NO is produced from the nasal passages and from the lungs of normal human subjects and can be detected in exhaled gas. The measurement of exhaled NO has been investigated for its utility in assessment of respiratory tract diseases. Measurement of exhaled NO may prove to be useful in diagnosis and assessment of severity of asthma and in respiratory tract infections (Haddad *et al.*, 2000; Zeidler *et al.*, 2003).

Toxicity of NO

Administered at low concentrations (0.1 to 50 ppm), inhaled NO appears to be safe and without significant side effects. Pulmonary toxicity can occur with levels higher than 50 to 100 ppm. In the context of NO as an atmospheric pollutant, the Occupational Safety and Health Administration places the 7-hour exposure limit at 50 ppm. Part of the toxicity of NO may be related to its further oxidation to nitrogen dioxide (NO₂) in the presence of high concentrations of oxygen. Even low concentrations of NO₂ (2 ppm) have been shown to be highly toxic in animal models, with observed changes in lung histopathology, including loss of cilia, hypertrophy, and focal hyperplasia in the epithelium of terminal bronchioles. It is important, therefore, to keep NO₂ formation during NO therapy at a low level. This can be achieved through appropriate filters and scavengers and the use of high-quality gas mixtures. Laboratory studies have suggested potential additional toxic effects of chronic low doses of inhaled NO, including surfactant inactivation and the formation of peroxynitrite by interaction with superoxide. The ability of NO to inhibit or alter the function of a number of iron- and heme-containing proteins—including cyclooxygenase, lipoxygenases, and oxidative cytochromes—as well as its interactions with ADP-ribosylation, suggests a need for further investigation of the toxic potential of NO under therapeutic conditions (Stuedel *et al.*, 1999; Haddad *et al.*, 2000).

The development of methemoglobinemia is a significant complication of inhaled NO at higher concentrations, and rare deaths have been reported with overdoses of NO. The blood content of methemoglobin, however, generally will not increase to toxic levels with appropriate use of inhaled NO. Methemoglobin concentrations should be monitored intermittently during NO inhalation (Stuedel *et al.*, 1999; Haddad *et al.*, 2000).

Inhaled NO can inhibit platelet function and has been shown to increase bleeding time in some clinical studies, although bleeding complications have not been reported.

In patients with impaired function of the left ventricle, NO has a potential to further impair left ventricular performance by dilating the pulmonary circulation and increasing the blood flow to the left ventricle, thereby increasing left atrial pressure and promoting pulmonary edema formation. Careful monitoring of cardiac output, left atrial pressure, or pulmonary capillary wedge pressure is important in this situation (Stuedel *et al.*, 1999).

Despite these concerns, there are limited reports of inhaled NO-related toxicity in humans. The most important requirements for safe NO inhalation therapy include (1) continuous measurement of NO and NO₂ concentrations using either chemiluminescence or electrochemical analyzers; (2) frequent calibration of monitoring equipment; (3) intermittent analysis of blood methemoglobin levels; (4) the use of certified tanks of NO; and (5) administration of the lowest NO concentration required for therapeutic effect (Steudel *et al.*, 1999).

Methods of Administration

Courses of treatment of patients with inhaled NO are highly varied, extending from 0.1 to 40 ppm in dose and for periods of a few hours to several weeks in duration. The minimum effective inhaled NO concentration should be determined for each patient to minimize the chance for toxicity. Commercial NO systems are available that will accurately deliver inspired NO concentrations between 0.1 and 80 ppm and simultaneously measure NO and NO₂ concentrations. A constant inspired concentration of NO is obtained by administering NO in nitrogen to the inspiratory limb of the ventilator circuit in either a pulse or continuous mode. While inhaled NO may be administered to spontaneously breathing patients *via* a closely fitting mask, it usually is delivered during mechanical ventilation. Nasal prong administration is being employed in therapeutic trials of home administration for treatment of primary pulmonary hypertension (Steudel *et al.*, 1999; Haddad *et al.*, 2000).

Acute discontinuation of NO inhalation can lead to a rebound pulmonary artery hypertension with an increase in right-to-left intrapulmonary shunting and a decrease in oxygenation. To avoid this phenomenon, a graded decrease of inhaled NO concentration is important in the process of weaning a patient from inhaled NO (Steudel *et al.*, 1999; Haddad *et al.*, 2000).

HELIUM

Helium is an inert gas whose low density, low solubility, and high thermal conductivity provide the basis for its medical and diagnostic uses. Helium is produced by separation from liquefied natural gas and is supplied in brown cylinders. Helium can be mixed with oxygen and administered by mask or tracheal tube. Under hyperbaric conditions, it can be substituted for the bulk of other gases, resulting in a mixture of much lower density that is easier to breathe.

The primary uses of helium are in pulmonary function testing, the treatment of respiratory obstruction, during laser airway surgery, for diving at depth, and most recently, as a label in imaging studies. The determinations of residual lung volume, functional residual capacity, and related lung volumes require a highly diffusible nontoxic gas that is insoluble (and thus does not leave the lung *via* the bloodstream) so that, by dilution, the lung volume can be measured. Helium is well suited to these needs and is much cheaper than alternatives. In these tests, a breath of a

known concentration of helium is given, and the concentration of helium then is measured in the mixed expired gas, allowing calculation of the other pulmonary volumes.

Pulmonary gas flow is normally laminar, but with increased flow rate or narrowed flow pathway, a component becomes turbulent. Helium can be added to oxygen to treat the turbulence due to airway obstruction: the density of helium is substantially less than that of air and the viscosity of helium is greater than that of air; addition of helium reduces the Reynolds number of the mixture (the Reynolds number is proportional to density and inversely proportional to viscosity), thereby reducing turbulence. Indeed, flow rates are increased with lower density gases. Thus, with mixtures of helium and oxygen, the work of breathing is less. Several factors limit the utility of this approach, however. Oxygenation is often the principal problem in airway obstruction, and the practical need for increased inspired O₂ concentration may limit the fraction of helium that can be used. Furthermore, even though helium reduces the Reynolds number of the gas mixture, the viscosity of helium is higher than that of air, and the increased viscosity increases the resistance to flow according to Poiseuille's law, whereby flow is inversely proportional to viscosity.

Helium has high thermal conductivity, which makes it useful during laser surgery on the airway. This more rapid conduction of heat away from the point of contact of the laser beam reduces the spread of tissue damage and the likelihood that the ignition point of flammable materials in the airway will be reached. Its low density improves the flow through the small endotracheal tubes typically used in such procedures.

Recently, laser-polarized helium has been used as an inhalational contrast agent for pulmonary magnetic resonance imaging. Optical pumping of nonradioactive helium increases the signal from the gas in the lung sufficiently to permit detailed imaging of the airways and inspired airflow patterns (Kauczor *et al.*, 1998).

Hyperbaric Applications. The depth and duration of diving activity are limited by oxygen toxicity, inert gas (nitrogen) narcosis, and nitrogen supersaturation when decompressing. Oxygen toxicity is a problem with prolonged exposure to compressed air at 500 kPa (5 atm) or more. This problem can be minimized by dilution of oxygen with helium, which lacks narcotic potential even at very high pressures and is quite insoluble in body tissues. This low solubility reduces the likelihood of bubble formation after decompression, which therefore can be achieved more rapidly. The low density of helium also reduces the work of breathing in the otherwise dense hyperbaric atmosphere. The lower heat capacity of helium also decreases respiratory heat loss, which can be significant when diving at depth.

HYPNOTICS AND SEDATIVES

Dennis S. Charney, S. John Mihic, and R. Adron Harris

A great variety of agents have the capacity to depress the function of the central nervous system (CNS) such that calming or drowsiness (sedation) is produced. Older sedative-hypnotic drugs depress the CNS in a dose-dependent fashion, progressively producing sedation, sleep, unconsciousness, surgical anesthesia, coma, and ultimately, fatal depression of respiration and cardiovascular regulation. The CNS depressants discussed in this chapter include benzodiazepines, barbiturates, and sedative-hypnotic agents of diverse chemical structure (*e.g.*, *paraldehyde* and *chloral hydrate*).

A *sedative* drug decreases activity, moderates excitement, and calms the recipient, whereas a *hypnotic* drug produces drowsiness and facilitates the onset and maintenance of a state of sleep that resembles natural sleep in its electroencephalographic characteristics and from which the recipient can be aroused easily. The latter effect sometimes is called *hypnosis*, but the sleep induced by hypnotic drugs does not resemble the artificially induced passive state of suggestibility also called *hypnosis*.

The nonbenzodiazepine sedative-hypnotic drugs belong to a group of agents that depress the CNS in a dose-dependent fashion, progressively producing calming or drowsiness (sedation), sleep (pharmacological hypnosis), unconsciousness, coma, surgical anesthesia, and fatal depression of respiration and cardiovascular regulation. They share these properties with a large number of chemicals, including general anesthetics (*see* Chapter 13) and aliphatic alcohols, most notably ethanol (*see* Chapter 22). Only two landmarks on the continuum of CNS depression produced by increasing concentrations of these agents can be defined with a reasonable degree of precision: surgical anesthesia, a state in which painful stimuli elicit no behavioral or autonomic response (*see* Chapter 13), and death,

resulting from sufficient depression of medullary neurons to disrupt coordination of cardiovascular function and respiration. The “end points” at lower concentrations of CNS depressants are defined with less precision—in terms of deficits in cognitive function (including attention to environmental stimuli) or motor skills (*e.g.*, ataxia) or of the intensity of sensory stimuli needed to elicit some reflex or behavioral response. Other important indices of decreased CNS activity, such as analgesia and seizure suppression, do not necessarily fall along this continuum; they may not be present at subanesthetic concentrations of a CNS-depressant drug (*e.g.*, a barbiturate), or they may be achieved with minimal sedation or other evidence of CNS depression (*e.g.*, with low doses of opioids, *phenytoin*, or *ethosuximide*).

Sedation is a side effect of many drugs that are not general CNS depressants (*e.g.*, antihistamines and neuroleptics). Although such agents can intensify the effects of CNS depressants, they usually produce more specific therapeutic effects at concentrations far lower than those causing substantial CNS depression. For example, they cannot induce surgical anesthesia in the absence of other agents. The benzodiazepine sedative-hypnotics resemble such agents; although coma may occur at very high doses, neither surgical anesthesia nor fatal intoxication is produced by benzodiazepines in the absence of other drugs with CNS-depressant actions; an important exception is *midazolam*, which has been associated with decreased tidal volume and respiratory rate. Moreover, specific antagonists of benzodiazepines exist. This constellation of properties sets the benzodiazepines apart from other sedative-hypnotic drugs and imparts a measure of safety that has resulted in benzodiazepines largely displacing older agents for the treatment of insomnia and anxiety.

History. Since antiquity, alcoholic beverages and potions containing *laudanum* and various herbals have been used to induce sleep. In the middle of the nineteenth century, *bromide* was the first agent to be introduced specifically as a sedative-hypnotic. Chloral hydrate, paraldehyde, *urethane*, and *sulfonal* came into use before the introduction of *barbital* in 1903 and *phenobarbital* in 1912. Their success spawned the synthesis and testing of more than 2500 barbiturates, of which approximately 50 were distributed commercially. The barbiturates were so dominant that less than a dozen other sedative-hypnotics were marketed successfully before 1960.

The partial separation of sedative-hypnotic-anesthetic from anticonvulsant properties embodied in phenobarbital led to searches for agents with more selective effects on CNS functions. As a result, relatively nonsedating anticonvulsants, notably phenytoin and *trimethadione*, were developed in the late 1930s and early 1940s (see Chapter 19). The advent of *chlorpromazine* and *meprobamate* in the early 1950s, with their taming effects in animals, and the development of increasingly sophisticated methods for evaluating the behavioral effects of drugs set the stage in the 1950s for the synthesis of *chlordiazepoxide* by Sternbach and the discovery of its unique pattern of actions by Randall. The introduction of chlordiazepoxide into clinical medicine in 1961 ushered in the era of benzodiazepines. Most of the benzodiazepines that have reached the marketplace were selected for high anxiolytic potency in relation to their depression of CNS function. However, all benzodiazepines possess sedative-hypnotic properties to varying degrees; these properties are exploited extensively clinically, especially to facilitate sleep. Mainly because of their remarkably low capacity to produce fatal CNS depression, the benzodiazepines have displaced the barbiturates as sedative-hypnotic agents.

BENZODIAZEPINES

All benzodiazepines in clinical use have the capacity to promote the binding of the major inhibitory neurotransmitter γ -aminobutyric acid (GABA) to the GABA_A subtype of GABA receptors, which exist as multisubunit, ligand-gated chloride channels, thereby enhancing the GABA-induced ionic currents through these channels (see Chapter 12). Pharmacological investigations have provided evidence for heterogeneity among sites of binding and action of benzodiazepines, whereas biochemical and molecular biological investigations have revealed the numerous varieties of subunits that make up the GABA-gated chloride channels expressed in different neurons. Since receptor subunit composition appears to govern the interaction of various allosteric modulators with these channels, there has been a surge in efforts to find agents displaying different combinations of benzodiazepinelike properties that may reflect selective actions on one or more subtypes of GABA receptors.

These efforts led to the development of *zolpidem*, an imidazopyridine, and the pyrazolopyrimidines *zaleplon* and *indiplon* (under review by the Food and Drug Administration); these compounds all apparently exert sedative-hypnotic effects by interacting with a subset of benzodiazepine binding sites.

Although the benzodiazepines exert qualitatively similar clinical effects, important quantitative differences in their pharmacodynamic spectra and pharmacokinetic properties have led to varying patterns of therapeutic application. A number of distinct mechanisms of action are thought to contribute to the sedative-hypnotic, muscle-relaxant, anxiolytic, and anticonvulsant effects of the benzodiazepines, and specific subunits of the GABA_A receptor are responsible for specific pharmacological properties of benzodiazepines. While only the benzodiazepines used primarily for hypnosis are discussed in detail, this chapter describes the general properties of the group and important differences among individual agents (see Chapters 17 and 19).

Chemistry. The structures of the benzodiazepines in use in the United States are shown in Table 16–1, as are those of a few related compounds discussed below. The term *benzodiazepine* refers to the portion of the structure composed of a benzene ring (A) fused to a seven-membered diazepine ring (B). Since all the important benzodiazepines contain a 5-aryl substituent (ring C) and a 1,4-diazepine ring, the term has come to mean the 5-aryl-1,4-benzodiazepines. Various modifications in the structure of the ring systems have yielded compounds with similar activities, including 1,5-benzodiazepines (e.g., *clobazam*) and compounds in which the fused benzene ring is replaced with heteroaromatic systems such as thieno (e.g., *brotizolam*). The chemical nature of substituents at positions 1 to 3 can vary widely and can include triazolo or imidazolo rings fused at positions 1 and 2. Replacement of ring C with a keto function at position 5 and a methyl substituent at position 4 is an important structural feature of the benzodiazepine antagonist *flumazenil* (ROMAZICON).

In addition to various benzodiazepine or imidazobenzodiazepine derivatives, a large number of nonbenzodiazepine compounds compete with classic benzodiazepines or flumazenil for binding at specific sites in the CNS. These include representatives from the β -carbolines (containing an indole nucleus fused to a pyridine ring), imidazopyridines (e.g., *zolpidem*; see below), imidazopyrimidines, imidazoquinolones, and cyclopyrrolones (e.g., *zopiclone*).

Pharmacological Properties

Virtually all effects of the benzodiazepines result from their actions on the CNS. The most prominent of these effects are sedation, hypnosis, decreased anxiety, muscle relaxation, anterograde amnesia, and anticonvulsant activity. Only two effects of these drugs result from peripheral actions: coronary vasodilation, seen after

Table 16-1
Benzodiazepines: Names and Structures*

BENZODIAZEPINE	R ₁	R ₂	R ₃	R ₇	R ₂ '
Alprazolam	[Fused triazolo ring] ^b		—H	—Cl	—H

*Alphabetical footnotes refer to alterations of the general formula; symbolic footnotes are used for other comments. [†]Not available for clinical use in the United States. [‡]Major metabolite of chlordiazepoxide. [§]Major metabolite of diazepam and others; also referred to as nordiazepam and desmethyl-diazepam. ^aNo substituent at position 4, except for chlordiazepoxide and demoxepam, which are N-oxides; R₄ is —CH₃ in flumazenil, in which there is no double bond between positions 4 and 5; R₄ is =O in clobazam, in which position 4 is C and position 5 is N.

^gNo ring C.

intravenous administration of therapeutic doses of certain benzodiazepines, and neuromuscular blockade, seen only with very high doses.

A number of benzodiazepinelike effects have been observed *in vivo* and *in vitro* and have been classified as *full agonistic effects* (*i.e.*, faithfully mimicking agents such as diazepam with relatively low fractional occupancy of binding sites) or *partial agonistic effects* (*i.e.*, producing less intense maximal effects and/or requiring relatively high fractional occupancy compared with agents such as diazepam). Some compounds produce effects opposite to those of diazepam in the absence of benzodiazepinelike agonists and have been termed *inverse agonists*; *partial inverse agonists* also have been recognized. The vast majority of effects of agonists and inverse agonists can be reversed or prevented by the benzodiazepine antagonist *flumazenil*, which competes with agonists and inverse agonists for binding to the GABA_A receptor. In addition, compounds from other chemical classes can act to block only the effects of agonists or inverse agonists.

Central Nervous System. While benzodiazepines affect activity at all levels of the neuraxis, some structures are affected preferentially. The benzodiazepines do not produce the same degrees of neuronal depression as do barbiturates and volatile anesthetics. All the benzodiazepines have similar pharmacological profiles. Nevertheless, the drugs differ in selectivity, and the clinical usefulness of individual benzodiazepines thus varies considerably.

As the dose of a benzodiazepine is increased, sedation progresses to hypnosis and then to stupor. The clinical literature often refers to the “anesthetic” effects and uses of certain benzodiazepines, but the drugs do not cause a true general anesthesia because awareness usually persists, and relaxation sufficient to allow surgery cannot be achieved. However, at “preanesthetic” doses, there is amnesia for events subsequent to administration of the drug; this may create the illusion of previous anesthesia.

Although considerable attempts have been made to separate the anxiolytic actions of benzodiazepines from their sedative-hypnotic effects, distinguishing between these behaviors still is problematic. Measurements of anxiety and sedation are difficult in human beings, and the validity of animal models for anxiety and sedation is uncertain. The existence of multiple benzodiazepine receptors may explain in part the diversity of pharmacological responses in different species.

Animal Models of Anxiety. In animal models of anxiety, most attention has focused on the ability of benzodiazepines to increase locomotor, feeding, or drinking behavior that has been suppressed by novel or aversive stimuli. In one paradigm, animal behaviors that previously had been rewarded by food or water are punished periodically by an electric shock. The time during which shocks are delivered is signaled by some auditory or visual cue, and untreated animals stop performing almost completely when the cue is perceived. The difference in behavioral responses during the punished and unpunished periods is eliminated by benzodiazepine agonists, usually at doses that do not reduce the rate of unpunished responses or produce other signs of impaired motor function. Similarly, rats placed in an unfamiliar environment exhibit markedly reduced exploratory behavior (neophobia), whereas animals treated with benzodiazepines do not. Opioid analgesics and neuroleptic (antipsychotic) drugs do not increase suppressed behaviors, and phenobarbital and meprobamate usually do so only at doses that also reduce spontaneous or unpunished behaviors or produce ataxia.

The difference between the dose required to impair motor function and that necessary to increase punished behavior varies widely among the benzodiazepines and depends on the species and experimental protocol. Although such differences may have encouraged the marketing of some benzodiazepines as selective sedative-hypnotic agents, they have not predicted with any accuracy the magnitude of sedative effects among those benzodiazepines marketed as anxiolytic agents.

Tolerance to Benzodiazepines. Studies on tolerance in laboratory animals often are cited to support the belief that disinhibitory effects of benzodiazepines are distinct from their sedative-ataxic effects. For example, tolerance to the depressant effects on rewarded or neutral behavior occurs after several days of treatment with benzodiazepines; the disinhibitory effects of the drugs on punished behavior are augmented initially and decline after 3 to 4 weeks (*see* File, 1985). Although most patients who ingest benzodiazepines chronically report that drowsiness wanes over a few days, tolerance to the impairment of some measures of psychomotor performance (*e.g.*, visual tracking) usually is not observed. The development of tolerance to the anxiolytic effects of benzodiazepines is a subject of debate (Lader and File, 1987). However, many patients can maintain themselves on a fairly constant dose; increases or decreases in dosage appear to correspond with changes in problems or stresses. Nevertheless, some patients either do not reduce their dosage when stress is relieved or steadily escalate dosage. Such behavior may be associated with the development of drug dependence (*see* Chapter 23).

Some benzodiazepines induce muscle hypotonia without interfering with normal locomotion and can decrease rigidity in patients with cerebral palsy. In contrast to effects in animals, there is only a limited degree of selectivity in human beings. *Clonazepam* in nonsedative doses does cause muscle relaxation, but diazepam and most other benzodiazepines do not. Tolerance occurs to the muscle relaxant and ataxic effects of these drugs.

Experimentally, benzodiazepines inhibit seizure activity induced by either *pentylentetrazol* or *picROTOXIN*, but *strychnine*- and maximal electroshock-induced seizures are suppressed only at doses that also severely impair locomotor activity. *Clonazepam*, *nitrazepam*, and *nordazepam* have more selective anticonvulsant activity than most other benzodiazepines. Benzodiazepines also suppress photic seizures in baboons and ethanol-withdrawal seizures in human beings. However, the development of tolerance to the anticonvulsant effects has lim-

ited the usefulness of benzodiazepines in the treatment of recurrent seizure disorders in human beings (see Chapter 19).

Although analgesic effects of benzodiazepines have been observed in experimental animals, only transient analgesia is apparent in humans after intravenous administration. Such effects actually may involve the production of amnesia. However, unlike the barbiturates, the benzodiazepines do not cause hyperalgesia.

Effects on the Electroencephalogram (EEG) and Sleep Stages.

The effects of benzodiazepines on the waking EEG resemble those of other sedative-hypnotic drugs. Alpha activity is decreased, but there is an increase in low-voltage fast activity. Tolerance occurs to these effects.

Most benzodiazepines decrease sleep latency, especially when first used, and diminish the number of awakenings and the time spent in stage 0 (a stage of wakefulness). Time in stage 1 (descending drowsiness) usually is decreased, and there is a prominent decrease in the time spent in slow-wave sleep (stages 3 and 4). Most benzodiazepines increase the time from onset of spindle sleep to the first burst of rapid-eye-movement (REM) sleep, and the time spent in REM sleep usually is shortened. However, the number of cycles of REM sleep usually is increased, mostly late in the sleep time. *Zolpidem* and *zaleplon* suppress REM sleep to a lesser extent than do benzodiazepines and thus may be superior to benzodiazepines for use as hypnotics (Dujardin *et al.*, 1998).

Despite the shortening of stage 4 and REM sleep, benzodiazepine administration typically increases total sleep time largely because of increased time spent in stage 2 (which is the major fraction of non-REM sleep). The effect is greatest in subjects with the shortest baseline total sleep time. In addition, despite the increased number of REM cycles, the number of shifts to lighter sleep stages (1 and 0) and the amount of body movement are diminished. Nocturnal peaks in the secretion of growth hormone, prolactin, and luteinizing hormone are not affected. During chronic nocturnal use of benzodiazepines, the effects on the various stages of sleep usually decline within a few nights. When such use is discontinued, the pattern of drug-induced changes in sleep parameters may “rebound,” and an increase in the amount and density of REM sleep may be especially prominent. If the dosage has not been excessive, patients usually will note only a shortening of sleep time rather than an exacerbation of insomnia.

Although some differences in the patterns of effects exerted by the various benzodiazepines have been noted, their use usually imparts a sense of deep or refreshing sleep. It is uncertain to which effect on sleep parameters this feeling can be attributed. As a result, variations in the pharmacokinetic properties of individual benzodiazepines appear to be much more important determinants of their effects on sleep than are any potential differences in their pharmacodynamic properties.

Molecular Targets for Benzodiazepine Actions in the CNS. Benzodiazepines are believed to exert most of their effects by interacting with inhibitory neurotransmitter receptors directly activated by GABA. GABA receptors are membrane-bound proteins that can be divided into two major subtypes: GABA_A and GABA_B receptors. The ionotropic GABA_A receptors are composed of five subunits that coassemble to form an integral chloride channel. GABA_A receptors are responsible for most inhibitory neurotransmission in the CNS. In

contrast, the metabotropic GABA_B receptors are G protein-coupled receptors. Benzodiazepines act at GABA_A but not GABA_B receptors by binding directly to a specific site that is distinct from that of GABA binding. Unlike barbiturates, benzodiazepines do not activate GABA_A receptors directly but rather require GABA to express their effects; *i.e.*, they only modulate the effects of GABA. Benzodiazepines and GABA analogs bind to their respective sites on brain membranes with nanomolar affinity. Benzodiazepines modulate GABA binding, and GABA alters benzodiazepine binding in an allosteric fashion.

Benzodiazepines and related compounds can act as agonists, antagonists, or inverse agonists at the benzodiazepine-binding site on GABA_A receptors. Agonists at the binding site increase and inverse agonists decrease the amount of chloride current generated by GABA_A-receptor activation. Agonists at the benzodiazepine binding site shift the GABA concentration–response curve to the left, whereas inverse agonists shift the curve to the right. Both these effects are blocked by antagonists at the benzodiazepine binding site. In the absence of an agonist or inverse agonist for the benzodiazepine binding site, an antagonist for this binding site does not affect GABA_A-receptor function. One such antagonist, flumazenil, is used clinically to reverse the effects of high doses of benzodiazepines. The behavioral and electrophysiological effects of benzodiazepines also can be reduced or prevented by prior treatment with antagonists at the GABA-binding site (*e.g.*, *bicuculline*).

The strongest evidence that benzodiazepines act directly on GABA_A receptors comes from recombinant expression of cDNAs encoding subunits of the receptor complex, which resulted in high-affinity benzodiazepine binding sites and GABA-activated chloride conductances that were enhanced by benzodiazepine receptor agonists (Burt, 2003). The properties of the expressed receptors generally resemble those of GABA_A receptors found in most CNS neurons. Each GABA_A receptor is believed to consist of a pentamer of homologous subunits. Thus far 16 different subunits have been identified and classified into seven subunit families: six α , three β , three γ and single δ , ϵ , π , and θ subunits. Additional complexity arises from RNA splice variants of some of these subunits (*e.g.*, $\gamma 2$ and $\alpha 6$). The exact subunit structures of native GABA receptors still are unknown, but it is thought that most GABA receptors are composed of α , β , and γ subunits that coassemble with some uncertain stoichiometry. The multiplicity of subunits generates heterogeneity in GABA_A receptors and is responsible, at least in part, for the pharmacological diversity in benzodiazepine effects in behavioral, biochemical, and functional studies. Studies of cloned GABA_A receptors have shown that the coassembly of a γ subunit with α and β subunits confers benzodiazepine sensitivity to GABA_A receptors (Burt, 2003). Receptors composed solely of α and β subunits produce functional GABA_A receptors that also respond to barbiturates, but they neither bind nor are affected by

benzodiazepines. Benzodiazepines are believed to bind at the interface between α and γ subunits, and both subunits determine the pharmacology of the benzodiazepine binding site (Burt, 2003). For example, receptors containing the $\alpha 1$ subunit are pharmacologically distinct from receptors containing $\alpha 2$, $\alpha 3$, or $\alpha 5$ subunits (Pritchett and Seeburg, 1990), reminiscent of the pharmacological heterogeneity detected with radioligand-binding studies using brain membranes. Receptors containing the $\alpha 6$ subunit do not display high-affinity binding of diazepam and appear to be selective for the benzodiazepine receptor inverse agonist RO 15-4513, which has been tested as an alcohol antagonist (Lüddens *et al.*, 1990). The subtype of γ subunit also modulates benzodiazepine pharmacology, with lower-affinity binding observed in receptors containing the $\gamma 1$ subunit. Although theoretically approximately a million different GABA_A receptors could be assembled from all these different subunits, constraints for the assembly of these receptors apparently limit their numbers (Sieghart *et al.*, 1999).

An understanding of which GABA_A receptor subunits are responsible for particular effects of benzodiazepines *in vivo* is emerging. The mutation to arginine of a histidine residue at position 101 of the GABA_A receptor $\alpha 1$ subunit renders receptors containing that subunit insensitive to the GABA-enhancing effects of diazepam (Kleingoor *et al.*, 1993). Mice bearing these mutated subunits fail to exhibit the sedative, the amnestic, and, in part, the anticonvulsant effects of diazepam while retaining sensitivity to the anxiolytic, muscle-relaxant, and ethanol-enhancing effects. Conversely, mice bearing the equivalent mutation in the $\alpha 2$ subunit of the GABA_A receptor are insensitive to the anxiolytic effects of diazepam (Burt, 2003). The attribution of specific behavioral effects of benzodiazepines to individual receptor subunits will aid in the development of new compounds exhibiting fewer undesired side effects. For example, the experimental compound L838,417 enhances the effects of GABA on receptors composed of $\alpha 2$, $\alpha 3$, or $\alpha 5$ subunits but lacks efficacy on receptors containing the $\alpha 1$ subunit; it is thus anxiolytic but not sedating (Burt, 2003).

GABA_A receptor subunits also may play roles in the targeting of assembled receptors to their proper locations in synapses. In knockout mice lacking the $\gamma 2$ subunit, GABA_A receptors did not localize to synapses, although they were formed and translocated to the cell surface (Essrich *et al.*, 1998). The synaptic clustering molecule gephyrin also plays a role in receptor localization.

GABA_A Receptor-Mediated Electrical Events: In Vivo Properties.

The remarkable safety of the benzodiazepines is likely related to the fact that their effects *in vivo* depend on the presynaptic release of GABA; in the absence of GABA, benzodiazepines have no effects on GABA_A receptor function. Although barbiturates also enhance the effects of GABA at low concentrations, they directly activate GABA receptors at higher concentrations, which can lead to profound CNS depression (*see below*). Further, the behavioral and sedative effects of benzodiazepines can be ascribed in part to potentiation of GABA-ergic pathways that serve to regulate the firing of neurons containing various monoamines (*see Chapter 12*). These neurons are known to promote behavioral arousal and are important mediators of the inhibitory effects of fear and punishment on behavior. Finally, inhibitory effects on muscular hypertonia or the spread of seizure activity can be rationalized by potentiation of inhibitory GABA-ergic circuits at various levels of the neuraxis. In most studies conducted *in vivo* or *in situ*, the local or systemic administration of benzodiazepines reduces the spontaneous or evoked electrical activity of major (large) neurons in all regions of the brain and spinal cord. The activity of these

neurons is regulated in part by small inhibitory interneurons (predominantly GABA-ergic) arranged in feedback and feedforward types of circuits. The magnitude of the effects produced by benzodiazepines varies widely depending on such factors as the types of inhibitory circuits that are operating, the sources and intensity of excitatory input, and the manner in which experimental manipulations are performed and assessed. For example, feedback circuits often involve powerful inhibitory synapses on the neuronal soma near the axon hillock, which are supplied predominantly by recurrent pathways. The synaptic or exogenous application of GABA to this region increases chloride conductance and can prevent neuronal discharge by shunting electric currents that otherwise would depolarize the membrane of the initial segment. Accordingly, benzodiazepines markedly prolong the period after brief activation of recurrent GABA-ergic pathways during which neither spontaneous nor applied excitatory stimuli can evoke neuronal discharge; this effect is reversed by the GABA_A-receptor antagonist *bicuculline*.

Molecular Basis for Benzodiazepine Regulation of GABA_A Receptor-Mediated Electrical Events. Electrophysiological studies *in vitro* have shown that the enhancement of GABA-induced chloride currents by benzodiazepines results primarily from an increase in the frequency of bursts of chloride channel opening produced by submaximal amounts of GABA (Twyman *et al.*, 1989). Inhibitory synaptic transmission measured after stimulation of afferent fibers is potentiated by benzodiazepines at therapeutically relevant concentrations. Prolongation of spontaneous miniature inhibitory postsynaptic currents (IPSCs) by benzodiazepines also has been observed. Although sedative barbiturates also enhance such chloride currents, they do so by prolonging the duration of individual channel-opening events. Macroscopic measurements of GABA_A receptor-mediated currents indicate that benzodiazepines shift the GABA concentration–response curve to the left without increasing the maximum current evoked with GABA. These findings collectively are consistent with a model in which benzodiazepines exert their major actions by increasing the gain of inhibitory neurotransmission mediated by GABA_A receptors. As noted earlier, certain experimental benzodiazepines and other structurally related compounds act as inverse agonists to reduce GABA-induced chloride currents, promote convulsions, and produce other *in vivo* effects opposite to those induced by the benzodiazepines in clinical use (*see Gardner et al.*, 1993). A few compounds, most notably flumazenil, can block the effects of clinically used benzodiazepines and inverse agonists *in vitro* and *in vivo*, but they have no detectable actions by themselves. Although benzodiazepines appear to act mainly at GABA_A receptors, some observations are difficult to reconcile with the hypothesis that all benzodiazepine effects are mediated *via* GABA_A receptors. Low concentrations of benzodiazepines that are not blocked by bicuculline or picrotoxin induce depressant effects on hippocampal neurons (Polc, 1988). The induction of sleep in rats by benzodiazepines also is insensitive to bicuculline or picrotoxin but is prevented by flumazenil (*see Mendelson*, 1992). At higher concentrations, corresponding to those producing hypnosis and amnesia during preanesthetic medication (*see Chapter 13*) or those achieved during the treatment of status epilepticus (*see Chapter 19*), the actions of the benzodiazepines may involve a number of other mechanisms. These include inhibition of the uptake of adenosine and the resulting potentiation of the actions of this endogenous neuronal depressant (*see Phillis and O'Regan*, 1988), as well as the GABA-independent inhibition of Ca²⁺ currents, Ca²⁺-dependent release of neu-

rotransmitter, and *tetrodotoxin*-sensitive Na⁺ channels (*see* Macdonald and McLean, 1986).

The macromolecular complex containing GABA-regulated chloride channels also may be a site of action of general anesthetics, ethanol, inhaled drugs of abuse, and certain metabolites of endogenous steroids (Whiting, 2003). Among the latter, *allopregnanolone* (3 α -hydroxy, 5 α -dihydroprogesterone) is of particular interest. This compound, a metabolite of progesterone that can be formed in the brain from precursors in the circulation, as well as from those synthesized by glial cells, produces barbituratelike effects, including promotion of GABA-induced chloride currents and enhanced binding of benzodiazepines and GABA-receptor agonists. As with the barbiturates, higher concentrations of the steroid activate chloride currents in the absence of GABA, and its effects do not require the presence of a γ subunit in GABA_A receptors expressed in transfected cells. Unlike the barbiturates, however, the steroid cannot reduce excitatory responses to glutamate (*see* below). These effects are produced very rapidly and apparently are mediated by interactions at sites on the cell surface. A congener of allopregnanolone (*alfaxalone*) was used previously outside the United States for the induction of anesthesia.

Respiration. Hypnotic doses of benzodiazepines are without effect on respiration in normal subjects, but special care must be taken in the treatment of children (Kriel *et al.*, 2000) and individuals with impaired hepatic function, such as alcoholics (Guglielminotti *et al.*, 1999). At higher doses, such as those used for preanesthetic medication or for endoscopy, benzodiazepines slightly depress alveolar ventilation and cause respiratory acidosis as the result of a decrease in hypoxic rather than hypercapnic drive; these effects are exaggerated in patients with chronic obstructive pulmonary disease (COPD), and alveolar hypoxia and/or CO₂ narcosis may result. These drugs can cause apnea during anesthesia or when given with opioids. Patients severely intoxicated with benzodiazepines only require respiratory assistance when they also have ingested another CNS-depressant drug, most commonly ethanol.

In contrast, hypnotic doses of benzodiazepines may worsen sleep-related breathing disorders by adversely affecting control of the upper airway muscles or by decreasing the ventilatory response to CO₂ (*see* Guilleminault, in Symposium, 1990). The latter effect may cause hypoventilation and hypoxemia in some patients with severe COPD, although benzodiazepines may improve sleep and sleep structure in some instances. In patients with obstructive sleep apnea (OSA), hypnotic doses of benzodiazepines may decrease muscle tone in the upper airway and exaggerate the impact of apneic episodes on alveolar hypoxia, pulmonary hypertension, and cardiac ventricular load. Many clinicians consider the presence of OSA to be a contraindication to the use of alcohol or any sedative-hypnotic agent, including a benzodiazepine; caution also should be exercised with patients who snore reg-

ularly, because partial airway obstruction may be converted to OSA under the influence of these drugs. In addition, benzodiazepines may promote the appearance of episodes of apnea during REM sleep (associated with decreases in oxygen saturation) in patients recovering from a myocardial infarction (Guilleminault, in Symposium, 1990); however, no impact of these drugs on survival of patients with cardiac disease has been reported.

Cardiovascular System. The cardiovascular effects of benzodiazepines are minor in normal subjects except in severe intoxication; the adverse effects in patients with obstructive sleep disorders or cardiac disease were noted above. In preanesthetic doses, all benzodiazepines decrease blood pressure and increase heart rate. With midazolam, the effects appear to be secondary to a decrease in peripheral resistance, but with diazepam, they are secondary to a decrease in left ventricular work and cardiac output. Diazepam increases coronary flow, possibly by an action to increase interstitial concentrations of adenosine, and the accumulation of this cardiodepressant metabolite also may explain the negative inotropic effects of the drug. In large doses, midazolam decreases cerebral blood flow and oxygen assimilation considerably (Nugent *et al.*, 1982).

Gastrointestinal Tract. Benzodiazepines are thought by some gastroenterologists to improve a variety of “anxiety related” gastrointestinal disorders. There is a paucity of evidence for direct actions. Benzodiazepines partially protect against stress ulcers in rats, and diazepam markedly decreases nocturnal gastric secretion in human beings. Other agents are considerably more effective in acid-peptic disorders (*see* Chapter 36).

Absorption, Fate, and Excretion. The physicochemical and pharmacokinetic properties of the benzodiazepines greatly affect their clinical utility. They all have high lipid–water distribution coefficients in the nonionized form; nevertheless, lipophilicity varies more than fiftyfold according to the polarity and electronegativity of various substituents.

All the benzodiazepines are absorbed completely, with the exception of *clorazepate*; this drug is decarboxylated rapidly in gastric juice to *N*-desmethyldiazepam (nordazepam), which subsequently is absorbed completely. Some benzodiazepines (*e.g.*, *prazepam* and *flurazepam*) reach the systemic circulation only in the form of active metabolites.

Drugs active at the benzodiazepine receptor may be divided into four categories based on their elimination half-

lives: (1) ultra-short-acting benzodiazepines, (2) short-acting agents, with half-lives less than 6 hours, including *triazolam*, the nonbenzodiazepine *zolpidem* (half-life approximately 2 hours), and *zopiclone* (half-life 5 to 6 hours), (3) intermediate-acting agents, with half-lives of 6 to 24 hours, including *estazolam* and *temazepam*, and (4) long-acting agents, with half-lives of greater than 24 hours, including *flurazepam*, *diazepam*, and *quazepam*.

The benzodiazepines and their active metabolites bind to plasma proteins. The extent of binding correlates strongly with lipid solubility and ranges from about 70% for *alprazolam* to nearly 99% for *diazepam*. The concentration in the cerebrospinal fluid is approximately equal to the concentration of free drug in plasma. While competition with other protein-bound drugs may occur, no clinically significant examples have been reported.

The plasma concentrations of most benzodiazepines exhibit patterns that are consistent with two-compartment models (*see* Chapter 1), but three-compartment models appear to be more appropriate for the compounds with the highest lipid solubility. Accordingly, there is rapid uptake of benzodiazepines into the brain and other highly perfused organs after intravenous administration (or oral administration of a rapidly absorbed compound); rapid uptake is followed by a phase of redistribution into tissues that are less well perfused, especially muscle and fat. Redistribution is most rapid for drugs with the highest lipid solubility. In the regimens used for nighttime sedation, the rate of redistribution sometimes can have a greater influence than the rate of biotransformation on the duration of CNS effects (Dettli, in Symposium, 1986a). The kinetics of redistribution of *diazepam* and other lipophilic benzodiazepines are complicated by enterohepatic circulation. The volumes of distribution of the benzodiazepines are large and in many cases are increased in elderly patients. These drugs cross the placental barrier and are secreted into breast milk.

The benzodiazepines are metabolized extensively by cytochrome P450 enzymes, particularly CYP3A4 and CYP2C19. Some benzodiazepines, such as *oxazepam*, are conjugated directly and are not metabolized by these enzymes (*see* Tanaka, 1999). *Erythromycin*, *clarithromycin*, *ritonavir*, *itraconazole*, *ketoconazole*, *nefazodone*, and grapefruit juice are inhibitors of CYP3A4 and can affect the metabolism of benzodiazepines (Dresser *et al.*, 2000). Because active metabolites of some benzodiazepines are biotransformed more slowly than are the parent compounds, the duration of action of many benzodiazepines bears little relationship to the half-life of elimination of the drug that has been administered. For example, the half-life of *flurazepam* in plasma is 2 to 3 hours, but

that of a major active metabolite (*N*-desalkylflurazepam) is 50 hours or more. Conversely, the rate of biotransformation of agents that are inactivated by the initial reaction is an important determinant of their duration of action; these agents include *oxazepam*, *lorazepam*, *temazepam*, *triazolam*, and *midazolam*. Metabolism of the benzodiazepines occurs in three major stages. These and the relationships between the drugs and their metabolites are shown in Table 16–2.

For benzodiazepines that bear a substituent at position 1 (or 2) of the diazepine ring, the initial and most rapid phase of metabolism involves modification and/or removal of the substituent. With the exception of *triazolam*, *alprazolam*, *estazolam*, and *midazolam*, which contain either a fused triazolo or imidazolo ring, the eventual products are *N*-desalkylated compounds that are biologically active. One such compound, *nordazepam*, is a major metabolite common to the biotransformation of *diazepam*, *clorazepate*, and *prazepam*; it also is formed from *demoxepam*, an important metabolite of *chlordiazepoxide*.

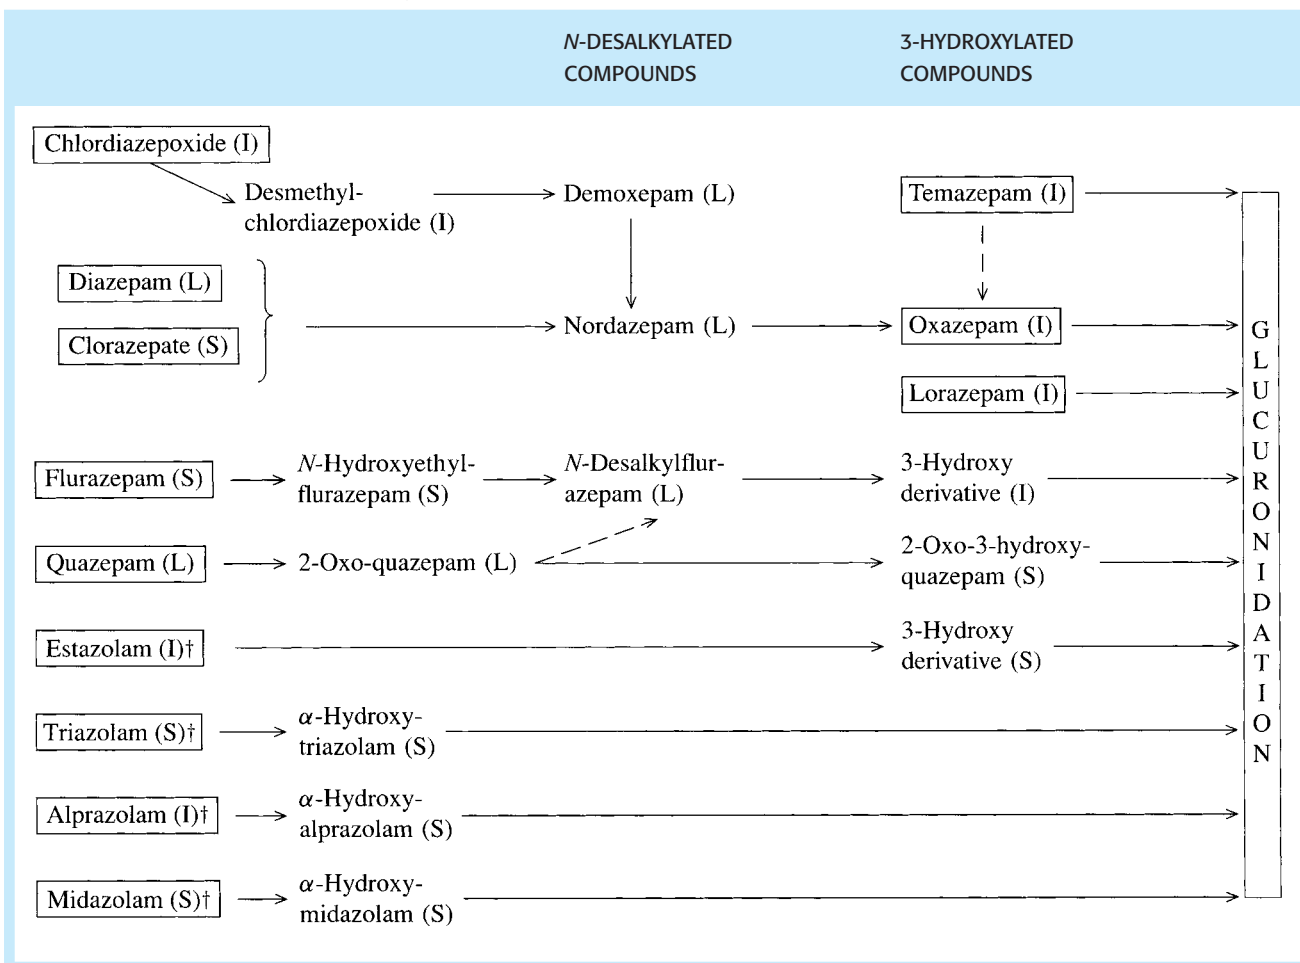

The second phase of metabolism involves hydroxylation at position 3 and also usually yields an active derivative (*e.g.*, *oxazepam* from *nordazepam*). The rates of these reactions are usually very much slower than the first stage (half-lives > 40 to 50 hours) such that appreciable accumulation of hydroxylated products with intact substituents at position 1 does not occur. There are two significant exceptions to this rule: (1) Small amounts of *temazepam* accumulate during the chronic administration of *diazepam* (not shown in Table 16–2), and (2) following the replacement of sulfur with oxygen in *quazepam*, most of the resulting 2-oxoquazepam is hydroxylated slowly at position 3 without removal of the *N*-alkyl group. However, only small amounts of the 3-hydroxyl derivative accumulate during the chronic administration of *quazepam* because this compound is conjugated at an unusually rapid rate. In contrast, the *N*-desalkylflurazepam that is formed by the “minor” metabolic pathway does accumulate during *quazepam* administration, and it contributes significantly to the overall clinical effect.

The third major phase of metabolism is the conjugation of the 3-hydroxyl compounds, principally with glucuronic acid; the half-lives of these reactions usually are between 6 and 12 hours, and the products invariably are inactive. Conjugation is the only major route of metabolism for *oxazepam* and *lorazepam* and is the preferred pathway for *temazepam* because of the slower conversion of this compound to *oxazepam*. *Triazolam* and *alprazolam* are metabolized principally by initial hydroxylation of the methyl group on the fused triazolo ring; the absence of a chlorine residue in ring C of *alprazolam* slows this reaction significantly. The products, sometimes referred to as *α*-hydroxylated compounds, are quite active but are metabolized very rapidly, primarily by conjugation with glucuronic acid, such that there is no appreciable accumulation of active metabolites. The fused triazolo ring in *estazolam* lacks a methyl group and is hydroxylated to only a limited extent; the major route of metabolism involves the formation of the 3-hydroxyl derivative. The corresponding hydroxyl derivatives of *triazolam* and *alprazolam* also are formed to a significant extent. Compared with compounds without the triazolo ring, the rate of this reaction for all three drugs is unusually swift, and the 3-hydroxyl compounds are rapidly conjugated or oxidized further to benzophenone derivatives before excretion.

Midazolam is metabolized rapidly, primarily by hydroxylation of the methyl group on the fused imidazo ring; only small amounts

Table 16-2

Major Metabolic Relationships among Some of the Benzodiazepines*

*Compounds enclosed in boxes are marketed in the United States. The approximate half-lives of the various compounds are denoted in parentheses; S (short-acting), $t_{1/2} < 6$ hours; I (intermediate-acting), $t_{1/2} = 6$ to 24 hours; L (long-acting), $t_{1/2} > 24$ hours. All compounds except clorazepate are biologically active; the activity of 3-hydroxydesalkylflurazepam has not been determined. Clonazepam (not shown) is an *N*-desalkyl compound, and it is metabolized primarily by reduction of the 7-NO₂ group to the corresponding amine (inactive), followed by acetylation; its half-life is 20 to 40 hours. †See text for discussion of other pathways of metabolism.

of 3-hydroxyl compounds are formed. The α -hydroxylated compound, which has appreciable biological activity, is eliminated with a half-life of 1 hour after conjugation with glucuronic acid. Variable and sometimes substantial accumulation of this metabolite has been noted during intravenous infusion (Oldenhof *et al.*, 1988).

The aromatic rings (A and C) of the benzodiazepines are hydroxylated only to a small extent. The only important metabolism at these sites is reduction of the 7-nitro substituents of clonazepam, nitrazepam, and *flunitrazepam*; the half-lives of these reactions are usually 20 to 40 hours. The resulting amines are inactive and are acetylated to varying degrees before excretion.

Because the benzodiazepines apparently do not significantly induce the synthesis of hepatic cytochrome P450 enzymes, their chronic administration usually does not result in the accelerated metabolism of other substances or of the benzodiazepines. *Cimetidine* and oral contraceptives inhibit *N*-dealkylation and 3-hydroxyla-

tion of benzodiazepines. Ethanol, isoniazid, and phenytoin are less effective in this regard. These reactions usually are reduced to a greater extent in elderly patients and in patients with chronic liver disease than are those involving conjugation.

An ideal hypnotic agent would have a rapid onset of action when taken at bedtime, a sufficiently sustained action to facilitate sleep throughout the night, and no residual action by the following morning. Among the benzodiazepines that are used commonly as hypnotic agents, triazolam theoretically fits this description most closely. Because of the slow rate of elimination of *desalkylflurazepam*, flurazepam (or quazepam) might seem to be unsuitable for this purpose. In practice, there appear to be some disadvantages

to the use of agents that have a relatively rapid rate of disappearance, including the early-morning insomnia that is experienced by some patients and a greater likelihood of rebound insomnia on drug discontinuation (*see Gillin et al., 1989; Roth and Roehrs, 1992*). With careful selection of dosage, flurazepam and other benzodiazepines with slower rates of elimination than triazolam can be used effectively. The biotransformation and pharmacokinetic properties of the benzodiazepines have been reviewed (*Greenblatt, 1991; Laurijssens and Greenblatt, 1996*).

Therapeutic Uses

The therapeutic uses and routes of administration of individual benzodiazepines that are marketed in the United States

are summarized in Table 16–3. It should be emphasized that most benzodiazepines can be used interchangeably. For example, diazepam can be used for alcohol withdrawal, and most benzodiazepines work as hypnotics. In general, the therapeutic uses of a given benzodiazepine depend on its half-life and may not match the Food and Drug Administration (FDA) approved indications. Benzodiazepines that are useful as anticonvulsants have a long half-life, and rapid entry into the brain is required for efficacy in treatment of status epilepticus. A short elimination half-life is desirable for hypnotics, although this carries the drawback of increased abuse liability and severity of withdrawal after drug discontinuation. Antianxiety agents, in contrast, should have a long half-life despite the drawback of the risk of neuropsychological deficits caused by drug accumulation.

Table 16–3

Trade Names, Routes of Administration, and Therapeutic Uses of Benzodiazepines

COMPOUND (TRADE NAME)	ROUTES OF ADMINISTRATION*	EXAMPLES OF THERAPEUTIC USES†	COMMENTS	$t_{1/2}$, HOURS‡	USUAL SEDATIVE- HYPNOTIC DOSAGE, MG¶
Alprazolam (XANAX)	Oral	Anxiety disorders, agoraphobia	Withdrawal symptoms may be especially severe	12±2	—
Chlordiazep- oxide (LIBRIUM, others)	Oral, IM, IV	Anxiety disorders, management of alcohol withdraw- al, anesthetic pre- medication	Long-acting and self- tapering because of active metabolites	10±3.4	50–100, qd– qid [§]
Clonazepam (KLONOPIN)	Oral	Seizure disorders, adjunctive treat- ment in acute mania and certain move- ment disorders	Tolerance develops to anticonvulsant effects	23±5	—
Clorazepate (TRANXENE, others)	Oral	Anxiety disorders, seizure disorders	Prodrug; activity due to formation of nor- dazepam during absorption	2.0±0.9	3.75–20, bid– qid [§]
Diazepam (VALIUM, others)	Oral, IM, IV, rectal	Anxiety disorders, sta- tus epilepticus, skel- etal muscle relax- ation, anesthetic premedication	Prototypical benzodiazepine	43±13	5–10, tid–qid [§]
Estazolam (PROSOM)	Oral	Insomnia	Contains triazolo ring; adverse effects may be similar to those of triazolam	10–24	1–2

COMPOUND (TRADE NAME)	ROUTES OF ADMINISTRATION*	EXAMPLES OF THERAPEUTIC USES†	COMMENTS	$t_{1/2}$, HOURS‡	USUAL SEDATIVE- HYPNOTIC DOSAGE, MG¶
Flurazepam (DALMANE)	Oral	Insomnia	Active metabolites accumulate with chronic use	74±24	15–30
Lorazepam (ATIVAN)	Oral, IM, IV	Anxiety disorders, pre- anesthetic medica- tion	Metabolized solely by conjugation	14±5	2–4
Midazolam (VERSED)	IV, IM	Preanesthetic and intraoperative medication	Rapidly inactivated	1.9±0.6	— [#]
Oxazepam (SERAX)	Oral	Anxiety disorders	Metabolized solely by conjugation	8.0±2.4	15–30, tid–qid [§]
Quazepam (DORAL)	Oral	Insomnia	Active metabolites accumulate with chronic use	39	7.5–15
Temazepam (RESTORIL)	Oral	Insomnia	Metabolized mainly by conjugation	11±6	7.5–30
Triazolam (HALCION)	Oral	Insomnia	Rapidly inactivated; may cause disturb- ing daytime side effects	2.9±1.0	0.125–0.25

*IM, intramuscular injection; IV, intravenous administration; qd, once a day; bid, twice a day; tid, three times a day; qid, four times a day. †The therapeutic uses are identified as examples to emphasize that most benzodiazepines can be used interchangeably. In general, the therapeutic uses of a given benzodiazepine are related to its half-life and may not match the marketed indications. The issue is addressed more extensively in the text. ‡Half-life of active metabolite may differ. See Appendix II for additional information. ¶For additional dosage information, see Chapter 13 (anesthesia), Chapter 17 (anxiety), and Chapter 19 (seizure disorders). §Approved as a sedative-hypnotic only for management of alcohol withdrawal; doses in a nontolerant individual would be smaller. #Recommended doses vary considerably depending on specific use, condition of patient, and concomitant administration of other drugs.

Untoward Effects. At the time of peak concentration in plasma, hypnotic doses of benzodiazepines can be expected to cause varying degrees of lightheadedness, lassitude, increased reaction time, motor incoordination, impairment of mental and motor functions, confusion, and anterograde amnesia. Cognition appears to be affected less than motor performance. *All these effects can greatly impair driving and other psychomotor skills, especially if combined with ethanol.* When the drug is given at the intended time of sleep, the persistence of these effects during the waking hours is adverse. These dose-related residual effects can be insidious because most subjects underestimate the degree of their impair-

ment. Residual daytime sleepiness also may occur, even though successful drug therapy can reduce the daytime sleepiness resulting from chronic insomnia (*see Dement, 1991*). The intensity and incidence of CNS toxicity generally increase with age; both pharmacokinetic and pharmacodynamic factors are involved (*see Meyer, 1982; Monane, 1992*).

