ 60 minutes after a 1-g intramuscular dose. Nafcillin is about 90% bound to plasma protein. Peak concentrations of nafcillin in bile are well above those found in plasma. Concentrations of the drug in CSF appear to be adequate for therapy of staphylococcal meningitis.

The Aminopenicillins: Ampicillin, Amoxicillin, and Their Congeners

These agents have similar antibacterial activity and a spectrum that is broader than the antibiotics heretofore discussed. They all are destroyed by β -lactamase (from both gram-positive and gram-negative bacteria).

Antimicrobial Activity. Ampicillin and the related aminopenicillins are bactericidal for both gram-positive and gram-negative bacteria. The meningococci and *L. monocytogenes* are sensitive to this class of drugs. Many pneumococcal isolates have varying levels of resistance to ampicillin. Penicillin-resistant strains should be considered ampicillin/amoxicillin-resistant. *H. influenzae* and the *viridans* group of streptococci exhibit varying degrees of resistance. Enterococci are about twice as sensitive to ampicillin on a weight basis as they are to penicillin G (MIC for ampicillin averages 1.5 $\mu\text{g/ml}$). Although most strains of *N. gonorrhoeae*, *E. coli*, *P. mirabilis*, *Salmonella*, and *Shigella* were highly susceptible when ampicillin was first used in the early 1960s, an increasing percentage of these species now is resistant. From 30% to 50% of *E. coli*, a significant number of *P. mirabilis*, and practically all species of *Enterobacter* presently are insensitive. Resistant strains of *Salmonella* (plasmid mediated) have been recovered with increasing frequency in various parts of the world. Most strains of *Shigella* now are resistant. Most strains of *Pseudomonas*, *Klebsiella*, *Serratia*, *Acinetobacter*, and indole-positive *Proteus* also are resistant to this group of penicillins; these antibiotics are less active against *B. fragilis* than is penicillin G. However, concurrent administration of a β -lactamase inhibitor such as clavulanate or *sulbactam* markedly expands the spectrum of activity of these drugs (see below).

Ampicillin. This drug is the prototype of the group. Its structural formula is shown in Table 44–1.

Pharmacological Properties. Ampicillin (PRINCIPEN, others) is stable in acid and is well absorbed after oral administration. An oral dose of 0.5 g produces peak concentrations in plasma of about 3 $\mu\text{g/ml}$ at 2 hours. Intake of food prior to ingestion of ampicillin diminishes absorption. Intramuscular injection of 0.5 or 1 g sodium ampicillin yields peak plasma concentrations of about 7 or 10 $\mu\text{g/ml}$, respectively, at 1 hour; these decline exponentially, with a half-life of approximately 80 minutes. Severe renal impairment markedly prolongs the persistence of ampicillin in the plasma. Peritoneal dialysis is ineffective in

removing the drug from the blood, but hemodialysis removes about 40% of the body store in about 7 hours. Adjustment of the dose of ampicillin is required in the presence of renal dysfunction. Ampicillin appears in the bile, undergoes enterohepatic circulation, and is excreted in appreciable quantities in the feces.

Amoxicillin. This drug, a penicillinase-susceptible semi-synthetic penicillin, is a close chemical and pharmacological relative of ampicillin (Table 44–1). The drug is stable in acid and is designed for oral use. It is absorbed more rapidly and completely from the gastrointestinal tract than is ampicillin, which is the major difference between the two. The antimicrobial spectrum of amoxicillin is essentially identical to that of ampicillin, with the important exception that amoxicillin appears to be less effective than ampicillin for shigellosis.

Peak plasma concentrations of amoxicillin (AMOXIL, others) are 2 to 2^{1/2} times greater for amoxicillin than for ampicillin after oral administration of the same dose; they are reached at 2 hours and average about 4 $\mu\text{g/ml}$ when 250 mg is administered. Food does not interfere with absorption. Perhaps because of more complete absorption of this congener, the incidence of diarrhea with amoxicillin is less than that following administration of ampicillin. The incidence of other adverse effects appears to be similar. While the half-life of amoxicillin is similar to that for ampicillin, effective concentrations of orally administered amoxicillin are detectable in the plasma for twice as long as with ampicillin, again because of the more complete absorption. About 20% of amoxicillin is protein-bound in plasma, a value similar to that for ampicillin. Most of a dose of the antibiotic is excreted in an active form in the urine. Probenecid delays excretion of the drug.

Therapeutic Indications for the Aminopenicillins.

Upper Respiratory Infections. Ampicillin and amoxicillin are active against *S. pyogenes* and many strains of *S. pneumoniae* and *H. influenzae*, which are major upper respiratory bacterial pathogens. The drugs constitute effective therapy for sinusitis, otitis media, acute exacerbations of chronic bronchitis, and epiglottitis caused by sensitive strains of these organisms. Amoxicillin is the most active of all the oral β -lactam antibiotics against both penicillin-sensitive and penicillin-resistant *S. pneumoniae* (Friedland and McCracken, 1994). Based on the increasing prevalence of pneumococcal resistance to penicillin, an increase in dose of oral amoxicillin (from 40 to 45 up to 80 to 90 mg/kg per day) for empirical treatment of acute otitis media in children is recommended (Dowell *et al.*, 1999). Ampicillin-resistant *H. influenzae* may be a problem in many areas.

The addition of a β -lactamase inhibitor (amoxicillin–clavulanate or ampicillin–sulbactam) extends the spectrum to β -lactamase-producing *H. influenzae* and Enterobacteriaceae. Bacterial pharyngitis should be treated with penicillin G or penicillin V because *S. pyogenes* is the major pathogen.

Urinary Tract Infections. Most uncomplicated urinary tract infections are caused by Enterobacteriaceae, and *E. coli* is the most common species; ampicillin often is an effective agent, although resistance is increasingly common. Enterococcal urinary tract infections are treated effectively with ampicillin alone.

Meningitis. Acute bacterial meningitis in children is most frequently due to *S. pneumoniae* or *N. meningitidis*. Since 20% to 30% of strains of *S. pneumoniae* now may be resistant to this antibiotic, ampicillin is not indicated for single-agent treatment of meningitis. Ampicillin has excellent activity against *L. monocytogenes*, a cause of meningitis in immunocompromised persons. Thus the combination of ampicillin and vancomycin plus a third-generation cephalosporin is a rational regimen for empirical treatment of suspected bacterial meningitis.

Salmonella Infections. Disease associated with bacteremia, disease with metastatic foci, and the enteric fever syndrome (including typhoid fever) respond favorably to antibiotics. A fluoroquinolone or ceftriaxone is considered by some to be the drug of choice, but the administration of trimethoprim–sulfamethoxazole or high doses of ampicillin (12 g/day for adults) also is effective. In some geographical areas, resistance to ampicillin is common. The typhoid carrier state has been eliminated successfully in patients without gallbladder disease with ampicillin, trimethoprim–sulfamethoxazole, or ciprofloxacin.

Antipseudomonal Penicillins: The Carboxypenicillins and the Ureidopenicillins

The carboxypenicillins, *carbenicillin* and *ticarcillin* and their close relatives, are active against some isolates of *P. aeruginosa* and certain indole-positive *Proteus* spp. that are resistant to ampicillin and its congeners. They are ineffective against most strains of *S. aureus*, *Enterococcus faecalis*, *Klebsiella*, and *L. monocytogenes*. *B. fragilis* is susceptible to high concentrations of these drugs, but penicillin G is actually more active on the basis of weight. The ureidopenicillins, *mezlocillin* and *piperacillin*, have superior activity against *P. aeruginosa* compared with carbenicillin and ticarcillin. In addition, mezlocillin and piperacillin are useful for treatment of infections with *Klebsiella*. The carboxypenicillins and the ureidopenicillins are sensitive to destruction by β -lactamases.

Carbenicillin and Carbenicillin Indanyl. Carbenicillin. This drug is a penicillinase-susceptible derivative of 6-aminopenicillanic acid. Its structural formula is shown in Table 44–1. Carbenicillin was the first penicillin with activity against *P. aeruginosa* and some *Proteus* strains that are resistant to ampicillin. Because carbenicillin is supplied as a disodium salt, it contains about 5 mEq Na⁺ per gram of drug, and this will result in the administration of more than 100 mEq Na⁺ when patients are treated for *P. aeruginosa* infections. Carbenicillin has been superseded by ticarcillin or piperacillin (*see below*).

Preparations of carbenicillin may cause adverse effects in addition to those which follow the use of other penicillins (*see below*). Congestive heart failure may result from the administration of excessive Na⁺. Hypokalemia may occur because of obligatory excretion of cation with the large amount of nonreabsorbable anion (carbenicillin) presented to the distal renal tubule. The drug interferes with platelet function, and bleeding may occur because of abnormal aggregation of platelets.

Carbenicillin Indanyl Sodium (GEOCILLIN). This congener is the indanyl ester of carbenicillin; it is acid stable and is suitable for oral administration. After absorption, the ester is converted rapidly to carbenicillin by hydrolysis of the ester linkage. The antimicrobial spectrum of the drug is therefore that of carbenicillin. Although the concentration of carbenicillin reached in the serum is not high enough to treat a systemic *Pseudomonas* infection, the active moiety is excreted rapidly in the urine, where it achieves effective concentrations. Thus the only use of this drug is for the management of urinary tract infections caused by *Proteus* spp. other than *P. mirabilis* and by *P. aeruginosa*.

Ticarcillin (TICAR). This semisynthetic penicillin (Table 44–1) is very similar to carbenicillin, but it is two to four times more active against *P. aeruginosa*. Ticarcillin is inferior to piperacillin for the treatment of serious infections caused by *Pseudomonas*.

Mezlocillin. This ureidopenicillin is more active against *Klebsiella* than is carbenicillin; its activity against *Pseudomonas in vitro* is similar to that of ticarcillin. It is more active than ticarcillin against *E. faecalis*. *Mezlocillin sodium* (MEZLIN) has been discontinued in the United States.

Piperacillin. Piperacillin (PIPRACIL) extends the spectrum of ampicillin to include most strains of *P. aeruginosa*, Enterobacteriaceae (non- β -lactamase-producing), many *Bacteroides* spp., and *E. faecalis*. In combination with a β -lactamase inhibitor (*piperacillin–tazobactam*, ZOSYN) it has the broadest antibacterial spectrum of the penicillins. Pharmacokinetic properties are reminiscent of the other ureidopenicillins. High biliary concentrations are achieved.

Therapeutic Indications. Piperacillin and related agents are important agents for the treatment of patients with serious infections caused by gram-negative bacteria. Such patients frequently have impaired immunological defenses, and their infections often are acquired in the hospital. Therefore, these penicillins find their greatest use in treat-

ing bacteremias, pneumonias, infections following burns, and urinary tract infections owing to microorganisms resistant to penicillin G and ampicillin; the bacteria especially responsible include *P. aeruginosa*, indole-positive strains of *Proteus*, and *Enterobacter* spp. Since *Pseudomonas* infections are common in neutropenic patients, therapy for severe bacterial infections in such individuals should include a β -lactam antibiotic such as piperacillin with good activity against these microorganisms.

Untoward Reactions to Penicillins

Hypersensitivity Reactions. Hypersensitivity reactions are by far the most common adverse effects noted with the penicillins, and these agents probably are the most common cause of drug allergy. Allergic reactions complicate between 0.7% and 4% of all treatment courses. There is no convincing evidence that any single penicillin differs from the group in its potential for causing true allergic reactions. In approximate order of decreasing frequency, manifestations of allergy to penicillins include maculopapular rash, urticarial rash, fever, bronchospasm, vasculitis, serum sickness, exfoliative dermatitis, Stevens–Johnson syndrome, and anaphylaxis (Weiss and Adkinson, 2000). The overall incidence of such reactions to the penicillins varies from 0.7% to 10% in different studies.

Hypersensitivity reactions may occur with any dosage form of penicillin; allergy to one penicillin exposes the patient to a greater risk of reaction if another is given. On the other hand, the occurrence of an untoward effect does not necessarily imply repetition on subsequent exposures. Hypersensitivity reactions may appear in the absence of a previous known exposure to the drug. This may be caused by unrecognized prior exposure to penicillin in the environment (*e.g.*, in foods of animal origin or from the fungus-producing penicillin). Although elimination of the antibiotic usually results in rapid clearing of the allergic manifestations, they may persist for 1 or 2 weeks or longer after therapy has been stopped. In some cases, the reaction is mild and disappears even when the penicillin is continued; in others, immediate cessation of penicillin treatment is required. In a few instances, it is necessary to interdict the future use of penicillin because of the risk of death, and the patient should be so warned. It must be stressed that fatal episodes of anaphylaxis have followed the ingestion of very small doses of this antibiotic or skin testing with minute quantities of the drug.

Penicillins and their breakdown products act as haptens after covalent reaction with proteins. The most abundant breakdown product is the penicilloyl moiety [major determinant moiety (MDM)], which is formed when the β -lac-

tam ring is opened. A large percentage of IgE-mediated reactions are to the MDM, but at least 25% of reactions are to other breakdown products, and the severities of the reactions to the various products are comparable. These products are formed *in vivo* and can be found in solutions of penicillin prepared for administration. The terms *major* and *minor determinants* refer to the frequency with which antibodies to these haptens appear to be formed. They do not describe the severity of the reaction that may result. In fact, anaphylactic reactions to penicillin usually are mediated by IgE antibodies against the minor determinants.