Other relatively common side effects of benzodiazepines are weakness, headache, blurred vision, vertigo, nausea and vomiting, epigastric distress, and diarrhea; joint pains, chest pains, and incontinence are much more rare. Anticonvulsant benzodiazepines sometimes actually increase the frequency of seizures in patients with epilep-

sy. The possible adverse effects of alterations in the sleep pattern are discussed below.

Adverse Psychological Effects. Benzodiazepines may cause paradoxical effects. Flurazepam occasionally increases the incidence of nightmares—especially during the first week of use—and sometimes causes garrulousness, anxiety, irritability, tachycardia, and sweating. Amnesia, euphoria, restlessness, hallucinations, and hypomanic behavior have been reported to occur during use of various benzodiazepines. The release of bizarre uninhibited behavior has been noted in some users, whereas hostility and rage may occur in others; collectively, these are sometimes referred to as *disinhibition* or *dyscontrol reactions*. Paranoia, depression, and suicidal ideation also occasionally may accompany the use of these agents. Such paradoxical or disinhibition reactions are rare and appear to be dose-related. Because of reports of an increased incidence of confusion and abnormal behaviors, triazolam has been banned in the United Kingdom, although the FDA declared triazolam to be safe and effective in low doses of 0.125 to 0.25 mg. Surveys in the United Kingdom after the ban found that patients did not have fewer side effects with replacement treatments (Hindmarch *et al.*, 1993), which is consonant with controlled studies that do not support the conclusion that such reactions occur more frequently with any one benzodiazepine than with others (*see* Jonas *et al.*, 1992; Rothschild, 1992).

Chronic benzodiazepine use poses a risk for development of dependence and abuse (Woods *et al.*, 1992), but not to the same extent as seen with older sedatives and other recognized drugs of abuse (Ulenhuth *et al.*, 1999). Abuse of benzodiazepines includes the use of flunitrazepam (ROHYPNOL) as a “date-rape drug” (Woods and Winger, 1997). Mild dependence may develop in many patients who have taken therapeutic doses of benzodiazepines on a regular basis for prolonged periods. Withdrawal symptoms may include temporary intensification of the problems that originally prompted their use (*e.g.*, insomnia or anxiety). Dysphoria, irritability, sweating, unpleasant dreams, tremors, anorexia, and faintness or dizziness also may occur, especially when withdrawal of the benzodiazepine occurs abruptly (Petursson, 1994). Hence, it is prudent to taper the dosage gradually when therapy is to be discontinued. Despite their adverse effects, benzodiazepines are relatively safe drugs. Even huge doses are rarely fatal unless other drugs are taken concomitantly. Ethanol is a common contributor to deaths involving benzodiazepines, and true coma is uncommon in the absence of another CNS depressant. Although overdose with a benzodiazepine rarely causes severe cardiovascular or respiratory depression, therapeutic doses can further compromise respiration in patients with COPD or obstructive sleep apnea (*see* discussion of effects on respiration, above).

A wide variety of allergic, hepatotoxic, and hematologic reactions to the benzodiazepines may occur, but the incidence is quite low; these reactions have been associated with the use of flurazepam and triazolam but not with temazepam. Large doses taken just before or during labor may cause hypothermia, hypotonia, and mild respiratory depression in the neonate. Abuse by the pregnant mother can result in a withdrawal syndrome in the newborn.

Except for additive effects with other sedative or hypnotic drugs, reports of clinically important pharmacodynamic interactions between benzodiazepines and other drugs have been infrequent. Ethanol increases both the rate of absorption of benzodiazepines and the associated CNS depression. *Valproate* and benzodiazepines in

combination may cause psychotic episodes. Pharmacokinetic interactions were discussed earlier.

Novel Benzodiazepine-Receptor Agonists

Hypnotics in this class include *zolpicone* (not available in the United States), zolpidem (AMBIEN), zaleplon (SONATA), and indiplon (under review by the FDA). Although the chemical structures of these compounds do not resemble those of benzodiazepines, it is assumed that their therapeutic efficacies are due to agonist effects on the benzodiazepine site of the GABA_A receptor.

Zaleplon and zolpidem are effective in relieving sleep-onset insomnia. Both drugs have been approved by the FDA for use for up to 7 to 10 days at a time. Zaleplon and zolpidem have sustained hypnotic efficacy without occurrence of rebound insomnia on abrupt discontinuation (Mittler, 2000; Walsh *et al.*, 2000). Zaleplon and zolpidem have similar degrees of efficacy. Zolpidem has a half-life of about 2 hours, which is sufficient to cover most of a typical 8-hour sleep period, and is presently approved for bedtime use only. Zaleplon has a shorter half-life, about 1 hour, which offers the possibility for safe dosing later in the night, within 4 hours of the anticipated rising time. As a result, zaleplon is approved for use immediately at bedtime or when the patient has difficulty falling asleep after bedtime. Because of its short half-life, zaleplon has not been shown to be different from placebo in measures of duration of sleep and number of awakenings. Zaleplon and zolpidem may differ in residual side effects; late-night administration of zolpidem has been associated with morning sedation, delayed reaction time, and anterograde amnesia, whereas zaleplon has no more side effects than placebo.

Zaleplon. Zaleplon (SONATA) is a nonbenzodiazepine and is a member of the pyrazolopyrimidine class of compounds. The structural formula is:

Zaleplon preferentially binds to the benzodiazepine-binding site on GABA_A receptors containing the $\alpha 1$ receptor subunit. Zaleplon is absorbed rapidly and reaches peak plasma concentrations in about

1 hour. Its half-life is approximately 1 hour. Its bioavailability is approximately 30% because of presystemic metabolism. Zaleplon has a volume of distribution of approximately 1.4 L/kg and plasma-protein binding of approximately 60%. Zaleplon is metabolized largely by aldehyde oxidase and to a lesser extent by CYP3A4. Its oxidative metabolites are converted to glucuronides and eliminated in urine. Less than 1% of zaleplon is excreted unchanged in urine. None of zaleplon's metabolites is pharmacologically active.

Zaleplon (usually administered in 5-, 10-, or 20-mg doses) has been studied in clinical trials of patients with chronic or transient insomnia (for a review, *see* Dooley and Plosker, 2000). Studies have focused on its effects in decreasing sleep latency. Zaleplon-treated subjects with either chronic or transient insomnia have experienced shorter periods of sleep latency than have placebo-treated subjects. Tolerance to zaleplon does not appear to occur, nor do rebound insomnia or withdrawal symptoms after stopping treatment.

Zolpidem. Zolpidem (AMBIEN) is a nonbenzodiazepine sedative-hypnotic drug that became available in the United States in 1993 after 5 years of use in Europe (Holm and Goa, 2000). It is classified as an imidazopyridine and has the following chemical structure:

Although the actions of zolpidem are due to agonist effects on GABA_A receptors and generally resemble those of benzodiazepines, it produces only weak anticonvulsant effects in experimental animals, and its relatively strong sedative actions appear to mask anxiolytic effects in various animal models of anxiety (*see* Langtry and Benfield, 1990). Although chronic administration of zolpidem to rodents produces neither tolerance to its sedative effects nor signs of withdrawal when the drug is discontinued and flumazenil is injected (Perrault *et al.*, 1992), tolerance and physical dependence have been observed with chronic administration of zolpidem to baboons (Griffiths *et al.*, 1992).

Unlike the benzodiazepines, zolpidem has little effect on the stages of sleep in normal human subjects. The drug is as effective as benzodiazepines in shortening sleep latency and prolonging total sleep time in patients with insomnia. After discontinuation of zolpidem, the beneficial effects on sleep reportedly persist for up to 1 week (Herrmann *et al.*, 1993), but mild rebound insomnia on the first night also has occurred (Anonymous, 1993). Tolerance and physical dependence develop only rarely and under unusual circumstances (Cavallaro *et al.*, 1993; Morselli, 1993). Indeed, zolpidem-induced improvement in sleep time of chronic insomniacs was sustained during as much as 6 months of treatment without signs of withdrawal or rebound after stopping the drug (Kummer *et al.*, 1993). Nevertheless, zolpidem is approved only for the short-term treatment of insomnia. At therapeutic doses (5 to 10 mg), zolpidem infrequently produces residual daytime sedation or amnesia, and the incidence of other adverse effects (*e.g.*, gastrointestinal complaints or dizziness) also is low. As with the benzodiazepines, large overdoses of zolpidem do not produce severe respiratory depression unless other agents (*e.g.*, ethanol) also are ingested (Garnier *et al.*,

1994). Hypnotic doses increase the hypoxia and hypercarbia of patients with obstructive sleep apnea.

Zolpidem is absorbed readily from the gastrointestinal tract; first-pass hepatic metabolism results in an oral bioavailability of about 70%, but this value is lower when the drug is ingested with food because of slowed absorption and increased hepatic blood flow. Zolpidem is eliminated almost entirely by conversion to inactive products in the liver, largely through oxidation of the methyl groups on the phenyl and imidazopyridine rings to the corresponding carboxylic acids. Its plasma half-life is approximately 2 hours in individuals with normal hepatic blood flow or function. This value may be increased twofold or more in those with cirrhosis and also tends to be greater in older patients; adjustment of dosage often is necessary in both categories of patients. Although little or no unchanged zolpidem is found in the urine, elimination of the drug is slower in patients with chronic renal insufficiency largely owing to an increase in its apparent volume of distribution.

Flumazenil: A Benzodiazepine-Receptor Antagonist

Flumazenil (ROMAZICON) is an imidazobenzodiazepine (Table 16-1) that behaves as a specific benzodiazepine antagonist (Hoffman and Warren, 1993). Flumazenil binds with high affinity to specific sites on the GABA_A receptor, where it competitively antagonizes the binding and allosteric effects of benzodiazepines and other ligands. Both the electrophysiological and behavioral effects of agonist or inverse-agonist benzodiazepines and β -carbolines also are antagonized. In animal models, the intrinsic pharmacological actions of flumazenil have been subtle; effects resembling those of inverse agonists sometimes have been detected at low doses, whereas slight benzodiazepinelike effects often have been evident at high doses. The evidence for intrinsic activity in human subjects is even more vague, except for modest anticonvulsant effects at high doses. However, anticonvulsant effects cannot be relied on for therapeutic utility because the administration of flumazenil may precipitate seizures under certain circumstances (*see* below).

Flumazenil is available only for intravenous administration. Although absorbed rapidly after oral administration, less than 25% of the drug reaches the systemic circulation owing to extensive first-pass hepatic metabolism; effective oral doses are apt to cause headache and dizziness (Roncari *et al.*, 1993). On intravenous administration, flumazenil is eliminated almost entirely by hepatic metabolism to inactive products with a half-life of about 1 hour; the duration of clinical effects usually is only 30 to 60 minutes.

The primary indications for the use of flumazenil are the management of suspected benzodiazepine overdose and the reversal of sedative effects produced by benzodiazepines administered during either general anesthesia or diagnostic and/or therapeutic procedures.

The administration of a series of small injections is preferred to a single bolus injection. A total of 1 mg flumazenil given over 1 to 3 minutes usually is sufficient to abolish the effects of therapeutic doses of benzodiazepines; patients with suspected benzodiazepine overdose should respond adequately to a cumulative dose of 1 to 5 mg given over 2 to 10 minutes; a lack of response to 5 mg flumazenil strongly suggests that a benzodiazepine is not the major cause of sedation. Additional courses of treatment with flumazenil may be needed within 20 to 30 minutes should sedation reappear. Flumazenil is not effective in single-drug overdoses with either barbiturates or tricyclic antidepressants. To the contrary, the administration of flumazenil in these settings may be associated with the onset of seizures, especially in patients poisoned with tricyclic antidepressants

(Spivey, 1992). Seizures or other withdrawal symptoms also may be precipitated in patients who had been taking benzodiazepines for protracted periods and in whom tolerance and/or dependence may have developed.

BARBITURATES

The barbiturates were used extensively as sedative-hypnotic drugs. Except for a few specialized uses, they have been replaced largely by the much safer benzodiazepines.

Chemistry. Barbituric acid is 2,4,6-trioxohexahydropyrimidine. This compound lacks central depressant activity, but the presence of alkyl or aryl groups at position 5 confers sedative-hypnotic and sometimes other activities. The general structural formula for the barbiturates and the structures of selected compounds are included in Table 16-4.

The carbonyl group at position 2 takes on acidic character because of lactam-lactim ("keto"-enol") tautomerization, which is favored by its location between the two electronegative amido nitrogens. The lactim form is favored in alkaline solution, and salts result. Barbiturates in which the oxygen at C2 is replaced by sulfur sometimes are called *thiobarbiturates*. These compounds are more lipid-soluble than the corresponding *oxybarbiturates*. In general, structural changes that increase lipid solubility decrease duration of action, decrease latency to onset of activity, accelerate metabolic degradation, and increase hypnotic potency.

Pharmacological Properties

The barbiturates reversibly depress the activity of all excitable tissues. The CNS is exquisitely sensitive, and even when barbiturates are given in anesthetic concentrations, direct effects on peripheral excitable tissues are weak. However, serious deficits in cardiovascular and other peripheral functions occur in acute barbiturate intoxication.

Central Nervous System. Sites and Mechanisms of Action on the CNS. Barbiturates act throughout the CNS; non-anesthetic doses preferentially suppress polysynaptic responses. Facilitation is diminished, and inhibition usually is enhanced. The site of inhibition is either postsynaptic, as at cortical and cerebellar pyramidal cells and in the cuneate nucleus, substantia nigra, and thalamic relay neurons, or presynaptic, as in the spinal cord. Enhancement of inhibition occurs primarily at synapses where neurotransmission is mediated by GABA acting at GABA_A receptors.

The barbiturates exert several distinct effects on excitatory and inhibitory synaptic transmission. For example, (-)-*pentobarbital* potentiates GABA-induced increases in chloride conductance and depresses voltage-activated Ca²⁺ currents at similar concentrations (below 10 μM) in isolated hippocampal neurons; above 100 μM, chloride conductance is increased in the absence of GABA (ffrench-Mullen *et al.*, 1993). Phenobarbital is less efficacious and much less potent in producing these effects, whereas (+)-*pentobarbital* has

only weak activity. Thus the more selective anticonvulsant properties of phenobarbital and its higher therapeutic index may be explained by its lower capacity to depress neuronal function as compared with the anesthetic barbiturates.

As noted earlier, the mechanisms underlying the actions of barbiturates on GABA_A receptors appear to be distinct from those of either GABA or the benzodiazepines for reasons that include the following: (1) Although barbiturates also enhance the binding of GABA to GABA_A receptors in a chloride-dependent and picrotoxin-sensitive fashion, they promote (rather than displace) the binding of benzodiazepines; (2) barbiturates potentiate GABA-induced chloride currents by prolonging periods during which bursts of channel opening occur rather than by increasing the frequency of these bursts, as benzodiazepines do; (3) only α and β (not γ) subunits are required for barbiturate action; and (4) barbiturate-induced increases in chloride conductance are not affected by the deletion of the tyrosine and threonine residues in the β subunit that govern the sensitivity of GABA_A receptors to activation by agonists (Amin and Weiss, 1993).

Sub-anesthetic concentrations of barbiturates also can reduce glutamate-induced depolarizations (Macdonald and McLean, 1982) (*see also* Chapter 12); only the AMPA subtypes of glutamate receptors sensitive to kainate or quisqualate appear to be affected (Marszalec and Narahashi, 1993). At higher concentrations that produce anesthesia, pentobarbital suppresses high-frequency repetitive firing of neurons, apparently as a result of inhibiting the function of voltage-dependent, tetrodotoxin-sensitive Na⁺ channels; in this case, however, both stereoisomers are about equally effective (Frenkel *et al.*, 1990). At still higher concentrations, voltage-dependent K⁺ conductances are reduced. Taken together, the findings that barbiturates activate inhibitory GABA_A receptors and inhibit excitatory AMPA receptors can explain their CNS-depressant effects (Saunders and Ho, 1990).

The barbiturates can produce all degrees of depression of the CNS, ranging from mild sedation to general anesthesia. The use of barbiturates for general anesthesia is discussed in Chapter 13. Certain barbiturates, particularly those containing a 5-phenyl substituent (*e.g.*, phenobarbital and *mephobarbital*), have selective anticonvulsant activity (*see* Chapter 19). The anti-anxiety properties of the barbiturates are inferior to those exerted by the benzodiazepines.

Except for the anticonvulsant activities of phenobarbital and its congeners, the barbiturates possess a low degree of selectivity and therapeutic index. Thus, it is not possible to achieve a desired effect without evidence of general depression of the CNS. Pain perception and reaction are relatively unimpaired until the moment of unconsciousness, and in small doses, the barbiturates increase the reaction to painful stimuli. Hence they cannot be relied on to produce sedation or sleep in the presence of even moderate pain.

Effects on Stages of Sleep. Hypnotic doses of barbiturates increase the total sleep time and alter the stages of sleep in a dose-dependent manner. Like the benzodiazepines, these drugs decrease sleep latency, the number of awakenings, and the durations of REM and slow-wave sleep. During repetitive nightly administration, some tolerance to the effects on sleep occurs within a few days, and the effect on total sleep time may be reduced by as much as 50% after 2 weeks of use. Discontinuation leads to rebound increases in all the parameters reported to be decreased by barbiturates.

Tolerance. Pharmacodynamic (functional) and pharmacokinetic tolerance to barbiturates can occur. The former contributes more to the decreased effect than does the latter. With chronic administration of gradually increasing doses, pharmacodynamic tolerance continues to develop over a period of weeks to months, depending on the dosage schedule, whereas pharmacokinetic tolerance reaches its

Table 16–4

Structures, Trade Names, and Major Pharmacological Properties of Selected Barbiturates

COMPOUND (TRADE NAMES)	R ₃	R _{5a}	R _{5b}	ROUTES OF ADMINISTRATION†	HALF-LIFE, HOURS	THERAPEUTIC USES	COMMENTS
Amobarbital (AMYTAL)	—H	—C ₂ H ₅	—CH ₂ CH ₂ CH(CH ₃) ₂	IM, IV	10–40	Insomnia, preoperative sedation, emergency management of seizures	Only sodium salt administered parenterally
Butabarbital (BUTISOL, others)	—H	—C ₂ H ₅	—CH(CH ₃)CH ₂ CH ₃	Oral	35–50	Insomnia, preoperative sedation	Redistribution shortens duration of action of single dose to 8 hours
Butalbital	—H	—CH ₂ CH=CH ₂	CH ₂ CH(CH ₃) ₂	Oral	35–88	Marketed in combination with analgesics	Therapeutic efficacy questionable.
Mephobarbital (MEBARAL)	—CH ₃	—C ₂ H ₅		Oral	10–70	Seizure disorders, daytime sedation	Second-line anti-convulsant
Methohexital (BREVITAL)	—CH ₃	—CH ₂ CH=CH ₂	—CH(CH ₃)C≡CCH ₂ CH ₃	IV	3–5‡	Induction and maintenance of anesthesia	Only sodium salt is available; single injection provides 5 to 7 minutes of anesthesia‡
Pentobarbital (NEMBUTAL)	—H	—C ₂ H ₅	—CH(CH ₃)CH ₂ CH ₂ CH ₃	Oral, IM, IV, rectal	15–50	Insomnia, preoperative sedation, emergency management of seizures	Only sodium salt administered parenterally

Table 16-4

Structures, Trade Names, and Major Pharmacological Properties of Selected Barbiturates (Continued)

GENERAL FORMULA:							
COMPOUND (TRADE NAMES)	R ₃	R _{5a}	R _{5b}	ROUTES OF ADMINISTRATION†	HALF-LIFE, HOURS	THERAPEUTIC USES	COMMENTS
Phenobarbital (LUMINAL, others)	—H	—C ₂ H ₅		Oral, IM, IV	80–120	Seizure disorders, status epilepticus, daytime sedation	First-line anti-convulsant; only sodium salt administered parenterally
Secobarbital (SECONAL)	—H	—CH ₂ CH=CH ₂	—CH(CH ₃)CH ₂ CH ₂ CH ₃	Oral	15–40	Insomnia, preoperative sedation	Only sodium salt is available
Thiopental (PENTOTHAL)	—H	—C ₂ H ₅	—CH(CH ₃)CH ₂ CH ₂ CH ₃	IV	8–10‡	Induction and/or maintenance of anesthesia, preoperative sedation, emergency management of seizures	Only sodium salt is available; single injections provide short periods of anesthesia‡

*O except in thiopental, where it is replaced by S. †IM, intramuscular injection; IV, intravenous administration. ‡Value represents terminal half-life due to metabolism by the liver; redistribution following parenteral administration produces effects lasting only a few minutes.

peak in a few days to a week. Tolerance to the effects on mood, sedation, and hypnosis occurs more readily and is greater than that to the anticonvulsant and lethal effects; thus, as tolerance increases, the therapeutic index decreases. Pharmacodynamic tolerance to barbiturates confers tolerance to all general CNS-depressant drugs, including ethanol.

Abuse and Dependence. Like other CNS-depressant drugs, barbiturates are abused, and some individuals develop a dependence on them. Moreover, the barbiturates may have euphoriant effects. These topics are discussed in Chapter 23.

Peripheral Nervous Structures. Barbiturates selectively depress transmission in autonomic ganglia and reduce nicotinic excitation by choline esters. This effect may account, at least in part, for the fall in blood pressure produced by intravenous oxybarbiturates and by severe barbiturate intoxication. At skeletal neuromuscular junctions, the blocking effects of both *tubocurarine* and *decamethonium* are enhanced during barbiturate anesthesia. These actions probably result from the capacity of barbiturates at hypnotic or anesthetic concentrations to inhibit the passage of current through nicotinic cholinergic receptors. Several distinct mechanisms appear to be involved, and little stereoselectivity is evident.

Respiration. Barbiturates depress both the respiratory drive and the mechanisms responsible for the rhythmic character of respiration. The neurogenic drive is diminished by hypnotic doses but usually no more so than during natural sleep. However, neurogenic drive is essentially eliminated by a dose three times greater than that used normally to induce sleep. Such doses also suppress the hypoxic drive and, to a lesser extent, the chemoreceptor drive. At still higher doses, the powerful hypoxic drive also fails. However, the margin between the lighter planes of surgical anesthesia and dangerous respiratory depression is sufficient to permit the ultra-short-acting barbiturates to be used, with suitable precautions, as anesthetic agents.

The barbiturates only slightly depress protective reflexes until the degree of intoxication is sufficient to produce severe respiratory depression. Coughing, sneezing, hiccoughing, and laryngospasm may occur when barbiturates are employed as intravenous anesthetic agents. Indeed, laryngospasm is one of the chief complications of barbiturate anesthesia.

Cardiovascular System. When given orally in sedative or hypnotic doses, the barbiturates do not produce significant overt cardiovascular effects except for a slight decrease in blood pressure and heart rate such as occurs in normal sleep. In general, the effects of *thiopental* anesthesia on the cardiovascular system are benign in comparison with those of the volatile anesthetic agents; there usually is either no change or a fall in mean arterial pressure (see Chapter 13). Apparently, a decrease in cardiac output usually is sufficient to offset an increase in total calculated peripheral resistance, which sometimes is accompanied by an increase in heart rate. Cardiovascular reflexes are obtunded by partial inhibition of ganglionic transmission. This is most evident in patients with congestive heart failure or hypovolemic shock, whose reflexes already are operating maximally and in whom barbiturates can cause an exaggerated fall in blood pressure. Because barbiturates also impair reflex cardiovascular adjustments to inflation of the lung, positive-pressure respiration should be used cautiously and only when necessary to maintain adequate pulmonary ventilation in patients who are anesthetized or intoxicated with a barbiturate.

Other cardiovascular changes often noted when thiopental and other intravenous thiobarbiturates are administered after conventional preanesthetic medication include decreased renal and cerebral blood flow with a marked fall in CSF pressure. Although cardiac arrhythmias are observed only infrequently, intravenous anesthesia with barbiturates can increase the incidence of ventricular arrhythmias, especially when *epinephrine* and *halothane* also are present. Anesthetic concentrations of barbiturates have direct electrophysiological effects on the heart; in addition to depressing Na⁺ channels, they reduce the function of at least two types of K⁺ channels (Nattel *et al.*, 1990; Pancrazio *et al.*, 1993). However, direct depression of cardiac contractility occurs only when doses several times those required to cause anesthesia are administered, which probably contributes to the cardiovascular depression that accompanies acute barbiturate poisoning.

Gastrointestinal Tract. The oxybarbiturates tend to decrease the tone of the gastrointestinal musculature and the amplitude of rhythmic contractions. The locus of action is partly peripheral and partly central, depending on the dose. A hypnotic dose does not significantly delay gastric emptying in human beings. The relief of various GI symptoms by sedative doses is probably largely due to the central-depressant action.

Liver. The best known effects of barbiturates on the liver are those on the microsomal drug-metabolizing system (see Chapter 3). Acutely, the barbiturates combine with several CYPs and inhibit the biotransformation of a number of other drugs and endogenous substrates, such as steroids; other substrates may reciprocally inhibit barbiturate biotransformations. Drug interactions may result even when the other substances and barbiturates are oxidized by different microsomal enzyme systems.

Chronic administration of barbiturates markedly increases the protein and lipid content of the hepatic smooth endoplasmic reticulum, as well as the activities of glucuronyl transferase and CYPs 1A2, 2C9, 2C19, and 3A4. The induction of these enzymes increases the metabolism of a number of drugs and endogenous substances, including steroid hormones, cholesterol, bile salts, and vitamins K and D. This also results in an increased rate of barbiturate metabolism, which partly accounts for tolerance to barbiturates. Many sedative-hypnotics, various anesthetics, and ethanol also are metabolized by and/or induce the microsomal enzymes, and some degree of cross-tolerance therefore can occur. Not all microsomal biotransformations of drugs and endogenous substrates are affected equally, but a convenient rule of thumb is that at maximal induction in human beings, the rates are approximately doubled. The inducing effect is not limited to the microsomal enzymes; *e.g.*, there are increases in δ -aminolevulinic acid (ALA) synthetase, a mitochondrial enzyme, and aldehyde dehydrogenase, a cytosolic enzyme. The effect of barbiturates on ALA synthetase can cause dangerous disease exacerbations in persons with intermittent porphyria.

Kidney. Severe oliguria or anuria may occur in acute barbiturate poisoning largely as a result of the marked hypotension.

Absorption, Fate, and Excretion. For sedative-hypnotic use, the barbiturates usually are administered orally (Table 16-4). Such doses are absorbed rapidly and proba-

bly completely; sodium salts are absorbed more rapidly than the corresponding free acids, especially from liquid formulations. The onset of action varies from 10 to 60 minutes, depending on the agent and the formulation, and is delayed by the presence of food in the stomach. When necessary, intramuscular injections of solutions of the sodium salts should be placed deeply into large muscles to avoid the pain and possible necrosis that can result at more superficial sites. With some agents, special preparations are available for rectal administration. The intravenous route usually is reserved for the management of status epilepticus (phenobarbital sodium) or for the induction and/or maintenance of general anesthesia (*e.g.*, thiopental or *methohexital*).

Barbiturates are distributed widely, and they readily cross the placenta. The highly lipid-soluble barbiturates, led by those used to induce anesthesia, undergo redistribution after intravenous injection. Uptake into less vascular tissues, especially muscle and fat, leads to a decline in the concentration of barbiturate in the plasma and brain. With thiopental and methohexital, this results in the awakening of patients within 5 to 15 minutes of the injection of the usual anesthetic doses (*see* Chapter 13).

Except for the less lipid-soluble *aprobarbital* and phenobarbital, nearly complete metabolism and/or conjugation of barbiturates in the liver precedes their renal excretion. The oxidation of radicals at C5 is the most important biotransformation that terminates biological activity. Oxidation results in the formation of alcohols, ketones, phenols, or carboxylic acids, which may appear in the urine as such or as glucuronic acid conjugates. In some instances (*e.g.*, phenobarbital), *N*-glycosylation is an important metabolic pathway. Other biotransformations include *N*-hydroxylation, desulfuration of thiobarbiturates to oxybarbiturates, opening of the barbituric acid ring, and *N*-dealkylation of *N*-alkylbarbiturates to active metabolites (*e.g.*, mephobarbital to phenobarbital). About 25% of phenobarbital and nearly all of *aprobarbital* are excreted unchanged in the urine. Their renal excretion can be increased greatly by osmotic diuresis and/or alkalinization of the urine.

The metabolic elimination of barbiturates is more rapid in young people than in the elderly and infants, and half-lives are increased during pregnancy partly because of the expanded volume of distribution. Chronic liver disease, especially cirrhosis, often increases the half-life of the biotransformable barbiturates. Repeated administration, especially of phenobarbital, shortens the half-life of barbiturates that are metabolized as a result of the induction of microsomal enzymes (*see* above).

None of the barbiturates used for hypnosis in the United States appears to have an elimination half-life that is

short enough for elimination to be virtually complete in 24 hours (Table 16-4). However, the relationship between duration of action and half-time of elimination is complicated by the fact that enantiomers of optically active barbiturates often differ in both biological potencies and rates of biotransformation. Nevertheless, all these barbiturates will accumulate during repetitive administration unless appropriate adjustments in dosage are made. Furthermore, the persistence of the drug in plasma during the day favors the development of tolerance and abuse.

Therapeutic Uses

The major uses of individual barbiturates are listed in Table 16-4. As with the benzodiazepines, selection of particular barbiturates for a given therapeutic indication is based primarily on pharmacokinetic considerations.

CNS Uses. Although barbiturates largely have been replaced by benzodiazepines and other compounds for sedation, phenobarbital and *butabarbital* are still available as “sedatives” in a host of combinations of questionable efficacy for the treatment of functional gastrointestinal disorders and asthma. They also are included in analgesic combinations, possibly counterproductively. Barbiturates, especially butabarbital and phenobarbital, are used sometimes to antagonize unwanted CNS-stimulant effects of various drugs, such as *ephedrine*, *dextroamphetamine*, and *theophylline*, although a preferred approach is adjustment of dosage or substitution of alternative therapy for the primary agents. Phenobarbital still is used to treat hypnosedative withdrawal (Martin *et al.*, 1979).

Barbiturates are employed in the emergency treatment of convulsions, such as occur in tetanus, eclampsia, status epilepticus, cerebral hemorrhage, and poisoning by convulsant drugs; however, benzodiazepines generally are superior in these uses. Phenobarbital sodium is used most frequently because of its anticonvulsant efficacy; however, even when administered intravenously, 15 minutes or more may be required for it to attain peak concentrations in the brain. The ultra-short- and short-acting barbiturates have a low ratio of anticonvulsant to hypnotic action, and these drugs or inhalational anesthetic agents are employed only when general anesthesia must be used to control seizures refractory to other measures. Diazepam usually is chosen for the emergency treatment of seizures. The use of barbiturates in the symptomatic therapy of epilepsy is discussed in Chapter 19.

Ultra-short-acting agents such as thiopental or methohexital continue to be employed as intravenous anesthetics (*see* Chapter 13). In children, the rectal administration

of methohexital sometimes is used for the induction of anesthesia or for sedation during imaging procedures. Short- and ultra-short-acting barbiturates occasionally are used as adjuncts to other agents for obstetrical anesthesia. Although studies have failed to affirm gross depression of respiration in full-term infants, premature infants clearly are more susceptible. Since evaluation of the effects on the fetus and neonate is difficult, it therefore is prudent to avoid the use of barbiturates in this setting.

The barbiturates are employed as diagnostic and therapeutic aids in psychiatry; these uses sometimes are referred to as *narcoanalysis* and *narcotherapy*, respectively. In low concentrations, *amobarbital* has been administered directly into the carotid artery before neurosurgery as a means of identifying the dominant cerebral hemisphere for speech. Use of this procedure has been expanded to include a more extensive neuropsychological evaluation of patients with medically intractable seizure disorders who may benefit from surgical therapy (see Smith and Riskin, 1991).

Anesthetic doses of barbiturates attenuate cerebral edema resulting from surgery, head injury, or cerebral ischemia, and they may decrease infarct size and increase survival. General anesthetics do not provide protection. The procedure is not without serious danger, however, and the ultimate benefit to the patient has been questioned (see Shapiro, 1985; Smith and Riskin, 1991).

Hepatic Metabolic Uses. Because hepatic glucuronyl transferase and the bilirubin-binding Y protein are increased by the barbiturates, phenobarbital has been used successfully to treat hyperbilirubinemia and kernicterus in the neonate. The nondepressant barbiturate *phetharbital* (*N*-phenylbarbital) works equally well. Phenobarbital may improve the hepatic transport of bilirubin in patients with hemolytic jaundice.

Untoward Effects. After-Effects. Drowsiness may last for only a few hours after a hypnotic dose of barbiturate, but residual CNS depression sometimes is evident the following day, and subtle distortions of mood and impairment of judgment and fine motor skills may be demonstrable. For example, a 200-mg dose of *secobarbital* has been shown to impair performance of driving or flying skills for 10 to 22 hours. Residual effects also may take the form of vertigo, nausea, vomiting, or diarrhea or sometimes may be manifested as overt excitement. The user may awaken slightly intoxicated and feel euphoric and energetic; later, as the demands of daytime activities challenge possibly impaired faculties, the user may display irritability and temper.

Paradoxical Excitement. In some persons, barbiturates produce excitement rather than depression, and the patient may appear to be inebriated. This type of idiosyncrasy is relatively common among geriatric and debilitated patients and occurs most frequently with phenobarbital and *N*-methylbarbiturates. Barbiturates may cause restlessness, excitement, and even delirium when given in the presence of pain and may worsen a patient's perception of pain.

Hypersensitivity. Allergic reactions occur, especially in persons with asthma, urticaria, angioedema, or similar conditions. Hypersensitivity reactions include localized swellings, particularly of the eyelids, cheeks, or lips, and erythematous dermatitis. Rarely, exfoliative dermatitis may be caused by phenobarbital and can prove fatal; the skin eruption may be associated with fever, delirium, and marked degenerative changes in the liver and other parenchymatous organs.

Drug Interactions. Barbiturates combine with other CNS depressants to cause severe depression; ethanol is the most frequent offender, and interactions with first-generation antihistamines also are common. Isoniazid, methylphenidate, and monoamine oxidase inhibitors also increase the CNS-depressant effects.

Barbiturates competitively inhibit the metabolism of certain other drugs; however, the greatest number of drug interactions results from induction of hepatic CYPs and the accelerated disappearance of many drugs and endogenous substances. The metabolism of vitamins D and K is accelerated, which may hamper bone mineralization and lower Ca²⁺ absorption in patients taking phenobarbital and may be responsible for the reported coagulation defects in neonates whose mothers had been taking phenobarbital. Hepatic enzyme induction enhances metabolism of endogenous steroid hormones, which may cause endocrine disturbances, as well as of oral contraceptives, which may result in unwanted pregnancy. Barbiturates also induce the hepatic generation of toxic metabolites of chlorocarbon anesthetics and carbon tetrachloride and consequently promote lipid peroxidation, which facilitates the periportal necrosis of the liver caused by these agents.

Other Untoward Effects. Because barbiturates enhance porphyrin synthesis, they are absolutely contraindicated in patients with acute intermittent porphyria or porphyria variegata. In hypnotic doses, the effects of barbiturates on the control of respiration are minor; however, in the presence of pulmonary insufficiency, serious respiratory depression may occur, and the drugs thus are contraindicated. Rapid intravenous injection of a barbiturate may cause cardiovascular collapse before anesthesia ensues, so the CNS signs of depth of anesthesia may fail to give an adequate warning

of impending toxicity. Blood pressure can fall to shock levels; even slow intravenous injection of barbiturates often produces apnea and occasionally laryngospasm, coughing, and other respiratory difficulties.

Barbiturate Poisoning. The incidence of barbiturate poisoning has declined markedly, largely as a result of their decreased use as sedative-hypnotic agents. Nevertheless, poisoning with barbiturates is a significant clinical problem, and death occurs in a few percent of cases (Gary and Tresznewsky, 1983). Most of the cases are the result of deliberate attempts at suicide, but some are from accidental poisonings in children or in drug abusers. The lethal dose of barbiturate varies, but severe poisoning is likely to occur when more than 10 times the full hypnotic dose has been ingested at once. If alcohol or other depressant drugs also are present, the concentrations that can cause death are lower.

In severe intoxication, the patient is comatose; respiration is affected early. Breathing may be either slow or rapid and shallow. Superficial observation of respiration may be misleading with regard to actual minute volume and to the degree of respiratory acidosis and cerebral hypoxia. Eventually, blood pressure falls because the effect of the drug and of hypoxia on medullary vasomotor centers; depression of cardiac contractility and sympathetic ganglia also contributes. Pulmonary complications (*e.g.*, atelectasis, edema, and bronchopneumonia) and renal failure are likely to be the fatal complications of severe barbiturate poisoning.

The treatment of acute barbiturate intoxication is based on general supportive measures, which are applicable in most respects to poisoning by any CNS depressant. Hemodialysis or hemoperfusion is necessary only rarely, and the use of CNS stimulants is contraindicated because they increase the mortality rate.

Constant attention must be paid to the maintenance of a patent airway and adequate ventilation and to the prevention of pneumonia; oxygen should be administered. After precautions to avoid aspiration, gastric lavage should be considered if fewer than 24 hours have elapsed since ingestion, because the barbiturate can reduce GI motility. After lavage, the administration of activated charcoal and a cathartic such as *sorbitol* may shorten the half-life of the less lipid-soluble agents such as phenobarbital. If renal and cardiac functions are satisfactory, and the patient is hydrated, forced diuresis and alkalinization of the urine will hasten the excretion of aprobarbital and phenobarbital. Measures to prevent or treat atelectasis should be taken, and mechanical ventilation should be initiated when indicated.

In severe acute barbiturate intoxication, circulatory collapse is a major threat. Often the patient is admitted to the hospital with severe hypotension or shock, and dehydration frequently is severe. Hypovolemia must be corrected, and if necessary, the blood pressure can be supported with *dopamine*. Acute renal failure consequent to shock and hypoxia accounts for perhaps one-sixth of the deaths. In the event of renal failure, hemodialysis should be instituted.

MISCELLANEOUS SEDATIVE-HYPNOTIC DRUGS

Many drugs with diverse structures have been used for their sedative-hypnotic properties, including *paraldehyde* (introduced before the barbiturates), *chloral hydrate*, *ethchlorvynol*, *glutethimide*, *methyprylon*, *ethinamate*, and *meprobamate* (introduced just before the benzodiazepines).

With the exception of meprobamate, the pharmacological actions of these drugs generally resemble those of the barbiturates: they all are general CNS depressants that can produce profound hypnosis with little or no analgesia; their effects on the stages of sleep are similar to those of the barbiturates; their therapeutic index is limited, and acute intoxication, which produces respiratory depression and hypotension, is managed similarly to barbiturate poisoning; their chronic use can result in tolerance and physical dependence; and the syndrome after chronic use can be severe and life-threatening. The properties of meprobamate bear some resemblance to those of the benzodiazepines, but the drug has a distinctly higher potential for abuse and has less selective anti-anxiety effects. The clinical use of these agents has decreased markedly, and deservedly so. Nevertheless, some of them are useful in certain settings, particularly in hospitalized patients.

The chemical structures and major pharmacological properties of paraldehyde, ethchlorvynol (PLACIDYL, others), chloral hydrate (NOCTEC, others), and meprobamate are presented in Table 16–5. Further information on glutethimide, methyprylon, and ethinamate can be found in previous editions of this book.

Paraldehyde. Paraldehyde is a polymer of acetaldehyde, but it perhaps is best regarded as a cyclic polyether. It has a strong odor and a disagreeable taste. Orally, it is irritating to the throat and stomach, and it is not administered parenterally because of its injurious effects on tissues. When given rectally as a retention enema, the drug is diluted with olive oil.

Oral paraldehyde is absorbed rapidly and distributed widely; sleep usually ensues in 10 to 15 minutes after hypnotic doses. About 70% to 80% of a dose is metabolized in the liver, probably by depolymerization to acetaldehyde and subsequent oxidation to acetic acid, which ultimately is converted to carbon dioxide and water; most of the remainder is exhaled, producing a strong characteristic smell to the breath. Commonly observed consequences of poisoning with the drug include acidosis, gastritis, and fatty changes in the liver and kidney with toxic hepatitis and nephrosis.

The clinical uses of paraldehyde include the treatment of withdrawal reactions (especially delirium tremens in hospitalized patients) and other psychiatric states characterized by excitement. Paraldehyde also has been used for the treatment of convulsions (including status epilepticus) in children. Individuals who become addicted to paraldehyde may have become acquainted with the drug during treatment of their alcoholism and then, despite its disagreeable taste and odor, prefer it to alcohol.

Chloral Hydrate. Chloral hydrate is formed by adding one molecule of water to the carbonyl group of chloral (2,2,2-trichloroacetaldehyde). In addition to its hypnotic use, the drug has been employed in the past for the production of sedation in children undergoing diagnostic, dental, or other potentially uncomfortable procedures.

Chloral hydrate is reduced rapidly to the active compound, trichloroethanol ($\text{CCl}_3\text{CH}_2\text{OH}$), largely by alcohol dehydrogenase in the liver; significant amounts of chloral hydrate are not found in the blood after its oral administration. Therefore, its pharmacological effects probably are caused by trichloroethanol. Indeed, the latter compound can exert barbiturate-like effects on GABA_A-receptor channels *in vitro* (Lovinger *et al.*, 1993). Trichloroethanol is conjugated mainly with glucuronic acid, and the product (urochloral acid) is excreted mostly into the urine.

Chloral hydrate is irritating to the skin and mucous membranes. These irritant actions give rise to an unpleasant taste, epigastric distress, nausea, and occasional vomiting, all of which are particularly likely to

Table 16-5
Structures, Trade Names, and Major Pharmacological Properties of Miscellaneous Sedative-Hypnotic Drugs

COMPOUND (TRADE NAMES)	STRUCTURE	ROUTES OF ADMINISTRATION	HALF-LIFE, HOURS	COMMENTS
Paraldehyde (PARAL)		Oral, rectal	4–10	Used to treat delirium tremens in hospitalized patients; eliminated by hepatic metabolism (75%) and exhalation (25%), toxicities include acidosis, hepatitis, and nephrosis
Chloral hydrate	$\text{CCl}_3\text{CH}(\text{OH})_2$	Oral, rectal	5–10*	Rapidly converted by hepatic alcohol dehydrogenase to trichloroethanol, which is largely responsible for the effects of chloral hydrate; chronic use may cause hepatic damage; withdrawal syndrome is severe
Ethchlorvynol‡ (PLACIDYL)		Oral	10–20†	Redistribution shortens duration of action of single doses to 4 to 5 hours, which may result in early morning awakening; idiosyncratic responses include marked excitement, especially in the presence of pain
Meprobamate (MILTOWN, others)		Oral	6–17	Approved only for treatment of anxiety disorders, but widely used as a nighttime sedative; overdose can cause severe hypotension, respiratory depression, and death

*Value is for elimination of trichloroethanol, to which effects can be attributed. †Value represents terminal half-life due to metabolism by the liver; redistribution shortens duration of action to less than 5 hours. ‡Not available for use in the United States.

occur if the drug is insufficiently diluted or taken on an empty stomach. Undesirable CNS effects include lightheadedness, malaise, ataxia, and nightmares. Rarely, patients may exhibit idiosyncratic reactions to chloral hydrate and may be disoriented and incoherent and show paranoid behavior. Acute poisoning by chloral hydrate may cause jaundice. Individuals using chloral hydrate chronically may exhibit sudden, acute intoxication, which can be fatal; this situation results either from an overdose or from a failure of the detoxification mechanism owing to hepatic damage; parenchymatous renal injury also may occur. Sudden withdrawal from the habitual use of chloral hydrate may result in delirium and seizures, with a high frequency of death when untreated.

Ethchlorvynol. In addition to pharmacological actions that are very similar to those of barbiturates, ethchlorvynol has anticonvulsant and muscle-relaxant properties. Ethchlorvynol is absorbed rapidly and distributed widely after oral administration. Two-compartment kinetics are manifest, with a distribution half-life of about 1 to 3 hours and an elimination half-life of 10 to 20 hours. As a result, the duration of action of the drug is relatively short, and early-morning awakening may occur after its administration at bedtime. Approximately 90% of the drug eventually is metabolized in the liver. Ethchlorvynol is used as a short-term hypnotic for the management of insomnia.

The most common side effects caused by ethchlorvynol are a mintlike aftertaste, dizziness, nausea, vomiting, hypotension, and facial numbness. Mild “hangover” also is relatively common. An occasional patient responds with profound hypnosis, muscular weakness, and syncope unrelated to marked hypotension. Idiosyncratic responses range from mild stimulation to marked excitement and hysteria. Hypersensitivity reactions include urticaria, rare but sometimes fatal thrombocytopenia, and occasionally, cholestatic jaundice. Acute intoxication resembles that produced by barbiturates, except for more severe respiratory depression and a relative bradycardia. Ethchlorvynol may enhance the hepatic metabolism of other drugs such as oral anticoagulants, and it is contraindicated in patients with intermittent porphyria.

Meprobamate. Meprobamate is a *bis*-carbamate ester; it was introduced as an antianxiety agent in 1955, and this remains its only approved use in the United States. However, it also became popular as a sedative-hypnotic drug, and it is discussed here mainly because of its continued use for such purposes. The question of whether the sedative and antianxiety actions of meprobamate differ is unanswered, and clinical proof for the efficacy of meprobamate as a selective antianxiety agent in human beings is lacking.

The pharmacological properties of meprobamate resemble those of the benzodiazepines in a number of ways. Meprobamate can release suppressed behaviors in experimental animals at doses that cause little impairment of locomotor activity, and although it can cause widespread depression of the CNS, it cannot produce anesthesia. However, ingestion of large doses of meprobamate alone can cause severe or even fatal respiratory depression, hypotension, shock, and heart failure. Meprobamate appears to have a mild analgesic effect in patients with musculoskeletal pain, and it enhances the analgesic effects of other drugs.

Meprobamate is well absorbed when administered orally. Nevertheless, an important aspect of intoxication with meprobamate is the formation of gastric bezoars consisting of undissolved meprobamate tablets; hence treatment may require endoscopy, with mechanical removal of the bezoar. Most of the drug is metabolized in the liver, mainly to a side-chain hydroxy derivative and a glucuronide; the kinetics of elimination may depend on the dose. The half-life of meprobamate may be prolonged during its chronic administration, even though the drug can induce some hepatic CYPs.

The major unwanted effects of the usual sedative doses of meprobamate are drowsiness and ataxia; larger doses produce considerable impairment of learning and motor coordination and prolongation of reaction time. Like the benzodiazepines, meprobamate enhances the CNS depression produced by other drugs.

The abuse of meprobamate has continued despite a substantial decrease in the clinical use of the drug. *Carisoprodol* (SOMA), a skeletal muscle relaxant whose active metabolite is meprobamate, also has abuse potential and has become a popular “street drug” (Reeves *et al.*, 1999). Meprobamate is preferred to the benzodiazepines by subjects with a history of drug abuse. After long-term medication, abrupt discontinuation evokes a withdrawal syndrome usually characterized by anxiety, insomnia, tremors, and, frequently, hallucinations; generalized seizures occur in about 10% of cases. The intensity of symptoms depends on the dosage ingested.

Others. *Etomidate* (AMIDATE) is used in the United States and other countries as an intravenous anesthetic, often in combination with *fentanyl*. It is advantageous because it lacks pulmonary and vascular depressant activity, although it has a negative inotropic effect on the

heart. Its pharmacology and anesthetic uses are described in Chapter 13. It also is used in some countries as a sedative-hypnotic drug in intensive care units, during intermittent positive-pressure breathing, in epidural anesthesia, and in other situations. Because it is administered only intravenously, its use is limited to hospital settings. The myoclonus commonly seen after anesthetic doses is not seen after sedative-hypnotic doses.

Clomethiazole has sedative, muscle relaxant, and anticonvulsant properties. It is used outside the United States for hypnosis in elderly and institutionalized patients, for preanesthetic sedation, and especially in the management of withdrawal from ethanol (*see* Symposium, 1986b). Given alone, its effects on respiration are slight, and the therapeutic index is high. However, deaths from adverse interactions with ethanol are relatively frequent.

Propofol (DIPRIVAN) is a rapidly acting and highly lipophilic diisopropylphenol used in the induction and maintenance of general anesthesia (*see* Chapter 13), as well as in the maintenance of long-term sedation. Propofol sedation is of a similar quality to that produced by midazolam. Emergence from sedation occurs quickly owing to its rapid clearance (McKeage and Perry, 2003). Propofol has found use in intensive care sedation in adults (McKeage and Perry, 2003), as well as for sedation during gastrointestinal endoscopy procedures (Heuss and Inauen, 2004) and transvaginal oocyte retrieval (Dell and Cloote, 1998). Although its mechanism of action is not understood completely, propofol is believed to act primarily through enhancement of GABA_A-receptor function. Effects on other ligand-gated and G protein-coupled receptors, however, also have been reported (Trapani *et al.*, 2000).

Nonprescription Hypnotic Drugs. As part of the ongoing systematic review of over-the-counter (OTC) drug products, the FDA has ruled that *diphenhydramine* is the only ingredient that is recognized as generally safe and effective for use in nonprescription sleep aids. Despite the prominent sedative side effects encountered during the use of antihistamines previously included in OTC sleep aids (*e.g.*, *doxylamine* and *pyrilamine*), these agents have been eliminated as ingredients in the OTC nighttime sleep aids marketed in the United States. With an elimination half-life of about 9 hours, the nighttime use of diphenhydramine can be associated with prominent residual daytime sleepiness.

MANAGEMENT OF INSOMNIA

Insomnia is one of the most common complaints in general medical practice, and its treatment is predicated on proper diagnosis. Although the precise function of sleep is not known, adequate sleep improves the quality of daytime wakefulness, and hypnotics should be used judiciously to avoid its impairment.

A number of pharmacological agents are available for the treatment of insomnia. The “perfect” hypnotic would allow sleep to occur with normal sleep architecture rather than produce a pharmacologically altered sleep pattern. It would not cause next-day effects, either of rebound anxiety or of continued sedation. It would not interact with other medications. It could be used chronically without

causing dependence or rebound insomnia on discontinuation. Regular moderate exercise meets these criteria but often is not effective by itself, and many patients may not be able to exercise. However, even small amounts of exercise often are effective in promoting sleep.

Controversy in the management of insomnia revolves around two issues: pharmacological *versus* nonpharmacological treatment and the use of short-acting *versus* long-acting hypnotics. The side effects of hypnotic medications must be weighed against the sequelae of chronic insomnia, which include a fourfold increase in serious accidents (Balter and Uhlenhuth, 1992). Two aspects of the management of insomnia traditionally have been underappreciated: a search for specific medical causes and the use of nonpharmacological treatments. In addition to appropriate pharmacological treatment, the management of insomnia should correct identifiable causes, address inadequate sleep hygiene, eliminate performance anxiety related to falling asleep, provide entrainment of the biological clock so that maximum sleepiness occurs at the hour of attempted sleep, and suppress the use of alcohol and OTC sleep medications (Nino-Murcia, 1992).

Categories of Insomnia. The National Institute of Mental Health Consensus Development Conference (1984) divided insomnia into three categories:

1. **Transient insomnia** lasts less than 3 days and usually is caused by a brief environmental or situational stressor. It may respond to attention to sleep hygiene rules. If hypnotics are prescribed, they should be used at the lowest dose and for only 2 to 3 nights. However, benzodiazepines given acutely before important life events, such as examinations, may result in impaired performance (James and Savage, 1984).
2. **Short-term insomnia** lasts from 3 days to 3 weeks and usually is caused by a personal stressor such as illness, grief, or job problems. Again, sleep hygiene education is the first step. Hypnotics may be used adjunctively for 7 to 10 nights. Hypnotics are best used intermittently during this time, with the patient skipping a dose after 1 to 2 nights of good sleep.
3. **Long-term insomnia** is insomnia that has lasted for more than 3 weeks; no specific stressor may be identifiable. A more complete medical evaluation is necessary in these patients, but most do not need an all-night sleep study.

Insomnia Accompanying Major Psychiatric Illnesses. The insomnia caused by major psychiatric illnesses often responds to specific pharmacological treatment for that illness. In major depressive epi-

sodes with insomnia, for example, the selective serotonin reuptake inhibitors, which may cause insomnia as a side effect, usually will result in *improved* sleep because they treat the depressive syndrome. In patients whose depression is responding to the serotonin reuptake inhibitor but who have persistent insomnia as a side effect of the medication, judicious use of evening *trazodone* may improve sleep (Nierenberg *et al.*, 1994), as well as augment the antidepressant effect of the reuptake inhibitor. However, the patient should be monitored for priapism, orthostatic hypotension, and arrhythmias.

Adequate control of anxiety in patients with anxiety disorders often produces adequate resolution of the accompanying insomnia. Sedative use in the anxiety disorders is decreasing because of a growing appreciation of the effectiveness of other agents, such as β adrenergic receptor antagonists (*see* Chapter 10) for performance anxiety and serotonin reuptake inhibitors for obsessive-compulsive disorder and perhaps generalized anxiety disorder. The profound insomnia of patients with acute psychosis owing to schizophrenia or mania usually responds to dopamine-receptor antagonists (*see* Chapter 18). Benzodiazepines often are used adjunctively in this situation to reduce agitation; their use also will result in improved sleep.

Insomnia Accompanying Other Medical Illnesses. For long-term insomnia owing to other medical illnesses, adequate treatment of the underlying disorder, such as congestive heart failure, asthma, or COPD, may resolve the insomnia.

Adequate pain management in conditions of chronic pain, including terminal cancer pain, will treat both the pain and the insomnia and may make hypnotics unnecessary.

Many patients simply manage their sleep poorly. *Adequate attention to sleep hygiene, including reduced caffeine intake, avoidance of alcohol, adequate exercise, and regular sleep and wake times, often will reduce the insomnia.*

Conditioned (Learned) Insomnia. In those who have no major psychiatric or other medical illness and in whom attention to sleep hygiene is ineffective, attention should be directed to conditioned (learned) insomnia. These patients have associated the bedroom with activities consistent with wakefulness rather than sleep. In such patients, the bed should be used only for sex and sleep. All other activities associated with waking, even such quiescent activities as reading and watching television, should be done outside the bedroom.

Sleep-State Misperception. Some patients complain of poor sleep but have been shown to have no objective polysomnographic evidence of insomnia. They are difficult to treat.

Long-Term Insomnia. Nonpharmacological treatments are important for all patients with long-term insomnia. These include education about sleep hygiene, adequate exercise (where possible), relaxation training, and behavioral-modification approaches, such as sleep-restriction and stimulus-control therapies. In sleep-restriction therapy, the patient keeps a diary of the amount of time spent in bed and then chooses a time in bed of 30 to 60 minutes less than this time. This induces a mild sleep debt, which aids sleep onset. In stimulus-control therapy, the patient is instructed to go to bed only when sleepy, to use the bedroom only for sleep and sex, to get up and leave the bedroom if sleep does not occur within 15 to 20 minutes, to return to bed again only when sleepy, to arise at the same time each morning regardless of sleep quality the preceding night, and to avoid daytime naps. Nonpharmacological treatments for insomnia have been found to be par-

ticularly effective in reducing sleep-onset latency and time awake after sleep onset (Morin *et al.*, 1994).

Side effects of hypnotic agents may limit their usefulness for insomnia management. The use of hypnotics for long-term insomnia is problematic for many reasons. Long-term hypnotic use leads to a decrease in effectiveness and may produce rebound insomnia on discontinuance. Almost all hypnotics change sleep architecture. The barbiturates reduce REM sleep; the benzodiazepines reduce slow-wave non-REM sleep and, to a lesser extent, REM sleep. While the significance of these findings is not clear, there is an emerging consensus that slow-wave sleep is particularly important for physical restorative processes. REM sleep may aid in the consolidation of learning. The blockade of slow-wave sleep by benzodiazepines may partly account for their diminishing effectiveness over the long term, and it also may explain their effectiveness in blocking sleep terrors, a disorder of arousal from slow-wave sleep.

Long-acting benzodiazepines can cause next-day confusion, with a concomitant increase in falls, whereas shorter-acting agents can produce rebound next-day anxiety. Paradoxically, the acute amnesic effects of benzodiazepines may be responsible for the patient's subsequent report of restful sleep. Triazolam has been postulated to induce cognitive changes that blur the subjective distinction between waking and sleeping (Mendelson, 1993). Anterograde amnesia may be more common with triazolam. While the performance-disruptive effects of alcohol and diphenhydramine are reduced after napping, those of triazolam are not (Roehrs *et al.*, 1993).

Benzodiazepines may worsen sleep apnea. Some hypersomnia patients do not feel refreshed after a night's sleep and so may ask for sleeping pills to improve the quality of their sleep. The consensus is that hypnotics should not be given to patients with sleep apnea, especially of the obstructive type, because these agents decrease upper airway muscle tone while also decreasing the arousal response to hypoxia (Robinson and Zwillich, 1989). These individuals benefit from all-night sleep studies to guide treatment.

Insomnia in Older Patients. The elderly, like the very young, tend to sleep in a *polyphasic* (multiple sleep episodes per day) pattern rather than the *monophasic* pattern characteristic of younger adults. They may have single or multiple daytime naps in addition to nighttime sleep. This pattern makes assessment of adequate sleep time difficult. Anyone who naps regularly will have shortened nighttime sleep without evidence of impaired daytime wakefulness, regardless of age. This pattern is exemplified in "siesta" cultures and probably is adaptive.

Changes in the pharmacokinetic profiles of hypnotic agents occur in the elderly because of reduced body water, reduced renal function, and increased body fat, leading to a longer half-life for benzodiazepines. A dose that produces pleasant sleep and adequate daytime wakefulness during week 1 of administration may produce daytime confusion and amnesia by week 3 as the level continues to rise, particularly with long-acting hypnotics. For example, the benzodiazepine diazepam is highly lipid soluble and is excreted by the kidney. Because of the increase in body fat and the decrease in

renal excretion that typically occur from age 20 to 80, the half-life of the drug may increase fourfold over this span.

Elderly people who are living full lives with relatively unimpaired daytime wakefulness may complain of insomnia because they are not sleeping as long as they did when they were younger. Injudicious use of hypnotics in these individuals can produce daytime cognitive impairment and so impair overall quality of life.

Once an older patient has been taking benzodiazepines for an extended period, whether for daytime anxiety or for nighttime sedation, terminating the drug can be a long, involved process. Since attempts at drug withdrawal may not be successful, it may be necessary to leave the patient on the medication, with adequate attention to daytime side effects.

Management of Patients after Long-Term Treatment with Hypnotic Agents.

Patients who have been taking hypnotics for many months or even years pose a special problem (Fleming, 1993). If a benzodiazepine has been used regularly for more than 2 weeks, it should be tapered rather than discontinued abruptly. In some patients on hypnotics with a short half-life, it is easier to switch first to a hypnotic with a long half-life and then to taper. In a study in which the nonbenzodiazepine agent zopiclone was abruptly substituted for a benzodiazepine agent for 1 month and then itself abruptly terminated, improved sleep was reported during the zopiclone treatment, and withdrawal effects were absent on discontinuation of zopiclone (Shapiro *et al.*, 1993).

The onset of withdrawal symptoms from medications with a long half-life may be delayed. Consequently, the patient should be warned about the symptoms associated with withdrawal effects.

Prescribing Guidelines for the Management of Insomnia.

Hypnotics that act at GABA_A receptors, including the benzodiazepine hypnotics and the newer agents zolpidem, zopiclone, and zaleplon, are preferred to barbiturates because they have a greater therapeutic index, are less toxic in overdose, have smaller effects on sleep architecture, and have less abuse potential. Compounds with a shorter half-life are favored in patients with sleep-onset insomnia but without significant daytime anxiety who need to function at full effectiveness all day. These compounds also are appropriate for the elderly because of a decreased risk of falls and respiratory depression. However, the patient and physician should be aware that early-morning awakening, rebound daytime anxiety, and amnesic episodes also may occur.

These undesirable side effects are more common at higher doses of the benzodiazepines.

Benzodiazepines with longer half-lives are favored for patients who have significant daytime anxiety and who may be able to tolerate next-day sedation but would be impaired further by rebound daytime anxiety. These benzodiazepines also are appropriate for patients receiving treatment for major depressive episodes because the short-acting agents can worsen early-morning awakening. However, longer-acting benzodiazepines can be associated with next-day cognitive impairment or delayed daytime cognitive impairment (after 2 to 4 weeks of treatment) as a result of drug accumulation with repeated administration.

Older agents such as barbiturates, glutethimide, and meprobamate should be avoided for the management of insomnia. They have high abuse potential and are dangerous in overdose.

DRUG THERAPY OF DEPRESSION AND ANXIETY DISORDERS

Ross J. Baldessarini

The availability and use of drugs with demonstrable efficacy in psychiatric disorders has grown since the late 1950s to the point that 10% to 15% of prescriptions written in the U.S. are for medications intended to affect mental processes—to sedate, stimulate or otherwise modify mood, thinking or behavior. The optimal use of psychotropic drugs requires familiarity with the differential diagnosis of psychiatric conditions (American Psychiatric Association, 2000; and Sadock and Sadock, 2000).

The development of psychotropic agents has occurred in conjunction with studies of receptor-effector systems and bio-synthetic and degradative pathways of monoamine neurotransmitters (e.g., catecholamines and serotonin [5-HT]), as described in Chapters 6, 11 and 12). Mechanistic interpretations of the efficacy of psychotropic drugs in the CNS have propelled investigations into the causes of mental illness (Baldessarini, 2000). The antipsychotic, mood-stabilizing, and antidepressant agents used to treat the most severe mental illnesses have had a remarkable impact on psychiatric practice and theory—an impact that legitimately can be called revolutionary and one that is experiencing continued innovation.

Although the rational development and assessment of efficacy of any drug is imperfect, the psychoactive drugs are particularly challenging. We do not understand the underlying pathogenesis of these disorders. Moreover, the essential characteristics of human mental disorders cannot be reproduced in animal models, just as affective states, communication, and social relationships in animals are difficult to compare with corresponding human conditions. Thus, screening procedures in animals for the discovery of novel psychotherapeutic agents have been of limited utility. Finally, clinical evaluation of

new drugs is hampered by the lack of homogeneity within diagnostic groups and difficulty in applying valid and sensitive measurements of therapeutic effect. As a consequence, clinical trials of psychotropic agents often have yielded equivocal or inconsistent results. However, contemporary pharmacology provides many techniques for characterizing the actions of known psychotropic and other CNS-active agents at the cellular and molecular levels (*see* Chapters 1 and 12). Strategies that define the affinity of compounds for specific receptors or transporters can identify new agents and hopefully provide novel drugs for the therapy of psychiatric disorders (Kent, 2000).

Biological Hypotheses in Mental Illness. The introduction of relatively effective and selective drugs for the management of patients with schizophrenia and bipolar disorder encouraged the formulation of biological concepts for the pathogenesis of these major mental illnesses. In addition, other agents have been shown to mimic some of the symptoms of severe mental illness. These include LSD, which induces hallucinations and altered emotional states; antihypertensive agents such as reserpine, which can induce depression; and stimulants, which can induce manic or psychotic states when taken in excess. A leading hypothesis that arose from such considerations was that antidepressants enhance the biological activity of monoamine neurotransmitters in the CNS and that anti-adrenergic compounds may induce depression. These observations led to speculation that a deficiency of aminergic transmission in the CNS might cause depression, whereas an excess may result in mania. Further, antipsychotic-antimanic agents antagonize the neurotransmitter actions of dopamine in the forebrain, suggesting a possible state of functional overactivity of dopamine in the limbic system or cerebral cortex in schizophrenia or mania. Alternatively, an endogenous psychotomimetic compound might be produced either uniquely or in excessive quantities in psychotic patients. This “pharmacocentric” approach to the construction of hypotheses was appealing and gained strong encouragement from studies of the actions of antipsychotic and antidepressant drugs while further encouraging

development of similar agents. In turn, the plausibility of such biological hypotheses has generated interest in genetic and clinical biochemical studies. Despite extensive efforts, attempts to document metabolic changes in human subjects predicted by these hypotheses have not provided consistent or compelling corroboration (Baldessarini, 2000; Musselman *et al.*, 1998). Moreover, results of genetic studies have demonstrated that inheritance accounts for only a portion of the causation of mental illnesses, leaving room for environmental and psychological hypotheses.

The antipsychotic, antianxiety, antimanic, and antidepressant drugs have effects on cortical, limbic, hypothalamic, and brainstem mechanisms that are of fundamental importance in the regulation of arousal, consciousness, affect, and autonomic functions. Physiological and pharmacological modifications of these brain regions may have important behavioral consequences and useful clinical effects regardless of the underlying cause of any mental disorder. The lack of diagnostic or even syndromal specificity of most psychotropic drugs tends to reduce the chances of finding a discrete metabolic correlate for a specific disease conceived simply on the actions of therapeutic agents. Finally, technical problems in studying changes in brain metabolism *in vivo* or the postmortem chemistry of the human brain are formidable. Among these are artifacts introduced by drug treatment itself.

In summary, there is no definitive link between discrete biological lesions and the pathogenesis of the most severe mental illnesses (other than delirium and the dementias). Even without such a link, we can provide effective medical treatment for psychiatric patients. It would be clinical folly to underestimate the importance of psychological and social factors in the manifestations of mental illnesses or to overlook psychological aspects of the conduct of biological therapies (Baldessarini, 2000).

CHARACTERIZATION OF DEPRESSIVE AND ANXIETY DISORDERS

The primary clinical manifestations of major depression are significant depression of mood and impairment of function. Some features of depressive disorders overlap those of the anxiety disorders, including *panic-agoraphobia* syndrome, severe *phobias*, *generalized anxiety disorder*, *social anxiety disorder*, *posttraumatic stress disorder*, and *obsessive-compulsive disorder*. Extremes of mood also may be associated with psychosis, as manifested by disordered or delusional thinking and perceptions that often are congruent with the predominant mood. Conversely, secondary changes in mood may be associated with psychotic disorders. This overlap of disorders can lead to errors in diagnosis and suboptimal treatment (American Psychiatric Association, 2000). Mood and anxiety disorders are the most common mental illnesses, each affecting up to 10% of the general population at some time in their lives (Kessler *et al.*, 1994).

Clinical depression must be distinguished from normal grief, sadness, disappointment, and the dysphoria or

demoralization often associated with medical illness. The condition is underdiagnosed and frequently undertreated (McCombs *et al.*, 1990; Suominen *et al.*, 1998). Major depression is characterized by feelings of intense sadness and despair, mental slowing and loss of concentration, pessimistic worry, lack of pleasure, self-deprecation, and variable agitation or hostility. Physical changes also occur, particularly in severe, vital, or “melancholic” depression. These include insomnia or hypersomnia; altered eating patterns, with anorexia and weight loss or sometimes overeating; decreased energy and libido; and disruption of the normal circadian and ultradian rhythms of activity, body temperature, and many endocrine functions. As many as 10% to 15% of individuals with severe clinical depression, and up to 25% of those with bipolar disorder, display suicidal behavior at some time (Tondo *et al.*, 2003). Depressed patients usually respond to antidepressant drugs, or, in severe or treatment-resistant cases, to electroconvulsive therapy (ECT). This method remains the most rapid and effective treatment for severe acute depression and sometimes is life-saving for acutely suicidal patients (Rudorfer *et al.*, 1997). Efficacy of other forms of biological treatment of depression (*e.g.*, magnetic stimulation of the brain, or electrical stimulation of the vagus nerve) has not been well established. The decision to treat with an antidepressant is guided by the presenting clinical syndrome, its severity, and by the patient’s personal and family history.

The major disorders of mood or affect include the syndromes of *major depression* (formerly termed *melancholia*) and *bipolar disorder* (formerly termed *manic-depressive disorder*). The lifetime prevalence of bipolar disorder is 1% to 2% for type I (with *mania*). It is about twice that rate if cases of recurrent depression with milder upswings of mood (*hypomania*) are included (type II bipolar disorder). Lifetime risk for major depression is considerably higher, at 5% to 10%, and approximately twice the risk in women than in men. These disorders commonly include disordered autonomic functioning (*e.g.*, altered rhythms of activity, sleep, and appetite) and behavior, as well as persistent abnormalities of mood. These disorders are associated with increased risk of self-harm or suicide as well as increased mortality from stress-sensitive general medical conditions, medical complications of comorbid abuse of alcohol or illicit drugs, or from accidents. Bipolar disorder is marked by a high likelihood of recurrences of severe depression and manic excitement, often with psychotic features.

The less pervasive psychiatric disorders include conditions formerly termed *psychoneuroses*, which currently are viewed as anxiety-associated disorders. The ability to comprehend reality is retained, but suffering and disability sometimes are severe. Anxiety disorders may be acute and transient, or more commonly, recurrent or persistent. Their symptoms may include mood changes (fear, panic, or dysphoria) or limited abnormalities of thought (obsessions, irrational fears, or phobias) or of behavior (avoidance, rituals or

compulsions, pseudoneurological or “hysterical” conversion signs, or fixation on imagined or exaggerated physical symptoms). In such disorders drugs can have beneficial effects, particularly by modifying associated anxiety and depression to facilitate a more comprehensive program of treatment and rehabilitation. Antidepressants and sedative-anxiolytic agents are commonly used to treat anxiety disorder.

Antidepressants

Most antidepressants exert important actions on the metabolism of monoamine neurotransmitters and their receptors, particularly norepinephrine and serotonin (Buckley and Waddington, 2000; Owens *et al.*, 1997) (Table 17–1).

History. Monoamine Oxidase Inhibitors. In 1951 *isoniazid* and its isopropyl derivative, *iproniazid*, were developed for the treatment of tuberculosis. *Iproniazid*, a hydrazine derivative, was observed to have mood-elevating effects in patients with tuberculosis, but owing to hepatotoxicity was abandoned for this use. In 1952 Zeller and coworkers found that *iproniazid*, in contrast to *isoniazid*, inhibited monoamine oxidase (MAO). Following investigations by Kline and by Crane in the mid-1950s, *iproniazid* (MARSILID) was used to treat depressed patients; historically, it was the first antidepressant to be used clinically (Healy, 1997). Two other hydrazine-derivative inhibitors of MAO, *phenelzine* (the structural analog of phenethylamine, an endogenous amine) and *isocarboxazid*, subsequently were introduced into clinical practice. *Tranlycypromine*, structurally related to amphetamine, was the first MAO inhibitor unrelated to hydrazine to be discovered and brought to the market. The development of reversible, selective MAO inhibitors with potentially broad applications (e.g., *selegiline* [eldepryl] for Parkinson’s disease) was stimulated by the understanding that the early MAO inhibitors result in irreversible and nonselective blockade of both MAO-A and MAO-B, which were responsible for the metabolic breakdown of dopamine, norepinephrine, and serotonin in neuronal tissues. Three other MAO inhibitors that are used for purposes unrelated to MAO inhibition are *furazolidone* (FUROXONE, an anti-infective); *procarbazine* (MATULANE; N-methylhydrazine, indicated for the treatment of Hodgkin’s disease); and *linezolid* (ZYVOX, an antibiotic used for serious infections).

Tricyclic Antidepressants and Selective Serotonin Reuptake Inhibitors. Häfliger and Schindler in the late 1940s synthesized a series of more than 40 iminodibenzyl derivatives for possible use as antihistamines, sedatives, analgesics, and antiparkinsonism drugs. One of these was *imipramine*, a dibenzazepine compound, which differs from the phenothiazines by replacement of the sulfur with an ethylene bridge to produce a seven-membered central ring analogous to the benzazepine antipsychotic agents (see Chapter 18). Following screening in animals, a few compounds, including *imipramine*, were selected for therapeutic trial on the basis of sedative or hypnotic properties. During clinical investigation of these putative phenothiazine analogs, Kuhn (1958) fortuitously found that unlike the phenothiazines, *imipramine* was relatively ineffective in quieting agitated psychotic patients, but it had a remarkable effect on depressed patients. Since then, indisputable evidence of its effectiveness in major depression has accumulated (Potter *et al.*, 1998; Thase and Nolen, 2000).

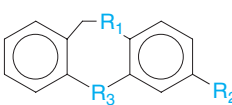

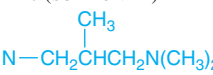

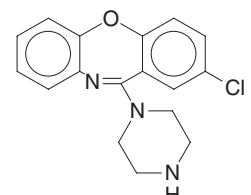

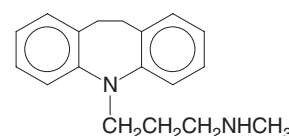

Older tricyclic antidepressants with a tertiary-amine side chain (including *amitriptyline*, *doxepin*, and *imipramine*) block neuronal uptake of both serotonin and norepinephrine, whereas *clomipramine* is relatively selective against serotonin (Table 17–2). Following this lead, even more selective serotonin reuptake inhibitors were developed in the early 1970s, arising from observations by Carlsson that antihistamines, including *chlorpheniramine* and *diphenhydramine* inhibited the transport of serotonin or norepinephrine. Chemical modifications led to the earliest selective serotonin reuptake inhibitor, *zimelidine*, soon followed by development of *fluoxetine* and *fluvoxamine* (Table 17–2) (Carlsson and Wong, 1997; Fuller, 1992; Masand and Gupta, 1999; Tollefson and Rosenbaum, 1998; Wong and Bymaster, 1995). Although first to market, *zimelidine* was withdrawn due to an association with febrile illness and Guillain-Barré ascending paralysis. Thus, *fluoxetine* and *fluvoxamine* were the first widely used selective serotonin reuptake inhibitors (often abbreviated as SSRIs or SRIs). Development of these agents was paralleled by the identification of compounds with selectivity for norepinephrine reuptake, along with others effective against both serotonin and norepinephrine reuptake—again with potential for applications beyond depression and/or anxiety (e.g., *atomoxetine* [STRATTERA]).

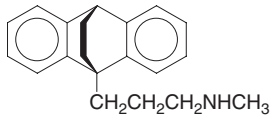

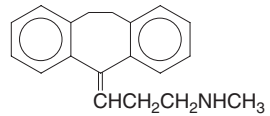

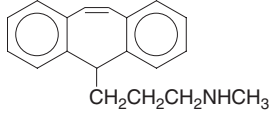

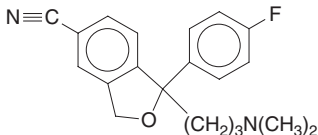

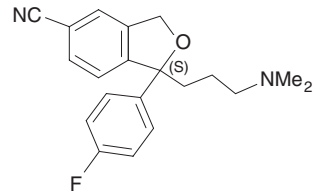

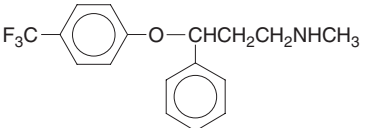

Chemistry and Structure-Activity Relationships. Tricyclic Antidepressants. The search for compounds related chemically to *imipramine* yielded multiple analogs. In addition to the dibenzazepines, *imipramine* and its secondary-amine congener and major active metabolite *desipramine*, and its 3-chloro derivative *clomipramine*, there are *amitriptyline* and its N-demethylated metabolite *nortriptyline* (dibenzocycloheptadienes), as well as *doxepin* (a dibenzoxepine) and *protriptyline* (a dibenzocycloheptatriene). Other structurally related agents are *trimipramine* (a dibenzazepine, with only weak effects on amine transport); *maprotiline* (a “tetracyclic” containing an additional ethylene bridge across the central six-carbon ring); and *amoxapine* (a piperazinyldibenzoxazepine with mixed antidepressant and neuroleptic properties). Since these agents all have a three-ring molecular core and most share pharmacological (norepinephrine-reuptake inhibition) and clinical (antidepressant and anxiolytic) properties, the name “tricyclic antidepressants” is used for this group. Structures and other features of antidepressant compounds are given in Table 17–1.

Selective Serotonin Reuptake Inhibitors. *Citalopram* and *fluoxetine* are racemates; *sertraline* and *paroxetine* are separate enantiomers. *Escitalopram* is the (S)-enantiomer of *citalopram*. *Fluoxetine* and its major metabolite *norfluoxetine* are highly active against serotonin transport and also may have antimigraine effects not found with the (R)-enantiomer of *fluoxetine*. The (R)-enantiomer of *fluoxetine* also is active against serotonin transport and is shorter acting than the (S)-enantiomer, but its clinical development was halted due to adverse electrocardiographic effects. (R)-Norfluoxetine is virtually inactive (Wong *et al.*, 1993). Structure-activity relationships are not well established for the SSRIs. However, it is known that the *para*-location of the CF₃ substituent of *fluoxetine* (Table 17–1) is critical for serotonin transporter potency. Its removal and substitution at the *ortho*-position with a methoxy group yields *nisoxetine*, a highly selective norepinephrine-uptake inhibitor.

Nefazodone	60	200	360	1.80
Trimipramine	2,400	1,500	10,000	264
Bupropion	52,600	9,100	526	5.78

Note: Potency is expressed as inhibition constant (K_i) in nanomoles, based on radioactive ligand transport competition assays with membranes from cell lines transfected with human genes for specific transporter proteins (T). Agents are ranked in descending order of potency (increasing K_i) for the norepinephrine-transporter (NET) or serotonin transporter (SERT). Selectivity is based on the ratio of K_i values. Some drugs listed are not available for clinical use in the United States. Note that the most potent NET-selective agent is desipramine; the least potent is mirtazapine, and the most selective for NET over the SERT are oxaprotiline and its congener maprotiline. For SERT, the most potent agents are paroxetine and clomipramine; the least potent is bupropion, and citalopram is the most selective over NET. Bupropion is the only agent with some selectivity for the dopamine transporter (DAT) over NET and SERT.

SOURCES: Data adapted from Frazer, 1997; Owens *et al.*, 1997; and Leonard and Richelson, 2000.

Monoamine Oxidase Inhibitors. The nonselective MAO inhibitors in clinical use are reactive hydrazines (phenelzine and isocarboxazid) or amphetamine derivatives (tranylcypromine). Selegiline, a propargylamine, contains a reactive acetylenic bond and is relatively specific for MAO-B (Cesura and Pletscher, 1992). Following their oxidation to reactive intermediates by MAO, each of these “suicide” substrates interacts irreversibly to inactivate the flavin prosthetic group of the MAO enzyme (Krishnan, 1998). Cyclization of the side chain of amphetamine resulted in tranylcypromine. After formation of a reactive imine intermediate by MAO, inhibition of MAO by this cyclopropylamine derivative may involve the reaction of a sulfhydryl group in the active site of MAO. Due to the irreversible inactivation of MAO, these compounds produce long-acting inhibition that may persist for up to 2 weeks after drug discontinuation. Short-acting, reversible inhibitors of MAO-A (RIMAs) with antidepressant activity are being investigated. These include a piperidylbenzofuran (*brofaromine*), a morpholinobenzamide (*moclobemide*; [AURORIX, MANERIX]) and an oxazolidinone (toloxatone) (Danish University Antidepressant Group, 1993; Delini-Stula *et al.*, 1988).

Pharmacological Properties. Tricyclic Antidepressants and Other Norepinephrine-Reuptake Inhibitors. Knowledge of the pharmacological properties of antidepressant drugs remains incomplete, and coherent interpretation is limited by a lack of a compelling psychobiological theory of mood disorders. The actions of imipramine-like tricyclic antidepressants include a range of complex, secondary adaptations to their initial and sustained actions as inhibitors of norepinephrine neuronal transport (reuptake) and variable blockade of serotonin transport (Table 17–2) (Barker and Blakely, 1995; Beasley *et al.*, 1992; Leonard and Richelson, 2000; Potter *et al.*, 1998; Wamsley *et al.*, 1987). Tricyclic-type antidepressants with secondary-amine side chains or the *N*-demethylated (*nor*) metabolites of agents with tertiary-amine moieties (*e.g.*, amoxapine, desipramine, maprotiline, *norclomipramine*, *nordoxepin*, and nortriptyline) are relatively selective inhibitors of norepinephrine transport. Most tertiary-amine tricyclic antidepressants also inhibit the reuptake of serotonin.

It is likely that relatively selective inhibitors of norepinephrine reuptake, including atomoxetine and *reboxetine*, share many of the actions of older inhibitors of norepinephrine transport (Kent, 2000; Kratochvil *et al.*, 2003) such as desipramine (Delgado and Michaels, 1999). Among the tricyclic antidepressants, trimipramine is exceptional in that it lacks prominent inhibitory effects at monoamine transport (Table 17–2), and its clinical actions remain unexplained.

The tricyclic and other norepinephrine-active antidepressants do not block dopamine transport (Table 17–2), thereby differing from CNS stimulants, including cocaine, methylphenidate, and amphetamines (*see* Chapter 10). Neverthe-

less, they may facilitate effects of dopamine indirectly by inhibiting the nonspecific transport of dopamine into noradrenergic terminals in cerebral cortex. Tricyclic antidepressants also can desensitize D₂ dopamine autoreceptors, through uncertain mechanisms and with uncertain behavioral contributions (Potter *et al.*, 1998).

In addition to their transport-inhibiting effects, tricyclic antidepressants variably interact with adrenergic receptors (Table 17–3). The presence or absence of such receptor interactions appears to be critical for responses to increased availability of extracellular norepinephrine in or near synapses. Most tricyclic antidepressants have at least moderate and selective affinity for α_1 adrenergic receptors, much less for α_2 , and virtually none for β receptors. The α_2 receptors include presynaptic autoreceptors that limit the neurophysiological activity of noradrenergic neurons ascending from the locus ceruleus in brainstem to supply mid- and fore-brain projections. The same noradrenergic neurons provide descending projections to the spinal cord preganglionic cholinergic efferents to the peripheral autonomic ganglia (*see* Chapters 6 and 10). Autoreceptor mechanisms also reduce the synthesis of norepinephrine through the rate-limiting enzyme tyrosine hydroxylase, presumably through α_2 adrenergic receptor attenuation of cyclic AMP-mediated phosphorylation-activation of the enzyme. Activation of these receptors inhibits transmitter release by incompletely defined molecular and cellular actions that likely include suppression of voltage-gated Ca²⁺ currents and activation of G protein-coupled, receptor-operated K⁺ currents (Foote and Aston-Jones, 1995).

The α_2 receptor-mediated, presynaptic, negative-feedback mechanisms are rapidly activated after administration of tricyclic antidepressants. By limiting synaptic availability of norepinephrine, such mechanisms normally tend to maintain functional homeostasis. However, with repeated drug exposure, α_2 -receptor responses eventually are diminished. This loss may result from desensitization secondary to increased exposure to the endogenous agonist ligand norepinephrine, or alternatively from prolonged occupation of the norepinephrine transporter itself *via* an allosteric effect, as suggested for inhibitors of serotonin transporters on serotonergic neurons (Chaput *et al.*, 1991). Over a period of days to weeks, this adaptation allows the presynaptic production and release of norepinephrine to return to, or even exceed, baseline levels (Foote and Aston-Jones, 1995; Heninger and Charney, 1987; Potter *et al.*, 1998). However, long-term treatment eventually can reduce the expression of tyrosine hydroxylase as well as the norepinephrine transporter (NET) protein (Nestler *et al.*, 1990; Zhu *et al.*, 2002; Zhu *et al.*, 2004).

Table 17-3

Potencies of Selected Antidepressants at Muscarinic, Histamine H_1 , and α_1 Adrenergic Receptors

DRUG	Receptor Type		
	M*	H ₁	α_1
Amitriptyline	17.9	1.10	27.0
Amoxapine	1000	25.0	50.0
Atomoxetine	≥1000	≥1000	≥1000
Bupropion	40,000	6700	4550
R,S-Citalopram	1800	380	1550
S-Citalopram	1240	1970	3870
Clomipramine	37.0	31.2	38.5
Desipramine	196	110	130
Doxepin	83.3	0.24	23.8
Duloxetine	3000	2300	8300
Fluoxetine	2000	6250	5900
Fluvoxamine	24,000	>100,000	7700
Imipramine	90.9	11.0	90.9
Maprotiline	560	2.00	90.9
Mirtazapine	670	0.14	500
Nefazodone	11,000	21.3	25.6
Nortriptyline	149	10.0	58.8
Paroxetine	108	22,000	>100,000
Protriptyline	25.0	25.0	130
Reboxetine	6700	312	11,900
Sertraline	625	24,000	370
Trazodone	>100,000	345	35.7
Trimipramine	58.8	0.27	23.8
Venlafaxine	>100,000	>100,000	>100,000

Note: Data (K_i values in nM) are adapted from Leonard and Richelson, 2000, and reflect the ability of the antidepressant drug to compete with radioligands selective for muscarinic cholinergic receptors (M), histamine H_1 -receptors (H_1), and α_1 adrenergic receptors (α_1). Note that anticholinergic potency is particularly high with amitriptyline, protriptyline, clomipramine, trimipramine, doxepin, and imipramine; relatively high with paroxetine among selective serotonin reuptake inhibitors; and lowest with venlafaxine, trazodone, bupropion, fluvoxamine, and nefazodone. This effect contributes to many diverse autonomic effects. Antihistaminic potency is highest with the relatively sedating agents mirtazapine, doxepin, trimipramine, and amitriptyline, and lowest with venlafaxine, fluvoxamine, sertraline, and paroxetine. Anti- α_1 adrenergic potency is highest with doxepin, trimipramine, nefazodone, amitriptyline, trazodone, clomipramine, amoxapine, nortriptyline, imipramine, and maprotiline and particularly low with paroxetine, venlafaxine, reboxetine, fluvoxamine and fluoxetine. *Data were obtained with a radioligand that is nonselective for muscarinic receptor subtypes.

The density of functional postsynaptic β adrenergic receptors also gradually down-regulates over several weeks of repeated treatment with various types of antidepressants, including tricyclics, some SSRIs, MAO inhibitors, and electroshock (a model of ECT) in animals (Sulser and Mobley, 1980). Combinations of a serotonin transport inhibitor with a tricyclic antidepressant may have a more rapid β adrenergic receptor–desensitizing effect. The pharmacologic basis of this interaction is not clear, nor is its

potential for superior clinical efficacy proven (Nelson *et al.*, 1991). It is unlikely that diminished β -receptor signaling contributes directly to the mood-elevating effects of antidepressant treatment, since β -blockers tend to induce or worsen depression in vulnerable persons. Nevertheless, loss of inhibitory β adrenergic influences on serotonergic neurons may enhance release of serotonin and thus contribute indirectly to antidepressant effects (Leonard and Richelson, 2000; Wamsley *et al.*, 1987) (*see* Chapter 10).

Figure 17–1. Sites of action of antidepressants. **A.** In varicosities (“terminals”) along terminal arborizations of norepinephrine (NE) neurons projecting from brainstem to forebrain, L-tyrosine is oxidized to dihydroxyphenylalanine (L-DOPA) by tyrosine hydroxylase (TH), then decarboxylated to dopamine (DA) by aromatic L-amino acid decarboxylase (AAD) and stored in vesicles, where side-chain oxidation by dopamine β -hydroxylase ($D\beta H$) converts DA to NE. Following exocytotic release by depolarization in the presence of Ca^{2+} (inhibited by lithium), NE interacts with postsynaptic α and β adrenergic receptor (R) subtypes as well as presynaptic α_2 autoreceptors. Regulation of NE release by α_2 receptors is principally through attenuation of Ca^{2+} currents and activation of K^+ currents. Inactivation of trans-synaptic communication occurs primarily by active transport (“reuptake”) into presynaptic terminals (inhibited by most tricyclic antidepressants [TCAs] and stimulants), with secondary deamination (by mitochondrial monoamine oxidase [MAO], blocked by MAO inhibitors). Blockade of inactivation of NE by TCAs initially leads to α_2 receptor-mediated inhibition of firing rates, metabolic activity, and transmitter release from NE neurons; gradually, however, α_2 autoreceptor response diminishes and presynaptic activity returns. Postsynaptically, β adrenergic receptors activate the G_s -adenylyl cyclase (AC) to cyclic AMP (cAMP) pathway. Adrenergic α_1 (and other) receptors activate the phospholipase C- G_q -IP₃ pathway with secondary modulation of intracellular Ca^{2+} and protein kinases. Postsynaptic β receptors also desensitize, but α_1 receptors do not. (Continued)

With tricyclic antidepressant therapy, postsynaptic α_1 adrenergic receptors may be partially blocked initially, probably contributing to early hypotensive effects of many tricyclics. Over weeks of treatment, α_1 receptors remain available and may even become more sensitive to norepinephrine as clinical mood-elevating effects gradually emerge. Therefore, as antidepressant treatment gradually becomes clinically effective, inactivation of transmitter reuptake continues to be blocked, presynaptic production and release of norepinephrine returns to or may exceed baseline levels, and a postsynaptic α_1 adrenergic mechanism is in place to provide a critical functional output.

Additional neuropharmacological changes that may contribute to the clinical effects of tricyclic antidepressants include indirect facilitation of serotonin (and perhaps dopamine) neurotransmission through excitatory α_1 “heteroreceptors” on other monoaminergic neurons, or desensitized, inhibitory α_2 autoreceptors, as well as D_2 dopamine autoreceptors. Activated release of serotonin and dopamine may, in turn, lead to secondary down-regulation of serotonin 5-HT₁ autoreceptors, postsynaptic 5-HT₂ receptors, and perhaps dopamine D_2 autoreceptors and postsynaptic D_2 receptors (Leonard and Richelson, 2000).

Other adaptive changes have been observed in response to long-term treatment with tricyclic antidepressants. These include altered sensitivity of muscarinic acetylcholine receptors as well as decreases in gamma-aminobutyric acid (GABA_B) receptors and possibly *N*-methyl-D-aspartate (NMDA) glutamate receptors (Kitamura *et al.*, 1991; Leonard and Richelson, 2000). In addition, cyclic AMP production is increased and the activities of protein kinases altered in some cells, including those acting on cytoskeletal and other structural proteins that may alter neuronal growth and sprouting (Racagni *et al.*, 1991; Wong *et al.*, 1991). Transcription and neurotrophic factors also are affected, including the cyclic AMP-response-element binding protein (CREB) and brain-derived neurotrophic factor (BDNF) (Duman *et al.*, 1997; Siuciak *et al.*, 1997). Additional changes may be indirect effects of antidepressant

treatment or may reflect recovery from depressive illness. These include normalization of glucocorticoid release and glucocorticoid receptor sensitivity, as well as shifts in the production of prostaglandins and cytokines and in lymphocyte functions (Kitayama *et al.*, 1988; Leonard and Richelson, 2000).

The complex molecular and cellular changes induced by repeated antidepressant administration remain incompletely understood. Nevertheless, their occurrence underscores the important concept that repeated administration of neuroactive or psychotropic agents triggers a cascade of adaptive processes. The neuropharmacology of tricyclic antidepressants, in particular, is not accounted for simply by blockade of the transport-mediated removal of norepinephrine, even though this effect is no doubt a crucial initiating event that induces a series of important secondary adaptations (Duman *et al.*, 1997; Hyman and Nestler, 1996; Leonard and Richelson, 2000). Interactions of antidepressants with monoaminergic synaptic transmission are illustrated in Figure 17–1.

Selective Serotonin Reuptake Inhibitors (SSRIs). The late and indirect actions of these antidepressant and anti-anxiety agents remain less well understood than are those of tricyclic antidepressants. However, there are striking parallels between responses in the noradrenergic and serotonergic systems. Like tricyclic antidepressants, which block norepinephrine reuptake, the SSRIs block neuronal transport of serotonin both immediately and chronically, leading to complex secondary responses (Table 17–2).

Increased synaptic availability of serotonin stimulates a large number of postsynaptic 5-HT receptor types (Azmitia and Whitaker-Azmitia, 1995) (*see* Chapter 11). Stimulation of 5-HT₃ receptors is suspected to contribute to common adverse effects characteristic of this class of drugs, including gastrointestinal (nausea and vomiting) and sexual effects (delayed or impaired orgasm). Stimulation of 5-HT_{2C} receptors may contribute to the agitation or restlessness sometimes induced by serotonin reuptake inhibitors.

Figure 17–1. (Continued) Sites of action of antidepressants. B. Selective serotonin reuptake inhibitors (SSRIs) have analogous actions to TCAs at serotonin-containing neurons, and TCAs can interact with serotonergic neurons and receptors (*see* text and Chapters 11 and 12). Serotonin is synthesized from L-tryptophan by a relatively rate-limiting tryptophan hydroxylase (TPH), and the resulting 5-hydroxytryptophan is deaminated by AAD to 5-hydroxytryptamine (5-HT, serotonin). Following release, 5-HT interacts with a large number of postsynaptic 5-HT receptors that exert their effects through a variety of PLG and AC-mediated mechanisms. Inhibitory autoreceptors include types 5-HT_{1A} and perhaps 5-HT₇ receptor subtypes at serotonin cell bodies and dendrites, as well as 5-HT_{1D} receptors at the nerve terminals; these receptors probably become desensitized following prolonged treatment with a SSRI antidepressant that blocks 5-HT transporters. The adrenergic and serotonergic systems also influence each other, in part through complementary heteroreceptor mechanisms (inhibitory α_2 receptors on 5-HT neurons, and inhibitory 5-HT_{1D} and 5-HT_{2A} receptors on noradrenergic neurons).

An important parallel in responses of serotonin and norepinephrine neurons is that negative feedback mechanisms rapidly emerge to restore homeostasis (Azmitia and Whitaker-Azmitia, 1995). In the serotonin system, 5-HT₁-subtype autoreceptors (types 1A and 7 at raphe cell bodies and dendrites, type 1D at terminals) suppress serotonin neurons in the raphe nuclei of the brainstem, inhibiting both tryptophan hydroxylase (probably through reduced phosphorylation-activation) and neuronal release of serotonin. Repeated treatment leads to gradual down-regulation and desensitization of autoreceptor mechanisms over several weeks (particularly of 5-HT_{1D} receptors at nerve terminals), with a return or increase of presynaptic activity, production, and release of serotonin (Blier *et al.*, 1990; Chaput *et al.*, 1991; Tome *et al.*, 1997). Additional secondary changes include gradual down-regulation of postsynaptic 5-HT_{2A} receptors that may contribute to antidepressant effects directly, as well as by influencing the function of noradrenergic and other neurons *via* serotonergic heteroreceptors. Many other postsynaptic 5-HT receptors presumably remain available to mediate increased serotonergic transmission and contribute to the mood-elevating and anxiolytic effects of this class of drugs.

As in responses to norepinephrine-transport inhibitors, complex late adaptations occur upon repeated treatment with serotonin reuptake inhibitors. These may include indirect enhancement of norepinephrine output by reduction of tonic inhibitory effects of 5-HT_{2A} heteroreceptors. Finally, similar nuclear and cellular adaptations occur as with the tricyclic antidepressants, including increased intraneuronal cyclic AMP, activation/phosphorylation or transcription factors (*e.g.*, CREB), and increased production of BDNF (Azmitia and Whitaker-Azmitia, 1995; Hyman and Nestler, 1996).

Other Drugs Affecting Monoamine Neurotransmitters. Drugs that significantly inhibit dopamine uptake include the older psychostimulants (*see* Chapter 10) (Fawcett and Busch, 1998). These agents provide only limited benefit in major depression and may worsen agitation, psychosis, insomnia, and anorexia associated with severe depressive illness. *Nomifensine* is a structurally distinct antidepressant that inhibits the transport of both norepinephrine and dopamine; it was withdrawn from clinical use in 1996 owing to risk of hemolytic anemia and intravascular hemolysis. The aromatic aminoketone *bupropion* and its amphetaminelike active metabolites also inhibit dopamine and norepinephrine transport (Ascher *et al.*, 1995). The MAO inhibitor tranylcypromine is amphetaminelike in structure but interacts only weakly at dopamine transporters.

The phenylpiperazine *nefazodone*, and to a lesser extent, the structurally related *trazodone* have at least weak inhibitory actions on serotonin transport, and nefazodone also may have a minor effect on norepinephrine transport. This agent also has a prominent direct antagonistic effect at 5-HT_{2A} receptors that may contribute to antidepressant and anxiolytic activity. Both drugs also may inhibit presynaptic 5-HT₁ subtype autoreceptors to enhance neuronal release

of serotonin, though they probably also exert at least partial-agonist effects on postsynaptic 5-HT₁ receptors (Table 17–3) (Golden *et al.*, 1998). Trazodone also blocks cerebral α_1 adrenergic and H₁-histamine receptors (Table 17–3), possibly contributing to its tendency to induce priapism and sedation, respectively.

Finally, the atypical antidepressants *mirtazapine* and *mianserin* are structural analogs of serotonin with potent antagonistic effects at several postsynaptic serotonin receptor types (including 5-HT_{2A}, 5-HT_{2C}, and 5-HT₃ receptors) and can produce gradual down-regulation of 5-HT_{2A} receptors (Golden *et al.*, 1998). Mirtazapine also limits the effectiveness of inhibitory α_2 adrenergic heteroreceptors on serotonergic neurons as well as inhibitory α_2 autoreceptors and 5-HT_{2A} heteroreceptors on noradrenergic neurons. These effects may enhance release of amines and contribute to the antidepressant effects of these drugs. Mirtazapine also is a potent histamine H₁-receptor antagonist and is relatively sedating. Mianserin is not used in the United States owing largely to an association with bone marrow suppression.

Monoamine Oxidase Inhibitors. The MAOs comprise two structurally related flavin-containing enzymes, designated MAO-A and MAO-B, that share approximately 70% of their amino acids but are encoded by distinct genes (Abell and Kwan, 2000). They are localized in mitochondrial membranes and widely distributed throughout the body in nerve terminals, the liver, intestinal mucosa, platelets, and other organs. Within the CNS, MAO-A is expressed predominantly in noradrenergic neurons, while MAO-B is expressed in serotonergic and histaminergic neurons. MAO activity is closely linked functionally with an aldehyde reductase and an aldehyde dehydrogenase, depending on the substrate and tissue.

MAO regulates the metabolic degradation of catecholamines, serotonin, and other endogenous amines in the CNS and peripheral tissues. Hepatic MAO has a crucial defensive role in inactivating circulating monoamines or compounds, such as the indirect-acting sympathomimetic tyramine, that are ingested or originate in the gut and get absorbed into the portal circulation. Inhibition of this enzyme system by MAO inhibitors causes a reduction in metabolism and a subsequent increase in the concentrations of biogenic amines. Of the two major molecular species of MAO, MAO-A preferentially deaminates epinephrine, norepinephrine, and serotonin, and is selectively inhibited by clorgyline. MAO-B metabolizes phenethylamine and is inhibited by selegiline. Dopamine and tyramine are metabolized by both MAO isozymes and both types are inhibited by phenelzine, tranylcypromine, and isocarboxazid.

Experimentally, selective MAO-A inhibitors are thought to be more effective in treating major depression than type B inhibitors (Krishnan, 1998). The MAO-B inhibitor selegiline is approved for treatment of early Parkinson's disease and acts by potentiating remaining dopamine in degenerating nigrostriatal neurons and possibly by reducing neuronal damage due to reactive products of the oxidative metabolism of dopamine or other potential neurotoxins (*see* Chapter 20). Selegiline also has antidepressant effects, particularly at doses higher than 10 mg that also inhibit MAO-A or yield amphetamine-like metabolites. Administered experimentally in a transdermal dosage form, selegiline has a limited effect on MAO-A in the gut, possibly allowing liberalization of the tyramine-restricted diet that otherwise is necessary to avoid potentially fatal hypertensive crises (Wecker *et al.*, 2003). Several short-acting selective inhibitors of MAO-A (*e.g.*, brofaromine and moclobemide) and *toloxatone* have at least moderate antidepressant effects and are less likely to potentiate the pressor actions of tyramine and other indirect-acting sympathomimetic amines than are the nonselective, irre-

versible MAO inhibitors (Delini-Stula *et al.*, 1988; Kuhn and Muller, 1996; Lotufo-Neto *et al.*, 1999; Mann *et al.*, 1989).

In the clinical setting MAO inhibition occurs rapidly, and is usually maximal within a few days. As with other antidepressants, clinical benefits usually are delayed for several weeks. This delay remains unexplained but may reflect secondary adaptations, including down-regulation of serotonergic and adrenergic receptors. Evaluation of MAO activity in human subjects taking an MAO inhibitor has led to the impression that favorable clinical responses are likely to occur when human platelet MAO-B is inhibited by at least 85%. This relationship is best established for the nonselective MAO-A and MAO-B inhibitor phenelzine, and it suggests the need to use aggressive dosages to achieve the maximal therapeutic potential of MAO inhibitors. Finally, despite long-lasting inhibition of MAO by the irreversible inhibitors of MAO, optimal therapeutic benefit appears to require daily dosing.

Absorption and Bioavailability. Most antidepressants are fairly well absorbed after oral administration. A notable exception is that the bioavailability of nefazodone is only about 20%. The MAO inhibitors are absorbed readily when given by mouth. High doses of the strongly anticholinergic tricyclic antidepressants (Table 17–1) can slow gastrointestinal activity and gastric emptying time, resulting in slower or erratic drug absorption and complicating management of acute overdoses. Serum concentrations of most tricyclic antidepressants peak within several hours. Intravenous administration of some tricyclic antidepressants (notably clomipramine) or intramuscular injection (amitriptyline) was used at one time, particularly with severely depressed, anorexic patients who refused oral medication (DeBattista and Schatzberg, 1999), but injectable formulations are no longer commercially available in the United States.

Distribution and Serum Level Monitoring. Once absorbed, tricyclic antidepressants are widely distributed. They are relatively lipophilic and strongly bind to plasma proteins and constituents of tissues, leading to apparent volumes of distribution that can be as high as 10 to 50 L/kg. The tendency of tricyclic antidepressants and their relatively cardiotoxic, ring-hydroxy metabolites to accumulate in cardiac tissue adds to their cardiotoxic risks (Pollock and Perel, 1989; Prouty and Anderson, 1990; Wilens *et al.*, 1992). Serum concentrations of antidepressants that correlate meaningfully with clinical effects are not securely established except for a few tricyclic antidepressants (particularly amitriptyline, desipramine, imipramine, and nortriptyline), typically at concentrations of approximately 100 to 250 ng/ml (Perry *et al.*, 1994) (Table 17–4). Toxic effects of tricyclic antidepressants can be expected at serum concentrations above 500 ng/ml, while levels above 1 $\mu\text{g/ml}$ can be fatal (Burke and Preskorn, 1995; Catterson *et al.*, 1997; Preskorn, 1997; van Harten, 1993).

The utility of therapeutic drug monitoring in the routine clinical use of antidepressants is limited, and the relative safety of modern antidepressants has led to a diminished interest in this approach to guiding clinical dosing. Individual variance in tricyclic antidepressant levels in response to a given dose is as high as ten- to thirtyfold and is due largely to genetic control of hepatic cytochrome P450 isoenzymes (CYPs) (DeVane and Nemeroff, 2000). Predictable relationships between initial disposition of a relatively small test dose of nortriptyline or desipramine and doses required to achieve theoretically optimal serum concentrations have been proposed as a guide to clinical dosing of individual patients. Serum concentrations of antidepressants can be misleading when obtained postmortem for forensic purposes (Prouty and Anderson, 1990).

Metabolism, Half-Lives, and Duration of Action. Tricyclic antidepressants are oxidized by hepatic microsomal enzymes, followed by conjugation with glucuronic acid. The major metabolite of imipramine is desipramine; biotransformation of imipramine or desipramine occurs largely by oxidation to 2-hydroxy metabolites, which retain some ability to block the transport of amines and have particularly prominent cardiac depressant actions. In contrast, amitriptyline and its major demethylated by-product, nortriptyline, undergo preferential oxidation at the 10 position. The 10-hydroxy metabolites may have some biological activity, and may be less cardiotoxic than the 2-hydroxy metabolites of imipramine or desipramine (Pollock and Perel, 1989). Conjugation of ring-hydroxylated metabolites with glucuronic acid extinguishes any remaining biological activity. The *N*-demethylated metabolites of several tricyclic antidepressants are pharmacologically active and may accumulate in concentrations approaching or exceeding those of the parent drug, to contribute variably to overall pharmacodynamic activity.

Amoxapine is oxidized predominantly to the 8-hydroxy metabolite and less of the 7-hydroxy metabolite. The 8-hydroxy metabolite is pharmacologically active, including antagonistic interactions with D₂ dopamine receptors. Amoxapine has some risk of extrapyramidal side effects, including tardive dyskinesia, reminiscent of those of the *N*-methylated congener loxapine, a typical neuroleptic (*see* Chapter 18).

Mirtazapine is also *N*-demethylated and undergoes aromatic hydroxylation. Trazodone and nefazodone both are *N*-dealkylated to yield *meta*-chlorophenylpiperazine (mCPP), an active metabolite with serotonergic activity. Bupropion yields active metabolites that include amphetamine-like compounds. Clomipramine, fluoxetine, sertraline, and *venlafaxine* are *N*-demethylated to norclomipramine,

Table 17-4
Disposition of Antidepressants

DRUG	ELIMINATION HALF-LIFE,* HOURS, PARENT (ACTIVE METABOLITE)	TYPICAL SERUM CONCENTRATIONS, ng/ml	PREFERRED CYP ISOZYMES [‡]
<i>Tertiary-amine tricyclic antidepressants</i>			2D6, 2C19, 3A3/4
Amitriptyline	16 (30)	100–250	
Clomipramine	32 (70)	150–500	
Doxepin	16 (30)	150–250	
Imipramine	12 (30)	175–300	
Trimipramine	16 (30)	100–300	
<i>Secondary-amine tricyclic antidepressants</i>			2D6, 2C19, 3A3/4
Amoxapine	8 (30)	200–500	
Desipramine	30	125–300	
Maprotiline	48	200–400	
Nortriptyline	30	60–150	
Protriptyline	80	100–250	
<i>Selective serotonin reuptake inhibitors</i>			
<i>R,S</i> -Citalopram	36	75–150	3A4, 2C19
<i>S</i> -Citalopram	30	40–80	3A4, 2C19
Fluoxetine	50 (240)	100–500	2D6, 2C9
Fluvoxamine	18	100–200	2D6, 1A2, 3A4, 2C9
Paroxetine	22	30–100	2D6
Sertraline	24 (66)	25–50	2D6
Venlafaxine [†]	5 (11)	—	2D6, 3A4
<i>Atypical agents</i>			
Atomoxetine	5 (child: 3)	—	2D6, 3A3/4
Bupropion [†]	14	75–100	2B6
Duloxetine	11	—	2D6
Mirtazapine	16–30	—	2D6
Nefazodone	3	—	3A3/4
Reboxetine	12	—	—
Trazodone	6	800–1600	2D6

*Half-life is the approximate elimination (β) half-life (limited data for newer agents). Half-life values given in parentheses are those of active metabolites (commonly *N*-demethylated) that contribute to overall duration of action. [†]Agents available in slow-release forms that delay absorption but not elimination half-life; venlafaxine also inhibits norepinephrine transport at higher doses. [‡]Some serotonin reuptake inhibitors inhibit the hepatic oxidation of other agents: potent inhibition is produced by fluoxetine (2D6 and other CYP isozymes), fluvoxamine (1A2, 2C8, and 3A3/4), paroxetine (2D6), and nefazodone (3A3/4); sertraline produces moderate effects at high doses (2D6 and others); citalopram (2C19) and venlafaxine have weak interactions. Serum concentrations are levels encountered at typical clinical doses and not intended as guidelines to optimal dosing. Information was obtained from manufacturers' product information summaries.

norfluoxetine, norsertraline, and desmethylvenlafaxine, respectively (DeVane and Nemeroff, 2000; van Harten, 1993). As occurs with the tertiary-amine tricyclic antidepressants, the *N*-demethylated metabolites of serotonin reuptake inhibitors also are eliminated more slowly, and some are pharmacologically active. Norclomipramine contributes noradrenergic activity. Norfluoxetine is a very

long-acting inhibitor of serotonin transport (elimination half-life approximately 10 days) (Table 17-4) that requires several weeks for elimination (Wong *et al.*, 1993). Norfluoxetine also competes for hepatic CYPs and thereby elevates blood levels of other agents, including tricyclic antidepressants. These effects can persist for days after administration of the parent drug has been

stopped. Norsertaline, though also eliminated relatively slowly (half-life of 60 to 70 hours), appears to contribute limited pharmacological activity or risk of drug interactions. Nornefazodone contributes little to the biological activity or duration of action of nefazodone.

With some notable exceptions, inactivation and elimination of most antidepressants occurs over a period of several days. Generally, secondary-amine tricyclic antidepressants and the *N*-demethylated derivatives of serotonin reuptake inhibitors have elimination half-lives about twice those of the parent drugs (van Harten, 1993). Nevertheless, most tricyclics are almost completely eliminated within 7 to 10 days. An exceptionally long-acting tricyclic antidepressant is protriptyline (half-life of about 80 hours). Most MAO inhibitors are long acting, because recovery from their effects requires the synthesis of new enzyme over a period of 1 to 2 weeks.

At the other extreme, trazodone, nefazodone, and venlafaxine have short half-lives (about 3 to 6 hours), as does the active 4-hydroxy metabolite of venlafaxine (half-life of about 11 hours). The half-life of bupropion is about 14 hours. Owing to rapid aromatic hydroxylation, the half-life of nefazodone is very short (about 3 hours). The shorter duration of action of these agents usually implies the need for multiple daily doses. Some short-acting antidepressants have been prepared in slow-release preparations (notably bupropion and venlafaxine), to allow less frequent dosing and potentially to temper side effects related to agitation and GI disturbance.

Antidepressants are metabolized more rapidly by children and more slowly by patients over 60 years of age as compared with young adults (Wilens *et al.*, 1992). Dosages are adjusted accordingly, sometimes to daily doses in children that far exceed those typically given to adults (Wilens *et al.*, 1992).

The hydrazide MAO inhibitors are thought to be cleaved to liberate pharmacologically active products (*e.g.*, hydrazines). They are inactivated primarily by acetylation. About one-half the population of the United States and Europe (and more in certain Asian and Arctic regions) are “slow acetylators” of hydrazine-type drugs, including phenelzine, and this genetic trait may contribute to exaggerated effects observed in some patients given standard doses of phenelzine (*see* Chapters 3 and 4).

Interactions with Cytochrome P450 Isoenzymes. The metabolism of most antidepressants is greatly dependent on the activity of hepatic CYPs (*see* Chapter 3). Most tricyclic antidepressants are extensively oxidized by CYP1A2. *Citalopram*, imipramine, and the *meta*-chlorophenylpiperidine metabolite of trazodone and nefazodone are substrates for CYP2C19, while atomoxetine,

duloxetine, mirtazapine, paroxetine, trazodone, and some tricyclics are substrates for CYP2D6. Nefazodone and some tricyclic and SSRI antidepressants are oxidized by CYP3A3/4 (DeVane and Nemeroff, 2000; Lantz *et al.*, 2003; Sauer *et al.*, 2003; Skinner *et al.*, 2003; van Harten, 1993). In general, CYP1A2 and CYP2D6 mediate aromatic hydroxylation, and CYP3A3/4 mediate *N*-dealkylation and *N*-oxidation reactions in the metabolism of antidepressants.

Some antidepressants not only are substrates for metabolism by CYPs but also can inhibit the metabolic clearance of other drugs, sometimes producing clinically significant drug-drug interactions (*see* below). Notable inhibitory interactions include fluvoxamine with CYP1A2; fluoxetine and fluvoxamine with CYP2C9, and fluvoxamine with CYP1A2 and CYP2C19; paroxetine, fluoxetine, and less actively, sertraline with CYP2D6; norfluoxetine with CYP3A4; and fluvoxamine and nefazodone with CYP3A3/4. *Citalopram* or *S*-*citalopram* and venlafaxine interact much less with CYPs (Caccia, 2004; DeVane and Nemeroff, 2000; Hansten and Horn, 2000; Hemeryck and Belpaire, 2002; Preskorn, 1997; Spina *et al.*, 2003; Weber, 1999). Atomoxetine has weak effects on the metabolism of most other agents, but its clearance is inhibited by some SSRIs including paroxetine (Sauer *et al.*, 2003). Duloxetine can inhibit the metabolism of agents such as desipramine that are metabolized extensively through CYP2D6, and its own metabolism is inhibited by some SSRIs including paroxetine (Lantz *et al.*, 2003; Skinner *et al.*, 2003).

Potentially clinically significant interactions include the tendency for fluvoxamine to increase circulating concentrations of oxidatively metabolized benzodiazepines, clozapine, theophylline, and warfarin. Sertraline and fluoxetine can increase levels of benzodiazepines, clozapine, and warfarin. Paroxetine increases levels of clozapine, theophylline, and warfarin. Fluoxetine also potentiates tricyclic antidepressants and some class IC antiarrhythmics with a narrow therapeutic index (including *encainide*, *flecainide*, and *propafenone*; *see* Chapter 34). Nefazodone potentiates benzodiazepines other than *lorazepam* and *oxazepam*.