Antipenicillin antibodies are detectable in virtually all patients who have received the drug and in many who have never knowingly been exposed to it. Recent treatment with the antibiotic induces an increase in major-determinant-specific antibodies that are skin sensitizing. The incidence of positive skin reactors is three to four times higher in atopic than in nonatopic individuals. Clinical and immunological studies suggest that immediate allergic reactions are mediated by skin-sensitizing or IgE antibodies, usually of minor-determinant specificities. Accelerated and late urticarial reactions usually are mediated by major-determinant-specific skin-sensitizing antibodies. The recurrent-arthritis syndrome appears to be related to the presence of skin-sensitizing antibodies of minor-determinant specificities. Some maculopapular and erythematous reactions may be due to toxic antigen-antibody complexes of major-determinant-specific IgM antibodies. Accelerated and late urticarial reactions to penicillin may terminate spontaneously because of the development of blocking antibodies.

Skin rashes of all types may be caused by allergy to penicillin. Scarletiform, morbilliform, urticarial, vesicular, and bullous eruptions may develop. Purpuric lesions are uncommon and usually are the result of a vasculitis; thrombocytopenic purpura may occur very rarely. Henoch–Schönlein purpura with renal involvement has been a rare complication. Contact dermatitis is observed occasionally in pharmacists, nurses, and physicians who prepare penicillin solutions. Fixed-drug reactions also have occurred. More severe reactions involving the skin are exfoliative dermatitis and exudative erythema multiforme of either the erythematopapular or vesiculobullous type; these lesions may be very severe and atypical in distribution and constitute the characteristic Stevens–Johnson syndrome. The incidence of skin rashes appears to be highest following the use of ampicillin, being about 9%; rashes follow the administration of ampicillin in nearly all patients with infectious mononucleosis. When *allopurinol* and ampicillin are administered concurrently, the incidence of rash

also increases. Ampicillin-induced skin eruptions in such patients may represent a “toxic” rather than a truly allergic reaction. Positive skin reactions to the major and minor determinants of penicillin sensitization may be absent. The rash may clear even while administration of the drug is continued.

The most serious hypersensitivity reactions produced by the penicillins are angioedema and anaphylaxis. Angioedema, with marked swelling of the lips, tongue, face, and periorbital tissues, frequently accompanied by asthmatic breathing and “giant hives,” has been observed after topical, oral, or systemic administration of penicillins of various types.

Acute anaphylactic or anaphylactoid reactions induced by various preparations of penicillin constitute the most important immediate danger connected with their use. Among all drugs, the penicillins are most often responsible for this type of untoward effect. Anaphylactoid reactions may occur at any age. Their incidence is thought to be 0.004% to 0.04% in persons treated with penicillins (Kucers and Bennett, 1987). About 0.001% of patients treated with these agents die from anaphylaxis. It has been estimated that there are at least 300 deaths per year due to this complication of therapy. About 70% have had penicillin previously, and one-third of these reacted to it on a prior occasion. Anaphylaxis most often has followed the injection of penicillin, although it also has been observed after oral ingestion of the drug and even has resulted from the intradermal instillation of a very small quantity for the purpose of testing for the presence of hypersensitivity. The clinical pictures that develop vary in severity. The most dramatic is sudden, severe hypotension and rapid death. In other instances, bronchoconstriction with severe asthma; abdominal pain, nausea, and vomiting; extreme weakness and a fall in blood pressure; or diarrhea and purpuric skin eruptions have characterized the anaphylactic episodes.

Serum sickness varies from mild fever, rash, and leukopenia to severe arthralgia or arthritis, purpura, lymphadenopathy, splenomegaly, mental changes, electrocardiographic abnormalities suggestive of myocarditis, generalized edema, albuminuria, and hematuria. It is mediated by IgG antibodies. This reaction is rare, but when it occurs, it appears after penicillin treatment has been continued for 1 week or more; it may be delayed, however, until 1 or 2 weeks after the drug has been stopped. Serum sickness caused by penicillin may persist for a week or longer.

Vasculitis of the skin or other organs may be related to penicillin hypersensitivity. The Coombs reaction frequently becomes positive during prolonged therapy with a

penicillin or cephalosporin, but hemolytic anemia is rare. Reversible neutropenia may occur. It is not known if this is truly a hypersensitivity reaction; it has been noted with all the penicillins and has been seen in up to 30% of patients treated with 8 to 12 g nafcillin for longer than 21 days. The bone marrow shows an arrest of maturation.

Fever may be the only evidence of a hypersensitivity reaction to the penicillins. It may reach high levels and be maintained, remittent, or intermittent; chills occur occasionally. The febrile reaction usually disappears within 24 to 36 hours after administration of the drug is stopped but may persist for days.

Eosinophilia is an occasional accompaniment of other allergic reactions to penicillin. At times, it may be the sole abnormality, and eosinophils may reach levels of 10% to 20% or more of the total number of circulating white blood cells.

Penicillins rarely cause interstitial nephritis; methicillin has been implicated most frequently. Hematuria, albuminuria, pyuria, renal cell and other casts in the urine, elevation of serum creatinine, and even oliguria have been noted. Biopsy shows a mononuclear infiltrate with eosinophilia and tubular damage. IgG is present in the interstitium. This reaction usually is reversible.

Management of the Patient Potentially Allergic to Penicillin. Evaluation of the patient’s history is the most practical way to avoid the use of penicillin in patients who are at the greatest risk of adverse reaction. Most patients who give a history of allergy to penicillin should be treated with a different type of antibiotic. Unfortunately, there is no totally reliable means to confirm a history of penicillin allergy (Romano *et al.*, 2003). Skin testing for IgE-mediated immediate-type responses is compromised by the lack of a commercially available minor-determinant mixture. Skin testing using major and minor penicillin determinants to predict allergic reactions to synthetic penicillins is useful if the reagents are generally available. An NIAID multicenter study used major and minor determinants for skin testing. Of 726 patients with a history of penicillin allergy, 566 had negative skin tests. Of those, only 7 of 566 (1.2%) had possibly IgE-mediated immediate or accelerated penicillin allergy when given penicillin (Sogn *et al.*, 1992). Radioallergosorbent tests (RASTs) for IgE antipenicilloyl determinants suffer from the same limitations as skin tests (Weiss and Adkinson, 2000).

Occasionally, *desensitization* is recommended for penicillin-allergic patients who must receive the drug. This procedure consists of administering gradually increasing doses of penicillin in the hope of avoiding a severe reaction and should be performed only in an intensive care

setting. This may result in a subclinical anaphylactic discharge and the binding of all IgE before full doses are administered. Penicillin may be given in doses of 1, 5, 10, 100, and 1000 units intradermally in the lower arm, with 60-minute intervals between doses. If this is well tolerated, then 10,000 and 50,000 units may be given subcutaneously. Desensitization also may be accomplished by the oral administration of penicillin. When full doses are reached, penicillin should not be discontinued and then restarted because immediate reactions may recur (*see* Weiss and Adkinson, 2000, for details). The patient should be observed constantly during the desensitizing procedure, an intravenous line must be in place, and epinephrine and equipment and expertise for artificial ventilation must be on hand. It must be emphasized that this procedure may be dangerous, and its efficacy is unproven.

Patients with life-threatening infections (*e.g.*, endocarditis or meningitis) may be continued on penicillin despite the development of a maculopapular rash, although alternative antimicrobial agents should be used whenever possible. The rash often resolves as therapy is continued, perhaps owing to the development of blocking antibodies of the IgG class. The rash may be treated with *antihistamines* or *glucocorticoids*, although there is no evidence that this therapy is efficacious. Rarely, exfoliative dermatitis with or without vasculitis develops in these patients if therapy with penicillin is continued.

Other Adverse Reactions. The penicillins have minimal direct toxicity. Apparent toxic effects that have been reported include bone marrow depression, granulocytopenia, and hepatitis. The last-named effect is rare but is seen most commonly following the administration of oxacillin and nafcillin. The administration of penicillin G, carbenicillin, piperacillin, or ticarcillin has been associated with a potentially significant defect of hemostasis that appears to be due to an impairment of platelet aggregation; this may be caused by interference with the binding of aggregating agents to platelet receptors (Fass *et al.*, 1987).

Most common among the irritative responses to penicillin are pain and sterile inflammatory reactions at the sites of intramuscular injections—reactions that are related to concentration. Serum transaminases and lactic dehydrogenase may be elevated as a result of local damage to muscle. In some individuals who receive penicillin intravenously, phlebitis or thrombophlebitis develops. Many persons who take various penicillin preparations by mouth experience nausea, with or without vomiting, and some have mild to severe diarrhea. These manifestations often are related to the dose of the drug.

When penicillin is injected accidentally into the sciatic nerve, severe pain occurs and dysfunction in the area of distribution of this nerve develops and persists for weeks. Intrathecal injection of penicillin G may produce arachnoiditis or severe and fatal encephalopathy. Because of this, intrathecal or intraventricular administration of penicillins should be avoided. The parenteral administration of large doses of penicillin G (>20 million units per day, or less with renal insufficiency) may produce lethargy, confusion, twitching, multifocal myoclonus, or localized or generalized epileptiform seizures. These are

most apt to occur in the presence of renal insufficiency, localized lesions of the central nervous system (CNS), or hyponatremia. When the concentration of penicillin G in CSF exceeds 10 $\mu\text{g/ml}$, significant dysfunction of the CNS is frequent. The injection of 20 million units of penicillin G potassium, which contains 34 mEq of K^+ , may lead to severe or even fatal hyperkalemia in persons with renal dysfunction.

Injection of penicillin G procaine may result in an immediate reaction, characterized by dizziness, tinnitus, headache, hallucinations, and sometimes seizures. This is due to the rapid liberation of toxic concentrations of procaine. It has been reported to occur in 1 of 200 patients receiving 4.8 million units of penicillin G procaine to treat venereal disease.

Reactions Unrelated to Hypersensitivity or Toxicity. Regardless of the route by which the drug is administered, but most strikingly when it is given by mouth, penicillin changes the composition of the microflora by eliminating sensitive microorganisms. This phenomenon is usually of no clinical significance, and the normal microflora are reestablished shortly after therapy is stopped. In some persons, however, superinfection results from the changes in flora. Pseudomembranous colitis, related to overgrowth and production of a toxin by *Clostridium difficile*, has followed oral and, less commonly, parenteral administration of penicillins.

THE CEPHALOSPORINS

History and Source. *Cephalosporium acremonium*, the first source of the cephalosporins, was isolated in 1948 by Brotzu from the sea near a sewer outlet off the Sardinian coast. Crude filtrates from cultures of this fungus were found to inhibit the *in vitro* growth of *S. aureus* and to cure staphylococcal infections and typhoid fever in human beings. Culture fluids in which the Sardinian fungus was cultivated were found to contain three distinct antibiotics, which were named *cephalosporin P*, *N*, and *C*. With isolation of the active nucleus of cephalosporin C, 7-aminocephalosporanic acid, and with the addition of side chains, it became possible to produce semisynthetic compounds with antibacterial activity very much greater than that of the parent substance.

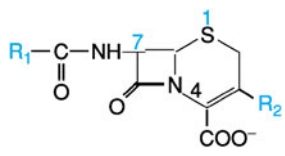

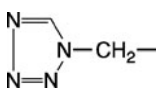

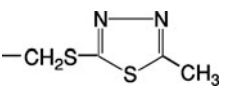

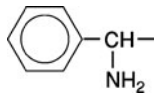

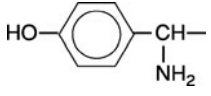

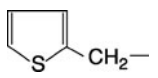

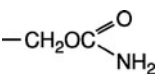

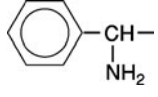

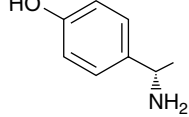

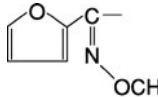

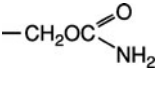

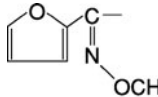

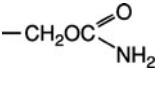

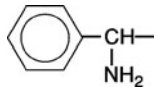

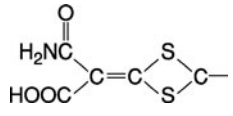

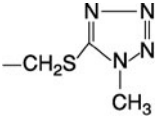

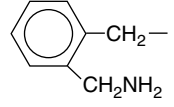

Chemistry. Cephalosporin C contains a side chain derived from D- α -aminoadipic acid, which is condensed with a dihydrothiazine β -lactam ring system (7-aminocephalosporanic acid). Compounds containing 7-aminocephalosporanic acid are relatively stable in dilute acid and highly resistant to penicillinase regardless of the nature of their side chains and their affinity for the enzyme.

Cephalosporin C can be hydrolyzed by acid to 7-aminocephalosporanic acid. This compound subsequently has been modified by the addition of different side chains to create a whole family of cephalosporin antibiotics. It appears that modifications at position 7 of the β -lactam ring are associated with alteration in antibacterial activity and that substitutions at position 3 of the dihydrothiazine ring are associated with changes in the metabolism and pharmacokinetic properties of the drugs.