Tolerance and Physical Dependence. Some tolerance to the sedative and autonomic effects of tricyclic antidepressants and to the initial nausea commonly associated with serotonin reuptake inhibitors tends to develop with continued drug use. The medical literature contains case reports of possible “tolerance” to the therapeutic effects of antidepressants after continued use. However, it is impor-

tant to emphasize that various antidepressants have been used for months or years by patients with severe recurring depression without obvious loss of efficacy, though such therapeutic tolerance may occur more often with serotonin reuptake inhibitors than with older agents (Viguera *et al.*, 1998). Sometimes this loss of benefit may be overcome by increasing the dose of antidepressant, by temporary addition of lithium or perhaps a small dose of an antipsychotic agent, or by changing to an antidepressant in a different class (Byrne and Rothschild, 1998). To avoid toxicity and precipitation of “serotonin syndrome” (*see* Drug Interactions, below), extreme caution is advised when these strategies are employed.

Occasionally, patients show physical dependence on the tricyclic antidepressants, with malaise, chills, coryza, muscle aches, and sleep disturbance following abrupt discontinuation, particularly of high doses. Similar reactions, along with gastrointestinal and sensory symptoms (paresthesias) and irritability, also occur with abrupt discontinuation of serotonin reuptake inhibitors, particularly with paroxetine and venlafaxine (Schatzberg *et al.*, 1997; Tollefson and Rosenbaum, 1998). Withdrawal reactions from MAO inhibitors may be severe, commencing 24 to 72 hours after drug discontinuation. MAO inhibitor withdrawal reactions are more common in patients using tranlycypromine and isocarboxazid at doses significantly in excess of the usual therapeutic range. Symptoms range from nausea, vomiting, and malaise to nightmares, agitation, psychosis, and convulsions.

Some withdrawal effects may reflect increased cholinergic activity following its inhibition by such agents as amitriptyline, imipramine, and paroxetine, but serotonergic mechanisms may contribute to the effects of abrupt discontinuation of serotonin reuptake inhibitors. Some of these reactions can be confused with clinical worsening of depressive symptoms. Emergence of agitated or manic reactions also has been observed after abrupt discontinuation of tricyclics. Such reactions to antidepressant discontinuation indicate that it is wise to discontinue antidepressants gradually over at least a week, or longer when feasible.

Another reaction to treatment discontinuation is suspected with several psychotropic agents, involving a period of risk of recurrence of morbidity that is greater than would be predicted by the natural history of untreated illness, particularly if long-term maintenance medication is withdrawn rapidly (Baldessarini *et al.*, 1999; Viguera *et al.*, 1998). This risk probably extends over several months. Evidence for the occurrence of this phenomenon is particularly strong with lithium in bipolar disorder, is likely with some antipsychotics, and may occur with anti-

depressants (Baldessarini *et al.*, 1999; Viguera *et al.*, 1998). Such risk may be reduced by gradual discontinuation of long-term medication over at least several weeks (*see* Chapter 18).

Adverse Effects. Significant adverse effects of antidepressants are common. Tricyclic antidepressants routinely produce adverse autonomic responses, in part related to their relatively potent antimuscarinic effects. These include dry mouth and a sour or metallic taste, epigastric distress, constipation, dizziness, tachycardia, palpitations, blurred vision (poor accommodation with increased risk of glaucoma), and urinary retention. Cardiovascular effects include orthostatic hypotension, sinus tachycardia, and variable prolongation of cardiac conduction times with the potential for arrhythmias, particularly with overdoses.

In the absence of cardiac disease, the principal problem associated with imipraminelike agents is postural hypotension, probably related to anti- α_1 adrenergic actions. Hypotension can be severe, with falls and injuries (Ray *et al.*, 1987; Roose, 1992). Among tricyclics, nortriptyline may have a relatively low risk of inducing postural blood pressure changes. Tricyclic antidepressants are avoided following an acute myocardial infarction; in the presence of defects in bundle-branch conduction or slowed repolarization; or when other cardiac depressants (including other psychotropic agents such as thioridazine) are being administered. They have direct cardiac-depressing actions like those of class I antiarrhythmics, related to actions at fast Na^+ channels (*see* Chapter 34). Mild congestive heart failure and the presence of some cardiac arrhythmias are not absolute contraindications to the short-term use of a tricyclic antidepressant when depression and its associated medical risks are severe, safer alternatives fail, and appropriate medical care is provided (Glassman *et al.*, 1993). Nevertheless, modern nontricyclic antidepressants—notably the SSRIs—have less risk and are a prudent choice for cardiac patients. ECT also can be an option.

Weakness and fatigue are attributable to central effects of tricyclic antidepressants, particularly tertiary amines (Table 17-1) and mirtazapine, all of which have potent central antihistaminic effects. Trazodone and nefazodone also are relatively sedating. Other CNS effects include variable risk of confusion or delirium, in large part owing to atropine-like effects of tricyclic antidepressants. Epileptic seizures can occur; this is especially likely with daily doses of bupropion above 450 mg, maprotiline above 250 mg, or acute overdoses of amoxapine or tricyclics (Johnston *et al.*, 1991). The risk of cerebral or cardiac intoxication can increase if such agents are given in relatively high doses, particularly when combined with

SSRIs that inhibit their metabolism (Table 17–4). MAO inhibitors can induce sedation or behavioral excitation and have a high risk of inducing postural hypotension, sometimes with sustained mild elevations of diastolic blood pressure.

Miscellaneous toxic effects of tricyclic antidepressants include jaundice, leukopenia, and rashes, but these are very infrequent. Weight gain is a common adverse effect of many antidepressants, but is less likely with the SSRIs, and is rare with bupropion (Table 17–1). Excessive sweating also is common, but its pathophysiology is not known.

Newer antidepressants generally present fewer or different side effects and toxic risks than older tricyclics and MAO inhibitors. As a group, the SSRIs have a high risk of nausea and vomiting, headache, and sexual dysfunction, including inhibited ejaculation in men and impaired orgasm in women. Adverse sexual effects also occur with tricyclic antidepressants but are less common with bupropion, nefazodone, and mirtazapine. Trazodone can produce priapism in men, presumably due to antiadrenergic actions. Some SSRIs, and perhaps fluoxetine in particular, have been associated with agitation and restlessness that resembles akathisia (*see* Chapter 18) (Hamilton and Opler, 1992). Bupropion can act as a stimulant, with agitation, anorexia, and insomnia. SSRIs, while generally less likely to produce adverse cardiovascular effects than older antidepressants, can elicit electrophysiological changes in cardiac tissue, including interference with Na⁺ and Ca²⁺ channels (Pacher *et al.*, 1999). SSRIs can also induce the syndrome of inappropriate secretion of antidiuretic hormone with hyponatremia (*see* Chapter 29) (Fisher *et al.*, 2002). Nefazodone has been associated with apparently increased risk of hepatic toxicity that has led to its removal in some countries. Such reactions are not unknown with tricyclic and MAO inhibitor antidepressants, but rarely are associated with the SSRIs (Lucena *et al.*, 2003).

Another risk of antidepressants in vulnerable patients (particularly those with unrecognized bipolar depression) is switching, sometimes suddenly, from depression to hypomanic or manic excitement, or mixed, dysphoric-agitated, manic-depressive states. To some extent this effect is dose-related, and is somewhat more likely in adults treated with tricyclic antidepressants than with serotonin reuptake inhibitors, bupropion, and perhaps with MAO inhibitors. Risk of mania with newer sedating antidepressants, including nefazodone and mirtazapine, also may be relatively low, but some risk of inducing mania can be expected with any treatment that elevates mood (Sachs *et al.*, 1994), including in children with unsuspected bipolar disorder (Faedda *et al.*, 2004).

Safety through the Life Cycle. Most antidepressants appear to be generally safe during pregnancy, in that pro-

posed teratogenic associations in newborns exposed to several tricyclic antidepressants and some newer antidepressants (particularly fluoxetine) are not convincing (McGrath *et al.*, 1999; Wisner *et al.*, 1999). Most antidepressants and lithium are secreted in breast milk, at least in small quantities, and their safety in nursing infants is neither established nor safely assumed (Birnbaum *et al.*, 1999). For severe depression during pregnancy and lactation, ECT can be a relatively safe and effective alternative.

Major affective disorders are being recognized more often in children, and antidepressants increasingly are used in this age group. Children are vulnerable to the cardiotoxic and seizure-inducing effects of high doses of tricyclic antidepressants (Kutcher, 1997). Deaths have occurred in children after accidental or deliberate overdose with only a few hundred milligrams of drug, and several cases of unexplained sudden death have been reported in preadolescent children treated with desipramine (Biederman *et al.*, 1995). Most children are relatively protected by vigorous hepatic metabolic clearing mechanisms that eliminate many drugs rapidly. Indeed, attaining serum concentrations of desipramine like those encountered in adults (Table 17–4) may require doses of 5 mg/kg of body weight (or more in some school-age children) compared to only 2 to 3 mg/kg in adults (Wilens *et al.*, 1992). Risk-benefit considerations of antidepressants in pediatric populations remain uncertain, particularly since many trials of tricyclic antidepressants in children have failed to show substantial superiority to placebo. The efficacy of modern agents, including SSRIs, is not securely established other than for fluoxetine (Kutcher, 1997; Milin *et al.*, 2003; Ryan, 2003; Wagner *et al.*, 2003; Williams and Miller, 2003) and sertraline; both have shown efficacy in depressed children in placebo-controlled trials (Emslie *et al.*, 2002; Wagner *et al.*, 2003). Other antidepressants have received little assessment in juveniles with various disorders (Emslie *et al.*, 1999; Kutcher, 1997; Steingard *et al.*, 1995; Milin *et al.*, 2003; Ryan, 2003). Antidepressants appear to be more effective in adolescents. In children, they risk inducing agitated states that may represent mania in undiagnosed juvenile bipolar disorder (Faedda *et al.*, 2004). The possibility that suicidal risk may increase in some juveniles treated with SSRIs also has been suggested, with proposed restrictions on their use (Whittington *et al.*, 2004).

Among geriatric patients, dizziness, postural hypotension, constipation, delayed micturition, edema, and tremor are found commonly with tricyclic antidepressants. These patients are much more likely to tolerate SSRIs and other modern antidepressants (Catterson *et al.*, 1997; Flint, 1998; Newman and Hassan, 1999; Oshima and Higuchi,

1999; Small, 1998). Risks in geriatric patients are higher due to decreased metabolic clearance of antidepressants and less ability to tolerate them.

Toxic Effects of Acute Overdoses. Acute poisoning with tricyclic antidepressants or MAO inhibitors is potentially life-threatening. Fatalities are much less common since modern antidepressants have widely replaced these drugs; however, suicide rates have not declined consistently as clinical usage of modern antidepressants has increased (Tondo *et al.*, 2003; Helgason *et al.*, 2004). Deaths have been reported with acute doses of approximately 2 g of imipramine, and severe intoxication can be expected at doses above 1 g, or about a week's supply. If a patient is severely depressed, potentially suicidal, impulsive, or has a history of substance abuse, prescribing a relatively safe antidepressant agent with close clinical follow-up is appropriate. If a potentially lethal agent is prescribed, it is best dispensed in small, sublethal quantities, with the risk that sustained adherence to recommended treatment may be compromised.

Acute poisoning with a tricyclic antidepressant often is clinically complex (Nicotra *et al.*, 1981). A typical pattern is brief excitement and restlessness, sometimes with myoclonus, tonic-clonic seizures, or dystonia, followed by rapid development of coma, often with depressed respiration, hypoxia, depressed reflexes, hypothermia, and hypotension. Antidepressants that have relatively strong antimuscarinic potency commonly induce an atropine-like syndrome of mydriasis, flushed dry skin and dry mucosae, absent bowel sounds, urinary retention, and tachycardia or other cardiac arrhythmias. A tricyclic antidepressant-intoxicated patient must be treated early, ideally in an intensive care unit. Gastric lavage with activated charcoal sometimes is useful, but dialysis and diuresis are ineffective. Coma abates gradually over 1 to 3 days, and excitement and delirium may reappear. Risk of life-threatening cardiac arrhythmias continues for at least several days, requiring close medical supervision (Settle, 1998; Buckley and Faunce, 2003; Cheeta *et al.*, 2004).

Cardiac toxicity and hypotension can be especially difficult to manage in patients with overdoses of tricyclic antidepressants. The most common cardiac effect is sinus tachycardia, due both to anticholinergic effects and diminished uptake of norepinephrine. Delayed depolarization due to inhibition of the sodium current may be evidenced by a prolonged QT interval or widened QRS complex. Intravenous administration of sodium bicarbonate can improve hypotension and cardiac arrhythmias, although the precise roles of alkalinization versus increased sodium have not been established. Cardiac glycosides and type I antiarrhythmic drugs such as quinidine, procainamide, and disopyramide are contraindicated, but phenytoin and lidocaine can be used for ventricular arrhythmias. If the prolonged QT interval results in *torsades de pointes*, magnesium, isoproterenol, and atrial pacing may be employed. Hypotension that does not respond to alkalinization should be treated with norepinephrine and intravenous fluids.

Effects of MAO inhibitor overdosage include agitation, hallucinations, hyperreflexia, fever, and convulsions. Both hypotension and hypertension can occur. Treatment of such intoxication is problematic, but conservative treatment often is successful.

Drug Interactions. Antidepressants are associated with several clinically important drug interactions (Hansten and Horn, 2000; Leipzig and Mendelowitz, 1992). Binding of tricyclic antidepressants to plasma albumin can be reduced by competition with a number of drugs, including phenytoin, aspirin, aminopyrine, scopolamine, and phenothiazines. Barbiturates and many anticonvulsant agents (particularly carbamazepine), as well as cigarette smoking, can increase the hepatic metabolism of antidepressants by inducing CYPs.

Conversely, the tendency for several SSRIs to compete for the metabolism of other drugs can lead to significant and potentially dangerous drug interactions. For example, during the use of combinations of SSRIs with tricyclic antidepressants, as is sometimes done to achieve more rapid therapeutic effect or to manage otherwise treatment resistant depressed patients, serum concentrations of the tricyclic drug may rise to toxic levels. Such an interaction can persist for days after discontinuing fluoxetine, due to the prolonged elimination half-life of norfluoxetine (Nelson *et al.*, 1991). As discussed above, several serotonin reuptake inhibitors are potent inhibitors of human hepatic CYPs (Crewe *et al.*, 1992). Venlafaxine, citalopram, and sertraline appear to have relatively low risk of such interactions (Caccia, 1998; Ereshefsky *et al.*, 1996; Preskorn, 1997; Preskorn, 1998). Significant interactions may be most likely in persons who are relatively rapid metabolizers through the microsomal oxidase system, including children (DeVane and Nemeroff, 2000; Preskorn, 1997; Preskorn, 1998).

Examples of drug interactions with SSRIs include potentiation of agents metabolized prominently by CYP1A2 (*e.g.*, β adrenergic receptor antagonists, caffeine, several antipsychotic agents, and most tricyclic antidepressants); CYP2C9 (carbamazepine); CYP2C19 (barbiturates, imipramine, propranolol, and phenytoin); CYP2D6 (β adrenergic receptor antagonists, some antipsychotics, and many antidepressants); and CYP3A3/4 (benzodiazepines, carbamazepine, many antidepressants, and several antibiotics). This specialized topic is reviewed elsewhere (DeVane and Nemeroff, 2000; Hansten and Horn, 2000; Preskorn, 1997; Weber, 1999) (*see* Chapter 3).

Antidepressants potentiate the effects of alcohol and probably other sedatives. The anticholinergic activity of tricyclic antidepressants can add to that of antiparkinsonism agents, antipsychotic drugs of low potency (especially clozapine and thioridazine), or other compounds with antimuscarinic activity to produce toxic effects. Tricyclic antidepressants have prominent and potentially dangerous potentiative interactions with biogenic amines such as norepinephrine, which normally are removed from their site of action by neuronal reuptake. However, these inhibitors of norepi-

nephine transport block the effects of indirectly acting amines such as tyramine, which must be taken up by sympathetic neurons to release norepinephrine. Presumably by a similar mechanism, tricyclic antidepressants prevent the antihypertensive action of adrenergic neuron blocking agents such as guanadrel. Tricyclic agents and trazodone also can block the centrally mediated antihypertensive action of clonidine.

Selective serotonin reuptake inhibitors and virtually any agent with serotonin-potentiating activity can interact dangerously or even fatally with MAO inhibitors (particularly long-acting MAO inhibitors). Other agents also have been implicated in dangerous interactions with MAO inhibitors, including meperidine and perhaps other phenylpiperidine analgesics, as well as pentazocine, dextromethorphan, fenfluramine, and infrequently, tricyclic antidepressants (Ener *et al.*, 2003). The resulting reactions are referred to as “serotonin syndrome.” Serotonin syndrome most commonly occurs in patients receiving combination therapy with 2 or more serotonergic agents. Besides the combination of MAO inhibitors with SSRIs, other drug combinations or conditions that increase serotonin synthesis (*e.g.*, L-tryptophan) or release (*e.g.*, amphetamines and cocaine), that act as serotonin agonists (*e.g.*, buspirone, dihydroergotamine, and sumatriptan), or that otherwise increase serotonin activity (*e.g.*, ECT and lithium) all have been implicated in the development of serotonin syndrome. This syndrome typically includes akathisia-like restlessness, muscle twitches and myoclonus, hyperreflexia, sweating, penile erection, shivering, and tremor as a prelude to more severe intoxication, with seizures and coma. The reaction often is self-limiting if the diagnosis is made quickly and the offending agents are discontinued. The precise pathophysiological mechanisms underlying these toxic syndromes remain ill-defined. Newer MAO inhibitors (*e.g.*, selegiline, moclobemide, and perhaps St. John’s wort preparations) also should be considered to have some risk of such interactions (Mason *et al.* 2000; Ener *et al.* 2003).

To avoid drug toxicity and prevent the precipitation of serotonin syndrome, duration of effect should be considered when switching between antidepressants. For example, an MAO inhibitor should not be started for 5 weeks after discontinuing fluoxetine, and 2 to 3 weeks should elapse between stopping a nonselective MAO inhibitor and initiating therapy with a tricyclic antidepressant.

The cerebral intoxication reactions associated with MAO inhibitors are distinguished from the hypertensive interaction of MAO inhibitors with indirectly acting pressor phenethylamines (*see* Chapter 10) such as tyramine. This interaction requires scrupulous avoidance of many agents, such as over-the-counter cold remedies containing indirect-acting sympathomimetic drugs (*see* Chapter 10) (Gardner *et al.*, 1996; Healy, 1997; Leipzig and Mendelowitz, 1992). Fatal intracranial bleeding has occurred in such hypertensive reactions. Headache is a common symptom, and fever frequently accompanies the hypertensive episode. Meperidine should never be used for such headaches (it could prove to be fatal), and blood pressure should be evaluated immediately when a patient taking an MAO inhibitor reports a severe throbbing headache or a feeling of pressure in the head. MAO inhibitors also can potentiate the effects of stimulants and bupropion (Weber, 1999; Hansten and Horn, 2000).

Therapeutic Uses. In addition to their use in adult major depression syndrome (*see* Drug Treatment of Mood Disorders, below), the various antidepressant agents have

found broad utility in other disorders that may or may not be related psychobiologically to the mood disorders. Encouragement to find new indications has increased with the advent of newer agents that are less toxic, simpler to use, and often better accepted by both physicians and patients (Edwards, 1995; Edwards *et al.*, 1997; Tollefson and Rosenbaum, 1998). Current applications include rapid but temporary suppression of enuresis with low (*e.g.*, 25 mg) pre-bedtime doses of tricyclic antidepressants, including imipramine and nortriptyline, by uncertain mechanisms in children and in geriatric patients, as well as a beneficial effect of duloxetine on urinary stress incontinence (Moore, 2004).

Antidepressants have a growing role in other disorders, including *attention-deficit/hyperactivity disorder* in children and adults, for which imipramine, desipramine, and nortriptyline appear to be effective, even in patients responding poorly to or who are intolerant of the stimulants (*e.g.*, methylphenidate) that have been the standard agents for this disorder. Newer norepinephrine selective reuptake inhibitors also may be useful in this disorder; atomoxetine is approved for this application (Biederman *et al.*, 2004; Kratochvil *et al.*, 2003; Simpson and Plosker, 2004). Utility of SSRIs in this syndrome is not established, and bupropion, despite its similarity to stimulants, appears to have limited efficacy (Kutcher, 1997; Spencer *et al.*, 1993; Wilens *et al.*, 1992). Antidepressants tend to provide a more sustained and continuous improvement of the symptoms of attention-deficit/hyperactivity disorder than do the stimulants, and they do not induce tics or other abnormal movements sometimes associated with the use of stimulants. Indeed, desipramine and nortriptyline may effectively treat tic disorders, either in association with the use of stimulants or in patients with both attention deficit disorder and Tourette’s syndrome (Spencer *et al.*, 1993). Antidepressants also are leading choices in the treatment of severe anxiety disorders, including panic disorder with agoraphobia, generalized anxiety disorder, social phobia, and obsessive-compulsive disorder (Feighner, 1999; Geller *et al.*, 2003; Masand and Gupta, 1999; Pigott and Seay, 1999; Pollack *et al.*, 2003; Rickels and Rynn, 2002; Sheehan, 2002; Waugh and Goa, 2003), as well as for the common comorbidity of anxiety in depressive illness (Boerner and Moller, 1999; Hoehn-Saric *et al.*, 2000). Antidepressants, especially SSRIs, also are employed in the management of posttraumatic stress disorder, which is marked by anxiety, startle, painful recollection of the traumatic events, and disturbed sleep (Asnis *et al.*, 2004). Initially, nonsedating antidepressants (Table 17–1) often are tolerated poorly by anxious patients, requiring slowly increased doses. Their beneficial actions

typically are delayed for several weeks in anxiety disorders, just as they are in major depression.

For panic disorder, tricyclic antidepressants and MAO inhibitors, as well as high-potency benzodiazepines (notably alprazolam, clonazepam, and lorazepam) (see Chapter 16) are effective in blocking the autonomic expression of panic itself, thus facilitating a comprehensive rehabilitation program (Argyropoulos and Nutt, 1999; Sheehan, 2002). Imipramine and phenelzine are well-studied antidepressants for panic disorder. SSRIs also may be effective (Sheehan, 2002), but β adrenergic receptor antagonists, buspirone, and low-potency benzodiazepines usually are not, and bupropion can worsen anxiety (Taylor, 1998).

The SSRIs are agents of choice in obsessive-compulsive disorder, as well as in possibly related syndromes of impulse dyscontrol or obsessive preoccupations, including compulsive gambling, trichotillomania, bulimia (but usually not anorexia) nervosa, and body dysmorphic disorder (Agras, 1998; Geller *et al.*, 1998; Hoehn-Saric *et al.*, 2000; Pigott and Seay, 1999; Sadock and Sadock, 2000). Although their benefits may be limited, SSRIs offer an important advance in the medical treatment of these often chronic and sometimes incapacitating disorders for which no other medical treatment by itself has been consistently effective. The effectiveness of pharmacological treatment for these disorders is greatly enhanced by use of behavioral treatments (Miguel *et al.*, 1997).

In addition to the wide use of modern antidepressants to treat depression associated with general medical illnesses (Schwartz *et al.*, 1989), several psychosomatic disorders may respond at least partly to treatment with tricyclic antidepressants, MAO inhibitors, or SSRIs. These include chronic pain disorders, including diabetic and other peripheral neuropathic syndromes (for which tertiary-amine tricyclics probably are superior to fluoxetine, and both duloxetine and venlafaxine also may be effective); fibromyalgia; peptic ulcer and irritable bowel syndrome; hot flashes of menopause; chronic fatigue; cataplexy; tics; migraine; and sleep apnea (Bradley *et al.*, 2003; Goldstein *et al.*, 2004; Gruber *et al.*, 1996; Guttuso, 2004; Masand and Gupta, 1999; Nemeroff *et al.*, 2002; Spencer *et al.*, 1993; Vu, 2004). These disorders may have some psychobiological relationship to mood or anxiety disorders (Hudson and Pope, 1990).

Drug Treatment of Mood Disorders

Disorders of mood (*affective disorders*) are very common, both in general medical practice and in psychiatry. The

severity of these conditions covers an extraordinarily broad range, from normal grief reactions and dysthymia to severe, incapacitating psychotic and melancholic illnesses that may result in death. The lifetime risk of suicide in severe forms of major affective disorders requiring hospitalization is 10% to 15%, but as low as 3% to 5% in less severely ill outpatients. These statistics do not begin to represent the morbidity and cost of these frequently underdiagnosed and undertreated illnesses. Perhaps 30% to 40% of cases of clinical depression are diagnosed, and a much smaller proportion of those diagnosed are adequately treated (Isacsson *et al.*, 1992; Katon *et al.*, 1992; Kind and Sorensen, 1993; McCombs *et al.*, 1990; Suominen *et al.*, 1998).

Clearly, not all types of human grief and misery call for medical treatment, and even severe mood disorders have a high rate of spontaneous remission provided that sufficient time (often a matter of months) passes. Antidepressants generally are reserved for the more severe and incapacitating depressive disorders. The most satisfactory results tend to occur in patients who have moderately severe illnesses with “endogenous” or “melancholic” characteristics without psychotic features (American Psychiatric Association, 2000; Montgomery, 1995; Peselow *et al.*, 1992; Sadock and Sadock, 2000). The data from clinical research in support of the efficacy of antidepressant agents for adult major depression generally are convincing (Burke and Preskorn, 1995; Keller *et al.*, 1998; Kasper *et al.*, 1994; Montgomery and Roberts, 1994; Workman and Short, 1993). Nevertheless, a number of shortcomings continue to be associated with all drugs used to treat affective disorders.

A major problem with antidepressants is that because placebo response rates tend to be as high as 30% to 40% among research subjects diagnosed with major depression (Healy, 1997), and possibly even higher in some anxiety disorders, statistical and clinical distinctions between active drug and placebo are difficult to prove (Fairchild *et al.*, 1986; Kahn *et al.*, 2000). Assessment-based changes in clinical ratings of depressive symptoms, rather than categorization as “treatment responsive,” often yields small average differences between active antidepressants and placebo in contemporary outpatient trials involving adult patients with depressive illness of only moderate severity, and even smaller and less consistent effects in juvenile depression (Healy, 1997; Kahn *et al.*, 2000; Moncrieff *et al.*, 2004; Storum *et al.*, 2004; Whittington *et al.*, 2004). Separation of response rates to active antidepressants from placebo improves when patients are selected for moderate but not extreme severity, presence and persistence of classic

melancholic or endogenous symptoms, and absence of psychotic features or of mixed bipolar states. Various metabolic, endocrinological, or other physiological testing procedures only marginally predict responses to antidepressant treatment and clinical utility (Baldessarini, 2000). These circumstances highlight the importance of continued reliance on placebo-controlled studies in the development of new agents, since comparisons against standard agents yielding no difference can risk an erroneous inference of equal efficacy.

Information on special depressed populations (pediatric, geriatric, medically ill, hospitalized, recurrently or chronically ill, and bipolar depressed patients) continues to be limited, despite the long-standing medical need for such information. Pediatric studies often have failed to show superiority of antidepressant drugs over placebo, particularly with older antidepressants, but also with most serotonin reuptake inhibitors, and the future of tricyclic antidepressant use in children is uncertain (Hazell *et al.*, 2002; Milin *et al.*, 2003; Whittington *et al.*, 2004). Geriatric depression includes an excess of chronic and psychotic illnesses, which tend to respond less well to antidepressant treatment alone, but may do better with ECT or when an antipsychotic agent is added (Schatzberg, 2003). Despite lack of consistency and convincingly demonstrated efficacy, the modern antidepressants have largely replaced the tricyclics as first-line options in children, adolescents, and the elderly, largely owing to their relative safety (*see* Safety Through the Life Cycle, above) (Montano, 1999). Finally, evidence concerning clinical dose-response and dose-risk relationships is especially limited with this class of drugs.

Choice of Antidepressant Medication and Dosing. The usual dosages and dose ranges of antidepressant medications are listed in Table 17-1, along with the severity of common side effects. Although they usually are used initially in divided doses, the relatively long half-lives and wide range of tolerated concentrations of most antidepressants permit gradual transition to a single daily dose. With the tricyclic antidepressants, dosing is most safely done with single doses up to the equivalent of 150 mg of imipramine.

Tricyclic and Selective Serotonin Reuptake Inhibitors. The imipramine-like tricyclics have been largely supplanted by the newer, less-toxic SSRIs and other atypical modern agents, which now are accepted broadly as drugs of first choice, particularly for medically ill or potentially suicidal patients and in the elderly and young (Brown and Khan, 1994; Flint, 1998; Oshima and Higuchi, 1999; Small, 1998; Whittington *et al.*, 2004). MAO inhibitors commonly are reserved for patients who fail to respond to vigorous trials of at least one of the newer agents and a standard tricyclic antidepressant, administered alone or with lithium or low doses of triiodothyronine to enhance overall therapeutic effectiveness (Bauer and Döpfner, 1999; Lasser and Baldessarini, 1997; Yamada and Yashuhara,

2004). The somewhat less anticholinergic secondary-amine tricyclics, particularly nortriptyline and desipramine, can be considered as an alternative or a second choice for elderly or medically ill patients, particularly if administered in moderate, divided doses (Table 17-1). Despite their potential for less favorable responses to simple antidepressant therapy, patients with severe, prolonged, disabling, psychotic, suicidal, or bipolar depression require vigorous and prompt medical intervention. Underdiagnosis of depressive illnesses arises in part from the sometimes misleading clinical presentation of many depressed patients with nonspecific somatic complaints, anxiety, or insomnia. In the past, undertreatment arose from the reluctance of physicians to prescribe potentially toxic or pharmacologically complicated tricyclic or MAO inhibitor antidepressants, especially to medically ill or elderly patients. This pattern is changing with the wide acceptance of less-toxic and better-accepted antidepressants among the serotonin reuptake inhibitors and atypical agents (Anderson, 2001; Montano, 1999).

MAO Inhibitors. Indications for the MAO inhibitors are limited and must be weighed against their potential toxicity and their complex interactions with other drugs. The MAO inhibitors generally are considered drugs of late choice for the treatment of severe depression, even though the evidence for the efficacy of adequate doses of tranlycypromine or phenelzine is convincing. Despite the favorable results obtained with tranlycypromine and with doses of phenelzine above 45 mg per day (Davis *et al.*, 1987; Krishnan, 1998), the possibility of toxic reactions has limited their acceptance by many clinicians and patients (Yamada and Yasuhara, 2004). Nevertheless, MAO inhibitors sometimes are used when vigorous trials of several standard antidepressants have been unsatisfactory and when ECT is refused. In addition, MAO inhibitors may have selective benefits for conditions other than typical major depression, including illnesses marked by phobias and anxiety or panic as well as dysphoria, and possibly in chronic dysthymic conditions (Liebowitz, 1993; Versiani, 1998). Similar benefits, however, may be found with imipramine-like agents or SSRIs.

Stimulants and Experimental Treatment Modalities. Stimulants, with or without added sedatives, are an outmoded and ineffective treatment for severe depression. Stimulants such as methylphenidate or amphetamines demonstrate well-established effectiveness for the treatment of pediatric and adult attention disorder (Zhang and Baldessarini, 2004), and some clinicians continue to use them in the short-term treatment of other selected patients (Fawcett and Busch, 1998), including some geriatric patients and those with mild dysphoria, temporary demoralization, or lack of energy associated with medical illnesses. However, none of these possible indications has been investigated systematically (Chiarello and Cole, 1987).

Experimental treatments for psychotic forms of severe depression include use of the glucocorticoid/progesterone receptor antagonist–abortifacient mifepristone (RU-486) (Belanoff *et al.*, 2002; Schatzberg, 2003).

Bipolar Forms of Depression. A particularly difficult clinical challenge is the safe and effective treatment of bipolar depression (*see* Chapter 18). This condition sometimes is misdiagnosed in patients with bipolar disorder who present with mixed dysphoric-agitated moods, who then are inappropriately treated with an antidepressant without a mood stabilizing agent to protect against worsening agitation or mania (Wehr and Goodwin, 1987; Ghaemi *et al.*, 2004; Faedda *et al.*, 2004). For this reason the management of manic, mixed, and depressive mood states in bipolar disorder best relies on lithium or other mood-stabilizing agents, notably the anticonvulsant lamotrigine, as the primary treatment (*see* Chapter

18). An antidepressant can be added cautiously and temporarily to treat bipolar depression, but the additional benefit and safety of sustained combinations of an antidepressant with a mood stabilizer are unproven (Ghaemi *et al.*, 2003; Ghaemi *et al.*, 2004; Hadjipavlou *et al.*, 2004; Post *et al.*, 2003). The choice of antidepressant in bipolar depression remains uncertain. Moderate doses of desipramine or nortriptyline have been used in the past; currently, the short-acting SSRIs, bupropion, nefazodone, or mirtazapine often are employed despite a lack of data regarding rational choice of agent, dose, or timing (Zornberg and Pope, 1993; Ghaemi *et al.*, 2003; Martin *et al.*, 2004). Bupropion and SSRIs in moderate doses may have a reduced tendency to induce mania or mood destabilization. The first combination SSRI/atypical antipsychotic (fluoxetine/olanzapine; SYMBYAX) recently was FDA approved for treatment of depressive episodes associated with bipolar disorder (Ketter *et al.*, 2004).

Duration of Treatment. The natural history of major depression (either as unipolar depression or depressive phases of bipolar disorder) is that individual episodes tend to remit spontaneously over 6 to 12 months; however, there is a high risk of relapse of depression for at least several months following discontinuation of a successful trial of antidepressant treatment. This risk is estimated at 50% within 6 months and 65% to 70% at 1 year of follow-up, rising to 85% by 3 years (Baldessarini and Tohen, 1988; Viguera *et al.*, 1998). To minimize this risk, it is best to continue antidepressant medication for not less than 6 months following apparent clinical recovery. Continued use of initially therapeutic doses is recommended, although tolerability and acceptance by patients may require flexibility in this regard at later times.

Many depressed patients follow a recurring course of episodic illness, often with lesser levels of symptoms and disability between major episodes, and therefore merit consideration of long-term maintenance medication to reduce the risk of recurrence, particularly in patients with 3 or more relatively severe episodes or chronic depressive or dysthymic disorders (Keller *et al.*, 1998; Viguera *et al.*, 1998). Such treatment has been tested for as long as 5 years, using relatively high doses of imipramine, with evidence that early dose reduction led to a higher risk of relapse (Frank *et al.*, 1993; Kupfer *et al.*, 1992). Long-term supplementation of an antidepressant with lithium may enhance the result (Baldessarini and Tohen, 1988). Prolonged maintenance treatment of patients with recurring major depression for more than a year has rarely been evaluated with modern antidepressants, and long-term dose-response data with any antidepressant are very limited (Frank *et al.*, 1993; Hirschfeld, 2000; Keller *et al.*, 1998; Viguera *et al.*, 1998). The decision to recommend indefinitely prolonged maintenance treatment with an antidepressant is guided by the past history of multiple, and especially severe or life-threatening, recurrences and the impression that recurrence risk is greater in older patients. Due to evidence that rapid discontinuation or even a sharp reduction in doses of antidepressants and lithium may contribute to excess early recurrence of illness, gradual reduction and close clinical follow-up over at least several weeks are recommended when maintenance treatment is to be discontinued, and ideally, even when stopping continuation therapy within the months following recovery from an acute episode of depression (Greden, 1998; Viguera *et al.*, 1998; Baldessarini *et al.*, 1999).

Other short-acting, reversible inhibitors of MAO-A (*e.g.*, brofaromine or moclobemide) appear to be moderately effective antidepressants with reduced risk of inducing hypertension when combined with indirectly acting sympathomimetic pressor amines (*see* Chapter 10).

PHARMACOTHERAPY OF ANXIETY

Anxiety is a cardinal symptom of many psychiatric disorders and an almost inevitable component of many medical and surgical conditions. Indeed, it is a universal human emotion, closely allied with appropriate fear and presumably serving psychobiologically adaptive purposes. A most important clinical generalization is that anxiety is rather infrequently a “disease” in itself. Anxiety that is typically associated with the former “psychoneurotic” disorders is not readily explained in biological or psychological terms; contemporary hypotheses implicate overactivity of adrenergic systems or dysregulation of serotonergic systems in the CNS (Stein and Uhde, 1998). In addition, symptoms of anxiety commonly are associated with depression and especially with dysthymic disorder (chronic depression of moderate severity), panic disorder, agoraphobia and other specific phobias, obsessive-compulsive disorder, eating disorders, and many personality disorders (Boerner and Moller, 1999; Liebowitz, 1993). Sometimes, despite a thoughtful evaluation of a patient, no treatable primary illness is found, or if one is found and treated, it may be desirable to deal directly with the anxiety at the same time. In such situations antianxiety medications are frequently and appropriately used (Taylor, 1998).

Currently, the benzodiazepines and the SSRIs are the most commonly employed medicinal treatments for the common clinical anxiety disorders (*see* Chapter 16). Some high-potency benzodiazepines (alprazolam, clonazepam, and lorazepam) are effective in severe anxiety with strong autonomic overactivity (panic disorder), as are several antidepressants, as discussed above. For generalized or nonspecific anxiety, the benzodiazepine selected seems to make little difference (Rickels and Rynn, 2002). In the elderly or in patients with impaired hepatic function, oxazepam in small, divided doses sometimes is favored due to its brief action and direct conjugation and elimination. The latter property is shared by lorazepam, but not by alprazolam (*see* Chapter 16). Benzodiazepines sometimes are given to patients presenting with anxiety mixed with symptoms of depression, although the efficacy of these agents in altering the core features of severe major depression has not been demonstrated (Argyropoulos and Nutt, 1999; Boerner and Moller, 1999; Liebowitz, 1993).

The most favorable responses to the benzodiazepines are obtained in situations that involve relatively acute anxiety reactions in medical or psychiatric patients who have either modifiable primary illnesses or primary anxiety disorders. However, this group of anxious patients also has a high response rate to placebo and is likely to

undergo spontaneous improvement. Antianxiety drugs also are used in the management of more persistent or recurrent primary anxiety disorders; guidelines for their appropriate long-term use for such disorders are less clear (Hollister *et al.*, 1993; Zohar, 2003).

Although there has been concern about the potential for habituation and abuse of benzodiazepines, some studies suggest that physicians tend to be conservative and may even undertreat patients with anxiety. They may either withhold drug unless symptoms or dysfunction are severe, or cease treatment within a few weeks, with a high proportion of relapses. Patients with personality disorders or a past history of abuse of sedatives or alcohol may be particularly at risk of dose escalation and dependence on benzodiazepines. Benzodiazepines carry some risk of impairing cognition and skilled motor functions, particularly in the elderly, in whom they are a common cause of confusion, delirium (sometimes mistaken for primary dementia), and falls with fractures (Ray *et al.*, 1987; Lawlor *et al.*, 2003). Risk of fatality on acute overdose of benzodiazepines is limited in the absence of other cerebrot toxins, including alcohol.

A particularly controversial aspect of the use of benzodiazepines, especially those of high potency, is in long-term management of patients with sustained or recurring symptoms of anxiety (Argyropoulos and Nutt, 1999; Hollister *et al.*, 1993; Soumerai *et al.*, 2003). Clinical benefit has been found for at least several months in such cases, but it is unclear to what extent the long-term benefits can be distinguished from nonspecific (“placebo”) effects following development of tolerance on the one hand, or prevention of related withdrawal-emergent anxiety on the other.

In the past, other classes of CNS-active drugs were used for daytime sedation and to treat anxiety. Such drugs included the *propanediol carbamates* (notably meprobamate), and the barbiturates (see Chapter 16). Their use for anxiety is now obsolete due primarily to their tendency to cause unwanted degrees of sedation or frank intoxication at doses required to alleviate anxiety. Meprobamate and the barbiturates also can induce tolerance, physical dependence, severe withdrawal reactions, and life-threatening toxicity with overdosage.

The antihistamine *hydroxyzine* is an effective antianxiety agent, but only at doses (about 400 mg per day) that produce marked sedation (see Chapter 24). *Propranolol* and *metoprolol*, lipophilic β adrenergic receptor antagonists that enter the CNS, can reduce the autonomic symptoms (nervousness and muscle tremor) associated with specific situational or social phobias, but do not appear to be effective in generalized anxiety or panic disorder (see Chapter 10). Similarly, other antiadrenergic agents, including *clonidine*, may modify autonomic expression of anxiety, but have not been demonstrated convincingly to be clinically useful in the treatment of severe anxiety disorders (see Chapters 10 and 32).

Another class of agents with beneficial effects in disorders marked by anxiety or dysphoria of moderate intensity are the azapirones (azaspirodecanediones), currently represented clinically by buspirone (BUSPAR) (Ninan *et al.*, 1998). The azapirones have limited antidopaminergic actions *in vivo* and do not induce clinical extrapyramidal side effects. Also, they do not interact with binding sites for benzodiazepines or facilitate the action of GABA. They are not anticonvulsant (and may even lower seizure threshold slightly), do not appear to cause tolerance or withdrawal reactions, and do not show cross-tolerance with benzodiazepines or other sedatives. Buspirone and several experimental congeners (*e.g.*, *gepirone*, *ipsa-pirone*, and *tiospirone*) have selective affinity for serotonin receptors of the 5-HT_{1A} type, for which they appear to be partial agonists (see Chapter 11).

Buspirone has beneficial actions in anxious patients, particularly those with generalized anxiety of mild or moderate severity (Ninan *et al.*, 1998; Taylor, 1998). Unlike potent benzodiazepines and antidepressants, buspirone lacks beneficial actions in severe anxiety with panic attacks. It is not efficacious as a monotherapy in obsessive-compulsive disorder, although it may have useful anti-obsessional activity when added to SSRIs (which are efficacious as monotherapy). A lack of cross-tolerance is consistent with a lack of clinical protection against withdrawal-emergent anxiety when changing abruptly from treatment with a benzodiazepine to buspirone; a gradual transition between these classes of antianxiety agents is more likely to be tolerated (Lader, 1987). Of note, the risk of suicide with buspirone is very low.

CLINICAL SUMMARY

Major affective and anxiety disorders continue to represent the most common psychiatric illnesses, and are those most often encountered by primary-care clinicians. Major depression may well represent a spectrum of disorders, varying in severity from mild and self-limited conditions that approach everyday human distress to extraordinarily severe, psychotic, incapacitating, and deadly diseases. Rates of diagnosis and appropriate treatment of major mood disorders have improved somewhat in recent years with the advent of better-accepted and safer mood-altering medicines. Nevertheless, the majority of patients with depression or bipolar disorder are diagnosed after years of delay, if at all, and many remain inadequately treated or studied, especially children, the elderly, those with bipolar depression, and those with severe, chronic, or psychotic forms of depression.

The major limitation to developing new antidepressant and antianxiety drugs is a fundamental lack of a coherent pathophysiology and etiology for major depression, bipolar disorder, and common anxiety disorders. Current medications (SSRIs and tricyclic antidepressants) focus on blockade of norepinephrine and serotonin uptake, thereby prolonging their synaptic effects. The relative success of these agents creates a conceptual impasse that limits iden-

tification of novel therapeutic targets for these disorders (Murphy *et al.*, 1995; Healy, 1997). Nevertheless, a number of novel products aimed at the treatment of depression or anxiety disorders are in development (NDA Pipeline, 2004). These include other inhibitors of neuronal transport of one or more monoamines, including norepinephrine or dopamine, as well as serotonin (*e.g.*, BTS-74398, DOV-216303, MCI-225; *milnacipran*, [DALCIPRAN, IXEL]); serotonin agonists (*e.g.*, sunepitron, PRX-0002), largely for anxiety; serotonin antagonists (*e.g.*, AR-A2, deramciclane, SB-243213), mainly for depression; agents with partial-agonist effects at dopamine and serotonin receptors, much like some atypical antipsychotics (*e.g.*, SLV-308, SLV-318); inhibitors of MAO-A (moclobemide, selegiline); inhibitors of phosphodiesterase 4 (*e.g.*, MEM-1414); glutamate α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor modulators (*ampakines*; *e.g.*, CX-516); glutamate metabotropic receptor agonists for anxiety (*e.g.*, LY-544344); GABA_A receptor agonists for anxiety (*e.g.*, CP-615003, DOV-51892; *ocinaplon*, *pagoclone*); inhibitors of neurokinin-1 (substance-P) receptors (*e.g.*, CP-122721, GB-823296, GW-597599, R-673, SB-823296); ligands for cerebral sigma-2 sites (*e.g.*, LU-28179); corticotropin (CRF-1) receptor antagonists (*e.g.*, AG-561, AVE-4579, DPC-368, NBI-30775, SB-733620); and the metabolic methyl donor S-adenosyl-L-methionine.

PHARMACOTHERAPY OF PSYCHOSIS AND MANIA

Ross J. Baldessarini and Frank I. Tarazi

I. DRUGS USED IN THE TREATMENT OF PSYCHOSES

The psychotic disorders include schizophrenia, the manic phase of bipolar (manic-depressive) illness, acute idiopathic psychotic illnesses, and other conditions marked by severe agitation. All exhibit major disturbances in reasoning, often with delusions and hallucinations. Several classes of drugs are effective for symptomatic treatment. Antipsychotic agents also are useful alternatives to electroconvulsive therapy (ECT) in severe depression with psychotic features, and sometimes are used in the management of patients with psychotic disorders associated with delirium or dementia, or induced by other agents (*e.g.*, stimulants or L-dopa).

Effective and clinically employed antipsychotic agents include *phenothiazines*, structurally similar *thioxanthenes*, *benzepines*, *butyrophenones* (phenylbutylpiperidines), *diphenylbutylpiperidines*, *indolones*, and other heterocyclic compounds. Because these chemically dissimilar drugs share many properties, information about their pharmacology and clinical uses is grouped. Particular attention is paid to *chlorpromazine*, the prototype of the phenothiazine–thioxanthene group of antipsychotic agents, and to *haloperidol*, the original butyrophenone and representative of several related classes of aromatic butylpiperidine derivatives. Contrasts to chemically dissimilar modern agents are highlighted.

The term *neuroleptic* is often applied to drugs that have relatively prominent experimental and clinical evidence of antagonism of D₂-dopamine receptor activity, with substantial risk of adverse extrapyramidal neurological effects (*see* Chapter 12) and increased release of prolactin. The term *atypical antipsychotic* is applied to agents that are associat-

ed with substantially lower risks of such extrapyramidal effects. Representative examples include *aripiprazole*, *clozapine*, *quetiapine*, *ziprasidone*, and low doses of *olanzapine* and *risperidone* (Blin, 1999; Markowitz *et al.*, 1999).

Although the antipsychotic drugs have had a revolutionary, beneficial impact on medical and psychiatric practice, their liabilities, especially the adverse effects of the older typical or neuroleptic agents, must be emphasized. Newer antipsychotics are atypical in having less risk of extrapyramidal side effects, but these agents present their own spectrum of adverse effects, including hypotension, seizures, weight gain, and increased risk of type II diabetes mellitus and hyperlipidemia.

The psychoses are among the most severe psychiatric disorders, in which there is not only marked impairment of behavior, but also a serious inability to think coherently, to comprehend reality, or to gain insight into the presence of these abnormalities. These common disorders (affecting perhaps 1% of the population at some age) typically include symptoms of false beliefs (*delusions*) and abnormal sensations (*hallucinations*). Their etiological basis remains unknown, although genetic, neurodevelopmental, and environmental causative factors have all been proposed. Representative syndromes in this category include schizophrenia, brief psychoses, and delusional disorders. Psychotic features also occur in major mood disorders, particularly mania and severe melancholic depression. Psychotic illnesses are characterized by disordered thought processes (as inferred from illogical or highly idiosyncratic communications) with disorganized or irrational behavior and varying degrees of altered mood that can range from excited agitation to severe emotional withdrawal. Idiopathic psychoses characterized by chronically disordered thinking and emotional withdrawal, and often associated with delusions and auditory hallucinations, are called *schizophrenia*. Acute and recurrent idiopathic psychoses that bear an uncertain relationship to schizophrenia or the major affective disorders also occur. Delusions that are more or less isolated are characteristic of *delusional disorder* or *paranoia*.

The beneficial effects of antipsychotic drugs are not limited to schizophrenia. They also are employed in disorders ranging from

postsurgical delirium and amphetamine intoxication to paranoia, mania, psychotic depression, and the agitation of Alzheimer's dementia. They are especially useful in severe depression and possibly in other conditions marked by severe turmoil or agitation.

TRICYCLIC ANTIPSYCHOTIC AGENTS

Several dozen phenothiazine antipsychotic drugs and chemically related agents are used worldwide. Other phenothiazines are marketed primarily for their antiemetic, antihistaminic, or anticholinergic effects.

History. The early development of the antipsychotic agents is well summarized by Swazey (1974) and Caldwell (1978), and is recounted in the personal observations of Tuillier (1999). In the early 1950s, some antipsychotic effects were obtained with extracts of the *Rauwolfia* plant, then with large doses of its purified active alkaloid *reserpine*, which Woodward later chemically synthesized. Although reserpine and related alkaloids that also deplete monoamines from their vesicular storage sites in nerve terminals exert antipsychotic effects, these are relatively weak and are associated with severe side effects, including sedation, hypotension, diarrhea, anergy, and depressed mood. Thus the clinical utility of reserpine primarily was to treat hypertension.

Phenothiazines were synthesized initially in Europe in the late nineteenth century as a consequence of the development of aniline dyes such as methylene blue. In the late 1930s a phenothiazine derivative, *promethazine*, was found to have antihistaminic and sedative effects. This discovery led to relatively unsuccessful attempts to use promethazine and other antihistamines to treat agitation in psychiatric patients. Promethazine was noted to prolong barbiturate sleeping time in rodents, and the drug was introduced into clinical anesthesia as a potentiating and autonomic stabilizing agent. This work prompted a search for phenothiazine derivatives with similar effects, and led in 1949–1950, to Charpentier's synthesis of chlorpromazine. Soon thereafter, Laborit and his colleagues described the ability of this compound to potentiate anesthetics and produce "artificial hibernation." Chlorpromazine by itself did not cause a loss of consciousness, but diminished arousal and motility, with some tendency to promote sleep. These central actions soon became known as *ataractic* or *neuroleptic*.

The first attempts to treat mental illness with chlorpromazine were made in Paris in 1951 and early 1952 by Paraire and Sigwald (Swazey, 1974). In 1952 Delay and Deniker became convinced that chlorpromazine achieved more than symptomatic relief of agitation or anxiety and that it had an ameliorative effect upon psychotic processes in diverse disorders, including mania and schizophrenia. In 1954 Lehmann and Hanrahan as well as Winkelman reported the initial use of chlorpromazine in North America for the treatment of psychomotor excitement and manic states as well as schizophrenia (Swazey, 1974). Clinical studies soon revealed that chlorpromazine was effective in the treatment of psychotic disorders of various types.

Chemistry and Structure–Activity Relationships. Phenothiazines have a tricyclic structure in which two benzene rings are linked by a sulfur and a nitrogen atom (Table 18–1). The chemically related thioxanthenes have a carbon in place of the nitrogen at position 10 with the R₁ moiety linked

through a double bond. Substitution of an electron-withdrawing group at position 2 increases the antipsychotic efficacy of phenothiazines and other tricyclic congeners (e.g., chlorpromazine vs. *promazine*). The nature of the substituent at position 10 also influences pharmacological activity. As can be seen in Table 18–1, the phenothiazines and thioxanthenes can be divided into three groups on the basis of substitution at this site. Those with an aliphatic side chain include chlorpromazine and *triflupromazine*. These compounds are relatively low in potency but not in clinical efficacy. Those with a *piperidine* ring in the side chain include *thioridazine* and *mesoridazine*; they have a somewhat lower incidence of adverse extrapyramidal effects, possibly due to increased central antimuscarinic activity, but have depressant effects on cardiac conduction and repolarization. Several potent phenothiazine antipsychotic compounds have a *piperazine* group in the side chain; *fluphenazine*, *perphenazine*, and *trifluoperazine* are examples. Most of these compounds have relatively weak antimuscarinic activity; their use at standard doses entails a greater risk of inducing adverse extrapyramidal effects, but a lower tendency to produce sedation or autonomic side effects, such as hypotension. Several piperazine phenothiazines are esterified at a free hydroxyl with long-chain fatty acids to produce long-acting, highly lipophilic prodrugs. The *decanoates* of fluphenazine and haloperidol are used commonly in the United States; several others (including esters of *pipotiazine* and *perphenazine*) are available elsewhere.

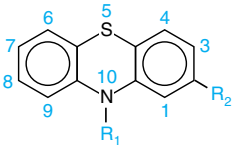

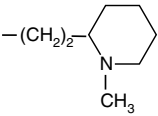

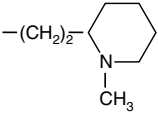

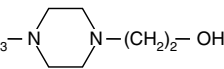

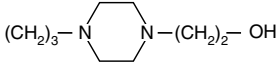

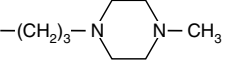

Thioxanthenes also have aliphatic or piperazine side-chain substituents. The analog of chlorpromazine among the thioxanthenes is *chlorprothixene*. Piperazine-substituted thioxanthenes include *clopenthixol*, *cis-flupentixol*, *piflutixol*, and *thiothixene*. They are all potent and effective antipsychotic agents, although only thiothixene (NAVANE) is available in the United States. Since thioxanthenes have an olefinic double bond between the central-ring carbon atom at position 10 and the side chain, geometric isomers exist. The *cis* isomers are more active. A series of experimental antipsychotic agents (*acridanes*) retain the sulfur and replace the nitrogen of the phenothiazine central ring with a carbon atom.

The antipsychotic phenothiazines and thioxanthenes have three carbon atoms interposed between position 10 of the central ring and the first amino nitrogen atom of the side chain at this position; the amine is always tertiary. Antihistaminic phenothiazines (e.g., promethazine) or strongly anticholinergic phenothiazines (e.g., *ethopropazine*, *diethazine*) have only two carbon atoms separating the amino group from position 10 of the central ring. Metabolic *N*-dealkylation of the side chain or increasing the size of amino *N*-alkyl substituents reduces antidopaminergic and antipsychotic activity.

Additional tricyclic antipsychotic agents are the benzepines, containing a 7-member central ring, of which *lox-*

*Antipsychotic agents for use in children under age 12 years include chlorpromazine, chlorprothixene (>6 years), thioridazine, and triflupromazine (among agents of low potency); and prochlorperazine and trifluoperazine (>6 years) (among agents of high potency). Haloperidol (orally) has also been used extensively in children. †Dosage forms are indicated as follows: I, regular or long-acting injection; L, oral liquid or oral liquid concentrate; O, oral solid; S, suppository; SR, oral, sustained-release ‡Except for the enanthate and decanoate forms of fluphenazine and haloperidol decanoate, dosage can be given intramuscularly up to every 6 hours for agitated patients. Haloperidol lactate has been given intravenously; this is experimental. §Extreme dosage ranges are occasionally exceeded cautiously and only when other appropriate measures have failed. Side effects: 0, absent; +, low; ++, moderate; +++, moderately high; +++++, high The indicated salts are not shown in the formulas but are commercially available forms of the drugs.

apine (a dibenzoxazepine; Table 18-1) and clozapine (a dibenzodiazepine) are available in the United States. Loxapine-like agents include potent and typical neuroleptics with prominent antidopaminergic activity (e.g., *clothiapine*, *metiapine*, *zotepine*, and others). They have an electron-withdrawing moiety at position 2, relatively close to the side-chain nitrogen atoms. Clozapine-like, atypical antipsychotic agents may lack a substituent on the aromatic ring (e.g., quetiapine, a dibenzothiazepine), have an analogous methyl substituent (notably olanzapine; Table 18-1), or have an electron-donating substituent at position 8 (e.g., clozapine, *fluperlapine*, and others). In addition to their moderate potencies at dopamine receptors, clozapine-like agents interact with varying affinities at several other classes of receptors (α_1 and α_2 adrenergic, 5-HT_{1A}, 5-HT_{2A}, 5-HT_{2C}, muscarinic cholinergic, histamine H₁, and others). Some are highly effective antipsychotic agents; clozapine

in particular has proved effective even in chronically ill patients who respond poorly to standard neuroleptics (Baldessarini and Frankenburg, 1991).

The introduction of clozapine strongly stimulated searches for additional, safer agents with antipsychotic activity and an atypically low risk of adverse extrapyramidal neurological effects. This search led to a series of atypical antipsychotic agents (Table 18-1) with some pharmacological similarities to clozapine: the structurally similar olanzapine and quetiapine, the mixed antidopaminergic-antiserotonergic agent risperidone (a benzisoxazole) (Owens and Risch, 1998; Waddington and Casey, 2000), and the newer agents ziprasidone (a benzisothiazolpiprazinyndolone derivative) (Seeger *et al.*, 1995) and aripiprazole (a quinolinone derivative) (Inoue *et al.*, 1996).

The butyrophenone (phenylbutylpiperidine) neuroleptics include haloperidol, originally developed as a sub-

stituted derivative of the phenylpiperidine analgesic meperidine (Janssen, 1974). Other experimental heterocyclic-substituted phenylbutylpiperidines include the *spiperones*. An analogous compound, *droperidol*, is a very short-acting, highly sedating neuroleptic that today is used almost exclusively in anesthesia (see Chapter 13). Additional analogs in the diphenylbutylpiperidine series include *fluspirilene*, *penfluridol*, and *pimozide* (Neumeyer and Booth, 2002). These are potent neuroleptics with prolonged action. In the United States, pimozide is indicated for the treatment of Tourette's syndrome and other tic disorders, although it also is an effective antipsychotic.

Several other classes of heterocyclic compounds have antipsychotic effects, but too few are available or sufficiently well characterized to permit conclusions regarding structure–activity relationships (Abraham, 2003; Neumeyer and Booth, 2002). These include several indole compounds (notably *molindone* and *oxypertine*) and structurally related compounds (including *sertindole* and ziprasidone). Another experimental compound, *butaclamol*, is a potent antidopaminergic agent that has a pentacyclic structure with a dibenzepine core and structural and pharmacological similarity to loxapine-like rather than clozapine-like dibenzepines. Its active (dextrorotatory) and inactive enantiomeric forms have been useful in characterizing the stereochemistry of sites of action of neuroleptics at dopamine receptors.

Risperidone has prominent antiserotonergic (5-HT_{2A}), antidopaminergic (D₂-like), antiadrenergic (α_1), and antihistaminic (H₁) activity, as well as very low antimuscarinic activity. Although risperidone and clozapine share relatively high serotonin 5-HT_{2A} and lower dopamine D₂-receptor affinities, risperidone has much more potent antidopaminergic and much less potent antimuscarinic activity. Unlike clozapine, it can induce extrapyramidal symptoms and prominent hyperprolactinemia. Nevertheless, risperidone can be considered an “atypical” antipsychotic in that its adverse extrapyramidal neurological effects are limited at low daily doses (*i.e.*, 6 mg or less), usually with adequate antipsychotic effects.

A growing series of heterocyclic antipsychotic agents are the enantiomeric, substituted *benzamides*. These include the gastroenterological agents *metoclopramide* and *cisapride*, which have antiserotonergic as well as peripheral anti-D₂-dopaminergic actions. In addition, several benzamides, like the butyrophenones and their congeners, are relatively selective antagonists at central D₂ dopamine receptors, and many have neuroleptic-antipsychotic activity. Experimental examples include *epidepride*, *eticlopride*, *nemonapride*, *raclopride*, *remoxipride*, and *sultopride*. *Sulpiride* is employed clinically as a sedative outside the United States; and its congener, *amisulpride*, is an effective antipsychotic that is not available in the United States.

The search for novel compounds that share the antidopaminergic and potent antiserotonergic actions of risperidone and clozapine led to the development of the indole-like heterocyclic agent ziprasidone. Ziprasidone (GEODON) is in clinical use, although it is associated with prolongation of the QTc interval. Ziprasidone is a combined dopamine D₂/5-HT_{2A,2C,1D} receptor antagonist and 5-HT_{1A} agonist (Gunasekara *et al.*, 2002; Stimmel *et al.*, 2002). In addition, ziprasidone has an antidepressant-like pharmacological feature: It inhibits 5-HT and norepinephrine reuptake with moderate potency. The combination of 5-HT_{1D} antagonism, 5-HT_{1A} agonism, and inhibition of monoamine reuptake by ziprasidone is consistent with potential for antidepressant or anxiolytic activity in patients with psychotic disorders. Ziprasidone also is indicated for the treatment of schizophrenia and mania (Stimmel *et al.*, 2002).

Efforts to develop dopamine D₂ receptor partial agonists as potential atypical antipsychotics produced *aripiprazole* (ABILIFY). In addition to its partial-agonist activity at D₂ receptors, aripiprazole has partial-agonist effects at serotonin 5-HT_{1A} receptors, as well as antagonistic activity at 5-HT_{2A} receptors (Potkin *et al.*, 2003). Other similar agents, including *bifeprunox*, are currently in clinical testing.

Pharmacological Properties

Antipsychotic drugs share many pharmacological effects and therapeutic applications (Davis *et al.*, 2003; Lehman *et al.*, 2003; Leucht *et al.*, 2003a; Leucht *et al.*, 2003b; Owens and Risch, 1998). Chlorpromazine and haloperidol are prototypic of the older, standard neuroleptic-type agents against which newer agents are compared and contrasted. Many antipsychotic drugs, especially chlorpromazine and other agents of low potency, have a prominent sedative effect. This is particularly conspicuous early in treatment, although some tolerance typically develops. Sedation can be of added value when very agitated psychotic patients are treated. Despite their sedative effects, neuroleptic drugs generally are not used to treat anxiety disorders or insomnia, largely because of their adverse autonomic and neurologic effects, which paradoxically can include severe anxiety and restlessness (akathisia). The risk of developing adverse extrapyramidal effects, including tardive dyskinesia, following long-term administration of neuroleptic drugs makes them less desirable than several alternative treatments for anxiety disorders (see Chapter 17).

The term *neuroleptic*—introduced to denote the effects of chlorpromazine and reserpine on the behavior of laboratory animals and in psychiatric patients—was intended to contrast their effects to those of sedatives and other CNS depressants. The neuroleptic syndrome involves suppression of spontane-

ous movements and complex behaviors, whereas spinal reflexes and unconditioned nociceptive-avoidance behaviors remain intact. In humans, neuroleptic drugs reduce initiative and interest in the environment as well as manifestations of emotion. Such effects led to their being considered “tranquilizers” before their unique antipsychotic and antimanic effects were well established. In clinical use, there may be some initial drowsiness and slowness in response to external stimuli. However, subjects are easily aroused, can answer questions, and retain intact cognition. Ataxia, incoordination, or dysarthria do not occur at ordinary doses. Typically, psychotic patients soon become less agitated, withdrawn or autistic patients sometimes become more responsive and communicative, and aggressive and impulsive behavior diminishes. Gradually (usually over a period of days), psychotic symptoms of hallucinations, delusions, and disorganized or incoherent thinking ameliorate. Neuroleptic agents also exert characteristic neurological effects—including bradykinesia, mild rigidity, tremor, and subjective restlessness (akathisia)—that resemble the signs of Parkinson’s disease.

Although the term *neuroleptic* initially encompassed this whole unique syndrome and is still used as a synonym for *antipsychotic*, it now is used to emphasize the more neurological aspects of the syndrome (*i.e.*, the parkinsonian and other extrapyramidal effects). Except for clozapine, aripiprazole, quetiapine, ziprasidone, and low doses of olanzapine and risperidone, antipsychotic drugs available in the United States also have effects on movement and posture and so can be called neuroleptic. However, the more general term *antipsychotic* is preferable, and the growing number of modern atypical antipsychotic drugs with little extrapyramidal action has reinforced this trend.

Behavioral Effects. Several animal behavioral models that mimic different aspects of psychotic disorders and predict the efficacy or potential adverse effects of antipsychotic agents have been proposed (Arnt and Skarsfeld, 1998; Geyer and Ellenbroek, 2003). Among the oldest of these is *conditioned avoidance* in response to an aversive stimulus, such as a foot-shock, following a warning stimulus. Escape or avoidance responses in such circumstances are selectively inhibited by most antipsychotics, whereas unconditioned escape or avoidance responses are not. Since correlations between antipsychotic effectiveness and conditioned avoidance tests are effective for many types of antipsychotics, they have been important in pharmaceutical screening procedures. Nevertheless, despite their empirical utility and quantitative characteristics, effects on conditioned avoidance have not provided important insights into the basis of clinical antipsychotic effects. For example, the effects of antipsychotic drugs on conditioned avoidance, but not their

clinical actions, are subject to tolerance and are blocked by anticholinergic agents. Moreover, close correlation between the potencies of drugs in conditioned avoidance tests and their ability to block the behavioral effects of dopaminergic agonists suggests that such avoidance tests may select for antidopaminergic agents with extrapyramidal and other neurological effects (Fielding and Lal, 1978; Janssen and Van Bever, 1978; Arnt and Skarsfeldt, 1998).

Another classical animal model is the effect of antipsychotics on *motor activity*. Nearly all antipsychotics, including newer agents, diminish spontaneous motor activity and reverse increases in motor activity induced by apomorphine, amphetamine, or phencyclidine (PCP) (Ellenbroek, 1993). Antipsychotics also block apomorphine-induced climbing in mice, which is believed to reflect D₂-like receptor activation.

A third model is *latent inhibition*—the retarding effects of prior stimulus exposure on subsequent stimulus-response learning (Feldon and Weiner, 1992). Most antipsychotics reverse amphetamine-induced reduction in latent inhibition. A related model is *prepulse inhibition* (PPI) of startle, which mimics deficits in sensory gating and information processing documented in many psychotic patients (Perry *et al.*, 1999). PPI is the reduction in startle response following presentation of a low-intensity, nonstartling stimulus (the prepulse) shortly before a stronger startle stimulus (Swerdlow *et al.*, 1994). PPI can be disrupted by administration of agonists and releasers of dopamine (apomorphine and amphetamine, respectively), serotonin (2,5-dimethoxy-4-iodoamphetamine [DOI]), and 3,4-methylenedioxyamphetamine (MDMA), as well as glutamate *N*-methyl-D-aspartate (NMDA) receptor antagonists (PCP, ketamine). As expected, virtually all typical and atypical antipsychotics with appreciable affinity for D₂ receptors block apomorphine-induced disruption of PPI. In contrast, only atypical antipsychotics, and not typical neuroleptics, reverse the PPI disruption induced by serotonin agonists or releasers, or by NMDA antagonists.

Auditory sensory gating (ASG) involves the response to two identical stimuli. It is reduced in many psychotic patients and disrupted in animals given amphetamine or PCP (Ellenbroek *et al.*, 1999). Typical neuroleptics such as haloperidol can normalize amphetamine- and PCP-induced deficits in this behavior, but effects of newer atypical agents are less well studied.

So-called “negative” social and cognitive symptoms of schizophrenia, particularly social withdrawal and isolation, can be mimicked in at least two animal models: amphetamine-induced social isolation in monkeys, and PCP-induced social withdrawal in rats. In both models, drug-treated animals avoid interactions with other animals. These social deficits are partially reversed by newer antipsychotics but not older neuroleptics (Ellenbroek *et al.*, 1999).

Extrapyramidal Effects of Antipsychotics. The acute adverse clinical effects of antipsychotic agents are best mimicked in animals by assessing catalepsy in rats (immobility that allows an animal to be placed in abnormal postures that persist) or dystonia in monkeys. Late dyskinesic effects of antipsychotics are represented by the development of vacuous chewing movements in rats (Casey, 1996; Ellenbroek *et al.*, 1999).

A particularly disturbing adverse effect of most antipsychotics is restless activity, termed *akathisia*, which is not readily mimicked by animal behavior. The cataleptic immobility of animals treated with classical antipsychotics resembles the catatonia seen in some psychotic patients and in a variety of metabolic and neurological disorders affecting the CNS. In patients, catatonic signs, along with other features of psychotic illnesses, are sometimes relieved by antipsychotic agents. However, rigidity and bradykinesia, which mimic catatonia, can be induced by administering large doses of potent traditional neuroleptics, and reversed by their removal or by addition of an antimuscarinic-antiparkinson agent (Fielding and Lal, 1978; Janssen and Van Bever, 1978). Theories concerning mechanisms underlying these extrapyramidal reactions and descriptions of their clinical presentations and management are provided below.

Effects on Cognitive Functions. Several cognitive functions, including auditory processing and attention, spatial organization, verbal learning, semantic and verbal memory, and executive functions, are impaired in schizophrenia patients and are a major source of social and occupational dysfunction and disability (Saykin *et al.*, 1991). Potent D₂-antagonist neuroleptics have very limited beneficial effects on such functions. Some atypical antipsychotic agents with mixed D₂/5-HT_{2A} activity (including clozapine, quetiapine, olanzapine, and risperidone), as well as the D₂ partial agonist aripiprazole, seem to improve cognitive functioning in psychotic patients (Kasper and Resinger, 2003; Purdon, 2000). Nevertheless, significant long-term gains in social and occupational function during long-term treatment of chronically psychotic patients with these drugs are not well documented.

Effects on Sleep. Antipsychotic drugs have inconsistent effects on sleep patterns but tend to normalize sleep disturbances characteristic of many psychoses and mania. The ability to prolong and enhance the effect of opioid and hypnotic drugs appears to parallel the sedative, rather than the neuroleptic, potency of a particular agent, so that potent, less-sedating antipsychotics do not enhance sleep.

Effects on Specific Areas of the Nervous System. The antipsychotic drugs affect all levels of the central nervous system. Although knowledge of the actions underlying the antipsychotic and many of the neurological effects of antipsychotic drugs remains incomplete, theories based on their ability to antagonize the actions of dopamine as a neurotransmitter in the basal ganglia and limbic portions

of the forebrain are most prominent. Although supported by a large body of data, these theories reflect a degree of circularity in the consideration of antipsychotic drug candidates for development after identifying their antidopaminergic activity (Baldessarini, 2000).

Cerebral Cortex. Since psychosis involves disordered thought processes, cortical effects of antipsychotic drugs are of particular interest. Antipsychotic drugs interact with dopaminergic projections to the prefrontal and deep-temporal (limbic) regions of the cerebral cortex, with relative sparing of these areas from adaptive changes in dopamine metabolism that would suggest tolerance to the actions of neuroleptics (Bunney *et al.*, 1987).

Seizure Threshold. Many neuroleptic drugs can lower the seizure threshold and induce discharge patterns in the electroencephalogram (EEG)—effects associated with epileptic seizure disorders. Clozapine, olanzapine, and aliphatic phenothiazines with low potency (such as chlorpromazine) seem particularly able to do this, while the more potent piperazine phenothiazines and thioxanthenes (notably fluphenazine and thiothixene), risperidone, and quetiapine are much less likely to have this effect (Baldessarini and Frankenburg, 1991; Centorrino *et al.*, 2002). The butyrophenones and molindone variably and unpredictably rarely cause seizures. Clozapine has a clearly dose-related risk of inducing EEG abnormalities and seizures in nonepileptic patients (Baldessarini and Frankenburg, 1991; Centorrino *et al.*, 2002). Antipsychotic agents, especially clozapine, olanzapine, and low-potency phenothiazines and thioxanthenes, should be used with *extreme caution*, if at all, in untreated epileptic patients and in patients undergoing withdrawal from CNS depressants such as alcohol, barbiturates, or benzodiazepines. Most antipsychotic drugs, especially the piperazines as well as the newer atypical agents aripiprazole, quetiapine, risperidone, and ziprasidone, can be used safely in epileptic patients if moderate doses are attained gradually and if concomitant anticonvulsant drug therapy is maintained (*see* Chapter 19).

Basal Ganglia. Because the extrapyramidal effects of many antipsychotic drugs are prominent, a great deal of interest has centered on their actions in the basal ganglia, notably the caudate nucleus, putamen, globus pallidus, and allied nuclei, which play a crucial role in the control of posture and the extrapyramidal aspects of movement. The critical pathogenic role of dopamine deficiency in this region in Parkinson's disease, the potent activity of neuroleptics as dopamine receptor antagonists, and the striking resemblance between clinical manifestations of Parkinson's disease and some of the neurological effects of neuroleptic drugs have all focused attention on the role of deficient dopaminergic activity in some of the neuroleptic-induced extrapyramidal effects (Carlsson, 1992).

The hypothesis that interference with dopamine signaling in the mammalian forebrain might contribute to the neurological and possibly the antipsychotic effects of the neuroleptic drugs arose from the observation that they consistently increased cerebral tissue concentrations of

dopamine metabolites, but variably affected the metabolism of other neurotransmitters. The importance of dopamine also was supported by histochemical studies, which indicated a preferential distribution of dopamine-containing fibers between midbrain and the basal ganglia (notably the nigrostriatal tract) and in the hypothalamus (*see* Chapter 12) (Neumeyer *et al.*, 2003). Other dopamine-containing neurons project from midbrain tegmental nuclei to forebrain regions associated with the limbic system and to temporal and prefrontal cerebral cortical areas closely related functionally to the limbic system. Thus a simplistic but attractive concept arose: many adverse extrapyramidal neurological and neuroendocrinological effects of the neuroleptics are mediated by antidopaminergic effects in the basal ganglia and hypothalamic systems, whereas their antipsychotic effects are mediated by modification of dopaminergic neurotransmission in the limbic and mesocortical systems.

Antagonism of dopamine-mediated synaptic neurotransmission is an important action of many antipsychotics (Carlsson, 1992). Thus, neuroleptic drugs (but not their inactive congeners) initially increase the rate of production of dopamine metabolites, the rate of conversion of the precursor amino acid L-tyrosine to L-dihydroxyphenylalanine (L-dopa) and its metabolites, and initially increase the rate of firing of dopamine-containing cells in the midbrain. These effects presumably represent adaptive responses of neuronal systems aimed at reducing the impact of impaired synaptic transmission at dopaminergic terminals in the forebrain.

Evidence supporting this interpretation includes the observation that small doses of neuroleptics block behavioral or neuroendocrine effects of systemically administered or intracerebrally injected dopaminergic agonists. Examples include apomorphine-induced stereotyped gnawing behavior and release of growth hormone in the rat. Many antipsychotic drugs also block the effects of agonists on dopamine-sensitive adenylyl cyclase associated with D₁/D₅-dopamine receptors in forebrain tissue (Figure 18–1). Atypical antipsychotic drugs such as clozapine and quetiapine are characterized by low affinity or weak actions in such tests (Campbell *et al.*, 1991). Initially, the standard antipsychotics increase firing and metabolic activity in dopaminergic neurons. These responses eventually are replaced by diminished presynaptic activity (“depolarization inactivation”) with reduced firing and production of dopamine, particularly in the extrapyramidal basal ganglia (Bunney *et al.*, 1987). The timing of these adaptive changes following the administration of neuroleptics correlates well with the gradual evolution of parkinsonian bradykinesia over several days (Tarsy *et al.*, 2002).

Radioligand-binding and autoradiographic assays for dopamine receptor subtypes have been used to define more precisely the mechanism of action of antipsychotic agents (Baldessarini and Tarazi, 1996; Civelli *et al.*, 1993; Neve and Neve, 1997; Tarazi *et al.*, 1997, 2001) (Table 18–2 and Figure 18–1). Estimated clinical potencies of most antipsychotic drugs correlate well with their relative potencies *in vitro* to inhibit binding of radioligands to D₂-dopamine receptors. This correlation with drug potency is partly obscured by the tendency of antipsychotics to accumulate in brain tissue to different degrees (Tsuneizumi *et al.*, 1992; Cohen *et al.*, 1992). Nevertheless, almost all clinically effective antipsychotic agents (with the notable exception of clozapine and quetiapine) have high or moderate affinity for D₂ receptors. Although some antipsychotics (especially thioxanthenes, phenothiazines, and clozapine) bind with relatively high affinity to D₁ receptors, they also block D₂ receptors and other D₂-like receptors, including the D₃ and D₄ subtypes (Sokoloff *et al.*, 1990; Van Tol *et al.*, 1991; Baldessarini and Tarazi, 1996; Tarazi and Baldessarini, 1999; Tarazi *et al.*, 1997, 2001). Butyrophenones and congeners (*e.g.*, haloperidol, pimozide, *N*-methylspiperone) and experimental benzamide neuroleptics are relatively selective antagonists of D₂ and D₃

dopamine receptors, with either high (nemonapride) or low (eticlopride, raclopride, remoxipride) D₄ affinity. The physiological and clinical consequences of selectively blocking D₁/D₅ receptors remain obscure, although experimental benzazepines (*e.g.*, SCH-23390 or SCH-39166 [ecopipam]) with such properties, but apparently with weak antipsychotic effects, are known (Daly and Waddington, 1992; Karlsson *et al.*, 1995; Keabian *et al.*, 1997).

Many other antipsychotic agents are active α_1 adrenergic antagonists (Baldessarini *et al.*, 1992; Richelson, 1999). This action may contribute to sedative and hypotensive side effects or may underlie useful psychotropic effects, although assessment of the psychotropic potential of centrally active antiadrenergic agents is limited.

Many antipsychotic agents also have affinity for forebrain 5-HT_{2A} serotonin receptors, including aripiprazole, clozapine, olanzapine, quetiapine, risperidone, and ziprasidone (Chouinard *et al.*, 1993; Leysen *et al.*, 1994) (*see* Chapter 11). This mixture of moderate affinities for several CNS receptor types (including muscarinic acetylcholine and H₁-histamine receptors) may contribute to the distinct pharmacological profiles of the atypical antipsychotic agent clozapine (Baldessarini and Frankenburg, 1991) and other newer atypical antipsychotics (Ichikawa and Meltzer, 1999; Meltzer and Nash, 1991).

Limbic System. Dopaminergic projections from the midbrain terminate on septal nuclei, the olfactory tubercle and basal forebrain, the amygdala, and other structures within the temporal and prefrontal cerebral lobes and the hippocampus. The dopamine hypothesis has focused considerable attention on the mesolimbic and mesocortical systems as possible sites where antipsychotic effects are mediated. Speculations about the pathophysiology of idiopathic psychoses such as schizophrenia have long centered on dopaminergic functions in the limbic system (Baldessarini, 2000). Such speculation has been given indirect encouragement by repeated “natural experiments” that have associated psychotic mental phenomena with lesions of the temporal lobe and other portions of the limbic system, as well as by psychotic syndromes produced by excessive exposure to psychostimulants.

Certain important effects of antipsychotic drugs are similar in extrapyramidal and limbic regions, including effects on ligand-binding assays for dopaminergic receptors. However, the extrapyramidal and antipsychotic actions of these drugs differ in several ways. For example, while some acute extrapyramidal effects of neuroleptics tend to diminish or disappear with time or with concurrent administration of anticholinergic drugs, antipsychotic effects do not. Dopaminergic subsystems in the forebrain differ functionally and in their physiological responses to drugs (Bunney *et al.*, 1987; Moore, 1987; Wolf and Roth, 1987). For example, anticholinergic agents block the increased turnover of dopamine in the basal ganglia induced by neuroleptic agents, but not in limbic areas containing dopaminergic terminals. Further, tolerance to the enhanced dopamine metabolism by antipsychotics is much less prominent in cortical and limbic areas than in extrapyramidal areas (Carlsson, 1992).

Newer Dopaminergic Receptors in Basal Ganglia and Limbic System. The discovery that D₃ and D₄ receptors are preferentially expressed in limbic areas has led to efforts to identify selective inhibitors for these receptors that might have antipsychotic efficacy and low

Figure 18–1. Sites of action of neuroleptics and lithium. In varicosities (“terminals”) along terminal arborizations of dopamine (DA) neurons projecting from midbrain to forebrain, tyrosine is oxidized to dihydroxyphenylalanine (DOPA) by tyrosine hydroxylase (TH), the rate-limiting step in catecholamine biosynthesis, then decarboxylated to DA by aromatic L-amino acid decarboxylase (AADC) and stored in vesicles. Following exocytotic release (inhibited by Li^+) by depolarization in the presence of Ca^{2+} , DA interacts with postsynaptic receptors (R) of D_1 and D_2 types (and structurally similar but less prevalent D_1 -like and D_2 -like receptors), as well as with presynaptic D_2 and D_3 autoreceptors. Inactivation of transsynaptic communication occurs primarily by active transport (“reuptake”) of DA into presynaptic terminals (inhibited by many stimulants), with secondary deamination by mitochondrial monoamine oxidase (MAO). Postsynaptic D_1 receptors, through G_s , activate adenylyl cyclase (AC) to increase cyclic AMP (cAMP), whereas D_2 receptors inhibit AC through G_i . D_2 receptors also activate receptor-operated K^+ channels, suppress voltage-gated Ca^{2+} currents, and stimulate phospholipase C (PLC), perhaps *via* the β subunits liberated from activated G_i (see Chapter 1), activating the IP_3 - Ca^{2+} pathway, thereby modulating a variety of Ca^{2+} -dependent activities including protein kinases. Lithium inhibits the phosphatase that liberates inositol (I) from inositol phosphate (IP). Both Li^+ and valproate can modify the abundance or function of G proteins and effectors, as well as protein kinases and several cell and nuclear regulatory factors. D_2 -like autoreceptors suppress synthesis of DA by diminishing phosphorylation of rate-limiting TH, and by limiting DA release (possibly through modulation of Ca^{2+} or K^+ currents). In contrast, presynaptic A_2 adenosine receptors (A_2R) activate AC and, *via* cyclic AMP production, TH activity. Nearly all antipsychotic agents block D_2 receptors and autoreceptors; some also block D_1 receptors (Table 18–2). Initially in antipsychotic treatment, DA neurons activate and release more DA, but following repeated treatment, they enter a state of physiological depolarization inactivation, with diminished production and release of DA, in addition to continued receptor blockade. ER, endoplasmic reticulum.

risk of extrapyramidal effects. Clozapine has modest selectivity for dopamine D_4 receptors over other dopamine-receptor types. D_4 receptors, preferentially localized in cortical and limbic brain regions in relatively low abundance (Tarazi and Baldessarini, 1999; Van Tol *et al.*, 1991), are upregulated after repeated administration of most typical and atypical antipsychotic drugs (Tarazi *et al.*, 1997, 2001). These receptors may contribute to clinical antipsychotic actions, but agents that are D_4 selective (*e.g.*, L-745,870, sonopiprazole) or mixed $\text{D}_4/5\text{-HT}_{2A}$ antagonists (*e.g.*, fananserin) have not proved effective in the treatment of psychotic patients (Baldessarini, 1997; Corrigan *et al.*, 2004; Keabian *et al.*, 1997; Kramer *et al.*, 1997; Lahti *et al.*, 1998; Tarazi and Baldessarini, 1999; Truffinet *et al.*, 1999). Other D_4 -selective compounds may emerge as novel treatments for other neuropsychiatric disorders, including attention-deficit/hyperactivity disorder or cognitive symptoms of psychotic disorders (Tarazi and Baldessarini, 1999; Zhang *et al.*, 2004).

In contrast to effects on D_2 and D_4 receptors, long-term administration of typical and atypical antipsychotic drugs does not alter D_3 receptor levels in rat forebrain regions (Tarazi *et al.*, 1997, 2001). These findings suggest that D_3 receptors are unlikely to play a pivotal role in antipsychotic drug actions, perhaps because their avid affinity for endogenous dopamine prevents their interaction with antipsychotics (Levant, 1997). Agents partially selective for the D_3 -dopamine receptor include several hydroxyaminotetralins (particularly R[+]-7-hydroxy-*N,N*-dipropylaminotetralin; the tricyclic analog PD-128,907); the hexahydrobenzophenanthridines, *nafadotride* and BP-897; and others in development (Baldessarini *et al.*, 1993; Sautel *et al.*, 1995; Keabian *et al.*, 1997; Pilla *et al.*, 1999). The subtle and atypical functional activities of cerebral D_3 receptors suggest that D_3 agonists rather than antagonists may have useful psychotropic effects, particularly in antagonizing stimulant-reward and dependence behaviors (Shafer and Levant, 1998; Pilla *et al.*, 1999).

Table 18-2

Potencies of Standard and Experimental Antipsychotic Agents at Neurotransmitter Receptors†‡*

*Data are Ki values (nM) determined by competition with radioligands for binding to the indicated receptors. †Compounds are in rank-order of dopamine D₂-receptor affinity; 5-HT_{2A}/D₂ ratio indicates relative preference for D₂ vs. serotonin 5-HT_{2A} receptors. Compounds include clinically used and experimental agents. ‡Muscarinic-cholinergic-receptor Ki values are pooled results obtained with radioligands that are nonselective for muscarinic-receptor subtypes or that are selective for the M₁ subtype.

SOURCES: Data are averaged from Roth *et al.*, 1995; Seeger *et al.*, 1995; Schotte *et al.*, 1996; Richelson, 1999, and a personal written communication from E. Richelson 1/26/00.

In Vivo Occupation of Cerebral Neurotransmitter Receptors. Levels of occupation of dopamine receptors and other receptors in human brain can be estimated with positron emission tomography (PET) brain imaging in patients treated with antipsychotic drugs. Such analyses not only support conclusions arising from laboratory studies of receptor occupancy (Table 18–2) but also assist in predicting clinical efficacy, extrapyramidal side effects, and clinical dosing, even in advance of controlled clinical trials (Farde *et al.*, 1995; Kasper *et al.*, 2002; Kapur and Seeman, 2001; Waddington and Casey, 2000). For example, occupation of more than 75% of D₂ receptors in the basal ganglia is associated with risk of acute extrapyramidal dysfunctions and is commonly found with clinical doses of typical neuroleptics (Farde *et al.*, 1995). In contrast, therapeutic doses of clozapine usually are associated with lower levels of occupation of D₂ receptors (averaging 40% to 50%), but higher levels of occupation (70% to 90%) of cortical 5-HT_{2A} receptors (Kapur *et al.*, 1999; Kapur and Seeman, 2001; Nordstrom *et al.*, 1995). Of the novel atypical antipsychotics, quetiapine has a notable clozapinelike *in vivo* receptor-occupancy profile, resembling clozapine's levels of occupation of both D₂ (40% to 50%) and 5-HT_{2A} receptors (50% to 70%; Gefvert *et al.*, 2001). Olanzapine and risperidone also block cortical 5-HT_{2A} receptors at high levels (80% to 100%), with greater occupancy at D₂ sites (typically 50% to 90%) than either clozapine or quetiapine (Farde *et al.*, 1995; Nordstrom *et al.*, 1998; Kapur *et al.*, 1999). In addition to its relatively high levels of D₂-receptor occupation, olanzapine is more antimuscarinic than is risperidone, perhaps contributing to its lower risk of acute extrapyramidal effects (Tables 18–1 and 18–2).

Clinical PET studies also indicate that ziprasidone occupies both D₂ and 5-HT_{2A} receptors. At conventional clinical doses, ziprasidone occupied 77% of striatal D₂ receptors and over 98% of cortical 5-HT_{2A} receptors (Bench *et al.*, 1996). Aripiprazole (10 to 30 mg) resulted in dose-dependent D₂ receptor occupancy (up to 84% to 94%; Yokoi *et al.*, 2002). Despite such high levels of D₂ receptor occupation, acute extrapyramidal side effects are virtually unknown with aripiprazole, consistent with evidence that it acts as a D₂ partial agonist.

Hypothalamus and Endocrine Systems. Endocrine changes occur because of effects of antipsychotic drugs on the hypothalamus or pituitary, including their antidopaminergic actions. Most older antipsychotics, reserpine, and risperidone increase prolactin secretion.

This effect on prolactin secretion probably is due to a blockade of the pituitary actions of the tuberoinfundibular dopaminergic neurons; these neurons project from the arcuate nucleus of the hypothalamus to the median eminence, where they deliver dopamine to the anterior pituitary *via* the hypophyseal portal blood vessels. D₂-dopaminergic receptors on lactotropes in the anterior pituitary mediate the tonic prolactin-inhibiting action of dopamine (Ben-Jonathan, 1985) (*see* Chapter 55).

Correlations between the potencies of antipsychotic drugs in stimulating prolactin secretion and causing behavioral effects are excellent for many types of agents (Sachar, 1978). Aripiprazole, clozapine, olanzapine, quetiapine, and ziprasidone are exceptional in having mini-

mal or transient effects on prolactin (Argo *et al.*, 2004; Arvanitis and Miller, 1997; Compton and Miller, 2002), while olanzapine produces only minor, transient increases in prolactin levels (Tollefson and Kuntz, 1999). Risperidone has an unusually potent prolactin-elevating effect, even at doses with little extrapyramidal impact (Grant and Fitton, 1994). Effects of neuroleptics on prolactin secretion generally occur at lower doses than do their antipsychotic effects. This may reflect their action outside the blood–brain barrier in the adenohypophysis, or differences in the regulation of pituitary and cerebral D₂ receptors. Little tolerance develops to the effect of antipsychotic drugs on prolactin secretion, even after years of treatment, correlating with a relative lack of up- or down-regulation of pituitary D₂ receptors and their relative sensitivity to dopamine partial agonists such as bromocriptine (Baldessarini *et al.*, 1994; Campbell *et al.*, 1989). However, the hyperprolactinemia effect of antipsychotics is rapidly reversible when the drugs are discontinued (Bitton and Schneider, 1992). This activity is presumed to be responsible for the breast engorgement and galactorrhea that occasionally are associated with their use, sometimes even in male patients given high doses of neuroleptics.

Because antipsychotic drugs are used chronically and thus cause sustained hyperprolactinemia, there has been concern about their possible contribution to risk of carcinoma of the breast, although supportive clinical evidence is lacking (Dickson and Glazer, 1999; Mortensen, 1994). Nevertheless, antipsychotic and other agents that stimulate secretion of prolactin should be avoided in patients with established carcinoma of the breast, particularly with metastases. Perhaps due to the effects of hyperprolactinemia, some antipsychotic drugs reduce the secretion of gonadotropins and sex steroids, which can cause amenorrhea in women and sexual dysfunction or infertility in men.

The effects of standard antipsychotics on other hypothalamic neuroendocrine functions are less well characterized, although these agents inhibit the release of growth hormone and may reduce stress-induced secretion of corticotropin-releasing hormone (CRH). Despite their capacity to interfere with secretion of pituitary growth hormone, classical antipsychotics are poor therapy for acromegaly, and there is no evidence that they retard growth or development of children. In addition, some antipsychotics can decrease secretion of neurohypophyseal hormones.

In addition to neuroendocrine effects, it is likely that other autonomic effects of antipsychotic drugs are mediated by the hypothalamus. An important example is the poikilothermic effect of chlorpromazine and other neuroleptic agents, which impairs the body's ability to regulate temperature such that hypo- or hyperthermia may result,

depending on the ambient temperature. Clozapine can induce moderate elevations of body temperature that can be confusing clinically. Central effects on temperature regulation and cardiovascular and respiratory functioning probably contribute to the features of *neuroleptic malignant syndrome* (see below).

Brainstem. Clinical doses of antipsychotic agents usually have little effect on respiration. However, vasomotor reflexes mediated by either the hypothalamus or the brainstem are depressed by some antipsychotics, which may lead to hypotension. This risk is associated particularly with older low-potency antipsychotics and with risperidone. Even in cases of acute overdose with suicidal intent, the antipsychotic drugs usually do not cause life-threatening coma or suppress vital functions. Haloperidol has been administered intravenously in doses exceeding 500 mg/24 hours to control agitation in delirious patients (Tesar *et al.*, 1985), although such aggressive dosing increased the risks of potentially life-threatening cardiac depressant effects (Hassaballa and Balk, 2003).

Chemoreceptor Trigger Zone (CTZ). Most antipsychotics protect against the nausea- and emesis-inducing effects of apomorphine and certain ergot alkaloids, all of which can interact with central dopaminergic receptors in the CTZ of the medulla. The antiemetic effect of most neuroleptics occurs with low doses. It can contribute to toxicity of acute overdoses of mixed agents by preventing their elimination by vomiting. Drugs or other stimuli that cause emesis by an action on the nodose ganglion or locally on the gastrointestinal tract are not antagonized by antipsychotic drugs, but potent piperazines and butyrophenones are sometimes effective against nausea caused by vestibular stimulation.

Autonomic Nervous System. Since various antipsychotic agents have antagonistic interactions at peripheral, α adrenergic, serotonin (5-HT_{2A/2C}), and histamine (H₁) receptors, their effects on the autonomic nervous system are complex and unpredictable. Chlorpromazine, clozapine, and thioridazine have particularly significant α adrenergic antagonistic activity. The potent piperazine tricyclic neuroleptics (*e.g.*, fluphenazine, trifluoperazine), haloperidol, and risperidone, have antipsychotic effects even when used in low doses, and show little antiadrenergic activity in patients.

The muscarinic-cholinergic blocking effects of most antipsychotic drugs are relatively weak, but the blurred vision commonly associated with chlorpromazine may be due to an anticholinergic action on the ciliary muscle. Chlorpromazine regularly produces miosis, which can be due to α adrenergic blockade. Other phenothiazines can cause mydriasis. This is especially likely to occur with clozapine or thioridazine, which are potent muscarinic antagonists. Chlorpromazine can cause constipation and decreased gastric secretion and motility; clozapine can decrease the efficiency of clearing saliva and severely impair intestinal motility (Rabinowitz *et al.*, 1996; Theret *et al.*, 1995). Decreased sweating and salivation also result from the anticholinergic effects of such drugs. Acute urinary retention is uncommon but can occur in males with prostatism. Anticholinergic effects are least frequently caused by the potent antipsychotics such as haloperidol and risperidone. However, olanzapine has substantial anticholinergic activity that may tend to offset its considerable D₂ antidopamine effects on the extrapyramidal system (Tarazi *et al.*, 2001). Clozapine is sufficiently anticholinergic as to induce an atropinelike poisoning on overdose (Schuster *et al.*, 1977). Its prominent, pharmacologically active metabolite, norclozapine, has allosteric agonist effects at the acetylcholine M₁ receptor and may potentiate the function of NMDA glutamate receptors (Sur

et al., 2003). The phenothiazines inhibit ejaculation without interfering with erection. Thioridazine produces this effect with some regularity, sometimes limiting its acceptance by men.

Kidney and Electrolyte Balance. Chlorpromazine may have weak diuretic effects in animals and human beings because of a depressant action on the secretion of vasopressin (also called antidiuretic hormone or ADH), inhibition of reabsorption of water and electrolytes by a direct action on the renal tubule, or both. The syndrome of idiopathic polydipsia and hyponatremia sometimes associated with psychotic illness has responded to clozapine, presumably *via* CNS actions (Siegel *et al.*, 1998).

Cardiovascular System. Chlorpromazine has complex actions on the cardiovascular system, directly affecting the heart and blood vessels and indirectly acting through CNS and autonomic reflexes. Chlorpromazine and less potent antipsychotic agents, as well as reserpine, risperidone, and olanzapine, can cause orthostatic hypotension, usually with rapid development of tolerance (Ray *et al.*, 1987).

Thioridazine, mesoridazine, and other phenothiazines with low potency, as well as ziprasidone, droperidol, and perhaps high doses of haloperidol have a potentially clinically significant direct negative inotropic action and a quinidinelike effect on the heart. Electrocardiographic (ECG) changes include prolongation of the QTc and PR intervals, blunting of T waves, and depression of the ST segment. Thioridazine in particular causes a high incidence of QTc- and T-wave changes and may rarely produce ventricular arrhythmias and sudden death (Zareba and Lin, 2003). These effects are less common with potent antipsychotic agents. Ziprasidone also has the propensity to prolong QTc, and prudent practice calls for extra caution when this agent, thioridazine, or mesoridazine are used in combination with other agents that depress cardiac conduction (*see* Chapter 34) (Daniel, 2003; Taylor, 2003).

Miscellaneous Pharmacological Effects. Interactions of antipsychotic drugs with central neurotransmitters other than dopamine may contribute to their antipsychotic effects or other actions. For example, many antipsychotics enhance the turnover of acetylcholine, especially in the basal ganglia, perhaps secondary to the blockade of inhibitory dopaminergic heteroreceptors on cholinergic neurons. In addition, there is an inverse relationship between antimuscarinic potency of antipsychotic drugs in the brain and the likelihood of extrapyramidal effects (Snyder and Yamamura, 1977). Chlorpromazine and low-potency antipsychotic agents, including clozapine and quetiapine, have antagonistic actions at histamine receptors that probably contribute to their sedative effects.

Absorption, Distribution, Fate, and Excretion. Some antipsychotic drugs have erratic and unpredictable patterns of absorption after oral administration. Parenteral (intramuscular) administration increases the bioavailability of active drug four- to tenfold. Most antipsychotic drugs are highly lipophilic, highly membrane- or protein-bound, and accumulate in the brain, lung, and other tissues with a rich blood supply. They also enter the fetal circulation and breast milk. It is virtually impossible and usually not necessary to remove these agents by dialysis.

The stated elimination half-lives with respect to total concentrations in plasma are typically 20 to 40 hours. However, complex patterns of delayed elimination may

occur with some agents, particularly the butyrophenones and their congeners (Cohen *et al.*, 1992). Biological effects of single doses of most antipsychotics usually persist for at least 24 hours, permitting once-daily dosing once the patient has adjusted to initial side effects. Elimination from the plasma may be more rapid than from sites of high lipid content and binding, notably in the CNS, but direct pharmacokinetic studies on this issue are few and inconclusive (Sedvall, 1992). Metabolites of some agents have been detected in the urine several months after drug administration was discontinued. Slow removal of drug may contribute to the typically delayed exacerbation of psychosis after stopping drug treatment. Repository (“depot”) preparations of esters of neuroleptic drugs, as well of risperidone, incorporated into carbohydrate microspheres, are absorbed and eliminated much more slowly than are oral preparations. For example, half of an oral dose of fluphenazine hydrochloride is eliminated in about 20 hours, while the decanoate ester injected intramuscularly has a nominal half-life of 7 to 10 days. Clearance of fluphenazine decanoate and normalization of hyperprolactinemia following repeated dosing can require 6 to 8 months (Sampath *et al.*, 1992). Effects of long-acting risperidone (RISPERIDAL CONSTA) are delayed for 2 to 3 weeks because of slow biodegradation of the microspheres and persist for at least 2 weeks after the injections are discontinued (Harrison and Goa, 2004).

The antipsychotic drugs are metabolized by oxidative processes mediated largely by hepatic cytochrome P450 isozymes (CYPs) and by glucuronidation, sulfation, and other conjugation processes. Hydrophilic metabolites of these drugs are excreted in the urine and to some extent in the bile. Most oxidized metabolites of antipsychotic drugs are biologically inactive; a few (*e.g.*, 7-hydroxychlorpromazine, mesoridazine, several *N*-demethylated metabolites of phenothiazines, the labile hydroxy metabolite of haloperidol, 9-hydroxyrisperidone, and dehydroaripiprazole) are not. These active metabolites may contribute to biological activity of the parent compound and complicate correlating blood drug levels with clinical effects (Baldessarini *et al.*, 1988). Less potent antipsychotic drugs like chlorpromazine may weakly induce their own hepatic metabolism, since their concentrations in blood are lower after several weeks of treatment at the same dosage. Alterations of gastrointestinal motility also may contribute. The fetus, the infant, and the elderly have diminished capacity to metabolize and eliminate antipsychotic agents, while young children tend to metabolize these drugs more rapidly than do adults (Kowatch and DelBello, 2003; Kutcher, 1997; Frazier *et al.*, 2003).

With several antipsychotic agents, bioavailability and drug acceptance by hospitalized patients is somewhat increased with liquid concentrates and rapidly disintegrating tablets that yield peak serum concentrations of chlorpromazine and other phenothiazines within 2 to 4 hours. Intramuscular administration avoids much of the first-pass enteric metabolism and provides measurable concentrations in plasma within 15 to 30 minutes. Bioavailability of chlorpromazine may be increased up to tenfold with injections, but the clinical dose usually is decreased by only three- to fourfold. Gastrointestinal absorption of chlorpromazine is modified unpredictably by food and probably is decreased by antacids. Concurrent administration of anticholinergic antiparkinsonian agents does not appreciably diminish intestinal absorption of neuroleptic agents (Simpson *et al.*, 1980). Chlorpromazine and other antipsychotic agents bind significantly to membranes and to plasma proteins. Typically, more than 85% of the drug in plasma is bound to albumin. Concentrations of some neuroleptics (*e.g.*, haloperidol) in brain can be more than 10 times those in the blood (Tsuneizumi *et al.*, 1992). Their apparent volume of distribution may be as high as 20 liters per kilogram.

Disappearance of chlorpromazine from plasma varies widely and includes a rapid distribution phase (half-life about 2 hours) and a slower elimination phase (half-life about 30 hours). The half-life of elimination from human brain is not known but may be estimated using modern brain-scanning technologies (Sedvall, 1992). Approximate elimination half-lives of clinically employed antipsychotic agents are provided in Table 18–3.

Table 18–3
Elimination Half-Lives of Antipsychotic Drugs

DRUG	HALF-LIFE (HOURS)*
Aripiprazole	75
Chlorpromazine	24 (8–35)
Clozapine	12 (4–66)
Fluphenazine	18 (14–24)
Haloperidol	24 (12–36) [†]
Loxapine	8 (3–12)
Mesoridazine	30 (24–48)
Molindone	12 (6–24)
Olanzapine	30 (20–54)
Perphenazine	12 (8–21)
Pimozide	55 (29–111) [†]
Quetiapine	6
Risperidone	20–24 [‡]
Thioridazine	24 (6–40)
Thiothixene	34
Trifluoperazine	18 (14–24) [§]
Ziprasidone	7.5

*Average and range. [†]May have multiphasic elimination with much longer terminal half-life. [‡]Half-life of the main active metabolite (parent drug half-life ca. 3–4 hours). [§]Estimated, assuming similarity to fluphenazine. SOURCES: Data from Ereshefsky (1996) and United States Pharmacopoeia, 2004.

Attempts to correlate plasma concentrations of chlorpromazine or its metabolites with clinical responses have been unsuccessful (Baldessarini *et al.*, 1988; Cooper *et al.*, 1976). Studies have revealed wide variations (at least tenfold) in plasma concentrations among individuals. Although plasma concentrations of chlorpromazine below 30 ng/ml are not likely to produce an adequate antipsychotic response, and levels above 750 ng/ml are likely to be poorly tolerated (Rivera-Calimlim and Hershey, 1984), the plasma concentrations that are associated with optimal clinical responses are not known. Again, modern brain-imaging techniques with radioligands for relevant cerebral receptors should provide correlations of receptor occupancy and plasma concentrations of specific drugs, as has been reported for haloperidol (Wolkin *et al.*, 1989), but few other agents (Gefvert *et al.*, 2001; Tauscher *et al.*, 2002).

At least 10 chlorpromazine metabolites occur in appreciable quantities in humans (Morselli, 1977). Quantitatively, the most important of these are nor₂-chlorpromazine (bis-demethylated), chlorphenothiazine (dealkylation), methoxy and hydroxy products, and glucuronide conjugates of the hydroxylated compounds. In the urine, 7-hydroxylated and *N*-dealkylated (nor and nor₂) metabolites and their conjugates predominate. Chlorpromazine and other phenothiazines are metabolized extensively by CYP2D6.

The pharmacokinetics and metabolism of thioridazine and fluphenazine are similar to those of chlorpromazine, but the strong anticholinergic action of thioridazine on the gut may modify its own absorption. Major metabolites of thioridazine and fluphenazine include *N*-demethylated, ring-hydroxylated, and *S*-oxidized products (Neumeyer and Booth, 2002). Concentrations of thioridazine in plasma are relatively high (hundreds of nanograms per milliliter), possibly because of its relative hydrophilicity. Thioridazine is prominently converted to the active product mesoridazine, which probably contributes to the antipsychotic activity of thioridazine.

The biotransformation of the thioxanthenes is similar to that of the phenothiazines, except that metabolism to sulfoxides is common and ring-hydroxylated products are uncommon. Piperazine derivatives of the phenothiazines and thioxanthenes also are handled much like chlorpromazine, although metabolism of the piperidine ring itself occurs.

Elimination of haloperidol and chemically related agents from human plasma is not a log-linear function, and the apparent half-life increases with observation time to a very prolonged terminal half-life of approximately 1 week (Cohen *et al.*, 1992). Haloperidol and other butyrophenones are metabolized primarily by an *N*-dealkylation reaction and the resultant inactive fragments can be conjugated with glucuronic acid. The metabolites of haloperidol are inactive, with the possible exception of a hydroxylated product formed by reduction of the keto moiety that may be reoxidized to haloperidol (Korpi *et al.*, 1983). A potentially neurotoxic derivative of haloperidol, a substituted phenylpiperidine analogous to the parkinsonism-inducing agent methylphenyltetrahydropyridine (MPTP), has been described and found in nanomolar quantities in postmortem brain tissue of persons who had been treated with haloperidol (Castagnoli *et al.*, 1999). Its pathophysiological significance is unknown. Typical plasma concentrations of haloperidol encountered clinically are about 5 to 20 ng/ml. These correspond to 80% to 90% occupancy of D₂-dopamine receptors in human basal ganglia, as demonstrated by PET brain scanning (Wolkin *et al.*, 1989).

For clozapine, typical peak serum concentrations after a single oral dose of 200 mg (100 to 770 ng/ml) are reached at 2.5 hours after administration, and serum levels during treatment are about 300 to 500 ng/ml. Clozapine is metabolized preferentially by

CYP3A4 into demethylated, hydroxylated, and *N*-oxide derivatives that are excreted in urine and feces. The elimination half-life of clozapine varies with dose and dosing frequency but averages about 12 hours (Table 18–3; Baldessarini and Frankenburg, 1991).

The clozapine analog olanzapine also is well absorbed, but about 40% of an oral dose is metabolized before reaching the systemic circulation. Plasma concentrations of olanzapine peak at about 6 hours after oral administration, and its elimination half-life ranges from 20 to 54 hours (Table 18–3). Major, readily excreted metabolites of olanzapine are the inactive 10-*N*-glucuronide and 4'-nor derivatives, formed mainly by the action of CYP1A2, with CYP2D6 as a minor alternative pathway (United States Pharmacopoeia, 2004).

The clozapine analog quetiapine is readily absorbed after oral administration. It reaches peak plasma levels after 1.5 hours, with a mean elimination half-life of 6 hours (Table 18–3). It is highly metabolized by hepatic CYP3A4 to inactive and readily excreted sulfoxide and acidic derivatives (United States Pharmacopoeia, 2004).

Risperidone is well absorbed and is metabolized in the liver by CYP2D6 to an active metabolite, 9-hydroxyrisperidone. Since this metabolite and risperidone are nearly equipotent, the clinical efficacy of the drug reflects both compounds. Following oral administration, peak plasma concentrations of risperidone and of its 9-hydroxy metabolite occur at 1 and 3 hours, respectively. The mean elimination half-life of both compounds is about 22 hours (Table 18–3).

The oral absorption of ziprasidone is increased up to twofold by food, and its elimination half-life is 6 to 7 hours (Beedham *et al.*, 2003; Stimmel *et al.*, 2002). Ziprasidone is highly metabolized to four major metabolites, only one of which, *S*-methyldihydroziprasidone, likely contributes to its clinical activity. In humans, less than 5% of the dose is excreted unchanged. Reduction by aldehyde oxidase accounts for about 66% of ziprasidone metabolism; two oxidative pathways involving hepatic CYP3A4 account for the remainder.

Bioavailability of aripiprazole is around 87%, with peak plasma concentrations attained at 3 to 5 hours after dosing. It is metabolized by dehydrogenation, oxidative hydroxylation, and *N*-dealkylation, largely mediated by hepatic CYPs 3A4 and 2D6 (Winans, 2003). Elimination half-life is approximately 75 hours, and the active metabolite, dehydroaripiprazole, has an elimination half-life of about 94 hours (Table 18–3).

Tolerance and Physical Dependence. As defined in Chapter 23, the antipsychotic drugs are not addicting. However, some degree of physical dependence may occur, with malaise and difficulty in sleeping developing several days after an abrupt drug discontinuation following prolonged use.

Some tolerance to sedative effects of antipsychotics usually develops over days or weeks. Loss of efficacy with prolonged treatment is not known to occur with antipsychotic agents. However, tolerance to antipsychotic drugs and cross-tolerance among the agents are demonstrable in behavioral and biochemical experiments in animals, particularly those directed toward evaluation of the blockade of dopaminergic receptors in the basal ganglia (Baldessarini and Tarsy, 1979). This form of tolerance may be less prominent in limbic and cortical areas of the forebrain. One correlate of tolerance in forebrain dopaminergic systems is the development of supersensitivity of those systems, which probably is mediated by upregulation and sensitization of dopamine receptors, particularly D₂ receptors. These changes may underlie the clinical phenomenon of withdrawal-emergent dyskinesias (*e.g.*, choreoathetosis on abrupt discontinuation of antipsychotic agents, especially following prolonged use of

high doses of potent agents) and may contribute to the pathophysiology of tardive dyskinesias (Baldessarini *et al.*, 1980).

Although cross-tolerance may occur among antipsychotic drugs, clinical problems occur in making rapid changes from high doses of one type of agent to another. Sedation, hypotension, and other autonomic effects or acute extrapyramidal reactions can result. Worsening of the clinical condition that routinely follows discontinuation of maintenance treatment with antipsychotic agents appears to depend on the rate of drug discontinuation (Viguera *et al.*, 1997). Clinical worsening of psychotic symptoms is particularly likely after rapid discontinuation of clozapine and is difficult to control with alternative antipsychotics (Baldessarini *et al.*, 1997).

Preparations and Dosage. The number of clinically employed agents with known antipsychotic effects is large. Table 18–1 summarizes those currently marketed in the United States for the treatment of psychotic disorders or mania.

Prochlorperazine (COMPazine) has questionable utility as an antipsychotic agent and frequently produces acute extrapyramidal reactions. It is rarely employed in psychiatry, although it is used as an antiemetic.

Thiethylperazine (TORECAN), marketed only as an antiemetic, is a potent dopaminergic antagonist with many neurolepticlike properties. At high doses, it may be an efficacious antipsychotic agent (Rotrosen *et al.*, 1978). Long-acting repository preparations of several antipsychotic agents, including phenothiazines, thioxanthenes, butyrophenones, diphenylbutylpiperidines, and benzamides are available in other countries. However, in the United States only the decanoates of fluphenazine and haloperidol and an injected carbohydrate microsphere preparation of risperidone are commonly employed as long-acting repository preparations.

Toxic Reactions and Adverse Effects. Antipsychotic drugs have a high therapeutic index and are generally safe agents. Furthermore, most phenothiazines, haloperidol, clozapine, and quetiapine have relatively flat dose–response curves and can be used over a wide range of dosages (Table 18–1). Although occasional deaths from overdoses have been reported, fatalities are rare in patients given medical care unless the overdose is complicated by concurrent ingestion of alcohol or other drugs. Based on animal data, the therapeutic index is lower for thioridazine and chlorpromazine than for the more potent phenothiazines (Janssen and Van Bever, 1978). Adults have survived doses of chlorpromazine up to 10 grams, and deaths from an overdose of haloperidol alone appear to be unknown, although the neuroleptic malignant syndrome and dystonic reactions that compromise respiration can be lethal.

Adverse effects often are extensions of the many pharmacological actions of these drugs. The most important are those on the cardiovascular, central and autonomic nervous, and endocrine systems. Other dangerous effects are seizures, agranulocytosis, cardiac toxicity, and pigmentary degeneration of the retina, all of which are rare (*see below*).

Therapeutic doses of phenothiazines may cause faintness, palpitations, and anticholinergic effects including nasal stuffiness, dry mouth, blurred vision, constipation, worsening of glaucoma, and urinary retention in males with prostatism.

Adverse Cardiovascular and Cerebrovascular Effects. The most common adverse cardiovascular effect is orthostatic hypotension, which may result in syncope, falls, and injuries. Hypotension is most likely to occur with administration of the phenothiazines with aliphatic side chains or atypical antipsychotics. Potent neuroleptics generally produce less hypotension.