The *cephamycins* are similar to the cephalosporins but have a methoxy group at position 7 of the β -lactam ring of the 7-aminocephalosporanic acid nucleus. The structural formulas of representative cephalosporins and cephamycins are shown in Table 44-2.

Table 44-2

Names, Structural Formulas, Dosage, and Dosage Forms of Selected Cephalosporins and Related Compounds

COMPOUND (TRADE NAMES)	R ₁	R ₂	DOSAGE FORMS,* ADULT DOSAGE FOR SEVERE INFECTION, AND t _{1/2}
 <p>Cephim nucleus</p>			
<i>First-generation</i>			
Cefazolin (ANCEF, KEFZOL, others)			I: 1 to 1.5 g every 6 hours t _{1/2} = about 2 hours
Cephalexin (KEFLEX, others)			O: 1 g every 6 hours t _{1/2} = 0.9 hour
Cefadroxil (DURICEF)			O: 1 g every 12 hours t _{1/2} = 1.1 hours
<i>Second-generation</i>			
Cefoxitin [†] (MEFOXIN)			I: 2 g every 4 hours or 3 g every 6 hours t _{1/2} = 0.7 hours
Cefaclor (CECLOR)			O: 1 g every 8 hours t _{1/2} = 0.7 hours
Cefprozil (CEFZIL)			O: 500 mg every 12 hours t _{1/2} = 1.3 hours
Cefuroxime (ZINACEF)			I: up to 3 g every 8 hours t _{1/2} = 1.7 hours
Cefuroxime acetyl [‡] (CEFTIN)			T: 500 mg every 12 hours
Loracarbef [¶] (LORABID)			O: 200 to 400 mg every 12 hours t _{1/2} = 1.1 hours
Cefotetan (CEFOTAN)			I: 2 to 3 g every 12 hours t _{1/2} = 3.3 hours
Ceforanide (PRECEF)			I: 1 g every 12 hours t _{1/2} = 2.6 hours

Ceftazidime (HORTAZ, others)			I: 2 g every 8 hours t _{1/2} = 1.8 hours
<i>Fourth-generation</i>			
Cefepime (MAXIPIME)			I: 2 g every 8 hours t _{1/2} = 2 hours

*T, tablet; C, capsule; O, oral suspension; I, injection †Cefoxitin, a cophamycin, has a -OCH₃ group at position 7 of cephem nucleus. ‡Cefuroxime axetil is the acetyloxyethyl ester of cefuroxime. §Loracarbef, a carbacephem, has a carbon instead of sulfur at position 1 of cephem nucleus. §Cefpodoxime proxetil has a -COOCH(CH₃)OCOCH(CH₃)₂ group at position 4 of cephem nucleus.

Table 44–3
Cephalosporin Generations

EXAMPLES	USEFUL SPECTRUM ^a
First Generation	
Cefazolin (ANCEF, ZOLICEF, others)	Streptococci ^b ; <i>Staphylococcus aureus</i> . ^c
Cephalexin monohydrate (KEFTAB)	
Cefadroxil (DURACEF)	
Cephradine (VELOSEF)	
Second Generation	
Cefuroxime (ZINACEF)	<i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Proteus</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> . Not as active against gram-positive organ- isms as first-generation agents.
Cefuroxime axetil (CEFTIN)	
Cefprozil (CEFZIL)	Inferior activity against <i>S. aureus</i> compared to cefuroxime but with added activity against <i>Bacteroides fragilis</i> and other <i>Bacteroides</i> spp.
Cefmetazole (ZEFAZONE)	
Loracarbef (LORABID)	
Third Generation	
Cefotaxime (CLAFORAN)	Enterobacteriaceae ^d ; <i>Pseudomonas aeruginosa</i> ^e ; <i>Serratia</i> ; <i>Neisseria</i> <i>gonorrhoeae</i> ; activity for <i>S. aureus</i> , <i>Streptococcus pneumoniae</i> , and <i>Streptococcus pyogenes</i> ^f comparable to first-generation agents. Activity against <i>Bacteroides</i> spp. inferior to that of cefoxitin and cefotetan.
Ceftriaxone (ROCEPHIN)	
Cefdinir (OMNICEF)	
Cefditoren pivoxil (SPECTRACEF)	
Ceftibuten (CEDAX)	
Cefpodoxime proxetil (VANTIN)	
Ceftizoxime (CEFIZOX)	
Cefoperazone (CEFOBID) } Ceftazidime (FORTAZ, others) }	Active against <i>Pseudomonas</i>
Fourth Generation	
Cefepine (MAXIPINE)	Comparable to third-generation but more resistant to some β -lactamases.

^aAll cephalosporins lack activity against enterococci, *Listeria monocytogenes*, *Legionella* spp., methicillin-resistant *S. aureus*, *Xanthomonas maltophilia*, and *Acinetobacter* species. ^bExcept for penicillin-resistant strains. ^cExcept for methicillin-resistant strains. ^dResistance to cephalosporins may be induced rapidly during therapy by de-repression of bacterial chromosomal β -lactamases, which destroy the cephalosporins. ^eCeftazidime only. ^fCeftazidime lacks significant gram-positive activity. Cefotaxime is most active in class against *S. aureus* and *S. pyogenes*.

Mechanism of Action. Cephalosporins and cephamycins inhibit bacterial cell wall synthesis in a manner similar to that of penicillin. This was discussed in detail earlier.

Classification. The large number of cephalosporins makes a system of classification most desirable. Although cephalosporins may be classified by their chemical structure, clinical pharmacology, resistance to β -lactamase, or antimicrobial spectrum, the well-accepted system of classification by “generations” is very useful, although admittedly somewhat arbitrary (Table 44–3).

Classification by generations is based on general features of antimicrobial activity (see Karchmer, 2000). The *first-generation* cephalosporins, epitomized by *cephalothin* and *cefazolin*, have good activity against gram-positive bacteria and relatively modest activity against gram-negative microorganisms. Most gram-positive cocci (with

the exception of enterococci, methicillin-resistant *S. aureus*, and *S. epidermidis*) are susceptible. Most oral cavity anaerobes are sensitive, but the *B. fragilis* group is resistant. Activity against *Moraxella catarrhalis*, *E. coli*, *K. pneumoniae*, and *P. mirabilis* is good. The *second-generation* cephalosporins have somewhat increased activity against gram-negative microorganisms but are much less active than the third-generation agents. A subset of second-generation agents (*cefoxitin*, *cefotetan*, and *cefmetazole*) also is active against the *B. fragilis* group. *Third-generation* cephalosporins generally are less active than first-generation agents against gram-positive cocci, but they are much more active against the Enterobacteriaceae, including β -lactamase-producing strains. A subset of third-generation agents (*ceftazidime* and *cefoperazone*) also is active against *P. aeruginosa* but less active than other third-generation agents against gram-positive cocci.

Fourth-generation cephalosporins, such as *cefepime*, have an extended spectrum of activity compared with the third generation and have increased stability from hydrolysis by plasmid and chromosomally mediated β -lactamases. Fourth-generation agents are particularly useful for the empirical treatment of serious infections in hospitalized patients when gram-positive microorganisms, Enterobacteriaceae, and *Pseudomonas* all are potential etiologies. It is important to remember that none of the cephalosporins has reliable activity against the following bacteria: penicillin-resistant *S. pneumoniae*, methicillin-resistant *S. aureus*, methicillin-resistant *S. epidermidis* and other coagulase-negative staphylococci, *Enterococcus*, *L. monocytogenes*, *Legionella pneumophila*, *L. micdadei*, *C. difficile*, *Xanthomonas maltophilia*, *Campylobacter jejuni*, and *Acinetobacter* spp.

Mechanisms of Bacterial Resistance to the Cephalosporins. Resistance to the cephalosporins may be related to the inability of the antibiotic to reach its sites of action or to alterations in the penicillin-binding proteins (PBPs) that are targets of the cephalosporins such that the antibiotics bind to bacterial enzymes (β -lactamases) that can hydrolyze the β -lactam ring and inactivate the cephalosporin. Alterations in two PBPs (1A and 2X) that release their affinity for cephalosporins render pneumococci resistant to third-generation cephalosporins because the other three high-molecular-weight PBPs have inherently low affinity (Spratt, 1994).

The most prevalent mechanism of resistance to cephalosporins is destruction of the cephalosporins by hydrolysis of the β -lactam ring. Many gram-positive microorganisms release relatively large amounts of β -lactamase into the surrounding medium. Although gram-negative bacteria seem to produce less β -lactamase, the location of their enzyme in the periplasmic space may make it more effective in destroying cephalosporins as they diffuse to their targets on the inner membrane, as is the case for the penicillins. The cephalosporins have variable susceptibility to β -lactamase. For example, of the first-generation agents, cefazolin is more susceptible to hydrolysis by β -lactamase from *S. aureus* than is cephalothin (no longer marketed). Cefoxitin, cefuroxime, and the third-generation cephalosporins are more resistant to hydrolysis by the β -lactamases produced by gram-negative bacteria than first-generation cephalosporins. Third-generation cephalosporins are susceptible to hydrolysis by inducible, chromosomally encoded (type I) β -lactamases. Induction of type I β -lactamases by treatment of infections owing to aerobic gram-negative bacilli (especially *Enterobacter* spp., *Citrobacter freundii*, *Morganella*, *Serratia*, *Providencia*, and *P. aeruginosa*) with second- or third-generation cephalosporins and/or imipenem may result in resistance to all third-generation cephalosporins. The fourth-generation cephalosporins, such as cefepime, are poor inducers of type I β -lactamases and are less susceptible to hydrolysis by type I β -lactamases than are the third-generation agents. These type I β -lactamases are not detected in routine laboratory testing until a mutation occurs that makes their expression constitutive.

General Features of the Cephalosporins. *Cephalexin*, *cephradine*, *cefactor*, *cefadroxil*, *loracarbef*, *cefprozil*, *cefpodoxime proxetil*, *ceftibuten*, and *cefuroxime axetil*

are absorbed readily after oral administration. Cefprozil, *cefdinir*, *ceftibuten*, and *cefditoren* are also effective orally. The other cephalosporins can be administered intramuscularly or intravenously.

Cephalosporins are excreted primarily by the kidney; dosage thus should be altered in patients with renal insufficiency. Probenecid slows the tubular secretion of most cephalosporins. *Cefpiramide* (not available in the United States) and cefoperazone are exceptions because they are excreted predominantly in the bile. *Cefotaxime* is deacetylated *in vivo*. The metabolite has less antimicrobial activity than the parent compound and is excreted by the kidneys. None of the other cephalosporins appears to undergo appreciable metabolism.

Several cephalosporins penetrate into CSF in sufficient concentration to be useful for the treatment of meningitis. These include cefotaxime, ceftriaxone, and cefepime (see “Therapeutic Uses” below). Cephalosporins also cross the placenta, and they are found in high concentrations in synovial and pericardial fluids. Penetration into the aqueous humor of the eye is relatively good after systemic administration of third-generation agents, but penetration into the vitreous humor is poor. There is some evidence that concentrations sufficient for therapy of ocular infections owing to gram-positive and certain gram-negative microorganisms can be achieved after systemic administration. Concentrations in bile usually are high, with those achieved after administration of cefoperazone and cefpiramide being the highest.

Specific Agents

First-Generation Cephalosporins. The antibacterial spectrum of cefazolin is typical of other first-generation cephalosporins except that it has activity against some *Enterobacter* spp. Cefazolin is relatively well tolerated after either intramuscular or intravenous administration, and concentrations of the drug in plasma after a 1-g intramuscular injection reach 64 $\mu\text{g/ml}$. Cefazolin is excreted by glomerular filtration and is bound to plasma proteins to a great extent (about 85%). Cefazolin usually is preferred among the first-generation cephalosporins because it can be administered less frequently owing to its longer half-life.

Cephalexin is available for oral administration, and it has the same antibacterial spectrum as the other first-generation cephalosporins. However, it is somewhat less active against penicillinase-producing staphylococci. Oral therapy with cephalexin results in peak concentrations in plasma of 16 $\mu\text{g/ml}$ after a dose of 0.5 g; this is adequate for the inhibition of many gram-positive and gram-negative pathogens. The drug is not metabolized, and between 70% and 100% is excreted in the urine.

Cephadrine is similar in structure to cephalexin, and its activity *in vitro* is almost identical. Cephadrine is not metabolized and, after rapid absorption from the gastrointestinal tract, is excreted unchanged in the urine. Cephadrine can be administered orally, intramuscularly, or intravenously. When administered orally, it is difficult to distinguish cephadrine from cephalexin; some authorities feel that these

two drugs can be used interchangeably. Because cephradine is so well absorbed, the concentrations in plasma are nearly equivalent after oral or intramuscular administration.

Cefadroxil is the *para*-hydroxy analog of cephalexin. Concentrations of cefadroxil in plasma and urine are at somewhat higher levels than are those of cephalexin. The drug may be administered orally once or twice a day for the treatment of urinary tract infections. Its activity *in vitro* is similar to that of cephalexin.

Second-Generation Cephalosporins. Second-generation cephalosporins have a broader spectrum than do the first-generation agents and are active against *Enterobacter* spp., indole-positive *Proteus* spp., and *Klebsiella* spp.