Some antipsychotic agents depress cardiac repolarization, as reflected in the QT interval corrected for heart rate (QTc). Prolongations above 500 msec can be dangerous clinically, particularly by increasing the risk of *torsades de pointes*, which often is a precursor of fatal cardiac arrest (*see Chapter 34*). Such cardiac depressant effects are especially prominent with thioridazine and its active metabolite, mesoridazine, as well as pimozide and perhaps high doses of haloperidol, and to some extent with ziprasidone (Daniel, 2003; Hassaballa and Balk, 2003; Taylor, 2003). These drugs are used cautiously, if at all, in combination with other agents with known cardiac-depressant effects, including tricyclic antidepressants (*see Chapter 17*), certain antiarrhythmic agents (*see Chapter 34*), other antipsychotics with similar actions (such as pimozide and thioridazine), or specific dopamine antagonists (cisapride and metoclopramide; *see Chapter 37*).

Clozapine has rarely been associated with myocarditis and cardiomyopathy (La Grenade, *et al.*, 2001). Some clinical observations have suggested increased risk of stroke among elderly patients treated with risperidone and perhaps olanzapine (Woollerton, 2002). The clinical significance of these uncommon cardiac and cerebrovascular events remains uncertain.

Adverse Neurological Effects. Many neurological syndromes, particularly involving the extrapyramidal motor system, occur following the use of most antipsychotic drugs. These reactions are particularly prominent with the high-potency D₂ dopamine receptor antagonists (tricyclic piperazines and butyrophenones). Acute adverse extrapyramidal effects are less likely with aripiprazole, clozapine, quetiapine, thioridazine, and ziprasidone, or low doses of olanzapine or risperidone. The neurological effects associated with antipsychotic drugs have been reviewed in detail (Baldessarini and Tarsy, 1979; Baldessarini *et al.*, 1980; Baldessarini, 1984; Baldessarini *et al.*, 1990; Kane *et al.*, 1992; Tarsy *et al.*, 2002).

Six distinct neurological syndromes are characteristic of older neuroleptic-antipsychotic drugs. Four of these

Table 18–4
Neurological Side Effects of Neuroleptic Drugs

REACTION	FEATURES	TIME OF MAXIMAL RISK	PROPOSED MECHANISM	TREATMENT
Acute dystonia	Spasm of muscles of tongue, face, neck, back; may mimic seizures; <i>not</i> hysteria	1 to 5 days	Unknown	Antiparkinsonian agents are diagnostic and curative*
Akathisia	Motor restlessness; <i>not</i> anxiety or “agitation”	5 to 60 days	Unknown	Reduce dose or change drug; antiparkinsonian agents,† benzo-diazepines or propranolol‡ may help
Parkinsonism	Bradykinesia, rigidity, variable tremor, mask facies, shuffling gait	5 to 30 days; can recur even after a single dose	Antagonism of dopamine	Antiparkinsonian agents helpful†
Neuroleptic malignant syndrome	Catonia, stupor, fever, unstable blood pressure, myoglobinemia; can be fatal	Weeks; can persist for days after stopping neuroleptic	Antagonism of dopamine may contribute	Stop neuroleptic immediately; dantrolene or bromocriptine§ may help; antiparkinsonian agents not effective
Perioral tremor (“rabbit syndrome”)	Perioral tremor (may be a late variant of parkinsonism)	After months or years of treatment	Unknown	Antiparkinsonian agents often help†
Tardive dyskinesia	Oral-facial dyskinesia; widespread choreo-athetosis or dystonia	After months or years of treatment (worse on withdrawal)	Excess function of dopamine hypothesized	Prevention crucial; treatment unsatisfactory

*Many drugs have been claimed to be helpful for acute dystonia. Among the most commonly employed treatments are diphenhydramine hydrochloride, 25 or 50 mg intramuscularly, or bethanechol mesylate, 1 or 2 mg intramuscularly or slowly intravenously, followed by oral medication with the same agent for a period of days to perhaps several weeks thereafter. †For details regarding the use of oral antiparkinsonian agents, see the text and Chapter 20: Treatment of Central Nervous System Degenerative Disorders. ‡Propranolol often is effective in relatively low doses (20–80 mg per day). Selective β_1 adrenergic receptor antagonists are less effective. §Despite the response to dantrolene, there is no evidence of an abnormality of Ca^{2+} transport in skeletal muscle; with lingering neuroleptic effects, bromocriptine may be tolerated in large doses (10–40 mg per day).

(acute dystonia, akathisia, parkinsonism, and the rare neuroleptic malignant syndrome) usually appear soon after administration of the drug. Two (tardive dyskinesias or dystonias, and rare perioral tremor) are late-appearing syndromes that evolve during prolonged treatment. The clinical features of these syndromes and guidelines for their management are summarized in Table 18–4.

Acute dystonic reactions commonly occur with the initiation of neuroleptic therapy, particularly with agents of high potency, and may include facial grimacing, torticollis, oculogyric crisis, and abnormal contraction of spinal muscles (including opisthotonos) and of muscles involved

in breathing. These syndromes may be mistaken for hysterical reactions or epileptic seizures, but respond dramatically to parenteral administration of anticholinergic antiparkinson drugs. Oral administration of anticholinergic agents also can prevent dystonia, particularly in young male patients given a high-potency neuroleptic (Arana *et al.*, 1988). Although readily treated, acute dystonic reactions are terrifying to patients. Sudden death has occurred, probably due to impaired respiration caused by dystonia of pharyngeal, laryngeal, and other muscles. Dystonia is especially common in young men. It usually is not immediate but occurs within the first 24 to 48 hours of treat-

ment, with diminishing risk thereafter except with repeated injections of long-acting agents. This timing, in association with the gradual emergence of bradykinesia, parallels the presynaptic adaptations that occur in dopaminergic neurons within the first week of exposure to neuroleptic agents.

Akathisia refers to strong subjective feelings of anxious distress or discomfort and a compelling need to be in constant movement rather than to follow any specific movement pattern. Patients typically feel that they must get up and walk or continuously move about and may be unable to control this tendency. Akathisia may be mistaken for agitation in psychotic patients, and the distinction is critical, since agitation might be treated with an increase in dosage. Because akathisia often responds poorly to antiparkinson drugs, treatment typically requires reduction of dosage or a change of the antipsychotic drug. Anti-anxiety agents or moderate doses of a relatively lipophilic β adrenergic receptor antagonist such as propranolol may be beneficial (Lipinski *et al.*, 1984; Reiter *et al.*, 1987). This common syndrome often interferes with patient adherence to neuroleptic treatment but frequently is not diagnosed. Akathisia occurs with newer antipsychotic agents, including risperidone, olanzapine, and even occasionally with clozapine (Tarsy *et al.*, 2002). This pattern adds to the impression that the underlying pathophysiology differs from that of the more clearly extrapyramidal reactions, such as dystonia and bradykinesia.

A *parkinsonian syndrome* that can be indistinguishable from idiopathic Parkinson's disease (*paralysis agitans*) commonly develops gradually during administration of antipsychotic drugs. This adverse effect, which almost certainly reflects deficient dopaminergic function in the extrapyramidal basal ganglia, varies in incidence with different agents (Tables 18-1 and 18-4). Clinically, there is a generalized slowing and impoverishment of volitional movement (bradykinesia or akinesia) with masked facies and reduced arm movements during walking. The syndrome characteristically evolves gradually over days to weeks as the risk of acute dystonia diminishes. The most noticeable signs are slowing of movements, and sometimes rigidity and variable tremor at rest, especially involving the upper extremities. "Pill-rolling" movements and other types of resting tremor (at a frequency of 3 to 5 Hz, as in Parkinson's disease) may be seen, although they are less prominent in neuroleptic-induced than in idiopathic parkinsonism. Bradykinesia and masked facies may be mistaken for clinical depression. This reaction usually is managed by use of either antiparkinson agents with anticholinergic properties, or amantadine (*see* Chapter 20). The use of levodopa or a directly acting dopamine

agonist incurs the risk of inducing agitation and worsening the psychotic illness. Antipsychotic agents sometimes are required in the clinical management of patients with idiopathic Parkinson's disease with spontaneous psychotic illness or psychotic reactions to dopaminergic therapy (*see* Chapter 20). Clozapine and perhaps quetiapine are least likely to worsen the neurological disorder (Menza *et al.*, 1999; Parkinson Study Group, 1999). Risperidone, olanzapine, and typical neuroleptics are relatively poorly tolerated by patients with Parkinson's disease, and aripiprazole and ziprasidone have not been adequately investigated in this setting (Tarsy *et al.*, 2002).

The rare *neuroleptic malignant syndrome* (NMS) resembles a very severe form of parkinsonism, with coarse tremor and catatonia, fluctuating in intensity. It includes signs of autonomic instability (hyperthermia and labile pulse, blood pressure, and respiration rate), stupor, elevation of creatine kinase in serum, and sometimes myoglobinemia with potential nephrotoxicity. In its most severe form, this syndrome may persist for more than a week after the offending agent is discontinued. Mortality exceeds 10%, mandating immediate medical attention. This reaction has been associated with various types of antipsychotics, but its prevalence may be greater when relatively high doses of potent agents are used, especially when they are administered parenterally. Aside from cessation of antipsychotic treatment and provision of supportive care, specific treatment is unsatisfactory; administration of *dantrolene* or the dopaminergic agonist *bromocriptine* may be helpful (Addonizio *et al.*, 1987; Pearlman, 1986). Although dantrolene also is used to manage the syndrome of malignant hyperthermia induced by general anesthetics, the neuroleptic-induced form of catatonia and hyperthermia probably is not associated with a defect in Ca^{2+} metabolism in skeletal muscle. Atypical antipsychotic agents including clozapine, olanzapine, and risperidone are associated with an atypical, but potentially lethal, neuroleptic malignant-like syndrome that is marked by fever and delirium without muscle rigidity (Farver, 2003).

Tardive dyskinesia is a late-appearing neurological syndrome (or syndromes) associated with neuroleptic drugs. It occurs more frequently in older patients, and risk may be somewhat greater in patients with mood disorders than in those with schizophrenia. Its prevalence averages 15% to 25% in young adults treated with older antipsychotics for more than a year. There is an annual incidence of 3% to 5% and a somewhat smaller annual rate of spontaneous remission, even with continued neuroleptic treatment. The risk is much lower with clozapine; lower with aripiprazole, olanzapine, and ziprasidone; and intermedi-

ate with risperidone (Correll *et al.*, 2004; Tarsy *et al.*, 2002). Tardive dyskinesia is characterized by stereotyped, repetitive, painless, involuntary, quick choreiform (tic-like) movements of the face, eyelids (blinks or spasm), mouth (grimaces), tongue, extremities, or trunk. There are varying degrees of slower athetosis (twisting movements) and sustained dystonic postures, which are more common in young men and may be disabling. Late (tardive) emergence of disorders marked mainly by dystonia or akathisia (restlessness) also are seen. These movements all disappear in sleep (as do many other extrapyramidal syndromes), vary in intensity over time, and are dependent on the level of arousal or emotional distress, sometimes reappearing during acute psychiatric illnesses following prolonged disappearance.

Tardive dyskinesic movements can be suppressed partially by use of a potent neuroleptic, and perhaps with a dopamine-depleting agent such as reserpine or tetrabenazine, but such interventions are reserved for severe dyskinesia, particularly with continuing psychosis. Some dyskinesic patients, typically those with dystonic features, benefit from use of clozapine, which has a very low risk of tardive dyskinesia. Symptoms sometimes persist indefinitely after discontinuation of neuroleptic medication. More often, they diminish or disappear gradually over months of follow-up, especially in younger patients (Gardos *et al.*, 1994; Morgenstern and Glazer, 1993; Smith and Baldessarini, 1980). Antiparkinson agents typically have little effect on, or may even exacerbate, tardive dyskinesia and other forms of choreoathetosis, such as in Huntington's disease. No adequate treatment of these conditions has been established (Adler *et al.*, 1999; Soares and McGrath, 1999; Tarsy *et al.*, 2002).

There is no established neuropathology in tardive dyskinesia, and its pathophysiological basis remains obscure. Compensatory increases in the function of dopamine as a neurotransmitter in the basal ganglia could be involved, including increased abundance and sensitivity of dopamine D₂-like receptors resulting from long-term administration of different classes of antipsychotic drugs (Baldessarini and Tarsy, 1979; Tarazi *et al.* 1997, 2001). This hypothesis is supported by the dissimilarities of therapeutic responses in patients with Parkinson's disease and those with tardive dyskinesia, and by the similar responses of patients with other choreoathetotic dyskinesias such as Huntington's disease (*see* Chapter 20). Thus antidopaminergic drugs tend to suppress manifestations of tardive dyskinesia and Huntington's disease, whereas dopaminergic agonists worsen them. In contrast to parkinsonism, antimuscarinic agents tend to worsen tardive dyskinesia, while cholinergic agents usually are ineffective. In laboratory animals, supersensitivity to dopaminergic agonists usually lasts only for a few weeks after withdrawal of dopamine antagonists. This phenomenon most likely plays a role in variants of tardive dyskinesia that resolve rapidly, usually referred to as *withdrawal-emergent dyskinesias*. The theoretical and clinical

aspects of this problem have been reviewed in detail (Baldessarini and Tarsy, 1979; Baldessarini *et al.*, 1980; Kane *et al.*, 1992).

A rare movement disorder that can appear late in chronic treatment with antipsychotic agents is *perioral tremor*, often referred to as the "rabbit syndrome" (Schwartz and Hocherman, 2004) because of the peculiar movements that characterize it. Rabbit syndrome shares many features with parkinsonism, because the tremor has a frequency of about 3 to 5 Hz, and often responds favorably to anticholinergic agents and removal of the offending agent.

Certain therapeutic guidelines should be followed to minimize the neurological syndromes that complicate the use of antipsychotic drugs. Routine use of antiparkinson agents in an attempt to avoid early extrapyramidal reactions usually is unnecessary; it adds complexity, side effects, and expense to the regimen. Antiparkinson agents are best reserved for cases of overt extrapyramidal reactions that respond favorably to such intervention. The need for such agents for the treatment of acute dystonic reactions ordinarily diminishes with time, but parkinsonism and akathisia typically persist. The thoughtful and conservative use of antipsychotic drugs, particularly modern atypical agents, in patients with chronic or frequently recurrent psychotic disorders almost certainly can reduce the risk of tardive dyskinesia. Although reduction of the dose of an antipsychotic agent is the best way to minimize its adverse neurological effects, this may not be practical in a patient with uncontrollable psychotic illness. The best preventive practice is to use the minimum dose of an antipsychotic drug that is effective. The growing number of modern atypical antipsychotic agents with a low risk of inducing extrapyramidal side effects provides an alternative for many patients, particularly those with continuing psychotic symptoms plus dyskinesia (Baldessarini and Frankenburg, 1991; Tarsy *et al.*, 2002).

Weight Gain and Metabolic Effects. Weight gain and its associated long-term complications can occur with extended treatment with most antipsychotic and antimanic drugs. Weight gain is especially prominent with clozapine and olanzapine; somewhat less with quetiapine; even less with fluphenazine, haloperidol, and risperidone; and is very low with aripiprazole, molindone, and ziprasidone (Allison *et al.*, 1999). Adverse effects of weight gain likely include increased risk of new-onset or worsening of type 2 diabetes mellitus, hypertension, and hyperlipidemia. Only some of these consequences are explained by risk factors associated with major psychiatric disorders themselves. The anticipated long-term public health impact of these emerging problems is not yet well defined (Cohen, 2004; Gaulin *et al.*, 1999; Henderson *et al.*, 2000; McIntyre *et al.*, 2003; Wirshing *et al.*, 1998). In some patients with morbid increases in weight, the airway may be compro-

mised (*Pickwickian syndrome*), especially during sleep (including *sleep apnea*).

Blood Dyscrasias. Mild leukocytosis, leukopenia, and eosinophilia occasionally occur with antipsychotic treatment, particularly with clozapine and less often with phenothiazines of low potency. It is difficult to determine whether leukopenia that develops during the administration of such agents is a forewarning of impending agranulocytosis. This serious complication occurs in not more than 1 in 10,000 patients receiving chlorpromazine or other low-potency agents (other than clozapine); it usually appears within the first 8 to 12 weeks of treatment (Alvir *et al.*, 1993).

Bone marrow suppression, or less commonly agranulocytosis, has been associated with the use of clozapine. The incidence approaches 1% within several months of treatment, independent of dose, without regular monitoring of white blood cell counts. Because blood dyscrasia may develop suddenly, the appearance of fever, malaise, or apparent respiratory infection in a patient being treated with an antipsychotic drug should be followed immediately by a complete blood count. Risk of agranulocytosis is greatly reduced, though not eliminated, by frequent white blood cell counts in patients being treated with clozapine, as is required in the United States (weekly for 6 months and biweekly thereafter). The safety of resuming even low doses of clozapine or other antipsychotics following recovery from agranulocytosis should not be assumed (Iqbal *et al.*, 2003).

Skin Reactions. Dermatological reactions to the phenothiazines, including urticaria or dermatitis, occur in about 5% of patients receiving chlorpromazine. Contact dermatitis may occur in personnel who handle chlorpromazine, and there may be a degree of cross-sensitivity to other phenothiazines. Sunburn and photosensitivity resembling severe sunburn occur and require use of an effective sunscreen preparation. Epithelial keratopathy often is observed in patients on long-term therapy with chlorpromazine, and opacities in the cornea and in the lens of the eye have been noted. Pigmentary retinopathy has been reported, particularly following doses of thioridazine in excess of 1000 mg per day. A maximum daily dose of 800 mg currently is recommended. Dermatological reactions to modern atypical antipsychotic agents are uncommon.

Gastrointestinal and Hepatic Effects. A mild jaundice, typically occurring early in therapy, may be observed in some patients receiving chlorpromazine. Pruritus is rare. The reaction probably is a manifestation of hypersensitivity because eosinophilia and eosinophilic infiltration of the liver occur unrelated to dose. Desensitization to chlorpromazine may occur with repeated administration, and jaundice may or may not recur if the same drug is given again. When the psychiatric disorder calls for uninterrupted drug therapy for a patient with neuroleptic-induced jaundice, it probably is safest to use low doses of a potent, dissimilar agent. Hepatic dysfunction with other antipsychotic agents is uncommon.

Clozapine specifically has two important risks of intestinal dysfunction: potentially severe ileus (Theret *et al.*, 1995) and sialor-

rhea, which may be related to deficient pharyngeal-esophageal clearing mechanisms most noticeable during sleep (Rabinowitz *et al.*, 1996).

Interactions with Other Drugs. The phenothiazines and thioxanthenes, especially those of lower potency, affect the actions of a number of other drugs, sometimes with important clinical consequences (DeVane and Nemeroff, 2000; Goff and Baldessarini, 1993). Antipsychotic drugs can strongly potentiate the effect of medically prescribed sedatives and analgesics, alcohol, nonprescription sedatives and hypnotics, antihistamines, and cold remedies. Chlorpromazine increases the miotic and sedative effects of morphine and may increase its analgesic actions. The drug markedly increases the respiratory depression produced by meperidine and can be expected to have similar effects when administered concurrently with other opioids. Obviously, neuroleptic drugs inhibit the actions of dopaminergic agonists and levodopa and worsen the neurological symptoms of Parkinson's disease (Tarsy *et al.*, 2002).

Other interactions involve the cardiovascular system. Chlorpromazine, some other antipsychotic drugs, and their *N*-demethylated metabolites may block the antihypertensive effects of guanethidine, probably by blocking its uptake into sympathetic nerves. Molindone and the more potent antipsychotic agents are less likely to cause this effect. Low-potency phenothiazines can promote postural hypotension, possibly due to their α adrenergic blocking properties. Thus interactions between phenothiazines and antihypertensive agents are unpredictable.

The antimuscarinic action of clozapine and thioridazine can cause tachycardia and enhance the peripheral and central effects (confusion, delirium) of other anticholinergic agents, such as the tricyclic antidepressants and antiparkinson agents.

Sedatives or anticonvulsants (*e.g.*, carbamazepine, oxcarbazepine, phenobarbital, and phenytoin, but not valproate) that induce CYPs (*see* Chapter 3) can enhance the metabolism of antipsychotic and many other agents (including anticoagulants and oral contraceptives), sometimes with significant clinical consequences. Conversely, selective serotonin reuptake inhibitors including fluvoxamine, fluoxetine, paroxetine, venlafaxine, sertraline, and nefazodone (*see* Chapter 17) compete for these enzymes and can elevate circulating levels of neuroleptics (Goff and Baldessarini, 1993).

DRUG TREATMENT OF PSYCHOSES

Short-Term Treatment. The antipsychotic drugs are not specific to the type of illness being treated. They clearly are effective in acute psychoses of unknown etiology, including mania, acute idiopathic psychoses, and acute exacerbations of schizophrenia. The best studied indications are for the acute and chronic phases of schizo-

phrenia and in acute mania. Antipsychotic drugs also are used empirically in many other neuromedical and idiopathic disorders with prominent psychotic symptoms or severe agitation.

Acceptance that neuroleptic agents are indeed antipsychotics came slowly. However, many clinical trials and five decades of clinical experience have established that they are effective and superior to sedatives, such as the barbiturates and benzodiazepines, or alternatives, such as electroconvulsive shock or other medical or psychological therapies (Baldessarini *et al.*, 1990). The “target” symptoms for which antipsychotic agents are especially effective include agitation, combativeness, hostility, hallucinations, acute delusions, insomnia, anorexia, poor self-care, negativism, and sometimes withdrawal and seclusiveness. More variable or delayed are improvements in motivation and cognition, including insight, judgment, memory, orientation, and functional recovery. The most favorable prognosis is for patients with acute illnesses of brief duration who had functioned relatively well prior to the illness.

No one drug or combination of drugs selectively affects a particular symptom complex in groups of psychotic patients. Although individual patients may apparently respond better with one agent than another, this can be determined only by trial and error. It is sometimes claimed that certain agents (particularly newer antipsychotic drugs) are specifically effective against “negative” symptoms in psychotic disorders (*e.g.*, abulia, social withdrawal, and lack of motivation). However, evidence supporting this proposal remains inconsistent, and such benefits usually are limited (Moller, 1999; Arango *et al.*, 2004). Generally, “positive” (irrational thinking, delusions, agitated turmoil, hallucinations) and “negative” symptoms tend to respond or not respond together with overall clinical improvement. This tendency is well documented with typical neuroleptics as well as modern atypical antipsychotic agents. It is clear that aripiprazole, clozapine, quetiapine, and ziprasidone induce less bradykinesia and other parkinsonian effects than do typical neuroleptics. In addition, aripiprazole and ziprasidone are minimally sedating. Minimizing such side effects is sometimes interpreted clinically as specific improvement in impoverished affective responsiveness and energy level.

The short-term clinical superiority of modern antipsychotic agents over older neuroleptics has been particularly hard to prove, and some comparison trials involve nonequivalent dosing of novel and older agents. Moreover, comparisons among modern agents are even less numerous, and their findings remain largely inconclusive (Gardner *et al.*, 2005). Nevertheless, at least in the United States, the modern atypical agents have come to dominate clinical practice, owing mainly to their perceived superior tolerability and acceptability.

It is important to simplify the treatment regimen and to ensure that the patient is receiving the drug. In cases of suspected severe and dangerous noncompliance or with failure of oral treatment, the patient can be treated with injections of fluphenazine decanoate, haloperidol decanoate, or other long-acting preparations, including risperidone microspheres.

Because the choice of an antipsychotic drug cannot be made reliably on the basis of anticipated therapeutic effect, drug selection

often depends on likely tolerability of specific side effects, the need for sedation, or on a previous favorable response. If the patient has a history of cardiovascular disease or stroke and the threat from hypotension is serious, a modern atypical agent or a potent older neuroleptic should be used in the smallest dose that is effective (Table 18–1; DeBattista and Schatzberg, 1999). If it seems important to minimize the risk of acute extrapyramidal symptoms, aripiprazole, clozapine, quetiapine, ziprasidone, or a low dose of olanzapine or risperidone should be considered. If the patient would be seriously discomfited by interference with ejaculation or if there are serious risks of cardiovascular or other autonomic toxicity, low doses of a potent neuroleptic might be preferred. If sedative effects are undesirable, a potent agent (aripiprazole or ziprasidone) is preferable. Small doses of antipsychotic drugs of high or moderate potency may be safest in the elderly, in whom the possible risk of stroke with risperidone and olanzapine must be considered. If hepatic function is compromised or there is a potential threat of jaundice, low doses of a high-potency agent may be used. The physician’s experience with a particular drug may outweigh other considerations. *Skill in the use of antipsychotic drugs depends on selection of an adequate but not excessive dose, knowledge of what to expect, and judgment as to when to stop therapy or change drugs.*

Some patients do not respond satisfactorily to antipsychotic drug treatment, and many chronically ill schizophrenia patients, while helped during periods of acute exacerbation of illness, may show unsatisfactory responses during less acute intervals. Individual non-responders cannot be identified beforehand with certainty, but a substantial minority of psychotic patients do poorly with any antipsychotic medicine, including clozapine. If a patient does not improve after a course of seemingly adequate treatment and fails to respond to another drug given in adequate dosage, the diagnosis should be reevaluated.

Usually 2 to 3 weeks or more are required to demonstrate obvious beneficial effects in schizophrenia patients. Maximum benefit in chronically ill patients may require several months. In contrast, improvement of some acutely psychotic or manic patients can be seen within 48 hours. Aggressive dosing with high doses of an antipsychotic drug at the start of an acute episode of psychosis has not been found to increase either the magnitude or the rate of therapeutic responses (Baldessarini *et al.*, 1988). However, parenteral agents in moderate doses can bring about rapid sedation and may be useful in acute behavioral control. Sedatives, such as the potent benzodiazepines, can be used briefly during the initiation of antipsychotic therapy, but are not effective in the long-term treatment of chronically psychotic, and especially, schizophrenic patients (Bradwejn *et al.*, 1990). After the initial response, drugs usually are used in conjunction with psychological, supportive, and rehabilitative treatments.

There is no convincing evidence that combinations of antipsychotic drugs offer clear or consistent advantages. A combination of an antipsychotic drug and an antidepressant may be useful in some cases, especially in depressed psychotic patients or in cases of agitated major depression with psychotic features. The first combination antipsychotic/antidepressant (olanzapine/fluoxetine; SYMBYAX) was recently FDA approved in the United States for treatment of depressive episodes associated with bipolar disorder. However, antidepressants and stimulants are unlikely to reduce apathy and withdrawal in schizophrenia, and they may induce clinical worsening in some cases. Adjunctive addition of lithium or an antimanic anticonvulsant may add benefit in some psychotic patients with prominent affective, aggressive, or resistant symptoms (Hosak and Libiger,

2002), and may produce earlier improvements in psychotic symptoms of acute schizophrenia patients (Casey *et al.*, 2003).

Optimal dosage of antipsychotic drugs requires individualization to determine doses that are effective, well tolerated, and accepted by the patient. Dose–response relationships for antipsychotic and adverse effects overlap, and it can be difficult to determine an end-point of a desired therapeutic response (DeBattista and Schatzberg, 1999). Typical effective daily doses are approximately 300 to 500 mg of chlorpromazine, 5 to 15 mg of haloperidol, 200 to 500 mg of clozapine, 5 to 15 mg of olanzapine, 4 to 6 mg of risperidone, 400 to 800 mg of quetiapine, 80 to 160 mg of ziprasidone, 5 to 30 mg of aripiprazole, or their equivalent. Doses of as little as 50 to 200 mg of chlorpromazine per day (or 2 to 6 mg of haloperidol or fluphenazine, 2 mg of risperidone, or 5 mg of olanzapine) may be effective and be better tolerated by many patients, especially after the initial improvement of acute symptoms (Baldessarini *et al.*, 1988, 1990). Careful observation of the patient's changing response is the best guide to dosage.

To achieve control of symptoms in the treatment of acute psychoses, the dose of antipsychotic drug is increased as tolerated during the first few days. The dose is then adjusted during the next several weeks as the patient's condition warrants. Parenteral short-acting medication sometimes is indicated for acutely agitated patients; 5 mg of haloperidol or fluphenazine, or a comparable dose of another agent, is given intramuscularly. Short-acting injectable preparations of both olanzapine and ziprasidone also have been developed (Altamura *et al.*, 2003; Wright *et al.*, 2003; Zimbroff, 2003). Desired clinical effects usually can be obtained by administering additional doses at intervals of 4 to 8 hours for the first 24 to 72 hours, because the appearance of effects may be delayed for several hours. Rarely is it necessary to administer a total daily dose of more than 20 to 30 mg of fluphenazine or haloperidol, 600 to 900 mg of clozapine, 6 to 8 mg of risperidone, 15 to 20 mg of olanzapine, 120 to 160 mg of ziprasidone (or up to 40 mg intramuscularly), or 20 to 30 mg of aripiprazole (or an equivalent amount of another agent). Severe and poorly controlled agitation usually can be managed safely by use of adjunctive sedation (*e.g.*, with a benzodiazepine such as lorazepam) and close supervision in a secure setting.

One must remain alert for acute dystonic reactions, which are especially likely to appear early with aggressive use of potent neuroleptics. Hypotension is most likely to occur if an agent of low potency, such as chlorpromazine, is given in a high dose or by injection and may occur early in treatment with atypical antipsychotic agents. Some antipsychotic drugs, including fluphenazine, other piperazines, and haloperidol, have been given in doses of several hundred milligrams a day without serious adverse effects. However, such high doses of potent agents do not yield significantly or consistently superior results in the treatment of acute or chronic psychosis, and may even yield inferior antipsychotic effects with increased risk of neurological, cardiovascular, and other adverse effects (Baldessarini *et al.*, 1988, 1990). After an initial period of stabilization, regimens based on a single daily dose (typically 5 to 10 mg per day of haloperidol or fluphenazine, 2 to 4 mg of risperidone, 5 to 15 mg of olanzapine, or their equivalent) often are effective and safe. The time of administration may be varied to minimize adverse effects.

Table 18–1 gives the usual and extreme ranges of dosage for antipsychotic drugs used in the United States (DeBattista and Schatzberg, 1999; United States Pharmacopoeia, 2004). The ranges have been established for the most part in the treatment of young and middle-aged adult patients diagnosed with schizophrenia or mania. Acutely disturbed hospitalized patients often require higher

doses of an antipsychotic drug than do more stable outpatients. However, the concept that a low or flexible maintenance dose often will suffice during follow-up care of a partially recovered or chronic psychotic patient is supported by several appropriately controlled trials (Baldessarini *et al.*, 1988, 1990; Herz *et al.*, 1991).

Despite the great success of the antipsychotic drugs, their use alone does not constitute optimal care of psychotic or manic patients. The acute care, protection, and support of such patients, as well as their long-term care and rehabilitation, also are critically important. Detailed reviews of the clinical use of antipsychotic drugs are available (Baldessarini *et al.*, 1990; Marder, 1998; Worrel *et al.*, 2000).

Long-Term Treatment. In reviews of nearly 30 controlled prospective studies involving several thousand schizophrenic patients, the mean overall relapse rate was 58% for patients withdrawn from antipsychotic drugs and given a placebo *versus* only 16% of those who continued on drug therapy (Baldessarini *et al.*, 1990; Gilbert *et al.*, 1995; Viguera *et al.*, 1997). Daily dosage in chronic cases often can be lowered to 50 to 200 mg of chlorpromazine or its equivalent without signs of relapse (Baldessarini *et al.*, 1988), but rapid dose reduction or discontinuation appears to increase risk of exacerbation or relapse (Viguera *et al.*, 1997). Flexible therapy in which dosage is adjusted to changing current requirements can be useful and can reduce the incidence of adverse effects.

If the modern or atypical antipsychotic agents have superiority to older neuroleptics, this advantage is most important in the long-term treatment of chronic or recurrent psychotic illnesses, where it is standard practice to continue maintenance treatment with moderate and well-tolerated doses of an antipsychotic agent indefinitely, as long as the clinical indications, benefits, and tolerability remain clear. The only agent with securely proven superiority, not only to older neuroleptics but also to some modern antipsychotics, is clozapine (Baldessarini and Frankenburg, 1991; Bagnall *et al.*, 2003; Davis *et al.*, 2003; Kane *et al.*, 1988; Leucht *et al.*, 2003a, 2003b; Tuunainen *et al.*, 2004; Wahlbeck *et al.*, 1999). Nevertheless, there is some evidence that modern atypical antipsychotics may yield superior results in long-term treatment, if only due to superior tolerability and adherence to treatment (Bagnall *et al.*, 2003; Czernansky *et al.*, 2003). Currently, the cost-benefit analysis does not always favor the more expensive modern agents (Rosenheck *et al.*, 2003; Gardner *et al.*, 2005).

Maintenance with injections of the decanoate ester of fluphenazine or haloperidol every 2 to 4 weeks, or with long-acting risperidone microspheres every 2 or 3 weeks, can be very effective (Kane *et al.*, 1983; Harrison and Goa, 2004; Lasser *et al.*, 2005). However, an expectation of superiority of long-acting injected antipsychotics is not well supported by available studies, most of which involve randomization of patients who already are largely cooperative with long-term oral treatment (Adams *et al.*, 2001; Bhanji *et al.*, 2004; Schooler, 2003). Further studies are required, ideally among difficult, complex, and poorly treatment-adherent populations of chronically psychotic patients.

Special Populations. The treatment of some symptoms and behaviors associated with delirium or dementia is another accepted use for the antipsychotic drugs. They may be administered temporarily while a specific and correctable structural, infectious, metabolic, or toxic cause is vigorously sought. They sometimes are used for prolonged periods when no correctable cause can be found. There are no drugs of choice or clearly established dosage guidelines for such indications, although older neuroleptics of high poten-

cy are preferred (Prien, 1973). Modern atypical agents have not established their place in the management of delirium or dementia (Ely *et al.*, 2004). In patients with delirium without likelihood of seizures, frequent small doses (*e.g.*, 2 to 6 mg) of haloperidol or another potent antipsychotic may be effective in controlling agitation. Agents with low potency should be avoided because of their greater tendency to produce sedation, hypotension, and seizures, and those with central anticholinergic effects may worsen confusion and agitation.

A challenging special population are Parkinson's disease patients with psychotic symptoms related to dopaminergic therapy (Neumeier *et al.*, 2003) (*see* Chapter 20). Standard neuroleptics, risperidone (even in small doses), and olanzapine often produce unacceptable worsening of bradykinesia-akinesia. Clozapine is relatively well tolerated and effective, though more complicated to use. Use of moderate doses of newer agents with very low risk of parkinsonism (aripiprazole, quetiapine, ziprasidone) requires further study (Tarsy *et al.*, 2002).

Most antipsychotics are rapidly effective in the treatment of mania and often are used concomitantly with the institution of lithium or anticonvulsant therapy (*see* below). Adequate studies of possible long-term preventive effects of antipsychotic drugs in manic-depressive illness are starting to emerge (Tohen *et al.*, 2003; Yatham, 2003).

Antipsychotic drugs also may have a limited role in the treatment of severe depression. Controlled studies have demonstrated the efficacy of several antipsychotic drugs in some depressed patients, especially those with striking agitation or psychotic features, and addition of an antipsychotic to an antidepressant in psychotic depression may yield results approaching those obtained with ECT (Brotman *et al.*, 1987; Chan *et al.*, 1987). Antipsychotic agents ordinarily are not used for the treatment of anxiety disorders. The use of clozapine in patients with schizophrenia and a high risk of suicidal behavior may reduce the risk of suicide attempts. Clozapine is the first drug to be FDA approved for an antisuicide indication (Meltzer *et al.*, 2003; Hennen and Baldessarini, 2004).

Drug treatment of childhood psychosis and other behavioral disorders of children is confused by diagnostic inconsistencies and a paucity of controlled trials. Antipsychotics can benefit children with disorders characterized by features that occur in adult psychoses, mania, autism, or Tourette's syndrome. Low doses of the more potent or modern atypical agents usually are preferred in an attempt to avoid interference with daytime activities or performance in school (Kutcher, 1997; Findling *et al.*, 1998). Attention deficit disorder, with or without hyperactivity, responds poorly to antipsychotic agents, but often if the condition is not comorbid with bipolar disorder, responds very well to stimulants and some antidepressants (Faedda *et al.*, 2004; Kutcher, 1997). Information on dosages of antipsychotic drugs for children is limited, as is the number of drugs currently approved in the United States for use in preadolescents. The recommended doses of antipsychotic agents for school-aged children with moderate degrees of agitation are lower than those for acutely psychotic children, who may require daily doses similar to those used in adults (Kutcher, 1997; Table 18-1).

Most relevant experience with pediatric patients is with chlorpromazine, for which the recommended dose is approximately 0.5 mg/kg of body weight given at intervals of 4 to 6 hours orally or 6 to 8 hours intramuscularly. Suggested dosage limits are 200 mg per day (orally) for preadolescents, 75 mg per day (intramuscularly) for children aged 5 to 12 years or weighing 23 to 45 kg, and 40 mg per day (intramuscularly) for children under 5 years of age or weighing

less than 23 kg. Usual single doses for other agents of relatively low potency are thioridazine, 0.25 to 0.5 mg/kg, and chlorprothixene, 0.5 to 1 mg/kg, to a total of 100 mg/day (over the age of 6). For neuroleptics of high potency, daily doses are trifluoperazine, 1 to 15 mg (6 to 12 years of age) and 1 to 30 mg (over 12 years of age); fluphenazine, 0.05 to 0.10 mg/kg, up to 10 mg (over 5 years of age); and perphenazine, 0.05 to 0.10 mg/kg, up to 6 mg (over 1 year of age). Haloperidol and pimozide have been used in children, especially for Tourette's syndrome; haloperidol is recommended for use in a dosage of 2 to 16 mg per day in children over 12 years of age. Doses of modern atypical antipsychotic agents for children and adolescents with psychotic or manic illness usually are started at the lower end of the range prescribed for adults (Findling, 2002; King *et al.*, 2003; Sikich *et al.*, 2004; Stigler *et al.*, 2001).

Poor tolerance of the adverse effects of the antipsychotic drugs often limits the dose in elderly patients. One should proceed cautiously, using small, divided doses of agents with moderate or high potency, with the expectation that elderly patients will require doses that are one-half or less of those needed for young adults (Eastham and Jeste, 1997; Jeste *et al.*, 1999a, 1999b; Zubenko and Sunderland, 2000). As previously mentioned, the potential risk of stroke associated with risperidone and olanzapine in elderly patients should be considered (Wooltorton, 2002).

MISCELLANEOUS MEDICAL USES FOR ANTIPSYCHOTIC DRUGS

Antipsychotic drugs have a variety of uses in addition to the treatment of psychotic or manic patients. Predominant among these are the treatment of nausea and vomiting, alcoholic hallucinosis, certain neuropsychiatric diseases such as autism and others marked by movement disorders (notably Tourette's syndrome and Huntington's disease), and occasionally, pruritus and intractable hiccough.

Nausea and Vomiting. Many antipsychotic agents can prevent vomiting due to specific etiologies when given in relatively low, nonsedative doses. This use is discussed in Chapter 37.

Other Neuropsychiatric Disorders. Antipsychotic drugs are useful in the management of several syndromes with psychiatric features that also are characterized by movement disorders. These include *Gilles de la Tourette's syndrome* (marked by tics, other involuntary movements, aggressive outbursts, grunts, and vocalizations that frequently are obscene) and Huntington's disease (marked by severe and progressive choreoathetosis, psychiatric symptoms, and dementia, with a well-characterized genetic basis; *see* Chapter 20). Haloperidol currently is regarded as a drug of choice for these conditions, although it probably is not unique in its antidyskinetic actions. Pimozide also is used (typically in daily doses of 2 to 10 mg). Pimozide carries some risk of impairing cardiac repolarization, and

it should be discontinued if the QTc interval exceeds 500 msec. Clonidine and tricyclic antidepressants such as nortriptyline also may be effective in Tourette's syndrome (Spencer *et al.*, 1993).

Withdrawal Syndromes. Antipsychotic drugs are *not* useful in the management of withdrawal from opioids, and their use in the management of withdrawal from barbiturates, other sedatives, or alcohol is contraindicated because of the high risk of seizures. They can be used safely and effectively in psychoses associated with chronic alcoholism—especially the syndrome known as *alcoholic hallucinosis* (Sadock and Sadock, 2000).

II. TREATMENT OF MANIA

ANTIMANIC MOOD-STABILIZING AGENTS: LITHIUM

Lithium carbonate was introduced into psychiatry in 1949 for the treatment of mania (Cade, 1949; Mitchell *et al.*, 1999). However, it was not FDA approved for this purpose in the United States until 1970, in part due to concerns of American physicians about its safety following reports of severe intoxication with lithium chloride from its uncontrolled use as a substitute for sodium chloride in patients with cardiac disease. Evidence for both the safety and the efficacy of lithium salts in the treatment of mania and the prevention of recurrent attacks of bipolar manic-depressive illness is both abundant and convincing (Baldessarini *et al.*, 2002; Davis *et al.*, 1999; Geddes *et al.*, 2004; Mitchell *et al.*, 1999). In recent years the limitations and adverse effects of lithium salts have become increasingly well appreciated, and efforts to find alternative antimanic or mood-stabilizing agents have intensified (Davis *et al.*, 1999; Goodwin and Jamison, 1990). The most successful alternatives or adjuncts to lithium to date are the anticonvulsants carbamazepine, *lamotrigine*, and valproic acid. Atypical antipsychotic agents also appear to be useful (Baldessarini *et al.*, 2003b; Goldsmith *et al.*, 2004; Post, 2000; Tohen *et al.*, 2003).

History. Lithium urate is very water soluble, and lithium salts were used in the nineteenth century as a treatment of gout. Lithium bromide was employed in that era as a sedative (including in manic patients) and as a putative anticonvulsant. Thereafter, lithium salts were unpopular until the late 1940s, when lithium chloride was employed as a salt substitute for cardiac and other chronically ill patients. This ill-advised use led to several reports of severe intoxication and death and to considerable notoriety concerning lithium salts within the medical profession. Cade, in Australia, while look-

ing for toxic nitrogenous substances in the urine of mental patients for testing in guinea pigs, administered lithium salts to the animals in an attempt to increase the solubility of urates. Lithium carbonate made the animals lethargic, and in an inductive leap, Cade gave lithium carbonate to several agitated or manic psychiatric patients, reporting that this treatment seemed to have a specific effect in mania (Cade, 1949; Mitchell *et al.*, 1999).

Chemistry. Lithium is the lightest of the alkali metals (group Ia); the salts of this monovalent cation share some characteristics with those of Na⁺ and K⁺. Li⁺ is readily assayed in biological fluids and can be detected in brain tissue by magnetic resonance spectroscopy (Riedl *et al.*, 1997). Traces of the ion occur normally in animal tissues, but it has no known physiological role. Lithium carbonate and lithium citrate currently are used therapeutically in the United States.

Pharmacological Properties

Therapeutic concentrations of lithium ion (Li⁺) have almost no discernible psychotropic effects in normal individuals. It is not a sedative, depressant, or euphoriant, and this characteristic differentiates Li⁺ from other psychotropic agents. The general biology and pharmacology of Li⁺ have been reviewed in detail (Jefferson *et al.*, 1983). The precise mechanism of action of Li⁺ as a mood-stabilizing agent remains unknown, although many molecular and cellular actions of Li⁺, as well as similarities of actions of other mood-stabilizing agents, including valproate, have been described (Manji *et al.*, 1999b, 2003; Manji and Zarate, 2002).

An important characteristic of Li⁺ is that, unlike Na⁺ and K⁺, it has a relatively small gradient of distribution across biological membranes. Although it can replace Na⁺ in supporting a single action potential in a nerve cell, it is not a “substrate” for the Na⁺ pump and therefore cannot maintain membrane potentials. It is uncertain whether therapeutic concentrations of Li⁺ (about 0.5 to 1 mEq per liter) affect the transport of other monovalent or divalent cations by nerve cells.

Central Nervous System. In addition to possibly altering cation distribution in the CNS, much attention has centered on the effects of therapeutic concentrations of Li⁺ on the metabolism of the biogenic monoamines that have been implicated in the pathophysiology of mood disorders and on second-messenger and other intracellular molecular mechanisms involved in signal transduction, gene regulation, and cell survival (Jope, 1999; Lenox and Manji, 1998; Manji *et al.*, 1999a, 1999b, 2003; Manji and Zarate, 2002).

In animal brain tissue, Li⁺ at concentrations of 1 to 10 mEq per liter inhibits the depolarization-provoked and Ca²⁺-dependent release of norepinephrine and dopamine, but *not* serotonin, from nerve terminals (Baldessarini and Vogt, 1988). Li⁺ may even transiently enhance

release of serotonin, especially in the limbic system (Treiser *et al.*, 1981; Manji *et al.*, 1999a, 1999b; Wang and Friedman, 1989). The ion has limited effects on catecholamine-sensitive adenylyl cyclase activity or on the binding of ligands to monoamine receptors in brain tissue (Manji *et al.*, 1999b; Turkka *et al.*, 1992). However, Li^+ can modify some hormonal responses mediated by adenylyl cyclase or phospholipase C in other tissues, including the actions of vasopressin and thyroid-stimulating hormone on their peripheral target tissues (Manji *et al.*, 1999b; Urabe *et al.*, 1991). There is some evidence that Li^+ can inhibit the effects of receptor-blocking agents that cause supersensitivity in such systems (Bloom *et al.*, 1983). In part, the actions of Li^+ may reflect its ability to interfere with the activity of both stimulatory and inhibitory G proteins (G_s and G_i) by keeping them in their less active $\alpha\beta\gamma$ trimeric state (Jope, 1999; Manji *et al.*, 1999b).

A consistently reported, selective action of Li^+ is to inhibit inositol monophosphatase (Berridge *et al.*, 1989) and thus interfere with the phosphatidylinositol pathway (Figure 18–1). This effect can lead to decreases in cerebral inositol concentrations, which can be detected with magnetic resonance spectroscopy in human brain tissue (Manji *et al.*, 1999a, 1999b). Physiological consequences of this effect may include interference with neurotransmission mechanisms by affecting the phosphatidylinositol pathway (Lenox and Manji, 1998; Manji *et al.*, 1999b).

Lithium treatment also leads to consistent decreases in the functioning of protein kinases in brain tissue, including PKC (Jope, 1999; Lenox and Manji, 1998), particularly subtypes α and β (Manji *et al.*, 1999b). Among other proposed antimanic or mood-stabilizing agents, this effect also is shared with valproic acid (particularly for PKC) but not carbamazepine (Manji *et al.*, 1993). In turn, these effects may alter the release of amine neurotransmitters and hormones (Wang and Friedman, 1989; Zatz and Reisine, 1985) as well as the activity of tyrosine hydroxylase (Chen *et al.*, 1998). A major substrate for cerebral PKC is the myristolated alanine-rich PKC-kinase substrate (MARCKS) protein, which has been implicated in synaptic and neuronal plasticity. The expression of MARCKS protein is reduced by treatment with both Li^+ and valproate, but not by carbamazepine or antipsychotic, antidepressant, or sedative drugs (Watson and Lenox, 1996; Watson *et al.*, 1998). Both Li^+ and valproate treatment inhibit glycogen synthase kinase-3 β (GSK-3 β), which is involved in neuronal and nuclear regulatory processes, including limiting expression of the regulatory protein β -catenin (Chen *et al.*, 1999b; Manji *et al.*, 1999b). Li^+ and valproic acid both interact with nuclear regulatory factors that affect gene expression. Such effects include increasing DNA binding of the transcription factor activator protein-1 (AP-1), as well as altered expression of other transcription factors, including AMI-1 β or PEBP-2 β (Chen *et al.*, 1999a, 1999c).

Treatment with Li^+ and valproate has been associated with increased expression of the regulatory protein B-cell lymphocyte protein-2 (bcl-2), which is associated with protection against neuronal degeneration (Chen *et al.*, 1999c; Manji *et al.*, 1999c). The significance of interactions of mood-stabilizing agents with cell-regulatory factors, and their potential utility in preventing cell loss or other pathological changes in brain tissue in various neuropsychiatric disorders remains to be clarified (Bauer *et al.*, 2003; Manji *et al.*, 2003; Manji and Zarate, 2002).

Absorption, Distribution, and Excretion. Li^+ is absorbed readily and almost completely from the gastrointestinal tract. Complete absorption occurs in about 8 hours, with

peak plasma concentrations occurring 2 to 4 hours after an oral dose. Slow-release preparations of lithium carbonate provide a slower rate of absorption and thereby minimize early peaks in plasma concentrations of the ion, but absorption can be variable, lower gastrointestinal tract symptoms may be increased, and elimination rate is not altered with such preparations. Li^+ initially is distributed in the extracellular fluid, then gradually accumulates in various tissues; it does not bind appreciably to plasma proteins. The concentration gradient across plasma membranes is much smaller than those for Na^+ and K^+ . The final volume of distribution (0.7 to 0.9 liter per kilogram) approaches that of total body water and is much lower than that of most other psychotropic agents, which are lipophilic and protein bound. Passage through the blood-brain barrier is slow, and when a steady state is achieved, the concentration of Li^+ in the cerebrospinal fluid and in brain tissue is about 40% to 50% of the concentration in plasma. The kinetics of Li^+ can be monitored in human brain with magnetic resonance spectroscopy (Plenge *et al.*, 1994; Riedl *et al.*, 1997).

Approximately 95% of a single dose of Li^+ is eliminated in the urine. From one- to two-thirds of an acute dose is excreted during a 6- to 12-hour initial phase of excretion, followed by slow excretion over the next 10 to 14 days. The elimination half-life averages 20 to 24 hours. With repeated administration, Li^+ excretion increases during the first 5 to 6 days until a steady state is reached between ingestion and excretion. When therapy with Li^+ is stopped, there is a rapid phase of renal excretion followed by a slow 10- to 14-day phase. Since 80% of the filtered Li^+ is reabsorbed by the proximal renal tubules, clearance of Li^+ by the kidney is about 20% of that for creatinine, ranging between 15 and 30 ml per minute. This rate is somewhat lower in elderly patients (10 to 15 ml per minute). Loading with Na^+ produces a small enhancement of Li^+ excretion, but Na^+ depletion promotes a clinically important degree of retention of Li^+ .

Although the pharmacokinetics of Li^+ vary considerably among subjects, the volume of distribution and clearance are relatively stable in an individual patient. However, a well-established regimen can be complicated by occasional periods of Na^+ loss, as may occur with an intercurrent febrile, diarrheal, or other medical illness, with losses or restrictions of fluids and electrolytes, or during treatment with a diuretic. Heavy sweating may be an exception due to a preferential secretion of Li^+ over Na^+ in sweat (Jefferson *et al.*, 1982).

Most of the renal tubular reabsorption of Li^+ occurs in the proximal tubule. Nevertheless, Li^+ retention can be increased by any diuretic that leads to depletion of Na^+ , particularly the thiazides (see Chapter 28) (Siegel *et al.*, 1998). Renal excretion can be increased by administration of osmotic diuretics, acetazolamide, or aminophylline, although they are of little help in the management of Li^+

intoxication. Triamterene may increase excretion of Li^+ , suggesting that some reabsorption of the ion may occur in the distal nephron. However, spironolactone does not increase the excretion of Li^+ . Some nonsteroidal antiinflammatory agents can facilitate renal proximal tubular resorption of Li^+ and thereby increase concentrations in plasma to toxic levels. This interaction appears to be particularly prominent with indomethacin, but also may occur with *ibuprofen*, *naproxen*, and cyclooxygenase-2 (COX-2) inhibitors, and possibly less so with *sulindac* and *aspirin* (Siegel *et al.*, 1998; Phelan *et al.*, 2003). A potential drug–drug interaction can occur with angiotensin-converting enzyme inhibitors, causing lithium retention (*see* Chapter 29).

Less than 1% of ingested Li^+ leaves the human body in the feces, and 4% to 5% is secreted in sweat. Li^+ is secreted in saliva in concentrations about twice those in plasma, while its concentration in tears is about equal to that in plasma. Since the ion also is secreted in human milk, women receiving Li^+ should not breast-feed infants.

Serum Level Monitoring and Dose. Because of the low therapeutic index for Li^+ , periodic determination of serum concentrations is crucial. Li^+ cannot be used with adequate safety in patients who cannot be tested regularly. Concentrations considered to be effective and acceptably safe are between 0.6 and 1.25 mEq per liter. The range of 0.9 to 1.1 mEq per liter is favored for treatment of acutely manic or hypomanic patients. Somewhat lower values (0.6 to 0.75 mEq per liter) are considered adequate and are safer for long-term use for prevention of recurrent manic-depressive illness. Some patients may not relapse at concentrations as low as 0.5 to 0.6 mEq per liter, and lower levels usually are better tolerated (Maj *et al.*, 1986; Tondo *et al.*, 1998, 2001a). The recommended concentration usually is attained by doses of 900 to 1500 mg of lithium carbonate per day in outpatients and 1200 to 2400 mg per day in hospitalized manic patients. The optimal dose tends to be larger in younger and heavier individuals.

Serum concentrations of Li^+ have been found to follow a clear dose-effect relationship between 0.4 and 0.9 mEq per liter, with a corresponding dose-dependent rise in polyuria and tremor as indices of adverse effects, and little gain in benefit at levels above 0.75 mEq per liter (Maj *et al.*, 1986). This pattern indicates the need for individualization of serum levels to obtain a favorable risk-benefit relationship. The concentration of Li^+ in blood usually is measured at a trough of the daily oscillations that result from repetitive administration (*i.e.*, from samples obtained 10 to 12 hours after the last oral dose of the day). Peaks can be two or three times higher at a steady state. When the peaks are reached, intoxication may result, even when concentrations in morning samples of plasma at the daily nadir are in the acceptable range of 0.6 to 1 mEq per liter. Single daily doses, with relatively large oscillations of the plasma concentration of Li^+ , may reduce the polyuria sometimes associated with this treatment, but the average

reduction is quite small (Baldessarini *et al.*, 1996b; Hetmar *et al.*, 1991). Nevertheless, because of the low margin of safety of Li^+ and because of its short half-life during initial distribution, divided daily doses are usually indicated even with slow-release formulations.

Toxic Reactions and Side Effects. The occurrence of toxicity is related to the serum concentration of Li^+ and its rate of rise following administration. Acute intoxication is characterized by vomiting, profuse diarrhea, coarse tremor, ataxia, coma, and convulsions. Symptoms of milder toxicity are most likely to occur at the absorptive peak of Li^+ and include nausea, vomiting, abdominal pain, diarrhea, sedation, and fine tremor. The more serious effects involve the nervous system and include mental confusion, hyperreflexia, gross tremor, dysarthria, seizures, and cranial nerve and focal neurological signs, progressing to coma and death. Sometimes both cognitive and motor neurological damage may be irreversible. Other toxic effects are cardiac arrhythmias, hypotension, and albuminuria. Other adverse effects common even in therapeutic dose ranges include nausea, diarrhea, daytime drowsiness, polyuria, polydipsia, weight gain, fine hand tremor, and dermatological reactions including acne (Baldessarini *et al.*, 1996b).

Therapy with Li^+ is associated initially with a transient increase in the excretion of 17-hydroxycorticosteroids, Na^+ , K^+ , and water. This effect usually is not sustained beyond 24 hours. In the subsequent 4 to 5 days, the excretion of K^+ becomes normal, Na^+ is retained, and in some cases dependent edema forms. Na^+ retention has been associated with increased aldosterone secretion and responds to administration of spironolactone. However, this maneuver incurs the risk of promoting the retention of Li^+ and increasing its concentration in plasma (*see* Chapter 28). Edema and Na^+ retention frequently disappear spontaneously after several days.

A small number of patients treated with Li^+ develop a benign, diffuse, nontender thyroid enlargement suggestive of compromised thyroid function. This effect may be associated with previous thyroiditis, particularly in middle-aged women. In patients treated with Li^+ , thyroid uptake of iodine is increased, plasma protein-bound iodine and free thyroxine tend to be slightly low, and thyroid-stimulating hormone (TSH) secretion may be moderately elevated. These effects appear to result from interference with the iodination of tyrosine, and therefore the synthesis of thyroxine. However, patients usually remain euthyroid, and overt hypothyroidism is rare. In patients who do develop goiter, discontinuation of Li^+ or treatment with thyroid hormone results in shrinkage of the gland. Adding supplemental thyroid hormones to bipolar disorder patients with low-normal thyroid hormone levels and continued depression or anergy may be useful clinically, although this is an area of considerable controversy. Moreover, proposed use of high doses of thyroxine (T_4) to control rapid-cycling bipolar disorder is not established as a safe practice (Bauer and Whybrow, 1990; Baumgartner *et al.*, 1994; Lasser and Baldessarini, 1997).