Cefoxitin is a cephamycin produced by *Streptomyces lactamdurans*. It is resistant to some β -lactamases produced by gram-negative rods (Barradell and Bryson, 1994). This antibiotic is less active than the first-generation cephalosporins against gram-positive bacteria. Cefoxitin is more active than other first- or second-generation agents (except cefotetan) against anaerobes, especially *B. fragilis*. After an intramuscular dose of 1 g, concentrations in plasma are about 22 $\mu\text{g}/\text{ml}$. The half-life is approximately 40 minutes. Cefoxitin's special role seems to be for treatment of certain anaerobic and mixed aerobic-anaerobic infections, such as pelvic inflammatory disease and lung abscess.

Cefaclor is used orally. The concentration in plasma after oral administration is about 50% of that achieved after an equivalent oral dose of cephalexin. However, cefaclor is more active against *H. influenzae* and *Moraxella catarrhalis*, although some β -lactamase-producing strains of these organisms may be resistant (Jorgensen *et al.*, 1990).

Loracarbef is an orally administered carbacephin, similar in activity to cefaclor, that is more stable against some β -lactamases (Jorgensen *et al.*, 1990). The serum half-life is 1.1 hours.

Cefuroxime is similar to loracarbef with broader gram-negative activity against some *Citrobacter* and *Enterobacter* spp. Unlike cefoxitin, cefmetazole, and cefotetan, cefuroxime lacks activity against *B. fragilis*. The half-life is 1.7 hours, and the drug can be given every 8 hours. Concentrations in CSF are about 10% of those in plasma, and the drug is effective (but inferior to ceftriaxone) for treatment of meningitis owing to *H. influenzae* (including strains resistant to ampicillin), *N. meningitidis*, and *S. pneumoniae* (Schaad *et al.*, 1990).

Cefuroxime axetil is the 1-acetyloxyethyl ester of cefuroxime. Between 30% and 50% of an oral dose is absorbed, and the drug then is hydrolyzed to cefuroxime; resulting concentrations in plasma are variable.

Cefotetan is a cephamycin, and like cefoxitin, it has good activity against *B. fragilis*. It also is effective against several other species of *Bacteroides*, and it is slightly more active than cefoxitin against gram-negative aerobes. After an intramuscular dose of 1 g, peak plasma concentrations of cefotetan average 70 $\mu\text{g}/\text{ml}$. It has a half-life of 3.3 hours (Phillips *et al.*, 1983; Wexler and Finegold, 1988). Hypoprothrombinemia and inhibition of vitamin K activation with bleeding have occurred in malnourished patients receiving cefotetan owing to the methyl-tetrazole-thiomethyl (MTT) group at position 3; this is preventable if vitamin K is administered as well.

Cefprozil is an orally administered agent that is more active than first-generation cephalosporins against penicillin-sensitive streptococci, *E. coli*, *P. mirabilis*, *Klebsiella* spp., and *Citrobacter* spp. It has a serum half-life of 1.2 to 1.4 hours (Barriere, 1992).

Third-Generation Cephalosporins. Cefotaxime is highly resistant to many (but not the extended-spectrum product) of the bacterial β -lac-

tamases and has good activity against many gram-positive and gram-negative aerobic bacteria. However, activity against *B. fragilis* is poor compared with agents such as clindamycin and metronidazole (Neu *et al.*, 1979). Cefotaxime has a half-life in plasma of about 1 hour and should be administered every 4 to 8 hours for serious infections. The drug is metabolized *in vivo* to desacetylcefotaxime, which is less active against most microorganisms than is the parent compound. However, the metabolite acts synergistically with the parent compound against certain microbes. Cefotaxime has been used effectively for meningitis caused by *H. influenzae*, penicillin-sensitive *S. pneumoniae*, and *N. meningitidis*.

Ceftizoxime has a spectrum of activity *in vitro* that is very similar to that of cefotaxime, except that it is less active against *S. pneumoniae* and more active against *B. fragilis* (Haas *et al.*, 1995). The half-life is somewhat longer, 1.8 hours, and the drug thus can be administered every 8 to 12 hours for serious infections. Ceftizoxime is not metabolized, and 90% is recovered in urine (Neu *et al.*, 1982).

Ceftriaxone has activity *in vitro* very similar to that of ceftizoxime and cefotaxime. A half-life of about 8 hours is the outstanding feature. Administration of the drug once or twice daily has been effective for patients with meningitis (Del Rio *et al.*, 1983; Brogden and Ward, 1988), whereas dosage once a day has been effective for other infections (Baumgartner and Glauser, 1983). About half the drug can be recovered from the urine; the remainder appears to be eliminated by biliary secretion. A single dose of ceftriaxone (125 to 250 mg) is effective in the treatment of urethral, cervical, rectal, or pharyngeal gonorrhea, including disease caused by penicillinase-producing microorganisms.

Cefpodoxime proxetil is an orally administered third-generation agent that is very similar in activity to the fourth-generation agent cefepime (*see below*) except that it is not more active against *Enterobacter* or *Pseudomonas* spp. It has a serum half-life of 2.2 hours.

Cefditoren pivoxil is a prodrug that is hydrolyzed by esterases during absorption to the active drug, cefditoren. Cefditoren has a half-life of approximately 1.6 hours and is eliminated unchanged in the urine. The drug is active against methicillin-susceptible strains of *S. aureus*, penicillin-susceptible strains of *S. pneumoniae*, *S. pyogenes*, *H. influenzae*, *H. parainfluenzae*, and *Moraxella catarrhalis*. Cefditoren pivoxil is only indicated for the treatment of mild-to-moderate pharyngitis, tonsillitis, uncomplicated skin and skin structure infections, and acute exacerbations of chronic bronchitis.

Ceftibuten is an orally effective cephalosporin with a half-life of 2.4 hours. It is less active against gram-positive and gram-negative organisms than cefixime, with activity limited to *S. pneumoniae* and *S. pyogenes*, *H. influenzae*, and *M. catarrhalis*. Ceftibuten is only indicated for acute bacterial exacerbations of chronic bronchitis, acute bacterial otitis media, pharyngitis, and tonsillitis.

Cefdinir is effective orally, with a half-life of approximately 1.7 hours; it is eliminated primarily unchanged in the urine. Cefdinir has a spectrum of activity similar to cefixime. It is inactive against *Pseudomonas* and *Enterobacter* spp.

Third-Generation Cephalosporins with Good Activity Against Pseudomonas. Ceftazidime is one-quarter to one-half as active by weight against gram-positive microorganisms as is cefotaxime. Its activity against the Enterobacteriaceae is very similar, but its major distinguishing feature is excellent activity against *Pseudomonas* and other gram-negative bacteria. Ceftazidime has poor activity against *B. fragilis* (Hamilton-Miller and Brumfitt, 1981). Its half-life in plasma is about 1.5 hours, and the drug is not metabolized. Ceftazidime is more active *in vitro* against *Pseudomonas* than is piperacillin (Edmond *et al.*, 1999; Sahn *et al.*, 1999).

Fourth-Generation Cephalosporins. Cefepime and *ceftiprome* are fourth-generation cephalosporins. Cefepime is available for use in the United States, but *ceftiprome* is not. Cefepime is stable to hydrolysis by many of the previously identified plasmid-encoded β -lactamases (called TEM-1, TEM-2, and SHV-1). It is a poor inducer of, and is relatively resistant to, the type I chromosomally encoded and some extended-spectrum β -lactamases. Thus it is active against many Enterobacteriaceae that are resistant to other cephalosporins *via* induction of type I β -lactamases but remains susceptible to many bacteria expressing extended-spectrum plasmid-mediated β -lactamases (such as TEM-3 and TEM-10). Against the fastidious gram-negative bacteria (*H. influenzae*, *N. gonorrhoeae*, and *N. meningitidis*), cefepime has comparable or greater *in vitro* activity than cefotaxime. For *P. aeruginosa*, cefepime has comparable activity to ceftazidime, although it is less active than ceftazidime for other *Pseudomonas* spp. and *X. maltophilia*. Cefepime has higher activity than ceftazidime and comparable activity to cefotaxime for streptococci and methicillin-sensitive *S. aureus* (Sanders, 1993). It is not active against methicillin-resistant *S. aureus*, penicillin-resistant pneumococci, enterococci, *B. fragilis*, *L. monocytogenes*, *Mycobacterium avium* complex, or *M. tuberculosis*. Cefepime is excreted almost 100% renally, and doses should be adjusted for renal failure. Cefepime has excellent penetration into the CSF in animal models of meningitis. When given at the recommended dosage for adults of 2 g intravenously every 12 hours, peak serum concentrations in human beings range from 126 to 193 $\mu\text{g/ml}$. The serum half-life is 2 hours.

Adverse Reactions. Hypersensitivity reactions to the cephalosporins are the most common side effects, and there is no evidence that any single cephalosporin is more or less likely to cause such sensitization. The reactions appear to be identical to those caused by the penicillins, perhaps related to the shared β -lactam structure of both groups of antibiotics (Bennett *et al.*, 1983). Immediate reactions such as anaphylaxis, bronchospasm, and urticaria are observed. More commonly, maculopapular rash develops, usually after several days of therapy; this may or may not be accompanied by fever and eosinophilia.

Because of the similar structures of the penicillins and cephalosporins, patients who are allergic to one class of agents may manifest cross-reactivity to a member of the other class. Immunological studies have demonstrated cross-reactivity in as many as 20% of patients who are allergic to penicillin, but clinical studies indicate a much lower frequency (about 1%) of such reactions. There are no skin tests that can reliably predict whether a patient will manifest an allergic reaction to the cephalosporins.

Patients with a history of a mild or a temporally distant reaction to penicillin appear to be at low risk of rash or other allergic reaction following the administration of a cephalosporin. However, patients who have had a recent severe, immediate reaction to a penicillin should be given a cephalosporin with great caution, if at all. A positive Coombs' reaction appears frequently in patients who receive large doses of a cephalosporin. Hemolysis usually is not associated with this phenomenon, although it has

been reported. Cephalosporins have produced rare instances of bone marrow depression, characterized by granulocytopenia (Kammer, 1984).

The cephalosporins have been implicated as potentially nephrotoxic agents, although they are not nearly as toxic to the kidney as are the aminoglycosides or the polymyxins. Renal tubular necrosis has followed the administration of *cephaloridine* in doses greater than 4 g/day; this agent is no longer available in the United States. Other cephalosporins are much less toxic and, when used by themselves in recommended doses, rarely produce significant renal toxicity. High doses of cephalothin (no longer available in the United States) have produced acute tubular necrosis in certain instances, and usual doses (8 to 12 g/day) have caused nephrotoxicity in patients with preexisting renal disease. There is good evidence that the concurrent administration of cephalothin and gentamicin or *tobramycin* act synergistically to cause nephrotoxicity (Wade *et al.*, 1978), especially in patients older than 60 years of age. Diarrhea can result from the administration of cephalosporins and may be more frequent with cefoperazone, perhaps because of its greater biliary excretion. Intolerance to alcohol (a disulfiram-like reaction) has been noted with cephalosporins that contain the MTT group, including *cefamandole* (no longer available in the United States), cefotetan, *moxalactam*, and cefoperazone. Serious bleeding related either to hypoprothrombinemia owing to the MTT group, thrombocytopenia, and/or platelet dysfunction has been reported with several β -lactam antibiotics (Bank and Kammer, 1983; Sattler *et al.*, 1986).

Therapeutic Uses. The cephalosporins are used widely and are therapeutically important antibiotics. Unfortunately, a wide array of bacteria is resistant to their activity. Clinical studies have shown cephalosporins to be effective as both therapeutic and prophylactic agents.

The first-generation cephalosporins are excellent agents for skin and soft tissue infections owing to *S. aureus* and *S. pyogenes*. A single dose of cefazolin just before surgery is the preferred prophylaxis for procedures in which skin flora are the likely pathogens (Medical Letter, 2004). For colorectal surgery, where prophylaxis for intestinal anaerobes is desired, the second-generation agents cefoxitin or cefotetan are preferred.

The second-generation cephalosporins generally have been displaced by third-generation agents. They have inferior activity against penicillin-resistant *S. pneumoniae* compared with either the third-generation agents or ampicillin and therefore should not be used for empirical treatment of meningitis or pneumonia. The oral second-generation cephalosporins can be used to treat respiratory tract

infections, although they are suboptimal (compared with oral amoxicillin) for treatment of penicillin-resistant *S. pneumoniae* pneumonia and otitis media. In situations where facultative gram-negative bacteria and anaerobes are involved, such as intra-abdominal infections, pelvic inflammatory disease, and diabetic foot infection, cefoxitin and cefotetan both are effective.

The third-generation cephalosporins, with or without aminoglycosides, have been considered to be the drugs of choice for serious infections caused by *Klebsiella*, *Enterobacter*, *Proteus*, *Providencia*, *Serratia*, and *Haemophilus* spp. Ceftriaxone is the therapy of choice for all forms of gonorrhea and for severe forms of Lyme disease. The third-generation cephalosporins cefotaxime or ceftriaxone are used for the initial treatment of meningitis in nonimmunocompromised adults and children older than 3 months of age (in combination with vancomycin and ampicillin pending identification of the causative agent) because of their antimicrobial activity, good penetration into CSF, and record of clinical success. They are the drugs of choice for the treatment of meningitis caused by *H. influenzae*, sensitive *S. pneumoniae*, *N. meningitidis*, and gram-negative enteric bacteria. Cefotaxime has failed in the treatment of meningitis owing to resistant *S. pneumoniae* (Friedland and McCracken, 1994); thus vancomycin should be added (Quagliarello and Scheld, 1997). Ceftazidime plus an aminoglycoside is the treatment of choice for *Pseudomonas* meningitis. Third-generation cephalosporins, however, lack activity against *L. monocytogenes* and penicillin-resistant pneumococci, which may cause meningitis. The antimicrobial spectrum of cefotaxime and ceftriaxone is excellent for the treatment of community-acquired pneumonia, *i.e.*, that caused by some pneumococci (achievable serum concentrations exceed MICs for many or most penicillin-resistant isolates), *H. influenzae*, or *S. aureus*.

The fourth-generation cephalosporins are indicated for the empirical treatment of nosocomial infections where antibiotic resistance owing to extended-spectrum β -lactamases or chromosomally induced β -lactamases are anticipated. For example, cefepime has superior activity against nosocomial isolates of *Enterobacter*, *Citrobacter*, and *Serratia* spp. compared with ceftazidime and piperacillin (Jones *et al.*, 1998).

OTHER β -LACTAM ANTIBIOTICS

Important therapeutic agents with a β -lactam structure that are neither penicillins nor cephalosporins have been developed.

Carbapenems

Carbapenems are β -lactams that contain a fused β -lactam ring and a five-membered ring system that differs from the penicillins in being unsaturated and containing a carbon atom instead of the sulfur atom. This class of antibiotics has a broader spectrum of activity than do most other β -lactam antibiotics.

Imipenem. Imipenem is marketed in combination with *cilastatin*, a drug that inhibits the degradation of imipenem by a renal tubular dipeptidase.

Source and Chemistry. Imipenem is derived from a compound produced by *Streptomyces cattleya*. The compound thienamycin is unstable, but imipenem, the *N*-formimidoyl derivative, is stable. The structural formula of imipenem is as follows:

Antimicrobial Activity. Imipenem, like other β -lactam antibiotics, binds to penicillin-binding proteins, disrupts bacterial cell wall synthesis, and causes death of susceptible microorganisms. It is very resistant to hydrolysis by most β -lactamases.

The activity of imipenem is excellent *in vitro* for a wide variety of aerobic and anaerobic microorganisms. Streptococci (including penicillin-resistant *S. pneumoniae*), enterococci (excluding *E. faecium* and non- β -lactamase-producing penicillin-resistant strains), staphylococci (including penicillinase-producing strains), and *Listeria* all are susceptible. Although some strains of methicillin-resistant staphylococci are susceptible, many strains are not. Activity is excellent against the Enterobacteriaceae, including organisms that are cephalosporin-resistant by virtue of expression of chromosomal or plasmid extended-spectrum β -lactamases. Most strains of *Pseudomonas* and *Acinetobacter* are inhibited. *X. maltophilia* is resistant. Anaerobes, including *B. fragilis*, are highly susceptible.

Pharmacokinetics and Adverse Reactions. Imipenem is not absorbed orally. The drug is hydrolyzed rapidly by a dipeptidase found in the brush border of the proximal renal tubule. Because concentrations of active drug in urine were low, cilastatin, an inhibitor of the dehydropeptidase, was synthesized. A preparation has been developed that contains equal amounts of imipenem and cilastatin (PRIMAXIN).

After the intravenous administration of 500 mg imipenem (as PRIMAXIN), peak concentrations in plasma average 33 $\mu\text{g}/\text{ml}$. Both imipenem and cilastatin have a half-life of about 1 hour. When administered concurrently with cilastatin, approximately 70% of administered imipenem is recovered in the urine as the active drug. Dosage should be modified for patients with renal insufficiency.

Nausea and vomiting are the most common adverse reactions (1% to 20%). Seizures also have been noted in up to 1.5% of patients, especially when high doses are given to patients with CNS lesions and to those with renal insufficiency. Patients who are allergic to other β -lactam antibiotics may have hypersensitivity reactions when given imipenem.

Therapeutic Uses. Imipenem–cilastatin is effective for a wide variety of infections, including urinary tract and lower respiratory infections; intra-abdominal and gynecological infections; and skin, soft tissue, bone, and joint infections. The drug combination appears to be especially useful for the treatment of infections caused by cephalosporin-resistant nosocomial bacteria, such as *Citrobacter freundii* and *Enterobacter* spp. It would be prudent to use imipenem for empirical treatment of serious infections in hospitalized patients who have recently received other β -lactam antibiotics because of the increased risk of infection with cephalosporin- and/or penicillin-resistant bacteria. Imipenem should not be used as monotherapy for infections owing to *P. aeruginosa* because of the risk of resistance developing during therapy.

Meropenem. *Meropenem* (MERREM IV) is a dimethyl-carbamoyl pyrrolidinyll derivative of *thienamycin*. It does not require coadministration with cilastatin because it is not sensitive to renal dipeptidase. Its toxicity is similar to that of imipenem except that it may be less likely to cause seizures (0.5% of meropenem- and 1.5% of imipenem-treated patients seized). Its *in vitro* activity is similar to that of imipenem, with activity against some imipenem-resistant *P. aeruginosa* but less activity against gram-positive cocci. Clinical experience with meropenem demonstrates therapeutic equivalence with imipenem.

Ertapenem. *Ertapenem* (INVANZ) differs from imipenem and meropenem by having a larger serum half-life that allows once-daily dosing and by having inferior activity against *P. aeruginosa* and *Acinetobacter* spp. Its spectrum of activity against gram-positive organisms, Enterobacteriaceae, and anaerobes makes it attractive for use in intra-abdominal and pelvic infections (Solomkin *et al.*, 2003).

Aztreonam. *Aztreonam* (AZACTAM) is a monocyclic β -lactam compound (a monobactam) isolated from *Chromobacterium violaceum* (Sykes *et al.*, 1981). Its structural formula is as follows:

Aztreonam interacts with penicillin-binding proteins of susceptible microorganisms and induces the formation of long filamentous bacterial structures. The compound is resistant to many of the β -lactamases that are elaborated by most gram-negative bacteria.

The antimicrobial activity of aztreonam differs from those of other β -lactam antibiotics and more closely resembles that of an aminoglycoside. Aztreonam has activity only against gram-negative bacteria; it has no activity against gram-positive bacteria and anaerobic organisms. However, activity against Enterobacteriaceae is excellent, as is that against *P. aeruginosa*. It is also highly active *in vitro* against *H. influenzae* and gonococci.

Aztreonam is administered either intramuscularly or intravenously. Peak concentrations of aztreonam in plasma average nearly 50 $\mu\text{g}/\text{ml}$ after a 1-g intramuscular dose. The half-life for elimination is 1.7 hours, and most of the drug is recovered unaltered in the urine. The half-life is prolonged to about 6 hours in anephric patients.

Aztreonam generally is well tolerated. Interestingly, patients who are allergic to penicillins or cephalosporins appear not to react to aztreonam, with the exception of ceftazidime.

The usual dose of aztreonam for severe infections is 2 g every 6 to 8 hours. This should be reduced in patients with renal insufficiency. Aztreonam has been used successfully for the therapy of a variety of infections. One of its notable features is little allergic cross-reactivity with β -lactam antibiotics, with the possible exception of ceftazidime (Perez Pimiento *et al.*, 1998), with which it has considerable structural similarity. Aztreonam is therefore quite useful for treating gram-negative infections that normally would be treated with a β -lactam antibiotic were it not for the history of a prior allergic reaction.

β -LACTAMASE INHIBITORS

Certain molecules can inactivate β -lactamases, thus preventing the destruction of β -lactam antibiotics that are substrates for these enzymes. β -Lactamase inhibitors are most active against plasmid-encoded β -lactamases (including the enzymes that hydrolyze ceftazidime and cefotaxime), but they are inactive at clinically achievable concentrations against the type I chromosomal β -lactamases induced in gram-negative bacilli (such as *Enterobacter*, *Acinetobacter*, and *Citrobacter*) by treatment with second- and third-generation cephalosporins.

Clavulanic acid is produced by *Streptomyces clavuligerus*; its structural formula is as follows:

It has poor intrinsic antimicrobial activity, but it is a “suicide” inhibitor that irreversibly binds β -lactamases produced by a wide range of gram-positive and gram-negative microorganisms. Clavulanic acid is well absorbed

by mouth and also can be given parenterally. It has been combined with amoxicillin as an oral preparation (AUGMENTIN) and with ticarcillin as a parenteral preparation (TIMENTIN).

Amoxicillin plus clavulanate is effective *in vitro* and *in vivo* for β -lactamase-producing strains of staphylococci, *H. influenzae*, gonococci, and *E. coli*. Amoxicillin-clavulanate plus ciprofloxacin has been shown to be an effective oral treatment for low-risk, febrile patients with neutropenia from cancer chemotherapy (Freifeld *et al.*, 1999; Kern *et al.*, 1999). It also is effective in the treatment of acute otitis media in children, sinusitis, animal or human bite wounds, cellulitis, and diabetic foot infections. The addition of clavulanate to ticarcillin (TIMENTIN) extends its spectrum such that it resembles imipenem to include aerobic gram-negative bacilli, *S. aureus*, and *Bacteroides* spp. There is no increased activity against *Pseudomonas* spp. (Bansal *et al.*, 1985). The dosage should be adjusted for patients with renal insufficiency. The combination is especially useful for mixed nosocomial infections and is used often with an aminoglycoside.

Sulbactam is another β -lactamase inhibitor similar in structure to clavulanic acid. It may be given orally or parenterally along with a β -lactam antibiotic. It is available for intravenous or intramuscular use combined with ampicillin (UNASYN). Dosage must be adjusted for patients with impaired renal function. The combination has good activity against gram-positive cocci, including β -lactamase-producing strains of *S. aureus*, gram-negative aerobes (but not *Pseudomonas*), and anaerobes; it also has been used effectively for the treatment of mixed intra-abdominal and pelvic infections.

Tazobactam is a penicillanic acid sulfone β -lactamase inhibitor. In common with the other available inhibitors, it has poor activity against the inducible chromosomal β -lactamases of Enterobacteriaceae but has good activity against many of the plasmid β -lactamases, including some of the extended-spectrum class. It has been combined with piperacillin as a parenteral preparation (ZOSYN) (see Bryson and Brogden, 1994).

The combination of piperacillin and tazobactam does not increase the activity of piperacillin against *P. aeruginosa* because resistance is due to either chromosomal β -lactamases or decreased permeability of piperacillin into the periplasmic space. Because the currently recommended dose (3 g piperacillin per 375 mg tazobactam every 4 to 8 hours) is less than the recommended dose of piperacillin when used alone for serious infections (3 to 4 g every 4 to 6 hours), concern has been raised that piperacillin-tazobactam may prove ineffective in the treatment of some *P. aeruginosa* infections that would have responded to piperacillin. The combination of piperacillin plus tazobactam should be equivalent in antimicrobial spectrum to ticarcillin plus clavulanate.

AMINOGLYCOSIDES

Henry F. Chambers

The aminoglycoside group includes *gentamicin*, *tobramycin*, *amikacin*, *netilmicin*, *kanamycin*, *streptomycin*, and *neomycin*. These drugs are used primarily to treat infections caused by aerobic gram-negative bacteria; streptomycin is an important agent for the treatment of tuberculosis. In contrast to most inhibitors of microbial protein synthesis, which are bacteriostatic, the aminoglycosides are bactericidal inhibitors of protein synthesis. Mutations affecting proteins in the bacterial ribosome, the target for these drugs, can confer marked resistance to their action. However, most commonly resistance is due to acquisition of plasmids or transposon-encoding genes for aminoglycoside-metabolizing enzymes or from impaired transport of drug into the cell. Thus there can be cross-resistance between members of the class.

These agents contain amino sugars linked to an aminocyclitol ring by glycosidic bonds (Figure 45–1). They are polycations, and their polarity is responsible in part for pharmacokinetic properties shared by all members of the group. For example, none is absorbed adequately after oral administration, inadequate concentrations are found in cerebrospinal fluid (CSF), and all are excreted relatively rapidly by the normal kidney. Although aminoglycosides are widely used and important agents, serious toxicity limits their usefulness. All members of the group share the same spectrum of toxicity, most notably nephrotoxicity and ototoxicity, which can involve the auditory and vestibular functions of the eighth cranial nerve.

History and Source. Aminoglycosides are natural products or semi-synthetic derivatives of compounds produced by a variety of soil actinomycetes. Streptomycin was first isolated from a strain of *Streptomyces griseus*. Gentamicin and netilmicin are broad-spectrum antibiotics derived from species of the actinomycete *Micromonospora*. The difference in spelling (*-micin*) compared with the other aminoglycoside antibiotics (*-mycin*) reflects this difference in origin. Tobramycin is one of several components of an aminoglycoside

complex (*nebramycin*) that is produced by *S. tenebrarius* (Higgins and Kastner, 1967). It is most similar in antimicrobial activity and toxicity to gentamicin. In contrast to the other aminoglycosides, amikacin, a derivative of kanamycin, and netilmicin, a derivative of *sisomicin*, are semisynthetic products. Other aminoglycoside antibiotics have been developed (e.g., *arbekacin*, *isepamicin*, and *sisomicin*), but they have not been introduced into clinical practice in the United States because numerous potent, less toxic alternatives (e.g., broad-spectrum β -lactam antibiotics and quinolones) are available.