The kidneys' ability to concentrate urine decreases during Li^+ therapy. Polydipsia and polyuria occur in patients treated with Li^+ ,

occasionally to a disturbing degree. Acquired nephrogenic diabetes insipidus can occur in patients maintained at therapeutic plasma concentrations of the ion (*see* Chapter 29) (Siegel *et al.*, 1998). Typically, mild polyuria appears early in treatment and then disappears. Late-developing polyuria is an indication to evaluate renal function, lower the dose of Li^+ , or consider adding a potassium-sparing agent such as amiloride (preferred to potassium-wasting thiazides) to counteract the polyuria (*see* Chapter 28) (Batlle *et al.*, 1985; Kosten and Forrest, 1986). Polyuria disappears with cessation of Li^+ therapy. The mechanism of polyuria may involve inhibition of the action of vasopressin on renal adenylyl cyclase as reflected in elevated circulating vasopressin and lack of responsiveness to exogenous vasopressin or synthetic analogs (Boton *et al.*, 1987; Siegel *et al.*, 1998). The result is decreased vasopressin stimulation of renal reabsorption of water. However, Li^+ also may alter renal function at steps beyond cyclic AMP synthesis. The effect of Li^+ on water metabolism is not sufficiently predictable to be therapeutically useful in treatment of the syndrome of inappropriate secretion of antidiuretic hormone. Evidence of chronic inflammatory changes in biopsied renal tissue has been found in a minority of patients given Li^+ for prolonged periods. Since progressive, clinically significant impairment of renal function is rare, these are considered incidental findings by most experts. Nevertheless, plasma creatinine and urine volume should be monitored during long-term use of Li^+ (Boton *et al.*, 1987; Hetmar *et al.*, 1991).

Li^+ also has a weak action on carbohydrate metabolism, causing an increase in skeletal muscle glycogen accompanied by depletion of glycogen from the liver.

The prolonged use of Li^+ causes a benign and reversible depression of the T wave of the ECG, an effect not related to depletion of Na^+ or K^+ .

Li^+ routinely causes EEG changes characterized by diffuse slowing, widened frequency spectrum, and potentiation with disorganization of background rhythm. Seizures have been reported in nonepileptic patients with therapeutic plasma concentrations of Li^+ . Myasthenia gravis may worsen during treatment with Li^+ (Neil *et al.*, 1976).

A benign, sustained increase in circulating polymorphonuclear leukocytes occurs during the chronic use of Li^+ and is reversed within a week after termination of treatment.

Allergic reactions such as dermatitis and vasculitis can occur with Li^+ administration. Worsening of acne vulgaris is a common problem, and some patients may experience mild alopecia.

In pregnancy, maternal polyuria may be exacerbated by lithium. Concomitant use of lithium with natriuretics and a low- Na^+ diet during pregnancy can contribute to maternal and neonatal Li^+ intoxication. During postpartum diuresis one can anticipate potentially toxic retention of Li^+ by the mother. Lithium freely crosses the placenta, and fetal or neonatal lithium toxicity may develop when maternal blood levels are within the therapeutic range. Lithium also is secreted in breast milk of nursing mothers. The use of Li^+ in pregnancy has been associated with neonatal goiter, CNS depression, hypotonia ("floppy baby" syndrome), and cardiac murmur. All of these conditions reverse with time, and no long-term neurobehavioral sequelae have been observed (Committee on Drugs. American Academy of Pediatrics, 2000; Iqbal *et al.*, 2001; Pinelli *et al.*, 2002).

The use of Li^+ in early pregnancy may be associated with an increase in the incidence of cardiovascular anomalies of the newborn, especially Ebstein's malformation (Cohen *et al.*, 1994). The basal risk of Ebstein's anomaly (malformed tricuspid valve, usually with a septal defect) of about 1 per 20,000 live births may rise severalfold, but probably not above 1 per 2500. Moreover, the defect typically is

detectable *in utero* by ultrasonography and often is surgically correctable after birth. In contrast, the antimanic anticonvulsants valproic acid and probably carbamazepine have an associated risk of irreversible spina bifida that may exceed 1 per 100, and so do not represent a rational alternative for pregnant women (Viguera *et al.*, 2000, 2002). In balancing the risk vs. benefit of using Li^+ in pregnancy, it is important to evaluate the risk of untreated manic-depressive disorder and to consider conservative measures, such as deferring intervention until symptoms arise or using a safer treatment, such as a neuroleptic or ECT (Cohen *et al.*, 1994; Viguera *et al.*, 2000, 2002).

Treatment of Lithium Intoxication. There is no specific antidote for Li^+ intoxication, and treatment is supportive. Vomiting induced by rapidly rising plasma Li^+ may tend to limit absorption, but fatalities have occurred. Care must be taken to assure that the patient is not Na^+ - and water-depleted. Dialysis is the most effective means of removing the ion from the body and is necessary in severe poisonings, *i.e.*, in patients exhibiting symptoms of toxicity or patients with serum Li^+ concentrations greater than 4 mEq/L in acute overdoses or greater than 1.5 mEq/L in chronic overdoses.

Interactions with Other Drugs. Interactions between Li^+ and diuretics (especially spironolactone and amiloride) and nonsteroidal anti-inflammatory agents have been discussed above (*see* Absorption, Distribution, and Excretion and Toxic Reactions and Side Effects; Siegel *et al.*, 1998). Relative to thiazides and other diuretics that deplete Na^+ , retention of Li^+ may be limited during administration of the weakly natriuretic agent amiloride as well as the loop diuretic furosemide. Amiloride and other diuretic agents (sometimes with reduced doses of Li^+) have been used safely to reverse the syndrome of diabetes insipidus occasionally associated with Li^+ therapy (Batlle *et al.*, 1985; Botton *et al.*, 1987) (*see* Chapter 29).

Li^+ often is used in conjunction with antipsychotic, sedative, antidepressant, and anticonvulsant drugs. A few case reports have suggested a risk of increased CNS toxicity when Li^+ was combined with haloperidol; however, this finding is at variance with many years of experience with this combination. Antipsychotic drugs may prevent nausea, which can be an early sign of Li^+ toxicity. There is, however, no absolute contraindication to the concurrent use of Li^+ and psychotropic drugs. Finally, anticholinergic and other agents that alter gastrointestinal motility also may alter Li^+ concentrations in blood over time.

Therapeutic Uses

Drug Treatment of Bipolar Disorder. Treatment with Li^+ ideally is conducted in cooperative patients with normal Na^+ intake and with normal cardiac and renal function. Occasionally, patients with severe systemic illnesses are treated with Li^+ , provided that the indications are compelling. Treatment of acute mania and the prevention of recurrences of bipolar illness in otherwise healthy adults or adolescents currently are the only uses approved by the FDA, even though the primary indication for Li^+

treatment is for long-term prevention of recurrences of major affective illness, particularly both mania and depression in bipolar I or II disorders (Baldessarini *et al.*, 1996b, 2002; Goodwin and Jamison, 1990; Shulman *et al.*, 1996; Tondo *et al.*, 1998).

In addition, on the basis of compelling evidence of efficacy, Li⁺ sometimes is used as an alternative or adjunct to antidepressants in severe, especially melancholic, recurrent depression, as a supplement to antidepressant treatment in acute major depression, including in patients who present clinically with only mild mood elevations or hypomania (bipolar II disorder), or as an adjunct when later response to an antidepressant alone is unsatisfactory (Austin *et al.*, 1991; Bauer and Döpfmer, 1999). In major affective disorders, lithium is associated with stronger evidence of reduction of suicide risk than any other treatment (Baldessarini *et al.*, 2003a; Tondo *et al.*, 2001b).

The beneficial effects of Li⁺ in major depression may be associated with the presence of clinical or biological features also found in bipolar affective disorder (Goodwin and Jamison, 1990; Baldessarini *et al.*, 1996b). Growing clinical experience also suggests the utility of Li⁺ in the management of childhood disorders that are marked by adultlike manic depression or by severe changes in mood and behavior, which are probable precursors to bipolar disorder in adults (Baldessarini *et al.*, 1996b; Faedda *et al.*, 1995, 2004).

Li⁺ has been evaluated in many additional disorders marked by an episodic course, including premenstrual dysphoria, episodic alcohol abuse, and episodic violence (Baldessarini *et al.*, 1996b, 2002). Evidence of efficacy in most of these conditions has been unconvincing. The side effects of the Li⁺ ion have been exploited in the management of hyperthyroidism and the syndrome of inappropriate antidiuretic hormone secretion, as well as in the reversal of spontaneous or drug-induced leukopenias, but usually with limited benefit.

Formulations. Most preparations currently used in the United States are tablets or capsules of lithium carbonate. Slow-release preparations of lithium carbonate also are available, as is a liquid preparation of lithium citrate (with 8 mEq of Li⁺, equivalent to 300 mg of carbonate salt, per 5 ml or 1 teaspoonful of citrate liquid). Salts other than the carbonate have been used, but the carbonate salt is favored for tablets and capsules because it is relatively less hygroscopic and less irritating to the gut than other salts, especially the chloride.

Drug Treatment of Mania and Prophylactic Treatment of Bipolar Disorder. The modern treatment of the manic, depressive, and mixed-mood phases of bipolar disorder was revolutionized by the introduction of lithium

in 1949, its gradual acceptance worldwide by the 1960s, and late official acceptance in the United States in 1970, initially for acute mania only, and later primarily for prevention of recurrences of mania. Lithium is effective in acute mania, but is rarely employed as a sole treatment due to its slow onset of action, need for monitoring blood Li⁺ concentrations, and the difficulties associated with adherence to the therapeutic regimen by highly agitated and uncooperative manic patients. Rather, an antipsychotic or potent sedative benzodiazepine (such as *lorazepam* or *clonazepam*) commonly is used to attain a degree of control of acute agitation (Licht, 1998; Tohen and Zarate, 1998). Alternatively, the anticonvulsant sodium valproate can provide rapid antimanic effects (Pope *et al.*, 1991; Bowden *et al.*, 1994), particularly when doses as high as 30 mg/kg and later 20 mg/kg daily are used to rapidly obtain serum concentrations of 90 to 120 $\mu\text{g/ml}$ (Grunze *et al.*, 1999; Hirschfeld *et al.*, 1999). Once patients are stabilized and cooperative, Li⁺ then can be introduced for longer-term mood stabilization, or the anticonvulsant may be continued alone (*see below*).

Li⁺ or an alternative antimanic agent usually is continued for at least several months after full recovery from a manic episode, due to a high risk of relapse or of cycling into depression within 12 months (Goodwin and Jamison, 1990). The clinical decision to recommend more prolonged maintenance treatment is based on balancing the frequency and severity of past episodes of manic-depressive illness, the age and estimated reliability of the patient, and the risk of adverse effects (Baldessarini *et al.*, 1996b; Zarin and Pass, 1987). Regardless of the number of previous episodes of mania or depression, or delay in initiating maintenance treatment, Li⁺ remains by far the best established long-term treatment to prevent recurrences of mania (and bipolar depression) (Baethge *et al.*, 2003; Baldessarini *et al.*, 2002; Bratti *et al.*, 2003; Davis *et al.*, 1999; Geddes *et al.*, 2004; Goodwin and Jamison, 1990). There is compelling evidence of substantial lowering of risk of suicide and suicide attempts during treatment with lithium but not with either carbamazepine or *divalproex* (Baldessarini *et al.*, 2003a; Goodwin *et al.*, 2003; Thies-Flechtner *et al.*, 1996; Tondo *et al.*, 2001).

Owing to the limited tolerability of Li⁺ and its imperfect protection from recurrences of bipolar illness, antimanic anticonvulsants, particularly sodium valproate and carbamazepine, also have been employed prophylactically in bipolar disorder. However, research supporting their long-term use remains limited (Calabrese *et al.*, 1992, 2002; Davis *et al.*, 1999; Bowden *et al.*, 2000; Davis *et al.*, 2000). There is growing evidence for the inferiority of carbamazepine compared to lithium (Dardennes *et al.*,

1995; Davis *et al.*, 1999; Denicoff *et al.*, 1997; Greil *et al.*, 1997; Post *et al.*, 1998; Post, 2000) and carbamazepine is not FDA approved for bipolar disorder. Divalproex, the sodium salt of valproic acid, is FDA approved for mania and is extensively used off-label for long-term prophylactic treatment of bipolar disorder patients. In addition, lamotrigine is the first agent given FDA approval for long-term prophylactic treatment in bipolar disorder without an indication for acute mania; it is particularly effective against bipolar depression with minimal risk of inducing mania (Bowden *et al.*, 2004; Calabrese *et al.*, 2002; Goldsmith *et al.*, 2004). Other anticonvulsants that may have utility in bipolar disorder (*topiramate*, *zonisamide*, and the carbamazepine congener *oxcarbazepine*) remain under investigation (Centorrino *et al.*, 2003; Evins, 2003).

Relevant pharmacology and dosing guidelines for the anticonvulsants are provided in Chapter 19. Doses established for their anticonvulsant effects are assumed to be appropriate for the treatment of manic-depressive patients, although formal dose-response studies in psychiatric patients are lacking. Thus, dosing usually is adjusted to provide plasma concentrations of 6 to 12 $\mu\text{g/ml}$ for carbamazepine and 60 to 120 $\mu\text{g/ml}$ for valproic acid. It also is common to combine Li^+ with an anticonvulsant, particularly valproate, when patients fail to be fully protected from recurrences of bipolar illness by monotherapy (Freeman and Stoll, 1998).

Antipsychotic drugs commonly have been employed empirically to manage manic and psychotic illness in bipolar disorder patients. Indeed, standard neuroleptics have been a mainstay of the treatment of acute mania (only chlorpromazine is FDA approved for this indication, although haloperidol has also been widely used) and for manic episodes that break through prophylactic treatment with Li^+ or an anticonvulsant (Segal *et al.*, 1998; Sernyak *et al.*, 1994; Tohen and Zarate, 1998). However, the older antipsychotics are not used routinely for long-term prophylactic treatment in bipolar disorder because their effectiveness is untested, some may worsen depression, and the risk of tardive dyskinesia in these syndromes may be higher than in schizophrenia (Kane, 1999).

Several modern, better-tolerated antipsychotic agents have recently received FDA approval for use in acute mania (olanzapine, quetiapine, and risperidone) (Baldessarini *et al.*, 2003b; Keck and Licht, 2001; Tohen *et al.*, 1999, 2003; Vieta *et al.*, 2004). There is also evidence of antimanic efficacy of others (aripiprazole, ziprasidone) (Keck *et al.*, 2003; Yatham, 2003). There also is evidence of long-term effectiveness of olanzapine in bipolar I disorder (Tohen *et al.*, 2003), for which olanzapine has

received an FDA approved indication. Other atypical antipsychotic drugs are under investigation for long-term prophylactic treatment of bipolar disorder. The risks and benefits of the atypical antipsychotic agents aripiprazole and ziprasidone for treatment of bipolar disorder require further study. Ziprasidone can have stimulating or apparent mood-elevating actions with an uncertain risk of inducing mania (Baldassano *et al.*, 2003).

Other alternatives to Li^+ (e.g., calcium channel blockers, long-chain unsaturated fatty acids) have been less well evaluated and are not established options for bipolar disorder (Dubovsky, 1998; Pazzaglia *et al.*, 1998; Stoll *et al.*, 1999).

Discontinuation of maintenance treatment with Li^+ carries a high risk of early recurrence and of suicidal behavior over a period of several months, even if the treatment had been successful for several years. Recurrence is much more rapid than is predicted by the natural history of untreated bipolar disorder, in which cycle lengths average about 1 year (Baldessarini *et al.*, 1996b, 1999; Tondo *et al.*, 1998). This risk probably can be moderated by slowing the gradual removal of Li^+ when that is medically feasible (Faedda *et al.*, 1993; Baldessarini *et al.*, 1999). Significant risk also is suspected after rapid discontinuation or even sharp dosage reduction during maintenance treatment with other agents, including antipsychotic, antidepressant, and anti-anxiety drugs (Baldessarini *et al.*, 1996a, 1999). This phenomenon hinders clinical researchers from employing and interpreting results from common study designs in which an ongoing maintenance treatment is interrupted to compare continued treatment to a placebo, to an alternative treatment, or to compare higher vs. lower doses (Baldessarini *et al.*, 1996a). As a result, direct comparisons between different maintenance options are limited.

Novel Treatments for Psychotic Disorders

Acceptance of clozapine for general use, and growing evidence that no alternative has proved superior in antipsychotic efficacy to clozapine, have stimulated interest in discovering other antipsychotic agents with a low risk of extrapyramidal neurological side effects and high efficacy, and without the need to monitor for the hematologic toxicity of clozapine (Baldessarini and Frankenburg, 1991). Not surprisingly, a substantial number of potential new antipsychotic agents with effects on dopaminergic systems are in development (NDA Pipeline, 2004). They include additional mixed *dopamine D₂/serotonin 5-HT_{2A} antagonists* (e.g., AD-5423, *asenapine*, *blonanserin*, *clothiapine*, *DHA-clozapine*, GSK-773812, *iloperidone*, *mazapertine*, *terguride*). Others are *D₂ partial agonists* like aripiprazole

(e.g., *bifeprunox*, CI-1007, DAB-452, *roxindole*). A few combine D₂ antagonist activity with *muscarinic agonist* or *antagonist* activity (e.g., BuTAC, AC-42, AC-90222). Several are D₃-receptor antagonists (e.g., AVE-5997, DTA-201, S-33138) whose behavioral effects remain to be determined. Several D₄ antagonists also have been brought to clinical trial, but have proved ineffective for the treatment of typical symptoms of schizophrenia.

Treatments that involve even more novel principles of antipsychotic action have remained elusive, but some have been proposed. Several involve targets other than the dopamine receptors that have dominated antipsychotic drug development for a half-century. Compounds that enhance glutamatergic neurotransmission have provided some interesting leads. Some act by stimulating the *glycine modulatory site* of the NMDA receptor (e.g., L-glycine, serine, D-cycloserine, S-18841). Others are *ampakines* that stimulate AMPA receptors (CX-516, ORG-23430, ORG-24448). Both types of glutamate enhancers may augment the beneficial therapeutic effects of atypical antipsychotic agents, particularly by improving cognition, but may not be effective or well tolerated when given alone (Goff *et al.*, 1999, 2001). In addition, preclinical studies suggest that novel compounds targeting selective G protein-coupled *metabotropic glutamate receptors*, GluR2/3 (LY354740, LY379268), mGluR3 (*N*-acetylaspartyl-glutamate [NAAG]), or mGlu5 (2-methyl-6-[phenylethynyl]-pyridine [MPEP]) may improve cognitive deficits in schizophrenia (Moghaddam, 2004). Finally, the active metabolite *norclozapine* appears to potentiate NMDA glutamatergic and M₁ cholinergic receptor activity (Sur *et al.*, 2003).

The development of antipsychotic agents that effect serotonergic neurotransmission, and recent advances in characterizing 5-HT receptor types have encouraged development of drugs selective for various serotonin receptors (see Chapter 11). Such potential novel antipsychotic agents include 5-HT_{2A}-receptor inverse agonists (AC-90179, ACP-103, AR-116081), 5-HT₆-receptor antagonists (SB-271046, SB-742457), and 5-HT₇-receptor antagonists (SB-269970). The clinical utility of such agents remains to be proved.

Additional novel products that target different molecular elements and cellular pathways and are aimed at improving particular symptoms of schizophrenia also are under development. They include α_4 - β_2 nicotinic receptor agonists (e.g., S1B-1553A), a cannabinoid CB₁ antagonist (SR141716), neurokinin-3 antagonists (SB-223412, SR-142801), neurotensin modulators (AC-7954, NT-69L, SR-48692), a somatostatin stimulator (FK-960), a urotensin-2 agonist (AC-7954), adenosine receptor agonist/modula-

tors (allopurinol, dipyridamole), a PLA₂ inhibitor (SC-111), a PDE5 inhibitor (T-0156), a PDE10A inhibitor (*papaverine*), sigma-1 site modulators (E-5842, NE-100), COX-2 inhibitors (celecoxib, GSK-644784), and neurosteroids [*dehydroepiandrosterone* (DHEA) and its sulfate derivative (DHEA-S)] (Miyamoto *et al.*, 2004; NDA Pipeline, 2004).

Novel Treatments for Bipolar Disorder

The clinical successes of valproate and carbamazepine as antimanic agents, and of lamotrigine as a mood-stabilizing agent, have strongly encouraged exploration of the growing number of other anticonvulsants being introduced into neurological practice (see Chapter 19). Several anticonvulsants are currently being tested in clinical trials (Ferrier and Calabrese, 2000; Keck and McElroy, 1998; Manji *et al.*, 2000; Post *et al.*, 1998; Post, 2000). Aside from extensions of the known principles of applying anticonvulsants and antipsychotics for the treatment of bipolar disorder, some highly innovative concepts have emerged. Given the overlapping actions of lithium and valproate, it may be possible to develop novel antimanic agents that act directly on effector mechanisms that mediate the actions of adrenergic and other neurotransmitter receptors (Manji *et al.*, 1999b). Under experimental development are drugs that affect PKC, such as the antiestrogen *tamoxifen* (Bebchuk *et al.*, 2000) and other novel kinase-inhibiting agents. For bipolar disorder, a critical challenge is to develop safe and effective antidepressants that do not induce mania and mood-stabilizing agents that consistently outperform lithium in broad effectiveness, with improved safety (see Baldessarini *et al.*, 1996b, 2002; Stoll *et al.*, 1994).

CLINICAL SUMMARY

Clinically effective antipsychotic agents include tricyclic phenothiazines, thioxanthenes, and benzepines, as well as butyrophenones and congeners, other heterocyclics, and experimental benzamides. Virtually all of these drugs block D₂-dopamine receptors and reduce dopaminergic neurotransmission in the forebrain; some also interact with D₁, D₃, D₄, 5-HT_{2A}, 5-HT_{2C}, α , and H₁ receptors. Antipsychotic drugs are relatively lipophilic and are metabolized mainly by hepatic oxidative enzymes; some have complex elimination kinetics. These drugs offer effective symptomatic treatment of both organic and idiopathic psychotic disorders with acceptable safety and practicality. Highly potent antipsychotic

agents tend to have more adverse extrapyramidal neurological effects; less potent agents have more sedative, hypotensive, and autonomic adverse effects. For older typical or “neuroleptic” antipsychotic agents, characteristic neurological adverse effects include dystonia, akathisia, bradykinesia, tremor, and acute as well as late dyskinesias. Other antipsychotic agents (e.g., aripiprazole, clozapine, quetiapine, ziprasidone, low doses of olanzapine and risperidone) have limited extrapyramidal effects and therefore are considered “atypical.” Treatment of acute psychotic illness typically involves daily doses up to the equivalent of 10 to 20 mg of fluphenazine or haloperidol (at serum concentrations of about 5 to 20 ng/ml), 300 to 600 mg of chlorpromazine, 200 to 500 mg of clozapine, 10 to 20 mg of olanzapine, 4 to 6 mg of risperidone, or the equivalent dose of another modern agent. Higher doses usually are not more effective but they increase risks of adverse effects. Long-term maintenance treatment usually requires relatively low doses, and late loss of efficacy (tolerance) is virtually unknown.

The treatment of mania and recurrences of mania and depression in bipolar disorder have long relied on the use of lithium. Lithium has a low therapeutic index and its safe use requires close control of serum concentrations. Antipsychotic agents commonly are used to control acute mania, with or without psychotic features; some agents (e.g., olanzapine) appear to have long-term mood-stabilizing effects. Potent sedative-anticonvulsant benzodiazepines, notably clonazepam and lorazepam (see Chapter 16) are used adjunctively for rapid sedation in acute mania. Additional alternative or adjunctive treatments for mania include the anticonvulsants sodium divalproex and carbamazepine. Lamotrigine has long-term protective effects in bipolar disorder, particularly for depression. Other anticonvulsants with preliminary support for efficacy in bipolar disorder include *levetiracetam*, *oxcarbazepine*, *topiramate*, and *zonisamide* (see Chapter 19).

PHARMACOTHERAPY OF THE EPILEPSIES

James O. McNamara

The epilepsies are common and frequently devastating disorders, affecting approximately 2.5 million people in the United States alone. More than 40 distinct forms of epilepsy have been identified. Epileptic seizures often cause transient impairment of consciousness, leaving the individual at risk of bodily harm and often interfering with education and employment. Therapy is symptomatic in that available drugs inhibit seizures, but neither effective prophylaxis nor cure is available. Compliance with medication is a major problem because of the need for long-term therapy together with unwanted effects of many drugs.

The mechanisms of action of antiseizure drugs fall into three major categories. Drugs effective against the most common forms of epileptic seizures, partial and secondarily generalized tonic-clonic seizures, appear to work by one of two mechanisms. One is to limit the sustained, repetitive firing of neurons, an effect mediated by promoting the inactivated state of voltage-activated Na^+ channels. A second mechanism appears to involve enhanced γ -aminobutyric acid (GABA)-mediated synaptic inhibition, an effect mediated either by a presynaptic or postsynaptic action. Drugs effective against absence seizure, a less common form of epileptic seizure, limit activation of a particular voltage-activated Ca^{2+} channel known as the T current.

Although many treatments are available, much effort is being devoted to novel approaches. Many of these approaches center on elucidating the genetic causes and the cellular and molecular mechanisms by which a normal brain becomes epileptic, insights that promise to provide molecular targets for both symptomatic and preventive therapies.

TERMINOLOGY AND EPILEPTIC SEIZURE CLASSIFICATION

The term *seizure* refers to a transient alteration of behavior due to the disordered, synchronous, and rhythmic firing of populations of brain neurons. The term *epilepsy* refers to a disorder of brain function characterized by the periodic and unpredictable occurrence of seizures. Seizures can be “nonepileptic” when evoked in a normal brain by treatments such as electroshock or chemical convulsants or “epileptic” when occurring without evident provocation. Pharmacological agents in current clinical use inhibit seizures, and thus are referred to as antiseizure drugs. Whether any of these prevent the development of epilepsy (epileptogenesis) is uncertain.

Seizures are thought to arise from the cerebral cortex, and not from other central nervous system (CNS) structures such as the thalamus, brainstem, or cerebellum. Epileptic seizures have been classified into *partial* seizures, those beginning focally in a cortical site, and *generalized* seizures, those that involve both hemispheres widely from the outset (Commission on Classification and Terminology, 1981). The behavioral manifestations of a seizure are determined by the functions normally served by the cortical site at which the seizure arises. For example, a seizure involving motor cortex is associated with clonic jerking of the body part controlled by this region of cortex. A *simple* partial seizure is associated with preservation of consciousness. A *complex* partial seizure is associated with impairment of consciousness. The majority of complex partial seizures originate from the temporal lobe. Examples of generalized seizures include absence, myoclonic, and tonic-clonic. The type of epileptic seizure is one determinant of the drug selected for therapy. More detailed information is presented in Table 19–1.

Table 19–1
Classification of Epileptic Seizures

SEIZURE TYPE	FEATURES	CONVENTIONAL ANTISEIZURE DRUGS	RECENTLY DEVELOPED ANTISEIZURE DRUGS
<i>Partial seizures:</i>			
Simple partial	Diverse manifestations determined by the region of cortex activated by the seizure (e.g., if motor cortex representing left thumb, clonic jerking of left thumb results; if somatosensory cortex representing left thumb, paresthesia of left thumb results), lasting approximating 20 to 60 seconds. <i>Key feature is preservation of consciousness.</i>	Carbamazepine, phenytoin, valproate	Gabapentin, lamotrigine, levetiracetam, tiagabine, topiramate, zonisamide
Complex partial	Impaired consciousness lasting 30 seconds to 2 minutes, often associated with purposeless movements such as lip smacking or hand wringing.	Carbamazepine, phenytoin, valproate	Gabapentin, lamotrigine, levetiracetam, tiagabine, topiramate, zonisamide
Partial with secondarily generalized tonic-clonic seizure	Simple or complex partial seizure evolves into a tonic-clonic seizure with loss of consciousness and sustained contractions (tonic) of muscles throughout the body followed by periods of muscle contraction alternating with periods of relaxation (clonic), typically lasting 1 to 2 minutes.	Carbamazepine, phenobarbital, phenytoin, primidone, valproate	Gabapentin, lamotrigine, levetiracetam, tiagabine, topiramate, zonisamide
<i>Generalized seizures:</i>			
Absence seizure	Abrupt onset of impaired consciousness associated with staring and cessation of ongoing activities typically lasting less than 30 seconds.	Ethosuximide, valproate	Lamotrigine
Myoclonic seizure	A brief (perhaps a second), shocklike contraction of muscles which may be restricted to part of one extremity or may be generalized.	Valproate	Lamotrigine, topiramate
Tonic-clonic seizure	As described above for partial with secondarily generalized tonic-clonic seizures except that it is not preceded by a partial seizure.	Carbamazepine, phenobarbital, phenytoin, primidone, valproate	Lamotrigine, topiramate

Apart from this epileptic seizure classification, an additional classification specifies *epileptic syndromes*, which refer to a cluster of symptoms frequently occurring together and include seizure types, etiology, age of onset, and other factors (Commission on Classification and Terminology, 1989). More than 40 distinct epi-

leptic syndromes have been identified and categorized into partial *versus* generalized epilepsies. The partial epilepsies may consist of any of the partial seizure types (Table 19–1) and account for roughly 60% of all epilepsies. The etiology commonly consists of a lesion in some part of the cortex, such as a tumor, developmental

malformation, damage due to trauma or stroke, etc. Such lesions often are evident on brain magnetic resonance imaging (MRI). Alternatively, the etiology may be genetic. The generalized epilepsies are characterized most commonly by one or more of the generalized seizure types listed in Table 19–1 and account for approximately 40% of all epilepsies. The etiology is usually genetic. The most common generalized epilepsy is referred to as juvenile myoclonic epilepsy, accounting for approximately 10% of all epileptic syndromes. The age of onset is in the early teens, and the condition is characterized by myoclonic, tonic-clonic, and often absence seizures. Like most of the generalized-onset epilepsies, juvenile myoclonic epilepsy is a complex genetic disorder that is probably due to inheritance of multiple susceptibility genes; there is a familial clustering of cases, but the pattern of inheritance is not mendelian. The classification of epileptic syndromes guides clinical assessment and management, and in some instances, selection of antiseizure drugs.

NATURE AND MECHANISMS OF SEIZURES AND ANTISEIZURE DRUGS

Partial Epilepsies. More than a century ago, John Hughlings Jackson, the father of modern concepts of epilepsy, proposed that seizures were caused by “occasional, sudden, excessive, rapid and local discharges of gray matter,” and that a generalized convulsion resulted when normal brain tissue was invaded by the seizure activity initiated in the abnormal focus. This insightful proposal provided a valuable framework for thinking about mechanisms of partial epilepsy. The advent of the electroencephalogram (EEG) in the 1930s permitted the recording of electrical activity from the scalp of humans with epilepsy and demonstrated that the epilepsies are disorders of neuronal excitability.

The pivotal role of synapses in mediating communication among neurons in the mammalian brain suggested that defective synaptic function might lead to a seizure. That is, a reduction of inhibitory synaptic activity or enhancement of excitatory synaptic activity might be expected to trigger a seizure; pharmacological studies of seizures supported this notion. The neurotransmitters mediating the bulk of synaptic transmission in the mammalian brain are amino acids, with γ -aminobutyric acid (GABA) and glutamate being the principal inhibitory and excitatory neurotransmitters, respectively (see Chapter 12). Pharmacological studies disclosed that *antagonists* of the GABA_A receptor or *agonists* of different glutamate-receptor subtypes (NMDA, AMPA, or *kainic acid*) (see Chapter 12) trigger seizures in experimental animals *in vivo*. Conversely, pharmacological agents that enhance GABA-mediated synaptic inhibition suppress seizures in diverse models. Glutamate-receptor antagonists also inhibit seizures in diverse models, including seizures evoked by electroshock and chemical convulsants such as pentylenetetrazol.

Such studies support the idea that pharmacological regulation of synaptic function can regulate the propensity for seizures and

provide a framework for electrophysiological analyses aimed at elucidating the role of both synaptic and nonsynaptic mechanisms in expression of seizures and epilepsy. Progress in techniques of electrophysiology has fostered the progressive refinement of the level of analysis of seizure mechanisms from the EEG to populations of neurons (field potentials) to individual neurons to individual synapses and individual ion channels on individual neurons. Cellular electrophysiological studies of epilepsy over roughly two decades beginning in the mid-1960s were focused on elucidating the mechanisms underlying the *depolarization shift* (DS), the intracellular correlate of the “interictal spike” (Figure 19–1). The interictal (or between-seizures) spike is a sharp waveform recorded in the EEG of patients with epilepsy; it is asymptomatic in that it is accompanied by no detectable change in the patient’s behavior. The location of the interictal spike helps localize the brain region from which seizures originate in a given patient. The DS consists of a large depolarization of the neuronal membrane associated with a burst of action potentials. In most cortical neurons, the DS is generated by a large excitatory synaptic current that can be enhanced by activation of voltage-regulated intrinsic membrane currents. Although the mechanisms generating the DS are increasingly understood, it remains unclear whether the interictal spike triggers a seizure, inhibits a seizure, or is an epiphenomenon with respect to seizure occurrence in an epileptic brain. While these questions remain unanswered, study of the mechanisms of DS generation set the stage for inquiry into the cellular mechanisms of a seizure.

During the 1980s, a diversity of *in vitro* models of seizures were developed in isolated brain slice preparations, in which many synaptic connections are preserved. Electrographic events with features similar to those recorded during seizures *in vivo* have been produced in hippocampal slices by multiple methods, including altering ionic constituents of media bathing the brain slices (McNamara, 1994) such as low Ca²⁺, zero Mg²⁺, or elevated K⁺. The accessibility and experimental control provided by these preparations has permitted mechanistic investigations into the induction of seizures. Analyses of multiple *in vitro* models confirmed the importance of synaptic function in initiation of a seizure, demonstrating that subtle (*e.g.*, 20%) reductions of inhibitory synaptic function could lead to epileptiform activity and that activation of excitatory synapses could be pivotal in seizure initiation. Many other important factors were identified, including the volume of the extracellular space as well as intrinsic properties of a neuron, such as voltage-regulated ion channels including those gating K⁺, Na⁺, and Ca²⁺ ions (Traynelis and Dingledine, 1988). Identification of these diverse synaptic and nonsynaptic factors controlling seizures *in vitro* provides potential pharmacological targets for regulating seizure susceptibility *in vivo*.

Additional studies have centered on understanding the mechanisms by which a normal brain is transformed into an epileptic brain. Some common forms of partial epilepsy arise months to years after cortical injury sustained as a consequence of stroke, trauma, or other factors. An effective prophylaxis administered to patients at high risk would be highly desirable. The drugs described in this chapter provide symptomatic therapy; that is, the drugs inhibit seizures in patients with epilepsy. No effective antiepileptogenic agent has been identified.

Understanding the mechanisms of epileptogenesis in cellular and molecular terms should provide a framework for development of novel therapeutic approaches. The availability of animal models provides an opportunity to investigate the underlying mechanisms.

Figure 19–1. Relations among cortical EEG, extracellular, and intracellular recordings in a seizure focus induced by local application of a convulsant agent to mammalian cortex. The extracellular recording was made through a high-pass filter. Note the high-frequency firing of the neuron evident in both extracellular and intracellular recording during the paroxysmal depolarization shift (PDS). (Modified with permission from Ayala *et al.*, 1973.)

One model, termed “kindling,” is induced by periodic administration of brief, low-intensity electrical stimulation of the amygdala or other limbic structures. Initial stimulations evoke a brief electrical seizure recorded on the EEG without behavioral change, but repeated (*e.g.*, 10 to 20) stimulations result in progressive intensification of seizures, culminating in tonic-clonic seizures. Once established, the enhanced sensitivity to electrical stimulation persists for the life of the animal. Despite the exquisite propensity to intense seizures, spontaneous seizures or a truly epileptic condition do not occur until 100 to 200 stimulations have been administered. The ease of control of kindling induction (*i.e.*, stimulations administered at the investigator’s convenience), its graded onset, and the ease of quantitating epileptogenesis (number of stimulations required to evoke tonic-clonic seizures) simplify experimental study. In mice, deletion of the gene encoding the receptor tyrosine kinase, TrkB, prevents epileptogenesis in the kindling model (He *et al.*, 2004), which advances TrkB and its downstream signaling pathways as attractive targets for developing small molecule inhibitors for prevention of epilepsy in individuals at high risk.

Additional models are produced by induction of continuous seizures for hours (“status epilepticus”), with the inciting agent being a chemoconvulsant, such as kainic acid or *pilocarpine*, or sustained electrical stimulation. The fleeting episode of status epilepticus is followed weeks later by the onset of spontaneous seizures, an intriguing parallel to the scenario of complicated febrile seizures in

young children preceding the emergence of spontaneous seizures years later. In contrast to the limited or absent neuronal loss characteristic of the kindling model, overt destruction of hippocampal neurons occurs in the status epilepticus models, reflecting aspects of hippocampal sclerosis observed in humans with severe limbic seizures. Indeed, the recent discovery that complicated febrile seizures precede and presumably are the cause of hippocampal sclerosis in young children (VanLandingham *et al.*, 1998) establishes yet another commonality between these models and the human condition.

Several questions arise with respect to these models. What transpires during the latent period between status epilepticus and emergence of spontaneous seizures that causes the epilepsy? Might similar mechanisms be operative in kindling development and during the latent period following status epilepticus? Might an antiepileptogenic agent that was effective in one of these models be effective in other models?

Important insights into the mechanisms of action of drugs that are effective against partial seizures have emerged in the past two decades (Macdonald and Greenfield, 1997). These insights largely have emerged from electrophysiological studies of relatively simple *in vitro* models, such as neurons isolated from the mammalian CNS and maintained in primary culture. The experimental control and accessibility provided by these models—together with careful attention to clinically relevant concentrations of the drugs—led to clarification of their mechanisms. Although it is difficult to prove

unequivocally that a given drug effect observed *in vitro* is both necessary and sufficient to inhibit a seizure in an animal or human being *in vivo*, there is an excellent likelihood that the putative mechanisms identified do in fact underlie the clinically relevant antiseizure effects.

Electrophysiological analyses of individual neurons during a partial seizure demonstrate that the neurons undergo depolarization and fire action potentials at high frequencies (Figure 19–1). This pattern of neuronal firing is characteristic of a seizure and is uncommon during physiological neuronal activity. Thus, selective inhibition of this pattern of firing would be expected to reduce seizures with minimal unwanted effects. *Carbamazepine*, *lamotrigine*, *phenytoin*, and *valproic acid* inhibit high-frequency firing at concentrations known to be effective at limiting seizures in humans (Macdonald and Greenfield, 1997). Inhibition of the high-frequency firing is thought to be mediated by reducing the ability of Na^+ channels to recover from inactivation (Figure 19–2). That is, depolarization-triggered opening of the Na^+ channels in the axonal membrane of a neuron is required for an action potential; after opening, the channels spontaneously close, a process termed *inactivation*. This inactivation is thought to cause the refractory period, a short time after an action potential during which it is not possible to evoke another action potential. Upon recovery from inactivation, the Na^+ channels are again poised to participate in another action potential. Because firing at a slow rate permits sufficient time for Na^+ channels to recover from inactivation, inactivation has little or no effect on low-frequency firing. However, reducing the rate of recovery of Na^+ channels from inactivation would limit the ability of a neuron to fire at high frequencies, an effect that likely underlies the effects of carbamazepine, lamotrigine, phenytoin, *topiramate*, valproic acid, and *zonisamide* against partial seizures.

Insights into mechanisms of seizures suggest that enhancing GABA-mediated synaptic inhibition would reduce neuronal excitability and raise the seizure threshold. Several drugs are thought to inhibit seizures by regulating GABA-mediated synaptic inhibition through an action at distinct sites of the synapse (Macdonald and

Greenfield, 1997). The principal postsynaptic receptor of synaptically released GABA is termed the GABA_A receptor (*see* Chapter 16). Activation of the GABA_A receptor inhibits the postsynaptic cell by increasing the inflow of Cl^- ions into the cell, which tends to hyperpolarize the neuron. Clinically relevant concentrations of both benzodiazepines and barbiturates enhance GABA_A receptor-mediated inhibition through distinct actions on the GABA_A receptor (Figure 19–3), and this enhanced inhibition probably underlies the effectiveness of these compounds against partial and tonic-clonic seizures in humans. At higher concentrations, such as might be used for status epilepticus, these drugs also can inhibit high-frequency firing of action potentials. A second mechanism of enhancing GABA-mediated synaptic inhibition is thought to underlie the antiseizure mechanism of *tiagabine*; tiagabine inhibits the GABA transporter, GAT-1, and reduces neuronal and glial uptake of GABA (Suzdak and Jansen, 1995) (Figure 19–3).

Generalized-Onset Epilepsies: Absence Seizures.

In contrast to partial seizures, which arise from localized regions of the cerebral cortex, generalized-onset seizures arise from the reciprocal firing of the thalamus and cerebral cortex (Huguenard, 1999). Among the diverse forms of generalized seizures, absence seizures have been studied most intensively. The striking synchrony in appearance of generalized seizure discharges in widespread areas of neocortex led to the idea that a structure in the thalamus and/or brainstem (the “centrencephalon”) synchronized these seizure discharges. Focus on the thalamus in particular emerged from the demonstration that low-frequency stimulation of midline thalamic structures triggered EEG rhythms in the cortex similar to spike-and-wave discharges characteristic of absence seizures. Intracerebral electrode recordings from humans subsequently demonstrated the presence of thalamic and neocortical involvement in the spike-and-wave discharge of absence seizures.

Many of the structural and functional properties of the thalamus and neocortex that lead to the generalized spike-and-wave discharges have been elucidated (Huguenard, 1999). The EEG hallmark of an absence seizure is generalized spike-and-wave discharges at a frequency of 3 per second (3 Hz). These bilaterally synchronous spike-and-wave discharges, recorded locally from electrodes in both the thalamus and the neocortex, represent oscillations between the thalamus and neocortex. A comparison of EEG and intracellular recordings reveals that the EEG spikes are associated with the firing of action potentials and the following slow wave with prolonged inhibition. These reverberatory, low-frequency rhythms are made possible by a combination of factors, including reciprocal excitatory synaptic connections between the neocortex and thalamus as well as intrinsic properties of neurons in the thalamus (Huguenard, 1999). One intrinsic property of thalamic neurons that is pivotally involved in the generation of the 3-Hz spike-and-wave discharges is a particular form of voltage-regulated Ca^{2+} current, the low threshold (“T”) current. In contrast to its small size in most neurons, the T current in many neurons throughout the thalamus has a large amplitude. Indeed, bursts of action potentials in thalamic neurons are mediated

Figure 19–2. Antiseizure drug-enhanced Na^+ channel inactivation. Some antiseizure drugs (shown in blue text) prolong the inactivation of the Na^+ channels, thereby reducing the ability of neurons to fire at high frequencies. Note that the inactivated channel itself appears to remain open, but is blocked by the inactivation gate (I). A, activation gate.

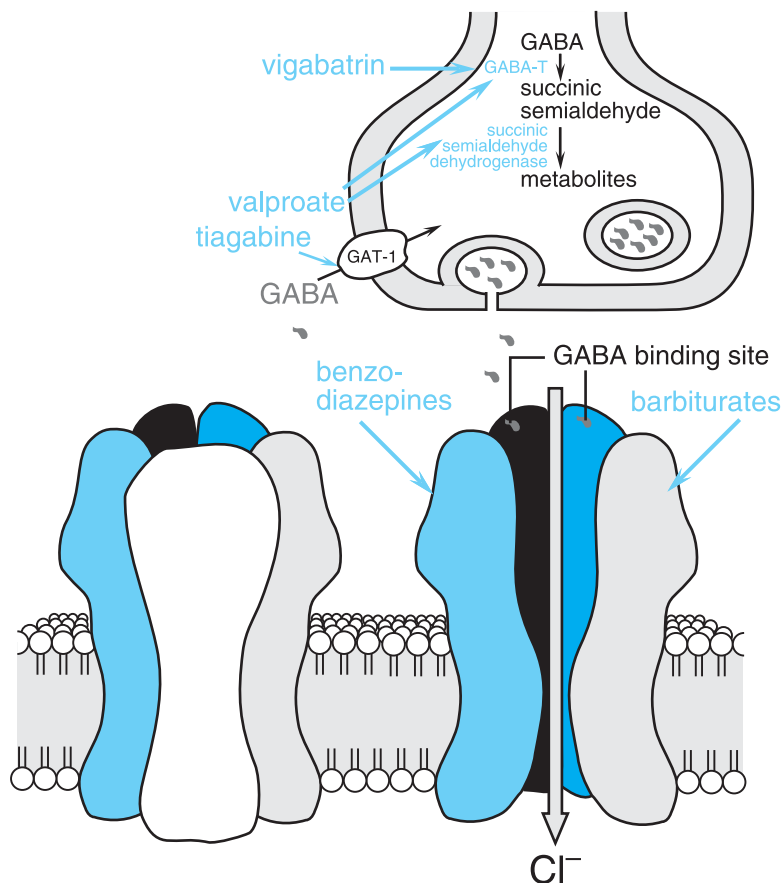

Figure 19-3. Enhanced GABA synaptic transmission. In the presence of GABA, the GABA_A receptor (structure on left) is opened, allowing an influx of Cl⁻, which in turn increases membrane polarization (see Chapter 16). Some antiseizure drugs (shown in larger blue text) act by reducing the metabolism of GABA. Others act at the GABA_A receptor, enhancing Cl⁻ influx in response to GABA. As outlined in the text, gabapentin acts presynaptically to promote GABA release; its molecular target is currently under investigation. GABA-T, GABA transaminase; GAT-1, GABA transporter.

by activation of the T current. The T current plays an amplifying role in thalamic oscillations, with one oscillation being the 3-Hz spike-and-wave discharge of the absence seizure. Importantly, the principal mechanism by which anti-absence-seizure drugs (*ethosuximide*, valproic acid) are thought to act is by inhibition of the T current (Figure 19-4) (Macdonald and Kelly, 1993). Thus, inhibiting voltage-regulated ion channels is a common mechanism of action of antiseizure drugs, with anti-partial-seizure drugs inhibiting voltage-activated Na⁺ channels and anti-absence-seizure drugs inhibiting voltage-activated Ca²⁺ channels.

Genetic Approaches to the Epilepsies. Genetic causes contribute to a wide diversity of human epilepsies. Genetic causes are solely responsible for some rare forms inherited in an autosomal dominant or autosomal recessive manner. Genetic causes also are mainly responsible for some more common forms such as juvenile myoclonic epilepsy (JME) or childhood absence epilepsy (CAE), the majority of which are likely due to inheritance of two or

Figure 19-4. Antiseizure drug-induced reduction of current through T-type Ca²⁺ channels. Some antiseizure drugs (shown in blue text) reduce the flow of Ca²⁺ through T-type Ca²⁺ channels (see Chapter 12), thus reducing the pacemaker current that underlies the thalamic rhythm in spikes and waves seen in generalized absence seizures.

more susceptibility genes. Genetic determinants also may contribute some degree of risk to epilepsies caused by injury of the cerebral cortex.

Enormous progress has been made in understanding the genetics of mammalian epilepsy. Mutant genes have been identified for a number of symptomatic epilepsies, in which the epilepsy seems to be a manifestation of some profound neurodegenerative disease. Because most patients with epilepsy are neurologically normal, elucidating the mutant genes underlying familial epilepsy in otherwise normal individuals is of particular interest; this led to the successful identification of 11 distinct genes implicated in distinct, albeit rare idiopathic epilepsy syndromes that account for less than 1% of all of the human epilepsies. Interestingly, almost all of the mutant genes encode ion channels that are gated by voltage or ligands (Scheffer and Berkovic, 2003). Mutations have been identified in voltage-gated sodium and potassium channels and in channels gated by GABA and acetylcholine. The genotype-phenotype correlations of these genetic syndromes are complex; the same mutation in one channel can be associated with divergent clinical syndromes ranging from simple febrile seizures to intractable seizures with intellectual decline. Conversely, clinically indistinguishable epilepsy syndromes have been associated with mutation of distinct genes. The implication of genes encoding ion channels in familial epilepsy is particularly interesting because episodic disorders involving other organs also result from mutations of these genes. For example, episodic disorders of the heart (cardiac arrhythmias), skeletal muscle (periodic paralyses), cerebellum (episodic ataxia), vasculature (familial hemiplegic migraine), and other organs all have been linked to mutations in genes encoding components of voltage-gated ion channels (Ptacek, 1997).

The cellular electrophysiological consequences of some of these mutations exhibit an intriguing relationship to mechanisms of seizures and antiseizure drugs. For example, generalized epilepsy with febrile seizures (GEFS+) is caused by a point mutation in the β subunit of a voltage-gated Na^+ channel (*SCN1B*). As described previously, several antiseizure drugs act on Na^+ channels to promote their inactivation; the phenotype of the mutated Na^+ channel appears to involve defective inactivation (Wallace *et al.*, 1998).

In no instance is it clear how a genotype leads to the epileptic phenotype, but the generation of mice with mutations in candidate genes should provide powerful tools with which to elucidate how the genotype produces the phenotype. The known human mutated channels, however, suggest some intriguing molecular targets for development of antiseizure drugs acting by novel mecha-

nisms. Moreover, it seems likely that many additional epilepsy genes will be identified.

ANTISEIZURE DRUGS: GENERAL CONSIDERATIONS

History. The first antiepileptic drug was *bromide*, which was used in the late nineteenth century. *Phenobarbital* was the first synthetic organic agent recognized as having antiseizure activity. Its usefulness, however, was limited to generalized tonic clonic seizures, and to a lesser degree, simple and complex partial seizures. It had no effect on absence seizures. Merritt and Putnam developed the electroshock seizure test in experimental animals to screen chemical agents for antiseizure effectiveness; in the course of screening a variety of drugs, they discovered that *diphenylhydantoin* (later renamed phenytoin) suppressed seizures in the absence of sedative effects. The electroshock seizure test is extremely valuable, because drugs that are effective against tonic hindlimb extension induced by electroshock generally have proven to be effective against partial and tonic-clonic seizures in humans. Another screening test, seizures induced by the chemoconvulsant pentylenetetrazol, is most useful in identifying drugs that are effective against myoclonic seizures in humans. These screening tests are still used. The chemical structures of most of the drugs introduced before 1965 were closely related to phenobarbital. These included the hydantoins and the succinimides. Between 1965 and 1990, the chemically distinct structures of the benzodiazepines, an iminostilbene (carbamazepine), and a branched-chain carboxylic acid (valproic acid) were introduced, followed in the 1990s by a phenyltriazine (lamotrigine), a cyclic analog of GABA (*gabapentin*), a sulfamate-substituted monosaccharide (topiramate), a nipecotic acid derivative (tiagabine), and a pyrrolidine derivative (*levetiracetam*).

Therapeutic Aspects. The ideal antiseizure drug would suppress all seizures without causing any unwanted effects. Unfortunately, the drugs used currently not only fail to control seizure activity in some patients, but frequently cause unwanted effects that range in severity from minimal impairment of the CNS to death from aplastic anemia or hepatic failure. The clinician who treats patients with epilepsy is thus faced with the task of selecting the appropriate drug or combination of drugs that best controls seizures in an individual patient at an acceptable level of untoward effects. As a general rule, complete control of seizures can be achieved in up to 50% of patients, while another 25% can be improved significantly. The degree of success varies as a function of seizure type, cause, and other factors.

To minimize toxicity, treatment with a single drug is preferred. If seizures are not controlled with the initial agent at adequate plasma concentrations, substitution of a second drug is preferred to the concurrent administration of another agent. However, multiple-drug therapy may be required, especially when two or more types of seizure occur in the same patient.

Measurement of drug concentrations in plasma facilitates optimizing antiseizure medication, especially when therapy is initiated, after dosage adjustments, in the event of therapeutic failure, when toxic effects appear, or when multiple-drug therapy is instituted. However, clinical effects of some drugs do not correlate well with their concentrations in plasma, and recommended concentrations are only guidelines for therapy. The ultimate therapeutic regimen must be determined by clinical assessment of effect and toxicity.

The general principles of the drug therapy of the epilepsies are summarized below, following discussion of the individual agents.

HYDANTOINS

Phenytoin

Phenytoin (diphenylhydantoin, DILANTIN) is effective against all types of partial and tonic-clonic seizures but not absence seizures. Properties of other hydantoin (*ethoin*, PEGANONE) are described in previous editions of this book.

History. Phenytoin was first synthesized in 1908 by Biltz, but its anticonvulsant activity was not discovered until 1938. In contrast to the earlier accidental discovery of the antiseizure properties of bromide and phenobarbital, phenytoin was the product of a search among non-sedative structural relatives of phenobarbital for agents capable of suppressing electroshock convulsions in laboratory animals. It was introduced for the treatment of epilepsy in the same year. Since this agent is not a sedative in ordinary doses, it established that antiseizure drugs need not induce drowsiness and encouraged the search for drugs with selective antiseizure action.

Structure–Activity Relationship. Phenytoin has the following structural formula:

PHENYTOIN

A 5-phenyl or other aromatic substituent appears essential for activity against generalized tonic-clonic seizures. Alkyl substituents in position 5 contribute to sedation, a property absent in phenytoin. The carbon 5 position permits asymmetry, but there appears to be little difference in activity between isomers.

Pharmacological Effects. Central Nervous System. Phenytoin exerts antiseizure activity without causing general depression of the CNS. In toxic doses, it may produce excitatory signs and at lethal levels a type of decerebrate rigidity.

The most significant effect of phenytoin is its ability to modify the pattern of maximal electroshock seizures. The characteristic tonic phase can be abolished completely, but the residual clonic seizure may be exaggerated and prolonged. This seizure-modifying action is observed with many other antiseizure drugs that are effective against generalized tonic-clonic seizures. By contrast, phenytoin does not inhibit clonic seizures evoked by pentylentetrazol.

Mechanism of Action. Phenytoin limits the repetitive firing of action potentials evoked by a sustained depolarization of mouse spinal cord neurons maintained *in vitro* (McLean and Macdonald, 1986b). This effect is mediated by a slowing of the rate of recovery of voltage-activated Na^+ channels from inactivation, an action that is both voltage- (greater effect if membrane is depolarized) and use-dependent. These effects of phenytoin are evident at concentrations in the range of therapeutic drug levels in cerebrospinal fluid (CSF) in humans, which correlate with the free (or unbound) concentration of phenytoin in the serum. At these concentrations, the effects on Na^+ channels are selective, and no changes of spontaneous activity or responses to iontophoretically applied GABA or glutamate are detected. At concentrations five- to tenfold higher, multiple effects of phenytoin are evident, including reduction of spontaneous activity and enhancement of responses to GABA; these effects may underlie some of the unwanted toxicity associated with high levels of phenytoin.

Pharmacokinetic Properties. Phenytoin is available in two types of oral formulations that differ in their pharmacokinetics: rapid-release and extended-release forms. Once-daily dosing is possible only with the extended-release formulations, and due to differences in dissolution and other formulation-dependent factors, the plasma phenytoin level may change when converting from one formulation to another. Confusion also can arise because different formulations can include either phenytoin or phenytoin sodium. Therefore, comparable doses can be approximated by considering “phenytoin equivalents,” but serum level monitoring is also necessary to assure therapeutic safety.

The pharmacokinetic characteristics of phenytoin are influenced markedly by its binding to serum proteins, by the nonlinearity of its elimination kinetics, and by its metabolism by CYPs. Phenytoin is extensively bound (about 90%) to serum proteins, mainly albumin. Small variations in the percentage of phenytoin that is bound dramatically affect the absolute amount of free (active) drug; increased proportions of free drug are evident in the neonate, in patients with hypoalbuminemia, and in uremic patients. Some agents, such as *valproate*, can compete with phenytoin for binding sites on plasma proteins; when combined with valproate-mediated inhibition of phenytoin metabolism, marked increases in free phenytoin can

result. Measurement of free rather than total phenytoin permits direct assessment of this potential problem in patient management.