Chemistry. The aminoglycosides consist of two or more amino sugars joined in glycosidic linkage to a hexose nucleus, which usually is in a central position (Figure 45–1). This hexose, or aminocyclitol, is either streptidine (found in streptomycin) or 2-deoxystreptamine (found in all other available aminoglycosides). These compounds thus are aminoglycosidic aminocyclitols, although the simpler term *aminoglycoside* is used commonly to describe them. A related compound, *spectinomycin*, is an aminocyclitol that does not contain amino sugars; it is discussed in Chapter 46.

The aminoglycoside families are distinguished by the amino sugars attached to the aminocyclitol. In the neomycin family, which includes *neomycin B* and *paromomycin*, an aminoglycoside used orally for the treatment of intestinal parasitic infections, there are three amino sugars attached to the central 2-deoxystreptamine. The kanamycin and gentamicin families have only two such amino sugars. Neomycin B has the following structural formula:

In the kanamycin family, which includes *kanamycins A and B*, amikacin, and tobramycin, two amino sugars are linked to a centrally located 2-deoxystreptamine moiety; one of these is a 3-aminohexose (Figure 45-1). The structural formula of kanamycin A, which is the major component of the commercial product, is as follows:

Amikacin is a semisynthetic derivative prepared from kanamycin A by acylation of the 1-amino group of the 2-deoxystreptamine moiety with 2-hydroxy-4-aminobutyric acid.

The gentamicin family, which includes *gentamicins C₁, C_{1a}, and C₂*, sisomicin, and netilmicin (the 1-*N*-ethyl derivative of sisomicin), contains a different 3-amino sugar (garosamine). Variations in methylation of the other amino sugar result in the different components of gentamicin (Figure 45-1). These modifications appear to have little effect on biological activity.

Streptomycin differs from the other aminoglycoside antibiotics in that it contains streptidine rather than 2-deoxystreptamine, and the aminocyclitol is not in a central position. The structural formula of streptomycin is as follows:

Mechanism of Action. The aminoglycoside antibiotics are rapidly bactericidal. Bacterial killing is concentration-

dependent: The higher the concentration, the greater is the rate at which bacteria are killed. A post-antibiotic effect, *i.e.*, residual bactericidal activity persisting after the serum concentration has fallen below the minimum inhibitory concentration (MIC), also is characteristic of aminoglycoside antibiotics; the duration of this effect also is concentration dependent. These properties probably account for the efficacy of once-daily dosing regimens of aminoglycosides. Although much is known about their capacity to inhibit protein synthesis and decrease the fidelity of translation of mRNA at the ribosome (Shannon and Phillips, 1982), the precise mechanism responsible for the rapidly lethal effect of aminoglycosides on bacteria is unknown.

Aminoglycosides diffuse through aqueous channels formed by porin proteins in the outer membrane of gram-negative bacteria to enter the periplasmic space. Transport of aminoglycosides across the cytoplasmic (inner) membrane depends on electron transport in part because of a requirement for a membrane electrical potential (interior negative) to drive permeation of these antibiotics. This phase of transport has been termed *energy-dependent phase I* (EDP₁). It is rate-limiting and can be blocked or inhibited by divalent cations (*e.g.*, Ca²⁺ and Mg²⁺), hyperosmolarity, a reduction in pH, and anaerobic conditions. The last two conditions impair the ability of the bacteria to maintain the membrane potential, which is the driving force necessary for transport. Thus the antimicrobial activity of aminoglycosides is reduced markedly in the anaerobic environment of an abscess, in hyperosmolar acidic urine, and in other conditions that limit EDP₁. Once inside the cell, aminoglycosides bind to polysomes and interfere with protein synthesis by causing misreading and premature termination of mRNA translation (Figure 45-2). The resulting aberrant proteins may be inserted into the cell membrane, leading to altered permeability and further stimulation of aminoglycoside transport (Busse *et al.*, 1992). This phase of aminoglycoside transport, termed *energy-dependent phase II* (EDP₂), is poorly understood; however, EDP₂ may link to disruption of the structure of the cytoplasmic membrane, perhaps by the aberrant proteins. This concept is consistent with the observed progression of the leakage of small ions, followed by larger molecules and, eventually, by proteins from the bacterial cell prior to aminoglycoside-induced death. This progressive disruption of the cell envelope, as well as other vital cell processes, may help to explain the lethal action of aminoglycosides (Bryan, 1989).

The primary intracellular site of action of the aminoglycosides is the 30S ribosomal subunit, which consists of 21 proteins and a single 16S molecule of RNA. At least three of these ribosomal pro-

Figure 45–1. Sites of activity of various plasmid-mediated enzymes capable of inactivating aminoglycosides. The symbol X indicates regions of the molecules that are protected from the designated enzyme. In gentamicin C₁, R₁=R₂=CH₃; in gentamicin C₂, R₁=CH₃, R₂=H; in gentamicin C_{1a}, R₁=R₂=H. (Modified with permission from Moellering, 1977.)

teins, and perhaps the 16S ribosomal RNA as well, contribute to the streptomycin-binding site, and alterations of these molecules markedly affect the binding and subsequent action of streptomycin. For example, a single amino acid substitution of asparagine for lysine at position 42 of one ribosomal protein (S₁₂) prevents binding of the drug; the resulting mutant is totally resistant to streptomycin. Substitution of glutamine for lysine creates a mutant that actually requires streptomycin for survival. The other aminoglycosides also bind to the 30S ribosomal subunit; however, they also appear to bind to several sites on the 50S ribosomal subunit (Davis, 1988).

Aminoglycosides disrupt the normal cycle of ribosomal function by interfering, at least in part, with the initiation of protein synthesis, leading to the accumulation of abnormal initiation complexes, or *streptomycin monosomes*, shown schematically in Figure 45–2B (Luzzatto *et al.*, 1969). Aminoglycosides also cause misreading of the mRNA template and incorporation of incorrect amino acids into the growing polypeptide chains. Aminoglycosides vary in their

capacity to cause misreading presumably owing to differences in their affinities for specific ribosomal proteins. Although there appears to be a strong correlation between bactericidal activity and the ability to induce misreading (Hummel and Böck, 1989), it remains to be established that this is the primary mechanism of aminoglycoside-induced cell death.

Microbial Resistance to the Aminoglycosides. Bacteria may be resistant to aminoglycosides because of failure of the antibiotic to penetrate intracellularly, low affinity of the drug for the bacterial ribosome, or inactivation of the drug by microbial enzymes. Clinically, drug inactivation is the most common mechanism for acquired microbial resistance to aminoglycosides. The genes encoding aminoglycoside-modifying enzymes are acquired primarily by conju-

Figure 45-2. Effects of aminoglycosides on protein synthesis. **A.** Aminoglycoside (represented by closed circles) binds to the 30S ribosomal subunit and interferes with initiation of protein synthesis by fixing the 30S–50S ribosomal complex at the start codon (AUG) of mRNA. As 30S–50S complexes downstream complete translation of mRNA and detach, the abnormal initiation complexes, so-called streptomycin monosomes, accumulate, blocking further translation of the message. Aminoglycoside binding to the 30S subunit also causes misreading of mRNA, leading to **B.** premature termination of translation with detachment of the ribosomal complex and incompletely synthesized protein or **C.** incorporation of incorrect amino acids (indicated by the X), resulting in the production of abnormal or nonfunctional proteins.

gation and transfer of resistance plasmids (Davies, 1994) (see Chapter 42). These enzymes phosphorylate, adenylate, or acetylate specific hydroxyl or amino groups (Figure 45–1). Amikacin is a suitable substrate for only a few of these inactivating enzymes (Figure 45–1); thus strains that are resistant to multiple other drugs tend to be susceptible to amikacin. The metabolites of the aminoglycosides may compete with the unaltered drug for transport across the inner membrane, but they are incapable of binding effectively to ribosomes and interfering with protein synthesis.

A significant percentage of clinical isolates of *Enterococcus faecalis* and *E. faecium* are highly resistant to all aminoglycosides. Infections caused by aminoglycoside-resistant strains of enterococci can be especially difficult to treat because of the loss of the synergistic bactericidal activity between a penicillin or vancomycin and an aminoglycoside (Spera and Farber, 1992; Vemuri and Zervos, 1993) and because these strains often also are cross-resistant to vancomycin and penicillin. Resistance to gentamicin indicates cross-resistance to tobramycin, amikacin, kanamycin, and netilmicin because the inactivating enzyme is bifunctional and can modify all these aminoglycosides (Murray, 1999). Owing to differences in the chemical structures of streptomycin and other aminoglycosides, this enzyme does not modify streptomycin, which is inactivated by another enzyme; consequently, gentamicin-resistant strains of enterococci may be susceptible to streptomycin. Natural resistance to aminoglycosides may be caused by failure of the drug to penetrate the cytoplasmic (inner) membrane. Penetration of drug across the outer membrane of gram-negative microorganisms into the periplasmic space can be slow, but resistance on this

basis is unimportant clinically. Transport of aminoglycosides across the cytoplasmic membrane is an oxygen-dependent active process. Strictly anaerobic bacteria thus are resistant to these drugs because they lack the necessary transport system. Similarly, facultative bacteria are resistant when they are grown under anaerobic conditions (Mates *et al.*, 1983). Resistance owing to mutations that alter ribosomal structure is relatively uncommon. Missense mutations in *Escherichia coli* that substitute a single amino acid in a crucial ribosomal protein may prevent binding of streptomycin. Although highly resistant to streptomycin, these strains are not widespread in nature. Similarly, only 5% of strains of *Pseudomonas aeruginosa* exhibit such ribosomal resistance to streptomycin. It has been estimated that approximately half the streptomycin-resistant strains of enterococci are ribosomally resistant (Eliopoulos *et al.*, 1984). Because ribosomal resistance usually is specific for streptomycin, these strains of enterococci remain sensitive to a combination of penicillin and gentamicin *in vitro*.

Antibacterial Spectrum of the Aminoglycosides. The antibacterial activity of gentamicin, tobramycin, kanamycin, netilmicin, and amikacin is directed primarily against aerobic gram-negative bacilli. Kanamycin, like streptomycin, has a more limited spectrum compared with other aminoglycosides; in particular, it should not be used to treat infections caused by *Serratia* or *P. aeruginosa*. Aminoglycosides have little activity against anaerobic microorganisms or facultative bacteria under anaerobic conditions. Their action against most gram-positive bacteria is limited, and they should not be used as single agents to

treat infections caused by gram-positive bacteria. In combination with a cell wall–active agent, such as a penicillin or vancomycin, an aminoglycoside (streptomycin and gentamicin have been tested most extensively) produces a synergistic bactericidal effect *in vitro* against enterococci, streptococci, and staphylococci. Clinically, the superiority of aminoglycoside combination regimens over β -lactams alone is not proven except in relatively few infections (discussed below).

The aerobic gram-negative bacilli vary in their susceptibility to the aminoglycosides (Table 45–1). Tobramycin and gentamicin exhibit similar activity against most gram-negative bacilli, although tobramycin usually is more active against *P. aeruginosa* and some *Proteus* spp. Many gram-negative bacilli that are resistant to gentamicin because of plasmid-mediated inactivating enzymes also will be resistant to tobramycin. Amikacin and, in some instances, netilmicin retain their activity against gentamicin-resistant strains because they are a poor substrate for many of the aminoglycoside-inactivating enzymes.

ABSORPTION, DISTRIBUTION, DOSING, AND ELIMINATION OF THE AMINOGLYCOSIDES

Absorption. The aminoglycosides are highly polar cations and therefore are very poorly absorbed from the gastrointestinal tract. Less than 1% of a dose is absorbed after either oral or rectal administration. The

drugs are not inactivated in the intestine and are eliminated quantitatively in the feces. Long-term oral or rectal administration of aminoglycosides may result in accumulation to toxic concentrations in patients with renal impairment. Absorption of gentamicin from the gastrointestinal tract may be increased by gastrointestinal disease (e.g., ulcers or inflammatory bowel disease). Instillation of these drugs into body cavities with serosal surfaces also may result in rapid absorption and unexpected toxicity, *i.e.*, neuromuscular blockade. Similarly, intoxication may occur when aminoglycosides are applied topically for long periods to large wounds, burns, or cutaneous ulcers, particularly if there is renal insufficiency.

All the aminoglycosides are absorbed rapidly from intramuscular sites of injection. Peak concentrations in plasma occur after 30 to 90 minutes and are similar to those observed 30 minutes after completion of an intravenous infusion of an equal dose over a 30-minute period. These concentrations typically range from 4 to 12 $\mu\text{g/ml}$ following a 1.5 to 2 mg/kg dose of gentamicin, tobramycin, or netilmicin and from 20 to 35 $\mu\text{g/ml}$ following a 7.5 mg/kg dose of amikacin or kanamycin. In critically ill patients, especially those in shock, absorption of drug may be reduced from intramuscular sites because of poor perfusion.

Distribution. Because of their polar nature, the aminoglycosides do not penetrate into most cells, the central nervous system (CNS), and the eye. Except for streptomycin, there is negligible binding of aminoglycosides to plasma albumin. The apparent volume of distribution of these drugs is 25% of lean body weight and approximates the volume of extracellular fluid.

Concentrations of aminoglycosides in secretions and tissues are low. High concentrations are found only in the renal cortex and the endolymph and perilymph of the inner ear; the high concentration in these sites likely contribute to the nephrotoxicity and ototoxicity caused by these drugs. As a result of active hepatic secretion, concentrations in bile approach 30% of those found in plasma, but this represents a very minor excretory route for the aminoglycosides. Penetration into respiratory secretions is poor (Levy, 1986). Diffu-

sion into pleural and synovial fluid is relatively slow, but concentrations that approximate those in the plasma may be achieved after repeated administration. Inflammation increases the penetration of aminoglycosides into peritoneal and pericardial cavities.

Concentrations of aminoglycosides achieved in CSF with parenteral administration usually are subtherapeutic. In experimental animals and human beings, concentrations in CSF in the absence of inflammation are less than 10% of those in plasma; this value may approach 25% when there is meningitis (Strausbaugh *et al.*, 1977). Intrathecal or intraventricular administration of aminoglycosides has been used to achieve therapeutic levels, but the availability of third- and fourth-generation cephalosporins has made this unnecessary in most cases. Penetration of aminoglycosides into ocular fluids is so poor that effective therapy of bacterial endophthalmitis requires periocular and intraocular injections of the drugs.

Administration of aminoglycosides to women late in pregnancy may result in accumulation of drug in fetal plasma and amniotic fluid. Streptomycin and tobramycin can cause hearing loss in children born to women who receive the drug during pregnancy. Insufficient data are available regarding the other aminoglycosides; it is therefore recommended that they be used with caution during pregnancy and only for strong clinical indications in the absence of suitable alternatives.

Dosing. Recommended doses of individual aminoglycosides in the treatment of specific infections are given in later sections of this chapter. Current practice is to give the total daily dose as a single injection, although historically it was administered as two or three equally divided doses. Numerous studies have shown that administration of the total dose once daily is associated with less toxicity and is just as effective as multiple-dose regimens (Buijk *et al.*, 2002; Charnas *et al.*, 1997; Gilbert *et al.*, 1998; Rybak *et al.*, 1999). This diminished toxicity is probably due to a threshold effect from accumulation of drug in the inner ear or in the kidney. More drug accumulates with higher plasma concentrations, particularly at trough, and with prolonged periods of exposure. Elimination of aminoglycoside from these organs occurs more slowly when plasma concentrations are relatively high (Figure 45-3). A once-daily dosing regimen, despite the higher peak concentration, provides a longer period when concentrations fall below the threshold for toxicity than does a multiple-dose regimen (12 hours *versus* less than 3 hours total in the example shown), accounting for its lower toxicity. Aminoglycoside bactericidal activity, on the other hand, is related directly to the peak concentration achieved because aminoglycosides cause concentration-dependent killing and a concentration-dependent postantibiotic effect. This enhanced activity at higher concentrations probably accounts for the equivalent efficacy of a once-daily regimen compared with a multiple-dose regimen despite the relatively prolonged periods of time that plasma concentrations are "subtherapeutic," *i.e.*, below the MIC.

Numerous studies in a variety of clinical settings employing virtually every commonly used aminoglycoside have demonstrated that once-daily regimens are as safe or safer than multiple-dose regimens with equal efficacy (Ferriols-Lisart and Alos-Alminana, 1996; Bailey *et al.*, 1997; Charnas *et al.*, 1997; Freeman *et al.*, 1997; Deamer, 1998). Once-daily dosing also costs less and is administered more easily. For these reasons, administration of aminoglycosides as a single daily dose generally is preferred; exceptions include use in pregnancy, neonatal and pediatric infections (Rastogi *et al.*, 2002; Knoderer *et al.*, 2003), and low-dose combination therapy of bacterial endocarditis because data documenting equivalent

Figure 45-3. Plasma concentrations ($\mu\text{g/ml}$) after administration of 5.1 mg/kg of gentamicin intravenously to a hypothetical patient either as a single dose (q24h) or as three divided doses (q8h). The threshold for toxicity has been chosen to correspond to a plasma concentration of 2 $\mu\text{g/ml}$, the maximum recommended. The once-daily regimen produces a threefold higher plasma concentration, which enhances efficacy that otherwise might be compromised due to prolonged sub-MIC concentrations later in the dosing interval compared with the every-8-hours regimen. The once-daily regimen provides a 12-hour period during which plasma concentrations are below the threshold for toxicity, thereby minimizing the toxicity that otherwise might result from the high plasma concentrations early on. The every-8-hours regimen, in contrast, provides only a brief period during which plasma concentrations are below the threshold for toxicity.

safety and efficacy are inadequate. Once-daily dosing also should be avoided in patients with creatinine clearances of less than 20 to 25 ml/min because accumulation is likely to occur. Less frequent dosing (*e.g.*, every 48 hours) is more appropriate for these patients.

Whether once-daily or multiple-daily dosing is chosen, the dose must be adjusted for patients with creatinine clearances of below 80 to 100 ml/min (Table 45-2), and plasma concentrations must be monitored. Use of nomograms may be helpful in selecting initial doses, but variability in aminoglycoside clearance among patients is too large for these to be relied on for more than a few days (Bartal, *et al.*, 2003). If it is anticipated that the patient will be treated with an aminoglycoside for more than 3 to 4 days, then plasma concentrations should be monitored to avoid drug accumulation. In addition, aminoglycosides generally should not be used as single agents except for urinary tract infections because of relatively poor tissue penetration and poorer outcomes associated with aminoglycoside monotherapy (Leibovici *et al.*, 1997).

For twice- or thrice-daily dosing regimens, both peak and trough plasma concentrations are determined. The trough sample is obtained just before a dose, and the peak sample is obtained 60 minutes after intramuscular injection or 30 minutes after an intravenous infusion given over 30 minutes. The peak concentration documents that the dose produces therapeutic concentrations, generally accepted to be 4 to 10 $\mu\text{g/ml}$ for gentamicin, netilmicin, and tobramycin and 15 to 30 $\mu\text{g/ml}$ for amikacin and streptomycin (Gilbert *et al.*, 1999). The trough concentration is used to avoid toxicity by monitoring for accumulation of drug. Trough concentrations should be less than 1 to

Table 45–2
Algorithm for Dose Reduction of Aminoglycosides Based on Calculated Creatinine Clearance

CREATININE CLEARANCE, ML/MIN	% OF MAXIMUM DAILY DOSE*	FREQUENCY OF DOSING
100	100	Every 24 hours
75	75	
50	50	
25	25	
20	80	Every 48 hours
10	60	
<10	40	

*The maximum adult daily dose for amikacin, kanamycin, and streptomycin is 15 mg/kg; for gentamicin and tobramycin, 5.5 mg/kg; and for netilmicin, 6.5 mg/kg.

2 $\mu\text{g/ml}$ for gentamicin, netilmicin, and tobramycin and 5 to 10 $\mu\text{g/ml}$ for amikacin and streptomycin.

Monitoring of aminoglycoside plasma concentrations also is important when using a once-daily dosing regimen, although peak concentrations are not determined routinely (these will be three to four times higher than the peak achieved with a multiple-daily-dosing regimen). Several approaches may be used to determine that drug is being cleared and not accumulating. The simplest method is to obtain a trough sample 24 hours after dosing and adjust the dose to achieve the recommended plasma concentration, *e.g.*, below 1 to 2 $\mu\text{g/ml}$ in the case of gentamicin or tobramycin. This approach probably is the least desirable. An undetectable trough concentration could reflect grossly inadequate dosing in patients who clear the drug rapidly with prolonged periods (perhaps well over half the dosing interval) during which concentrations are subtherapeutic. In contrast, a 24-hour trough concentration target of 1 to 2 $\mu\text{g/ml}$ actually would increase aminoglycoside exposure compared with a multiple-daily-dosing regimen (Barclay *et al.*, 1999), which defeats the goal of providing a washout with concentrations of 0 to 1 $\mu\text{g/ml}$ between 18 to 24 hours after a dose. A second approach relies on nomograms to target a range of concentrations in a sample obtained earlier in the dosing interval. For example, if the plasma concentration from a sample obtained 8 hours after a dose of gentamicin is between 1.5 and 6 $\mu\text{g/ml}$, then the concentration at 18 hours will be less than 1 $\mu\text{g/ml}$ (Chambers *et al.*, 1998). Target ranges of 1 to 1.5 $\mu\text{g/ml}$ for gentamicin at 18 hours for patients with creatinine clearances above 50 ml/min and 1 to 2.5 $\mu\text{g/ml}$ for those with clearances below 50 ml/min also have been used (Gilbert *et al.*, 1998). This method also tends to be inaccurate, particularly when conditions that alter aminoglycoside clearance are present (Bartal *et al.*, 2003; Toschlog *et al.*, 2003). The most accurate method for monitoring plasma levels for dose adjustment is to measure the concentration in two plasma samples drawn several hours apart (*e.g.*, at 2 and 12 hours after a dose). The clearance then can be calculated and the dose adjusted to achieve the desired target range.

Elimination. The aminoglycosides are excreted almost entirely by glomerular filtration, and urine concentrations of 50 to 200 $\mu\text{g/ml}$ are

achieved. A large fraction of a parenterally administered dose is excreted unchanged during the first 24 hours, with most of this appearing in the first 12 hours. The half-lives of the aminoglycosides in plasma are similar and vary between 2 and 3 hours in patients with normal renal function. Renal clearance of aminoglycosides is approximately two-thirds of the simultaneous creatinine clearance; this observation suggests some tubular reabsorption of these drugs.

After a single dose of an aminoglycoside, disappearance from the plasma exceeds renal excretion by 10% to 20%; however, after 1 to 2 days of therapy, nearly 100% of subsequent doses eventually is recovered in the urine. This lag period probably represents saturation of binding sites in tissues. The rate of elimination of drug from these sites is considerably longer than from plasma; the half-life for tissue-bound aminoglycoside has been estimated to range from 30 to 700 hours (Schentag and Jusko, 1977). For this reason, small amounts of aminoglycosides can be detected in the urine for 10 to 20 days after drug administration is discontinued. Aminoglycoside bound to renal tissue exhibits antibacterial activity and protects experimental animals against bacterial infections of the kidney even when the drug no longer can be detected in serum (Bergeron *et al.*, 1982).

The concentration of aminoglycoside in plasma produced by the initial dose depends only on the volume of distribution of the drug. Since the elimination of aminoglycosides depends almost entirely on the kidney, a linear relationship exists between the concentration of creatinine in plasma and the half-life of all aminoglycosides in patients with moderately compromised renal function. In anephric patients, the half-life varies from 20 to 40 times that determined in normal individuals. *Because the incidence of nephrotoxicity and ototoxicity is related to the concentration to which an aminoglycoside accumulates, it is critical to reduce the maintenance dosage of these drugs in patients with impaired renal function.* The size of the individual dose, the interval between doses, or both can be altered. There is no conclusive information on the best approach, and even the currently accepted therapeutic range has been questioned (McCormack and Jewesson, 1992). The most consistent plasma concentrations are achieved when the loading dose is given in milligrams per kilogram of body weight; and since aminoglycosides are distributed minimally in fatty tissue, the lean or expected body weight should be used. Methods for calculation of dosage are described in Appendix II.

There are obvious difficulties in using any of these approaches for ill patients with rapidly changing renal function (Lesar *et al.*, 1982). In addition, even when known factors are taken into consideration, concentrations of aminoglycosides achieved in plasma after a given dose vary widely among patients. If the extracellular volume is expanded, the volume of distribution is increased, and concentrations will be reduced. For unknown reasons, aminoglycoside clearances are increased and half-lives are reduced in patients with cystic fibrosis; the volume of distribution is increased in patients with leukemia (Rosenthal *et al.*, 1977; Spyker *et al.*, 1978). Patients with anemia (hematocrit <25%) have a concentration in plasma that is higher than expected probably because of reduction in the number of binding sites on red blood cells.

Determination of the concentration of drug in plasma is an essential guide to the proper administration of aminoglycosides. In patients with life-threatening systemic infections, aminoglycoside concentrations should be determined several times per week (more frequently if renal function is changing) and should be determined within 24 to 48 hours of a change in dosage.

Aminoglycosides can be removed from the body by either hemodialysis or peritoneal dialysis. Approximately 50% of the administered dose is removed in 12 hours by hemodialysis, which has been used for the treatment of overdosage. As a general rule, a dose equal to half the

loading dose administered after each hemodialysis should maintain the plasma concentration in the desired range; however, a number of variables make this a rough approximation at best. Continuous arteriovenous hemofiltration (CAVH) and continuous venovenous hemofiltration (CVVH) will result in aminoglycoside clearances approximately equivalent to 15 and 15 to 30 ml/min of creatinine clearance, respectively, depending on the flow rate. The amount of aminoglycoside removed can be replaced by administering approximately 15% to 30% of the maximum daily dose (Table 45-2) each day. Frequent monitoring of plasma drug concentrations is again crucial.

Peritoneal dialysis is less effective than hemodialysis in removing aminoglycosides. Clearance rates are approximately 5 to 10 ml/min for the various drugs but are highly variable. If a patient who requires dialysis has bacterial peritonitis, a therapeutic concentration of the aminoglycoside probably will not be achieved in the peritoneal fluid because the ratio of the concentration in plasma to that in peritoneal fluid may be 10:1 (Smithivas *et al.*, 1971). Thus it is recommended that antibiotic be added to the dialysate to achieve concentrations equal to those desired in plasma. For intermittent dosing *via* peritoneal dialysate, 2 mg/kg of amikacin is added to the bag once a day. The corresponding dose for gentamicin, netilmicin, or tobramycin is 0.6 mg/kg. For continuous dosing, the dose for amikacin is 12 mg/L (25 mg/L loading dose in the first bag), and the dose for gentamicin, netilmicin, or tobramycin is 4 mg/L in each bag (8 mg/L loading dose). This should be preceded by administration of a loading dose, either parenterally or in dialysis fluid.

Although excretion of aminoglycosides is similar in adults and children older than 6 months of age, half-lives of the drugs may be prolonged significantly in the newborn: 8 to 11 hours in the first week of life in newborns weighing less than 2 kg and approximately 5 hours in those weighing more than 2 kg (Yow, 1977). Thus it is critically important to monitor concentrations of aminoglycosides during treatment of neonates (Philips *et al.*, 1982).

Aminoglycosides can be inactivated by various penicillins *in vitro* (Konishi *et al.*, 1983) and in patients with end-stage renal failure (Blair *et al.*, 1982), thus making dosage recommendations even more difficult. Amikacin appears to be the least affected by this interaction.

UNTOWARD EFFECTS OF THE AMINOGLYCOSIDES

All aminoglycosides have the potential to produce reversible and irreversible vestibular, cochlear, and renal toxicity. These side effects complicate the use of these compounds and make their proper administration difficult.

Ototoxicity. Vestibular and auditory dysfunction can follow the administration of any of the aminoglycosides. Studies of animals and human beings have documented progressive accumulation of these drugs in the perilymph and endolymph of the inner ear. Accumulation occurs predominantly when concentrations in plasma are high. Diffusion back into the bloodstream is slow; the half-lives of the aminoglycosides are five to six times longer in the otic fluids than in plasma. Back-diffusion is concentration dependent and is facilitated at the trough concentration of drug in plasma. Ototoxicity is more

likely to occur in patients with persistently elevated concentrations of drug in plasma. However, even a single dose of tobramycin has been reported to produce slight temporary cochlear dysfunction during periods when the concentration in plasma is at its peak (Wilson and Ramsden, 1977). Ototoxicity has been linked to mutations in a mitochondrial ribosomal RNA gene, indicating that a genetic predisposition exists for this side effect (Bates, 2003). Oxidant stress probably plays a role, and *ras* activation has been implicated (Battaglia *et al.*, 2003). Ototoxicity is largely irreversible and results from progressive destruction of vestibular or cochlear sensory cells, which are highly sensitive to damage by aminoglycosides (Brummett, 1983). Studies in guinea pigs exposed to large doses of gentamicin reveal degeneration of the type I sensory hair cells in the central part of the crista ampullaris (vestibular organ) and fusion of individual sensory hairs into giant hairs (Wersäll *et al.*, 1973). Similar studies with gentamicin and tobramycin also demonstrate loss of hair cells in the cochlea of the organ of Corti (Theopold, 1977). With increasing dosage and prolonged exposure, damage progresses from the base of the cochlea, where high-frequency sounds are processed, to the apex, which is necessary for the perception of low frequencies. While these histological changes correlate with the ability of the cochlea to generate an action potential in response to sound, the biochemical mechanism for ototoxicity is poorly understood. Early changes induced by aminoglycosides have been shown in experimental ototoxicity to be reversible by Ca^{2+} . Once sensory cells are lost, however, regeneration does not occur; retrograde degeneration of the auditory nerve follows, resulting in irreversible hearing loss. It has been suggested that aminoglycosides interfere with the active transport system essential for the maintenance of the ionic balance of the endolymph (Neu and Bendush, 1976). This would lead to alteration in the normal concentrations of ions in the labyrinthine fluids, with impairment of electrical activity and nerve conduction. Eventually, the electrolyte changes, or perhaps the drugs themselves, damage the hair cells irreversibly. The degree of permanent dysfunction correlates with the number of destroyed or altered sensory hair cells and is thought to be related to sustained exposure to the drug. Interestingly, total dose and duration of aminoglycoside exposure and other risk factors, such as advanced age, bacteremia, liver disease, and renal disease, that reasonably might predispose one to ototoxicity have not been proven to do so (de Jager and van Altena, 2002). Repeated courses of aminoglycosides, each probably resulting in the loss of more cells, seem to lead to deafness. Drugs such as *ethacrynic acid* and *furosemide* potentiate the ototoxic effects of the aminoglycosides in animals (Brummett, 1983); data implicating furosemide are less convincing in humans (Moore *et al.*, 1984a). Hearing loss following exposure to these agents also

is more likely to develop in patients with preexisting auditory impairment. Although all aminoglycosides are capable of affecting cochlear and vestibular function, some preferential toxicity is evident. Streptomycin and gentamicin produce predominantly vestibular effects, whereas amikacin, kanamycin, and neomycin primarily affect auditory function; tobramycin affects both equally. The incidence of ototoxicity is extremely difficult to determine. Data from audiometry suggest that the incidence may be as high as 25% (Moore *et al.*, 1984a; de Jager and van Altena, 2002). The relative incidence appears to be equal for tobramycin, gentamicin, and amikacin. Initial studies in laboratory animals and human beings suggested that netilmicin is less ototoxic than other aminoglycosides (Lerner *et al.*, 1983); however, the incidence of ototoxicity from netilmicin is not negligible—such complications developed in 10% of patients in one clinical trial of netilmicin.

The incidence of vestibular toxicity is particularly high in patients receiving streptomycin; nearly 20% of individuals who received 500 mg twice daily for 4 weeks for enterococcal endocarditis developed clinically detectable irreversible vestibular damage (Wilson *et al.*, 1984). In addition, up to 75% of patients who received 2 g streptomycin for more than 60 days showed evidence of nystagmus or postural imbalance.

Since the initial symptoms may be reversible, it is recommended that patients receiving high doses and/or prolonged courses of aminoglycosides be monitored carefully for ototoxicity; however, deafness may occur several weeks after therapy is discontinued.

Clinical Symptoms of Cochlear Toxicity. A high-pitched tinnitus often is the first symptom of toxicity. If the drug is not discontinued, auditory impairment may develop after a few days. The tinnitus may persist for several days to 2 weeks after therapy is stopped. Since perception of sound in the high-frequency range (outside the conversational range) is lost first, the affected individual is not always aware of the difficulty, and it will not be detected unless careful audiometric examination is carried out. If the hearing loss progresses, the lower sound ranges are affected, and conversation becomes difficult.

Clinical Symptoms of Vestibular Toxicity. Moderately intense headache lasting 1 or 2 days may precede the onset of labyrinthine dysfunction. This is followed immediately by an acute stage in which nausea, vomiting, and difficulty with equilibrium develop and persist for 1 to 2 weeks. Prominent symptoms include vertigo in the upright position, inability to perceive termination of movement (“mental past-pointing”), and difficulty in sitting or standing without visual cues. Drifting of the eyes at the end of a movement so that both focusing and reading are difficult, a positive Romberg test, and rarely, pendular trunk movement and spontaneous nystagmus are outstanding signs. The acute stage ends suddenly and is followed by the appearance of manifestations consistent with chronic labyrinthitis, in which, although symptomless while in bed, the patient has difficulty when attempting to walk or make sudden movements; ataxia is the most prominent feature. The chronic phase persists for approximately 2 months; it is gradually superseded by a compensatory stage in which symptoms are latent and appear only when the eyes are closed. Adaptation to the impairment of labyrinthine function is accomplished by

the use of visual cues and deep proprioceptive sensation for determining movement and position. It is more adequate in the young than in the old but may not be sufficient to permit the high degree of coordination required in many special trades. Recovery from this phase may require 12 to 18 months, and most patients have some permanent residual damage. Although there is no specific treatment for the vestibular deficiency, early discontinuation of the drug may permit recovery before irreversible damage of the hair cells.

Nephrotoxicity. Approximately 8% to 26% of patients who receive an aminoglycoside for more than several days will develop mild renal impairment that is almost always reversible (Smith *et al.*, 1980). The toxicity results from accumulation and retention of aminoglycoside in the proximal tubular cells (Aronoff *et al.*, 1983; Lietman and Smith, 1983). The initial manifestation of damage at this site is excretion of enzymes of the renal tubular brush border (Patel *et al.*, 1975). After several days, there is a defect in renal concentrating ability, mild proteinuria, and the appearance of hyaline and granular casts. The glomerular filtration rate is reduced after several additional days (Schentag *et al.*, 1979). The nonoliguric phase of renal insufficiency is thought to be due to the effects of aminoglycosides on the distal portion of the nephron with a reduced sensitivity of the collecting-duct epithelium to endogenous antidiuretic hormone (Appel, 1982). While severe acute tubular necrosis may occur rarely, the most common significant finding is a mild rise in plasma creatinine (5 to 20 $\mu\text{g/ml}$; 40 to 175 μM). Hypokalemia, hypocalcemia, and hypophosphatemia are seen very infrequently. The impairment in renal function is almost always reversible because the proximal tubular cells have the capacity to regenerate.

Several variables appear to influence nephrotoxicity from aminoglycosides. Toxicity correlates with the total amount of drug administered. Consequently, toxicity is more likely to be encountered with longer courses of therapy. Continuous infusion is more nephrotoxic in animals than is intermittent dosing (Powell *et al.*, 1983); constantly elevated concentrations of drug in plasma above a critical level, which is manifest by elevated trough serum concentrations, correlate with toxicity in human beings (Keating *et al.*, 1979).

The nephrotoxic potential varies among individual aminoglycosides. The relative toxicity correlates with the concentration of drug found in the renal cortex in experimental animals. Neomycin, which concentrates to the greatest degree, is highly nephrotoxic in human beings and should not be administered systemically. Streptomycin does not concentrate in the renal cortex and is the least nephrotoxic. Most of the controversy has concerned the relative toxicities of gentamicin and tobramycin. Gentamicin is concentrated in the kidney to a greater degree than is tobramycin, but several controlled clinical trials have given different estimates of their relative nephrotoxicities (Smith *et al.*, 1980; Fong *et al.*, 1981; Keys *et al.*, 1981). If differences between the renal toxicity of these two aminoglycosides do exist in human beings, they appear to be slight. Comparative studies with amikacin, sisomicin, and netilmicin are not conclusive. Other drugs, such as *amphotericin B*, *vancomycin*, *angiotensin-converting enzyme inhibitors*, *cisplatin*, and *cyclosporine*, may potentiate aminoglycoside-induced nephrotoxicity (Wood *et al.*, 1986). Furose-

mide enhances the nephrotoxicity of aminoglycosides in rats if there is concurrent fluid depletion (Mitchell *et al.*, 1977). Clinical studies have not proven conclusively that furosemide itself potentiates nephrotoxicity (Smith and Lietman, 1983), but volume depletion and wasting of K⁺ that accompany its use have been incriminated.

Advanced age, liver disease, diabetes mellitus, and septic shock have been suggested as risk factors for the development of nephrotoxicity from aminoglycosides, but data are not convincing (Moore *et al.*, 1984b). Note, however, that renal function in the elderly patient is overestimated by measurement of creatinine concentration in plasma, and overdosing will occur if this value is used as the only guide in this patient population (Baciewicz *et al.*, 2003).

Even though aminoglycosides consistently alter the structure and function of renal proximal tubular cells, these effects usually are reversible. The most important result of this toxicity may be reduced excretion of the drug, which, in turn, predisposes to ototoxicity. Monitoring drug concentrations in plasma is useful, particularly during prolonged and/or high-dose therapy. However, it never has been proven that toxicity can be prevented by avoiding excessive peak or trough concentrations of aminoglycosides. In fact, experience with once-daily dosing regimens strongly suggests that high peaks (*e.g.*, 25 µg/ml or higher) do not increase toxicity.

The biochemical events leading to tubular cell damage and glomerular dysfunction are poorly understood but may involve perturbations of the structure of cellular membranes. Aminoglycosides inhibit various phospholipases, sphingomyelinases, and ATPases, and they alter the function of mitochondria and ribosomes (Queener *et al.*, 1983; Humes *et al.*, 1984). Because of the ability of cationic aminoglycosides to interact with anionic phospholipids, these drugs may impair the synthesis of membrane-derived autacoids and intracellular second messengers such as prostaglandins, inositol phosphates, and diacylglycerol. Derangements of prostaglandin metabolism may explain the relationship between tubular damage and reduction in glomerular filtration rate. Others have observed morphological changes in glomerular endothelial cells (decreased number of endothelial fenestrations) (Luft and Evan, 1980) and reduction in the glomerular capillary ultrafiltration coefficient in animals receiving aminoglycosides (Baylis *et al.*, 1977).