Phenytoin is one of the few drugs for which the rate of elimination varies as a function of its concentration (*i.e.*, the rate is nonlinear). The plasma half-life of phenytoin ranges between 6 and 24 hours at plasma concentrations below 10 $\mu\text{g/ml}$ but increases with higher concentrations; as a result, plasma drug concentration increases disproportionately as dosage is increased, even with small adjustments for levels near the therapeutic range.

The majority (95%) of phenytoin is metabolized principally in the hepatic endoplasmic reticulum by CYP2C9/10 and to a lesser extent CYP2C19 (Table 19–2). The principal metabolite, a parahydroxyphenyl derivative, is inactive. Because its metabolism is saturable, other drugs that are metabolized by these enzymes can inhibit the metabolism of phenytoin and increase its plasma concentration. Conversely, the degradation rate of other drugs that are substrates for these enzymes can be inhibited by phenytoin; one such drug is *warfarin*, and addition of phenytoin to a patient receiving *warfarin* can lead to bleeding disorders (*see* Chapter 54). An alternative mechanism of drug interactions arises from phenytoin's ability to induce diverse CYPs (*see* Chapter 3); coadministration of phenytoin and medications metabolized by these enzymes can lead to an

increased degradation of such medications. Of particular note in this regard are oral contraceptives, which are metabolized by CYP3A4; treatment with phenytoin could enhance the metabolism of oral contraceptives and lead to unplanned pregnancy. The potential teratogenic effects of phenytoin underscore the importance of attention to this interaction. Carbamazepine, *oxcarbazepine*, phenobarbital, and *primidone* also can induce CYP3A4 and likewise might increase degradation of oral contraceptives.

The low aqueous solubility of phenytoin hindered its intravenous use and led to production of *fosphenytoin*, a water-soluble prodrug. Fosphenytoin (CEREBYX) is converted into phenytoin by phosphatases in liver and red blood cells with a half-life of 8 to 15 minutes. Fosphenytoin is extensively bound (95% to 99%) to human plasma proteins, primarily albumin. This binding is saturable and fosphenytoin displaces phenytoin from protein binding sites. Fosphenytoin is useful for adults with partial or generalized seizures when intravenous or intramuscular administration is indicated.

Toxicity. The toxic effects of phenytoin depend on the route of administration, the duration of exposure, and the dosage.

When fosphenytoin, the water-soluble prodrug, is administered intravenously at an excessive rate in the emergency treat-

ment of status epilepticus, the most notable toxic signs are cardiac arrhythmias, with or without hypotension, and/or CNS depression. Although cardiac toxicity occurs more frequently in older patients and in those with known cardiac disease, it also can develop in young, healthy patients. These complications can be minimized by administering fosphenytoin at a rate of less than 150 mg of phenytoin sodium equivalents per minute, a rate that therefore should not be exceeded. Acute oral overdosage results primarily in signs referable to the cerebellum and vestibular system; high doses have been associated with marked cerebellar atrophy. Toxic effects associated with chronic treatment also are primarily dose-related cerebellar-vestibular effects but also include other CNS effects, behavioral changes, increased frequency of seizures, gastrointestinal symptoms, gingival hyperplasia, osteomalacia, and megaloblastic anemia. Hirsutism is an annoying untoward effect in young females. Usually, these phenomena can be diminished by proper adjustment of dosage. Serious adverse effects, including those on the skin, bone marrow, and liver, probably are manifestations of drug allergy. Although rare, they necessitate withdrawal of the drug. Moderate elevation of the plasma concentrations of hepatic transaminases sometimes are observed; since these changes are transient and may result in part from induced synthesis of the enzymes, they do not necessitate withdrawal of the drug.

Gingival hyperplasia occurs in about 20% of all patients during chronic therapy and is probably the most common manifestation of phenytoin toxicity in children and young adolescents. It may be more frequent in those individuals who also develop coarsened facial features. The overgrowth of tissue appears to involve altered collagen metabolism. Toothless portions of the gums are not affected. The condition does not necessarily require withdrawal of medication and can be minimized by good oral hygiene.

A variety of endocrine effects have been reported. Inhibition of release of antidiuretic hormone (ADH) has been observed in patients with inappropriate ADH secretion. Hyperglycemia and glycosuria appear to be due to inhibition of insulin secretion. Osteomalacia, with hypocalcemia and elevated alkaline phosphatase activity, has been attributed to both altered metabolism of vitamin D and the attendant inhibition of intestinal absorption of Ca^{2+} . Phenytoin also increases the metabolism of vitamin K and reduces the concentration of vitamin K–dependent proteins that are important for normal Ca^{2+} metabolism in bone. This may explain why the osteomalacia is not always ameliorated by the administration of vitamin D.

Hypersensitivity reactions include morbilliform rash in 2% to 5% of patients and occasionally more serious skin reactions, including Stevens-Johnson syndrome. Systemic lupus erythematosus and potentially fatal hepatic necrosis have been reported rarely. Hematological reactions include neutropenia and leukopenia. A few instances of red-cell aplasia, agranulocytosis, and mild thrombocytopenia also have been reported. Lymphadenopathy, resembling Hodgkin's disease and malignant lymphoma, is associated with reduced immunoglobulin A (IgA) production. Hypoprothrombinemia and hemorrhage have occurred in the newborns of mothers who received phenytoin during pregnancy; vitamin K is effective treatment or prophylaxis.

Plasma Drug Concentrations. A good correlation usually is observed between the total concentration of phenytoin in plasma and its clinical effect. Thus, control of seizures generally is obtained with con-

centrations above 10 $\mu\text{g/ml}$, while toxic effects such as nystagmus develop at concentrations around 20 $\mu\text{g/ml}$.

Drug Interactions. Concurrent administration of any drug metabolized by CYP2C9 or CYP2C10 can increase the plasma concentration of phenytoin by decreasing its rate of metabolism. Carbamazepine, which may enhance the metabolism of phenytoin, causes a well-documented *decrease* in phenytoin concentration. Conversely, phenytoin reduces the concentration of carbamazepine. Interaction between phenytoin and phenobarbital is variable.

Therapeutic Uses. Epilepsy. Phenytoin is one of the more widely used antiseizure agents, and it is effective against partial and tonic-clonic but not absence seizures. The use of phenytoin and other agents in the therapy of epilepsies is discussed further at the end of this chapter. Phenytoin preparations differ significantly in bioavailability and rate of absorption. In general, patients should consistently be treated with the same drug from a single manufacturer. However, if it becomes necessary to temporarily switch between products, care should be taken to select a therapeutically equivalent product and patients should be monitored for loss of seizure control or onset of new toxicities.

Other Uses. Some cases of trigeminal and related neuralgias appear to respond to phenytoin, but carbamazepine may be preferable. The use of phenytoin in the treatment of cardiac arrhythmias is discussed in Chapter 34.

ANTISEIZURE BARBITURATES

The pharmacology of the barbiturates as a class is considered in Chapter 16; discussion in this chapter is limited to the two barbiturates used for therapy of the epilepsies.

Phenobarbital

Phenobarbital (LUMINAL, others) was the first effective organic antiseizure agent. It has relatively low toxicity, is inexpensive, and is still one of the more effective and widely used drugs for this purpose.

Structure–Activity Relationship. The structural formula of phenobarbital (5-phenyl-5-ethylbarbituric acid) is shown in Chapter 16. The structure–activity relationships of the barbiturates have been studied extensively. Maximal antiseizure activity is obtained when one substituent at carbon 5 position is a phenyl group. The 5,5-diphenyl derivative has less antiseizure potency than does phenobarbital, but it is virtually devoid of hypnotic activity. By contrast, 5,5-dibenzyl barbituric acid causes convulsions.

Antiseizure Properties. Most barbiturates have antiseizure properties. However, only some of these agents, such

as phenobarbital, exert maximal antiseizure action at doses below those required for hypnosis, which determines their clinical utility as antiseizure agents. Phenobarbital is active in most antiseizure tests in animals but is relatively nonselective. It inhibits tonic hindlimb extension in the maximal electroshock model, clonic seizures evoked by pentylenetetrazol, and kindled seizures.

Mechanism of Action. The mechanism by which phenobarbital inhibits seizures likely involves potentiation of synaptic inhibition through an action on the GABA_A receptor. Intracellular recordings of mouse cortical or spinal cord neurons demonstrated that phenobarbital enhances responses to iontophoretically applied GABA. These effects have been observed at therapeutically relevant concentrations of phenobarbital. Analyses of single channels in outside-out patches isolated from mouse spinal cord neurons demonstrated that phenobarbital increased the GABA_A receptor-mediated current by increasing the duration of bursts of GABA_A receptor-mediated currents without changing the frequency of bursts (Twyman *et al.*, 1989). At levels exceeding therapeutic concentrations, phenobarbital also limits sustained repetitive firing; this may underlie some of the antiseizure effects of higher concentrations of phenobarbital achieved during therapy of status epilepticus.

Pharmacokinetic Properties. Oral absorption of phenobarbital is complete but somewhat slow; peak concentrations in plasma occur several hours after a single dose. It is 40% to 60% bound to plasma proteins and bound to a similar extent in tissues, including brain. Up to 25% of a dose is eliminated by pH-dependent renal excretion of the unchanged drug; the remainder is inactivated by hepatic microsomal enzymes, principally CYP2C9, with minor metabolism by CYP2C19 and CYP2E1. Phenobarbital induces uridine diphosphate-glucuronosyltransferase (UGT) enzymes as well as the CYP2C and CYP3A subfamilies. Drugs metabolized by these enzymes can be more rapidly degraded when coadministered with phenobarbital; importantly, oral contraceptives are metabolized by CYP3A4.

Toxicity. Sedation, the most frequent undesired effect of phenobarbital, is apparent to some extent in all patients upon initiation of therapy, but tolerance develops during chronic medication. Nystagmus and ataxia occur at excessive dosage. Phenobarbital sometimes produces irritability and hyperactivity in children, and agitation and confusion in the elderly.

Scarlatiniform or morbilliform rash, possibly with other manifestations of drug allergy, occurs in 1% to 2% of patients. Exfoliative dermatitis is rare. Hypoprothrombinemia with hemorrhage has been observed in the newborns of mothers who have received phenobarbital during pregnancy; vitamin K is effective for treatment or prophylaxis. As with phenytoin, megaloblastic anemia that responds

to folate and osteomalacia that responds to high doses of vitamin D occur during chronic phenobarbital therapy of epilepsy. Other adverse effects of phenobarbital are discussed in Chapter 16.

Plasma Drug Concentrations. During long-term therapy in adults, the plasma concentration of phenobarbital averages 10 $\mu\text{g/ml}$ per daily dose of 1 mg/kg; in children, the value is 5 to 7 $\mu\text{g/ml}$ per 1 mg/kg. Although a precise relationship between therapeutic results and concentration of drug in plasma does not exist, plasma concentrations of 10 to 35 $\mu\text{g/ml}$ are usually recommended for control of seizures.

The relationship between plasma concentration of phenobarbital and adverse effects varies with the development of tolerance. Sedation, nystagmus, and ataxia usually are absent at concentrations below 30 $\mu\text{g/ml}$ during long-term therapy, but adverse effects may be apparent for several days at lower concentrations when therapy is initiated or whenever the dosage is increased. Concentrations greater than 60 $\mu\text{g/ml}$ may be associated with marked intoxication in the nontolerant individual.

Since significant behavioral toxicity may be present despite the absence of overt signs of toxicity, the tendency to maintain patients, particularly children, on excessively high doses of phenobarbital should be resisted. The plasma phenobarbital concentration should be increased above 30 to 40 $\mu\text{g/ml}$ only if the increment is adequately tolerated and only if it contributes significantly to control of seizures.

Drug Interactions. Interactions between phenobarbital and other drugs usually involve induction of the hepatic CYPs by phenobarbital (*see* Chapters 3 and 16). The variable interaction with phenytoin has been discussed above. Concentrations of phenobarbital in plasma may be elevated by as much as 40% during concurrent administration of valproic acid (*see* below).

Therapeutic Uses. Phenobarbital is an effective agent for generalized tonic-clonic and partial seizures. Its efficacy, low toxicity, and low cost make it an important agent for these types of epilepsy. However, its sedative effects and its tendency to disturb behavior in children have reduced its use as a primary agent.

Mephobarbital (MEBARAL) is *N*-methylphenobarbital. It is *N*-demethylated in the hepatic endoplasmic reticulum, and most of its activity during long-term therapy can be attributed to the accumulation of phenobarbital. Consequently, the pharmacological properties, toxicity, and clinical uses of mephobarbital are the same as those for phenobarbital.

IMINOSTILBENES

Carbamazepine

Carbamazepine (TEGRETOL, CARBATROL, others) was initially approved in the United States for use as an antiseizure

zure agent in 1974. It has been employed since the 1960s for the treatment of trigeminal neuralgia. It is now considered to be a primary drug for the treatment of partial and tonic-clonic seizures.

Chemistry. Carbamazepine is related chemically to the tricyclic antidepressants. It is a derivative of iminostilbene with a carbamyl group at the 5 position; this moiety is essential for potent antiseizure activity. The structural formula of carbamazepine is:

Pharmacological Effects. Although the effects of carbamazepine in animals and humans resemble those of phenytoin in many ways, the two drugs exhibit important differences. Carbamazepine has been found to produce therapeutic responses in manic-depressive patients, including some in whom lithium carbonate is not effective. Further, carbamazepine has antidiuretic effects that are sometimes associated with reduced concentrations of antidiuretic hormone (ADH) in plasma. The mechanisms responsible for these effects of carbamazepine are not clearly understood.

Mechanism of Action. Like phenytoin, carbamazepine limits the repetitive firing of action potentials evoked by a sustained depolarization of mouse spinal cord or cortical neurons maintained *in vitro* (McLean and Macdonald, 1986b). This appears to be mediated by a slowing of the rate of recovery of voltage-activated Na⁺ channels from inactivation. These effects of carbamazepine are evident at concentrations in the range of therapeutic drug levels in CSF in humans. The effects of carbamazepine are selective at these concentrations, in that there are no effects on spontaneous activity or on responses to iontophoretically applied GABA or glutamate. The carbamazepine metabolite, 10,11-epoxycarbamazepine, also limits sustained repetitive firing at therapeutically relevant concentrations, suggesting that this metabolite may contribute to the antiseizure efficacy of carbamazepine.

Pharmacokinetic Properties. The pharmacokinetics of carbamazepine are complex. They are influenced by its limited aqueous solubility and by the ability of many antiseizure drugs, including carbamazepine itself, to increase their conversion to active metabolites by hepatic oxidative enzymes.

Carbamazepine is absorbed slowly and erratically after oral administration. Peak concentrations in plasma usually are observed 4 to 8 hours after oral ingestion, but may be delayed by as much as 24 hours, especially following the administration of a large dose. The drug distributes rapidly into all tissues. Approximately 75% of carbamazepine binds to plasma proteins and concentrations in the CSF appear to correspond to the concentration of free drug in plasma.

The predominant pathway of metabolism in humans involves conversion to the 10,11-epoxide. This metabolite is as active as the parent compound in various animals, and its concentrations in plasma and brain may reach 50% of those of carbamazepine, especially during the concurrent administration of phenytoin or phenobarbital. The 10,11-epoxide is metabolized further to inactive compounds, which are excreted in the urine principally as glucuronides. Carbamazepine also is inactivated by conjugation and hydroxylation. Hepatic CYP3A4 is primarily responsible for biotransformation of carbamazepine. Carbamazepine induces CYP2C, CYP3A, and UGT, thus enhancing the metabolism of drugs degraded by these enzymes. Of particular importance in this regard are oral contraceptives, which are also metabolized by CYP3A4.

Toxicity. Acute intoxication with carbamazepine can result in stupor or coma, hyperirritability, convulsions, and respiratory depression. During long-term therapy, the more frequent untoward effects of the drug include drowsiness, vertigo, ataxia, diplopia, and blurred vision. The frequency of seizures may increase, especially with overdosage. Other adverse effects include nausea, vomiting, serious hematological toxicity (aplastic anemia, agranulocytosis), and hypersensitivity reactions (dermatitis, eosinophilia, lymphadenopathy, splenomegaly). A late complication of therapy with carbamazepine is retention of water, with decreased osmolality and concentration of Na⁺ in plasma, especially in elderly patients with cardiac disease.

Some tolerance develops to the neurotoxic effects of carbamazepine, and they can be minimized by gradual increase in dosage or adjustment of maintenance dosage. Various hepatic or pancreatic abnormalities have been reported during therapy with carbamazepine, most commonly a transient elevation of hepatic transaminases in plasma in 5% to 10% of patients. A transient, mild leukopenia occurs in about 10% of patients during initiation of therapy and usually resolves within the first 4 months of continued treatment; transient thrombocytopenia also has been noted. In about 2% of patients, a persistent leukopenia may develop that requires withdrawal of the drug. The initial concern that aplastic anemia might be a frequent complication of long-term therapy with carbamazepine has not materialized. In most cases, the administration of multiple drugs or the presence of another underlying disease has made it difficult to establish a causal relationship. In any event, the prevalence of aplastic anemia appears to be about 1 in 200,000 patients who are treated with the drug. It is not clear whether

monitoring of hematological function can avert the development of irreversible aplastic anemia. Although carbamazepine is carcinogenic in rats, it is not known to be carcinogenic in humans. The induction of fetal malformations during the treatment of pregnant women is discussed below.

Plasma Drug Concentrations. There is no simple relationship between the dose of carbamazepine and concentrations of the drug in plasma. Therapeutic concentrations are reported to be 6 to 12 $\mu\text{g/ml}$, although considerable variation occurs. Side effects referable to the CNS are frequent at concentrations above 9 $\mu\text{g/ml}$.

Drug Interactions. Phenobarbital, phenytoin, and valproate may increase the metabolism of carbamazepine by inducing CYP3A4; carbamazepine may enhance the biotransformation of phenytoin. Concurrent administration of carbamazepine may lower concentrations of valproate, lamotrigine, tiagabine, and topiramate. Carbamazepine reduces both the plasma concentration and therapeutic effect of *haloperidol*. The metabolism of carbamazepine may be inhibited by *propoxyphene*, *erythromycin*, *cimetidine*, *fluoxetine*, and *isoniazid*.

Therapeutic Uses. Carbamazepine is useful in patients with generalized tonic-clonic and both simple and complex partial seizures. When it is used, renal and hepatic function and hematological parameters should be monitored. The therapeutic use of carbamazepine is discussed further at the end of this chapter.

Carbamazepine was introduced by Blom in the early 1960s and is now the primary agent for treatment of trigeminal and glossopharyngeal neuralgias. It is also effective for lightning tabetic pain associated with bodily wasting. Most patients with neuralgia benefit initially, but only 70% obtain continuing relief. Adverse effects have required discontinuation of medication in 5% to 20% of patients. The therapeutic range of plasma concentrations for antiseizure therapy serves as a guideline for its use in neuralgia. Carbamazepine also has found use in the treatment of bipolar affective disorders, as discussed further in Chapter 18.

Oxcarbazepine

Oxcarbazepine (TRILEPTAL) (10,11-dihydro-10-oxocarbamazepine) is a keto analog of carbamazepine. Oxcarbazepine functions as a prodrug, in that it is almost immediately converted to its main active metabolite, a 10-monohydroxy derivative, which is inactivated by glucuronide conjugation and eliminated by renal excretion. Its mechanism of action is similar to that of carbamazepine. Oxcarbazepine is a less potent enzyme inducer than is carbamazepine, and substitution of oxcarbazepine for carbamazepine is associated with increased levels of

phenytoin and valproic acid, presumably because of reduced induction of hepatic enzymes. Oxcarbazepine does not induce the hepatic enzymes involved in its own degradation. Although oxcarbazepine does not appear to reduce the anticoagulant effect of warfarin, it does induce CYP3A and thus reduces plasma levels of steroid oral contraceptives. It has been approved for monotherapy or adjunct therapy for partial seizures in adults and as adjunctive therapy for partial seizures in children ages 4 to 16.

SUCCINIMIDES

Ethosuximide

Ethosuximide (ZARONTIN) is a primary agent for the treatment of absence seizures.

Structure–Activity Relationship. Ethosuximide has the following structural formula:

The structure–activity relationship of the succinimides is in accord with that for other antiseizure classes. *Methsuximide* (CELONTIN) has phenyl substituents and is more active against maximal electroshock seizures. It is no longer in common use. Discussion of its properties can be found in previous editions of this book. Ethosuximide, with alkyl substituents, is the most active of the succinimides against seizures induced by pentylenetetrazol and is the most selective for absence seizures.

Pharmacological Effects. The most prominent characteristic of ethosuximide at nontoxic doses is protection against clonic motor seizures induced by pentylenetetrazol. By contrast, at nontoxic doses ethosuximide does not inhibit tonic hindlimb extension of electroshock seizures or kindled seizures. This profile correlates with efficacy against absence seizures in humans.

Mechanism of Action. Ethosuximide reduces low threshold Ca^{2+} currents (T currents) in thalamic neurons (Coulter *et al.*, 1989). The thalamus plays an important role in generation of 3-Hz spike-and-wave rhythms typical of absence seizures (Coulter, 1998). Neurons in the thalamus exhibit a large-amplitude T-current spike that underlies bursts of action potentials and likely plays an important role in thalamic oscillatory activity such as 3-

Hz spike-and-wave activity. At clinically relevant concentrations, ethosuximide inhibits the T current, as is evident in voltage-clamp recordings of acutely isolated, ventrobasal thalamic neurons from rats and guinea pigs. Ethosuximide reduces this current without modifying the voltage dependence of steady-state inactivation or the time course of recovery from inactivation. By contrast, succinimide derivatives with convulsant properties do not inhibit this current. Ethosuximide does not inhibit sustained repetitive firing or enhance GABA responses at clinically relevant concentrations. Current data are consistent with the idea that inhibition of T currents is the mechanism by which ethosuximide inhibits absence seizures.

Pharmacokinetic Properties. Absorption of ethosuximide appears to be complete, with peak concentrations in plasma within about 3 hours after a single oral dose. Ethosuximide is not significantly bound to plasma proteins; during long-term therapy, its concentration in the CSF is similar to that in plasma. The apparent volume of distribution averages 0.7 L/kg.

Approximately 25% of the drug is excreted unchanged in the urine. The remainder is metabolized by hepatic microsomal enzymes, but whether CYPs are responsible is unknown. The major metabolite, the hydroxyethyl derivative, accounts for about 40% of administered drug, is inactive, and is excreted as such and as the glucuronide in the urine. The plasma half-life of ethosuximide averages between 40 and 50 hours in adults and approximately 30 hours in children.

Toxicity. The most common dose-related side effects are gastrointestinal complaints (nausea, vomiting, and anorexia) and CNS effects (drowsiness, lethargy, euphoria, dizziness, headache, and hiccough). Some tolerance to these effects develops. Parkinsonlike symptoms and photophobia also have been reported. Restlessness, agitation, anxiety, aggressiveness, inability to concentrate, and other behavioral effects have occurred primarily in patients with a prior history of psychiatric disturbance.

Urticaria and other skin reactions, including Stevens-Johnson syndrome, as well as systemic lupus erythematosus, eosinophilia, leukopenia, thrombocytopenia, pancytopenia, and aplastic anemia also have been attributed to the drug. The leukopenia may be transient despite continuation of the drug, but several deaths have resulted from bone marrow depression. Renal or hepatic toxicity has not been reported.

Plasma Drug Concentrations. During long-term therapy, the plasma concentration of ethosuximide averages

about 2 $\mu\text{g/ml}$ per daily dose of 1 mg/kg. A plasma concentration of 40 to 100 $\mu\text{g/ml}$ usually is required for satisfactory control of absence seizures.

Therapeutic Uses. Ethosuximide is effective against absence seizures but not tonic-clonic seizures.

An initial daily dose of 250 mg in children (3 to 6 years old) and 500 mg in older children and adults is increased by 250-mg increments at weekly intervals until seizures are adequately controlled or toxicity intervenes. Divided dosage is required occasionally to prevent nausea or drowsiness associated with once-daily dosing. The usual maintenance dose is 20 mg/kg per day. Increased caution is required if the daily dose exceeds 1500 mg in adults or 750 to 1000 mg in children. The use of ethosuximide and the other antiseizure agents is discussed further at the end of the chapter.

VALPROIC ACID

The antiseizure properties of valproic acid (DEPAKENE, others) were discovered serendipitously when it was employed as a vehicle for other compounds that were being screened for antiseizure activity.

Chemistry. Valproic acid (*n*-dipropylacetic acid) is a simple branched-chain carboxylic acid; its structural formula is:

Certain other branched-chain carboxylic acids have potencies similar to that of valproic acid in antagonizing pentylenetetrazol-induced convulsions. However, increasing the number of carbon atoms to nine introduces marked sedative properties. Straight-chain acids have little or no activity.

Pharmacological Effects. Valproic acid is strikingly different from phenytoin or ethosuximide in that it is effective in inhibiting seizures in a variety of models. Like phenytoin and carbamazepine, valproate inhibits tonic hindlimb extension in maximal electroshock seizures and kindled seizures at nontoxic doses. Like ethosuximide, valproic acid at subtoxic doses inhibits clonic motor seizures induced by pentylenetetrazol. Its efficacy in diverse models parallels its efficacy against absence as well as partial and generalized tonic-clonic seizures in humans.

Mechanism of Action. Valproic acid produces effects on isolated neurons similar to those of phenytoin and ethosuximide. At thera-

apeutically relevant concentrations, valproate inhibits sustained repetitive firing induced by depolarization of mouse cortical or spinal cord neurons (McLean and Macdonald, 1986a). The action is similar to that of both phenytoin and carbamazepine and appears to be mediated by a prolonged recovery of voltage-activated Na^+ channels from inactivation. Valproic acid does not modify neuronal responses to iontophoretically applied GABA. In neurons isolated from the nodose ganglion, valproate also produces small reductions of the low-threshold (T) Ca^{2+} current (Kelly *et al.*, 1990) at clinically relevant but slightly higher concentrations than those that limit sustained repetitive firing; this effect on T currents is similar to that of ethosuximide in thalamic neurons (Coulter *et al.*, 1989). Together, these actions of limiting sustained repetitive firing and reducing T currents may contribute to the effectiveness of valproic acid against partial and tonic-clonic seizures and absence seizures, respectively.

Another potential mechanism that may contribute to valproate's antiseizure actions involves metabolism of GABA. Although valproate has no effect on responses to GABA, it does increase the amount of GABA that can be recovered from the brain after the drug is administered to animals. *In vitro*, valproate can stimulate the activity of the GABA synthetic enzyme, glutamic acid decarboxylase, and inhibit GABA degradative enzymes, GABA transaminase and succinic semialdehyde dehydrogenase. Thus far it has been difficult to relate the increased GABA levels to the antiseizure activity of valproate.

Pharmacokinetic Properties. Valproic acid is absorbed rapidly and completely after oral administration. Peak concentration in plasma is observed in 1 to 4 hours, although this can be delayed for several hours if the drug is administered in enteric-coated tablets or is ingested with meals. The apparent volume of distribution for valproate is about 0.2 L/kg. Its extent of binding to plasma proteins is usually about 90%, but the fraction bound is reduced as the total concentration of valproate is increased through the therapeutic range. Although concentrations of valproate in CSF suggest equilibration with free drug in the blood, there is evidence for carrier-mediated transport of valproate both into and out of the CSF.

The vast majority of valproate (95%) undergoes hepatic metabolism, with less than 5% excreted unchanged in urine. Its hepatic metabolism occurs mainly by UGT enzymes and β -oxidation. Valproate is a substrate for CYP2C9 and CYP2C19, but metabolism by these enzymes accounts for a relatively minor portion of its elimination. Some of the drug's metabolites, notably 2-propyl-2-pentenoic acid and 2-propyl-4-pentenoic acid, are nearly as potent antiseizure agents as the parent compound; however, only the former (2-en-valproic acid) accumulates in plasma and brain to a potentially significant extent. The half-life of valproate is approximately 15 hours but is reduced in patients taking other antiepileptic drugs.

Toxicity. The most common side effects are transient gastrointestinal symptoms, including anorexia, nausea, and vomiting in about 16% of patients. Effects on the CNS include sedation, ataxia, and tremor; these symptoms occur infrequently and usually respond to a decrease in dosage. Rash, alopecia, and stimulation of appetite have been observed occasionally and weight gain has been seen with chronic valproic acid treatment in some patients. Valproic acid has several effects on hepatic function. Elevation of hepatic transaminases in plasma is observed in up to 40% of patients and often occurs asymptotically during the first several months of therapy.

A rare complication is a fulminant hepatitis that is frequently fatal (Dreifuss *et al.*, 1989). Pathological examination reveals a microvesicular steatosis without evidence of inflammation or hypersensitivity reaction. Children below 2 years of age with other medical conditions who were given multiple antiseizure agents were especially likely to suffer fatal hepatic injury. At the other extreme, there were no deaths reported for patients over the age of 10 years who received only valproate. Acute pancreatitis and hyperammonemia also have been frequently associated with the use of valproic acid. Valproic acid can also produce teratogenic effects such as neural tube defects.

Plasma Drug Concentrations. The concentration of valproate in plasma that is associated with therapeutic effects is approximately 30 to 100 $\mu\text{g}/\text{ml}$. However, there is a poor correlation between the plasma concentration and efficacy. There appears to be a threshold at about 30 to 50 $\mu\text{g}/\text{ml}$; this is the concentration at which binding sites on plasma albumin begin to become saturated.

Drug Interactions. Valproate primarily inhibits the metabolism of drugs that are substrates for CYP2C9, including phenytoin and phenobarbital. Valproate also inhibits UGT and thus inhibits the metabolism of lamotrigine and lorazepam. A high proportion of valproate is bound to albumin, and the high molar concentrations of valproate in the clinical setting result in valproate's displacing phenytoin and other drugs from albumin. With respect to phenytoin in particular, valproate's inhibition of the drug's metabolism is exacerbated by displacement of phenytoin from albumin. The concurrent administration of valproate and *clonazepam* has been associated with the development of absence status epilepticus; however, this complication appears to be rare.

Therapeutic Uses. Valproate is effective in the treatment of absence, myoclonic, partial, and tonic-clonic seizures. The initial daily dose usually is 15 mg/kg, increased at weekly intervals by 5 to 10 mg/kg per day to a maximum daily dose of 60 mg/kg. Divided doses should be given when the total daily dose exceeds 250 mg. The therapeutic uses of valproate in epilepsy are discussed further at the end of this chapter.

BENZODIAZEPINES

The benzodiazepines are employed clinically primarily as sedative-anxiety drugs; their pharmacology is described in Chapters 16 and 17. Discussion here is limited to consideration of their usefulness in the therapy of the epilepsies. A large number of benzodiazepines have broad antiseizure properties, but only clonazepam (KLONOPIN) and *clorazepate* (TRANXENE-SD, others) have been approved in the United States for the long-term treatment of certain types of seizures. *Diazepam* (VALIUM, DIASTAT; others) and *lorazepam* (ATIVAN) have well-defined roles in the management of status epilepticus. The structures of the benzodiazepines are shown in Chapter 16.

Antiseizure Properties. In animals, prevention of pentylenetetrazol-induced seizures by the benzodiazepines is much more prominent than is their modification of the maximal electroshock seizure pattern. Clonazepam is unusually potent in antagonizing the effects of pentylenetetrazol, but it is almost without action on seizures induced by maximal electroshock. Benzodiazepines, including clonazepam, suppress the spread of kindled seizures and generalized convulsions produced by stimulation of the amygdala, but do not abolish the abnormal discharge at the site of stimulation.

Mechanism of Action. The antiseizure actions of the benzodiazepines, as well as other effects that occur at nonsedating doses, result in large part from their ability to enhance GABA-mediated synaptic inhibition. Molecular cloning and study of recombinant receptors have demonstrated that the benzodiazepine receptor is an integral part of the GABA_A receptor (see Chapter 16). At therapeutically relevant concentrations, benzodiazepines act at subsets of GABA_A receptors and increase the frequency, but not duration, of openings at GABA-activated Cl⁻ channels (Twyman *et al.*, 1989). At higher concentrations, diazepam and many other benzodiazepines can reduce sustained high-frequency firing of neurons, similar to the effects of phenytoin, carbamazepine, and valproate. Although these concentrations correspond to concentrations achieved in patients during treatment of status epilepticus with diazepam, they are considerably higher than those associated with antiseizure or anxiolytic effects in ambulatory patients.

Pharmacokinetic Properties. Benzodiazepines are well absorbed after oral administration, and concentrations in plasma are usually maximal within 1 to 4 hours. After intravenous administration, they are redistributed in a manner typical of that for highly lipid-soluble agents (see Chapter 1). Central effects develop promptly, but wane rapidly as the drugs move to other tissues. Diazepam is redistributed especially rapidly, with a half-life of redistribution of about 1 hour. The extent of

binding of benzodiazepines to plasma proteins correlates with lipid solubility, ranging from approximately 99% for diazepam to about 85% for clonazepam (see Appendix II).

The major metabolite of diazepam, *N*-desmethyl-diazepam, is somewhat less active than the parent drug and may behave as a partial agonist. This metabolite also is produced by the rapid decarboxylation of clorazepate following its ingestion. Both diazepam and *N*-desmethyl-diazepam are slowly hydroxylated to other active metabolites, such as *oxazepam*. The half-life of diazepam in plasma is between 1 and 2 days, while that of *N*-desmethyl-diazepam is about 60 hours. Clonazepam is metabolized principally by reduction of the nitro group to produce inactive 7-amino derivatives. Less than 1% of the drug is recovered unchanged in the urine. The half-life of clonazepam in plasma is about 1 day. Lorazepam is metabolized chiefly by conjugation with glucuronic acid; its half-life in plasma is about 14 hours.

Toxicity. The principal side effects of long-term oral therapy with clonazepam are drowsiness and lethargy. These occur in about 50% of patients initially, but tolerance often develops with continued administration. Muscular incoordination and ataxia are less frequent. Although these symptoms usually can be kept to tolerable levels by reducing the dosage or the rate at which it is increased, they sometimes force drug discontinuation. Other side effects include hypotonia, dysarthria, and dizziness. Behavioral disturbances, especially in children, can be very troublesome; these include aggression, hyperactivity, irritability, and difficulty in concentration. Both anorexia and hyperphagia have been reported. Increased salivary and bronchial secretions may cause difficulties in children. Seizures are sometimes exacerbated, and status epilepticus may be precipitated if the drug is discontinued abruptly. Other aspects of the toxicity of the benzodiazepines are discussed in Chapter 16. Cardiovascular and respiratory depression may occur after the intravenous administration of diazepam, clonazepam, or lorazepam, particularly if other antiseizure agents or central depressants have been administered previously.

Plasma Drug Concentrations. Because tolerance affects the relationship between drug concentration and drug antiseizure effect, plasma concentrations of benzodiazepines are of limited value.

Therapeutic Uses. Clonazepam is useful in the therapy of absence seizures as well as myoclonic seizures in chil-

dren. However, tolerance to its antiseizure effects usually develops after 1 to 6 months of administration, after which some patients will no longer respond to clonazepam at any dosage. The initial dose of clonazepam for adults should not exceed 1.5 mg per day and for children 0.01 to 0.03 mg/kg per day. The dose-dependent side effects are reduced if two or three divided doses are given each day. The dose may be increased every 3 days in amounts of 0.25 to 0.5 mg per day in children and 0.5 to 1 mg per day in adults. The maximal recommended dose is 20 mg per day for adults and 0.2 mg/kg per day for children.

While diazepam is an effective agent for treatment of status epilepticus, its short duration of action is a disadvantage, leading to the more frequent use of lorazepam. Although diazepam is not useful as an oral agent for the treatment of seizure disorders, clorazepate is effective in combination with certain other drugs in the treatment of partial seizures. The maximal initial dose of clorazepate is 22.5 mg per day in three portions for adults and 15 mg per day in two doses in children. Clorazepate is not recommended for children under the age of 9.

OTHER ANTISEIZURE DRUGS

Gabapentin

Gabapentin (NEURONTIN) is an antiseizure drug that consists of a GABA molecule covalently bound to a lipophilic cyclohexane ring. Gabapentin was designed to be a centrally active GABA agonist, with its high lipid solubility aimed at facilitating its transfer across the blood–brain barrier. The structure of gabapentin is:

Pharmacological Effects and Mechanisms of Action. Gabapentin inhibits tonic hindlimb extension in the electroshock seizure model. Interestingly, gabapentin also inhibits clonic seizures induced by pentylenetetrazol. Its efficacy in both these tests parallels that of valproic acid and distinguishes it from phenytoin and carbamazepine. The anticonvulsant mechanism of action of gabapentin is unknown. Despite its design as a

GABA agonist, gabapentin does not mimic GABA when iontophoretically applied to neurons in primary culture. Gabapentin may promote nonvesicular release of GABA through a poorly understood mechanism (Honmou *et al.*, 1995). Gabapentin binds a protein in cortical membranes with an amino acid sequence identical to that of the $\alpha 2\delta$ subunit of the L type of voltage-sensitive Ca^{2+} channel, yet gabapentin does not affect Ca^{2+} currents of the T, N, or L types of Ca^{2+} channels in dorsal root ganglion cells (Macdonald and Greenfield, 1997). Gabapentin has not been found consistently to reduce sustained repetitive firing of action potentials (Macdonald and Kelly, 1993).

Pharmacokinetics. Gabapentin is absorbed after oral administration and is not metabolized in humans. It is not bound to plasma proteins. It is excreted unchanged, mainly in the urine. Its half-life, when it is used as monotherapy, is 4 to 6 hours. It has no known interactions with other antiseizure drugs.

Therapeutic Uses. Gabapentin is effective for partial seizures, with and without secondary generalization, when used in addition to other antiseizure drugs.

Double-blind placebo-controlled trials of adults with refractory partial seizures demonstrated that addition of gabapentin to other antiseizure drugs was superior to placebo (Sivenius *et al.*, 1991). A double-blind study of gabapentin (900 or 1800 mg/day) monotherapy disclosed that gabapentin was equivalent to carbamazepine (600 mg/day) for newly diagnosed partial or generalized epilepsy (Chadwick *et al.*, 1998). Gabapentin also is being used for the treatment of migraine, chronic pain, and bipolar disorder.

Gabapentin usually is effective in doses of 900 to 1800 mg daily in three doses, although 3600 mg may be required in some patients to achieve reasonable seizure control. Therapy usually is begun with a low dose (300 mg once on the first day), which is increased in daily increments of 300 mg until an effective dose is reached.

Toxicity. Overall, gabapentin is well tolerated with the most common adverse effects of somnolence, dizziness, ataxia, and fatigue. These effects usually are mild to moderate in severity but resolve within 2 weeks of onset during continued treatment.

Lamotrigine

Lamotrigine (LAMICTAL) is a phenyltriazine derivative initially developed as an antifolate agent based on the incorrect idea that reducing folate would effectively combat seizures. Structure–activity studies indicate that its effectiveness as an antiseizure drug is unrelated to its anti-

folate properties (Macdonald and Greenfield, 1997). Approved by the FDA in 1994, its chemical structure is:

Pharmacological Effects and Mechanisms of Action.

Lamotrigine suppresses tonic hindlimb extension in the maximal electroshock model and partial and secondarily generalized seizures in the kindling model, but does not inhibit clonic motor seizures induced by pentyl-enetetrazol. Lamotrigine blocks sustained repetitive firing of mouse spinal cord neurons and delays the recovery from inactivation of recombinant Na⁺ channels, mechanisms similar to those of phenytoin and carbamazepine (Xie *et al.*, 1995). This may well explain lamotrigine's actions on partial and secondarily generalized seizures. However, as mentioned below, lamotrigine is effective against a broader spectrum of seizures than phenytoin and carbamazepine, suggesting that lamotrigine may have actions in addition to regulating recovery from inactivation of Na⁺ channels. The mechanisms underlying its broad spectrum of actions are incompletely understood. One possibility involves lamotrigine's inhibition of glutamate release in rat cortical slices treated with veratridine, a Na⁺ channel activator, raising the possibility that lamotrigine inhibits synaptic release of glutamate by acting at Na⁺ channels themselves.

Pharmacokinetics. Lamotrigine is completely absorbed from the gastrointestinal tract and is metabolized primarily by glucuronidation. The plasma half-life of a single dose is 15 to 30 hours. Administration of phenytoin, carbamazepine, or phenobarbital reduces the half-life and plasma concentrations of lamotrigine. Conversely, addition of valproate markedly increases plasma concentrations of lamotrigine, likely by inhibiting glucuronidation. Addition of lamotrigine to valproic acid produces a reduction of valproate concentrations by approximately 25% over a few weeks. Concurrent use of lamotrigine and carbamazepine is associated with increases of the 10,11-epoxide of carbamazepine and clinical toxicity in some patients.

Therapeutic Use. Lamotrigine is useful for monotherapy and add-on therapy of partial and secondarily generalized

tonic-clonic seizures in adults and Lennox-Gastaut syndrome in both children and adults. Lennox-Gastaut syndrome is a disorder of childhood characterized by multiple seizure types, mental retardation, and refractoriness to anti-seizure medication.

A double-blind comparison of lamotrigine and carbamazepine monotherapy and also of lamotrigine and phenytoin monotherapy in newly diagnosed partial or generalized tonic-clonic seizures revealed lamotrigine to be equivalent to carbamazepine and phenytoin, respectively (Brodie *et al.*, 1995; Steiner *et al.*, 1999). A double-blind, placebo-controlled trial of addition of lamotrigine to existing antiseizure drugs further demonstrated effectiveness of lamotrigine against tonic-clonic seizures and drop attacks in children with the Lennox-Gastaut syndrome (Motte *et al.*, 1997). Lamotrigine was also found to be superior to placebo in a double-blind study of children with newly diagnosed absence epilepsy (Frank *et al.*, 1999).

Patients who are already taking a hepatic enzyme-inducing anti-seizure drug (such as carbamazepine, phenytoin, phenobarbital, or primidone, but not valproate) should be given lamotrigine initially at 50 mg per day for 2 weeks. The dose is increased to 50 mg twice per day for 2 weeks and then increased in increments of 100 mg/day each week up to a maintenance dose of 300 to 500 mg/day divided into two doses. For patients taking valproate in addition to an enzyme-inducing antiseizure drug, the initial dose should be 25 mg every other day for 2 weeks, followed by an increase to 25 mg/day for 2 weeks; the dose then can be increased by 25 to 50 mg/day every 1 to 2 weeks up to a maintenance dose of 100 to 150 mg/day divided into two doses.

Toxicity. The most common adverse effects are dizziness, ataxia, blurred or double vision, nausea, vomiting, and rash when lamotrigine was added to another antiseizure drug. A few cases of Stevens-Johnson syndrome and disseminated intravascular coagulation have been reported. The incidence of serious rash in pediatric patients (approximately 0.8%) is higher than in the adult population (0.3%).

Levetiracetam

Levetiracetam (KEPPRA) is a pyrrolidine, the racemically pure S-enantiomer of α -ethyl-2-oxo-1-pyrrolidineacetamide. Its structure is:

Pharmacological Effects and Mechanism of Action.

Levetiracetam exhibits a novel pharmacological profile insofar as it inhibits partial and secondarily generalized

tonic-clonic seizures in the kindling model, yet is ineffective against maximum electroshock- and pentylenetetrazol-induced seizures, findings consistent with clinical effectiveness against partial and secondarily generalized tonic-clonic seizures. The mechanism by which levetiracetam exerts these antiseizure effects is unknown. No evidence for an action on voltage-gated Na⁺ channels or either GABA- or glutamate-mediated synaptic transmission has emerged. A stereoselective binding site has been identified in rat brain membranes and the synaptic vesicle protein SV2A has been shown to be a brain-binding target of levetiracetam (Lynch *et al.*, 2004).

Pharmacokinetics. Levetiracetam is rapidly and almost completely absorbed after oral administration and is not bound to plasma proteins. Ninety-five percent of the drug and its inactive metabolite are excreted in the urine, 65% of which is unchanged drug; 24% of the drug is metabolized by hydrolysis of the acetamide group. It neither induces nor is a high-affinity substrate for CYP isoforms or glucuronidation enzymes and thus is devoid of known interactions with other antiseizure drugs, oral contraceptives, or anticoagulants.

Therapeutic Use. A double-blind, placebo-controlled trial of adults with refractory partial seizures demonstrated that addition of levetiracetam to other antiseizure medications was superior to placebo. Insufficient evidence is available with respect to use of levetiracetam as monotherapy for partial or generalized epilepsy.

Toxicity. The drug is well tolerated. The most frequently reported adverse effects are somnolence, asthenia, and dizziness.

Tiagabine

Tiagabine (GABITRIL) is a derivative of nipecotic acid and was approved by the FDA in 1998 for treating partial seizures in adults when used in addition to other drugs. Its structure is:

Pharmacological Effects and Mechanism of Action.

Tiagabine inhibits the GABA transporter, GAT-1, and thereby reduces GABA uptake into neurons and glia. In CA1 neurons of the hippocampus, tiagabine increases the duration of inhibitory synaptic currents, findings consistent with prolonging the effect of GABA at inhibitory synapses through reducing its reuptake by GAT-1. Tiagabine inhibits maximum electroshock seizures and both limbic and secondarily generalized tonic-clonic seizures in the kindling model, results suggestive of clinical efficacy against partial and tonic-clonic seizures.

Pharmacokinetics. Tiagabine is rapidly absorbed after oral administration, extensively bound to serum or plasma proteins, and metabolized mainly in the liver, predominantly by CYP3A. Its half-life of about 8 hours is shortened by 2 to 3 hours when coadministered with hepatic enzyme-inducing drugs such as phenobarbital, phenytoin, or carbamazepine.

Therapeutic Use. Double-blind, placebo-controlled trials have established tiagabine's efficacy as add-on therapy of refractory partial seizures with or without secondary generalization. Its efficacy for monotherapy for newly diagnosed or refractory partial and generalized epilepsy has not been established.

Toxicity. The principal adverse effects include dizziness, somnolence, and tremor; they appear to be mild to moderate in severity and appear shortly after initiation of therapy. The fact that tiagabine and other drugs thought to enhance effects of synaptically released GABA can facilitate spike-and-wave discharges in animal models of absence seizures raises the possibility that tiagabine may be contraindicated in patients with generalized absence epilepsy. Patients with a history of spike-and-wave discharges have been reported to have exacerbations of their EEG abnormalities.

Topiramate

Topiramate (TOPAMAX) is a sulfamate-substituted monosaccharide. Its structure is:

Pharmacological Effects and Mechanisms of Action.

Topiramate reduces voltage-gated Na⁺ currents in cerebellar granule cells and may act on the inactivat-

ed state of the channel in a manner similar to that of phenytoin. In addition, topiramate activates a hyperpolarizing K^+ current, enhances postsynaptic GABA_A-receptor currents, and also limits activation of the AMPA-kainate-subtype(s) of glutamate receptor. Topiramate also is a weak carbonic anhydrase inhibitor. Topiramate inhibits maximal electroshock and pentylenetetrazol-induced seizures as well as partial and secondarily generalized tonic-clonic seizures in the kindling model, findings predictive of a broad spectrum of antiseizure actions clinically.

Pharmacokinetics. Topiramate is rapidly absorbed after oral administration, exhibits little (10% to 20%) binding to plasma proteins, and is mainly excreted unchanged in the urine. The remainder undergoes metabolism by hydroxylation, hydrolysis, and glucuronidation with no single metabolite accounting for more than 5% of an oral dose. Its half-life is about 1 day. Reduced estradiol plasma concentrations occur with concurrent topiramate, suggesting the need for higher doses of oral contraceptives when coadministered with topiramate.

Therapeutic Use. A double-blind study revealed topiramate to be equivalent to valproate and carbamazepine in children and adults with newly diagnosed partial and primary generalized epilepsy (Privitera *et al.*, 2003). Additional studies disclosed topiramate to be effective as monotherapy for refractory partial epilepsy (Sachdeo *et al.*, 1997) and refractory generalized tonic-clonic seizures (Biton *et al.*, 1999). Topiramate also was found to be significantly more effective than placebo against both drop attacks and tonic-clonic seizures in patients with Lennox-Gastaut syndrome (Sachdeo *et al.*, 1999).

Toxicity. Topiramate is well tolerated. The most common adverse effects are somnolence, fatigue, weight loss, and nervousness. It can precipitate renal calculi, which is most likely due to inhibition of carbonic anhydrase. Topiramate has been associated with cognitive impairment and patients may complain about a change in the taste of carbonated beverages.

Felbamate

Felbamate (FELBATOL) is a dicarbamate which was approved by the FDA for partial seizures in 1993. An association between felbamate and aplastic anemia in at least 10 cases resulted in a recommendation by the FDA and the manufacturer for the immediate withdrawal

of most patients from treatment with this drug. The structure of felbamate is:

Felbamate is effective in both the maximal electroshock and pentylenetetrazol seizure models. Clinically relevant concentrations of felbamate inhibit NMDA-evoked responses and potentiate GABA-evoked responses in whole-cell, voltage-clamp recordings of cultured rat hippocampal neurons (Rho *et al.*, 1994). This dual action on excitatory and inhibitory transmitter responses may contribute to the wide spectrum of action of the drug in seizure models.

An active control, randomized, double-blind protocol demonstrated the efficacy of felbamate in patients with poorly controlled partial and secondarily generalized seizures (Sachdeo *et al.*, 1992). Felbamate also was found to be efficacious against seizures in patients with Lennox-Gastaut syndrome (The Felbamate Study Group in Lennox-Gastaut Syndrome, 1993). The clinical efficacy of this compound, which inhibited responses to NMDA and potentiated those to GABA, underscores the potential value of additional antiseizure agents with similar mechanisms of action.

Zonisamide

Zonisamide (ZONEGRAN) is a sulfonamide derivative with the following chemical structure:

Pharmacological Effects and Mechanism of Action.

Zonisamide inhibits the T-type Ca^{2+} currents. In addition, zonisamide inhibits the sustained, repetitive firing of spinal cord neurons, presumably by prolonging the inactivated state of voltage-gated Na^+ channels in a manner similar to actions of phenytoin and carbamazepine. Zonisamide inhibits tonic hindlimb extension evoked by maximal electroshock and inhibits both partial and secondarily generalized seizures in the kindling model, results predictive of clinical effectiveness against partial and secondarily generalized tonic-clonic seizures. Zonisamide does not inhibit minimal clonic seizures induced by pentylenetetrazol, suggesting that the drug will not be effective clinically against myoclonic seizures.

Pharmacokinetics. Zonisamide is almost completely absorbed after oral administration, has a long half-life (about 63 hours), and is about 40% bound to plasma protein. Approximately 85% of an oral dose is excreted in the urine, principally as unmetabolized zonisamide and a glucuronide of sulfamoylacetophenol, which is a product of metabolism by CYP3A4. Phenobarbital, phenytoin, and carbamazepine decrease the plasma concentration/dose ratio of zonisamide, whereas lamotrigine increases this ratio. Conversely, zonisamide has little effect on the plasma concentrations of other antiseizure drugs.

Therapeutic Use. Double-blind, placebo-controlled studies of patients with refractory partial seizures demonstrated that addition of zonisamide to other drugs was superior to placebo. There is insufficient evidence for its efficacy as monotherapy for newly diagnosed or refractory epilepsy.

Toxicity. Overall, zonisamide is well tolerated. The most common adverse effects include somnolence, ataxia, anorexia, nervousness, and fatigue. Approximately 1% of individuals develop renal calculi during treatment with zonisamide, which may relate to its ability to inhibit carbonic anhydrase.

Acetazolamide

Acetazolamide, the prototype for the carbonic anhydrase inhibitors, is discussed in Chapter 28. Its antiseizure actions are discussed in previous editions of this textbook. Although it is sometimes effective against absence seizures, its usefulness is limited by the rapid development of tolerance. Adverse effects are minimal when it is used in moderate dosage for limited periods.

GENERAL PRINCIPLES AND CHOICE OF DRUGS FOR THE THERAPY OF THE EPILEPSIES

Early diagnosis and treatment of seizure disorders with a single appropriate agent offers the best prospect of achieving prolonged seizure-free periods with the lowest risk of toxicity. An attempt should be made to determine the cause of the epilepsy with the hope of discovering a correctable lesion, either structural or metabolic. The drugs commonly used for distinct seizure types are listed in Table 19–1. The efficacy combined with the unwanted effects of a given drug determine which particular drug is optimal for a given patient.

The first issue that arises is whether and when to initiate treatment. For example, it may not be necessary to

initiate antiseizure therapy after an isolated tonic-clonic seizure in a healthy young adult who lacks a family history of epilepsy and who has a normal neurological exam, a normal EEG, and a normal brain MRI scan. That is, the odds of seizure recurrence in the next year (15%) approximate the risk of a drug reaction sufficiently severe to warrant discontinuation of medication (Bazil and Pedley, 1998). Alternatively, a similar seizure occurring in an individual with a positive family history of epilepsy, an abnormal neurological exam, an abnormal EEG, and an abnormal MRI carries a risk of recurrence approximating 60%, odds that favor initiation of therapy.

Unless extenuating circumstances such as status epilepticus exist, only monotherapy should be initiated. Initial dosage usually is that expected to provide a plasma drug concentration during the plateau state at least in the lower portion of the range associated with clinical efficacy. To minimize dose-related adverse effects, therapy with many drugs is initiated at reduced dosage. Dosage is increased at appropriate intervals, as required for control of seizures or as limited by toxicity, and such adjustment is preferably assisted by monitoring of drug concentrations in plasma. Compliance with a properly selected, single drug in maximal tolerated dosage results in complete control of seizures in approximately 50% of patients. If a seizure occurs despite optimal drug levels, the physician should assess the presence of potential precipitating factors such as sleep deprivation, a concurrent febrile illness, or drugs; drugs might consist of large amounts of caffeine or even over-the-counter medications, which can include drugs that can lower the seizure threshold.

If compliance has been confirmed yet seizures persist, another drug should be substituted. Unless serious adverse effects of the drug dictate otherwise, dosage always should be reduced gradually when a drug is being discontinued to minimize risk of seizure recurrence. In the case of partial seizures in adults, the diversity of available drugs permits selection of a second drug that acts by a distinct mechanism. Among previously untreated patients, 47% became seizure free with the first drug and an additional 14% became seizure free with a second or third drug (Kwan and Brodie, 2000).

In the event that therapy with a second single drug also is inadequate, many physicians resort to treatment with two drugs simultaneously. This decision should not be taken lightly, because most patients obtain optimal seizure control with fewest unwanted effects when taking a single drug. Nonetheless, some patients will not be controlled adequately without the simultaneous use of two or more antiseizure agents. No properly controlled studies have systematically compared one particular drug combination

with another. The chances of complete control with this approach are not high, as evidenced by Kwan and Brodie (2000), who found that epilepsy was controlled by treatment with two drugs in only 3% of patients. It seems wise to select two drugs that act by distinct mechanisms (*e.g.*, one that promotes Na⁺ channel inactivation and another that enhances GABA-mediated synaptic inhibition). Additional issues that warrant careful consideration are the unwanted effects of each drug and the potential drug interactions. As specified in Table 19–2, many of these drugs induce expression of CYPs and thereby impact the metabolism of themselves and/or other drugs. Overall, drugs introduced after 1990 present fewer problems with respect to drug interactions.

Essential to optimal management of epilepsy is the filling out of a seizure chart by the patient or a relative. Frequent visits to the physician or seizure clinic may be necessary early in the period of treatment, since hematological and other possible side effects may require consideration of a change in medication. Long-term follow-up with neurological examinations and possibly EEG and neuroimaging studies is appropriate. Most crucial for successful management is regularity of medication, since faulty compliance is the most frequent cause for failure of therapy with antiseizure drugs.

Measurement of plasma drug concentration at appropriate intervals greatly facilitates the initial adjustment of dosage for individual differences in drug elimination and the subsequent adjustment of dosage to minimize dose-related adverse effects without sacrifice of seizure control. Periodic monitoring during maintenance therapy can detect failure of the patient to take the medication as prescribed. Knowledge of plasma drug concentration can be especially helpful during multiple-drug therapy. If toxicity occurs, monitoring helps to identify the particular drug(s) responsible, and if pharmacokinetic drug interaction occurs, monitoring can guide readjustment of dosage.

Duration of Therapy. Once initiated, antiseizure drugs are typically continued for at least 2 years. If the patient is seizure free after 2 years, consideration should be given to tapering and discontinuing therapy. Factors associated with high risk for recurrent seizures following discontinuation of therapy include EEG abnormalities, a known structural lesion, abnormalities on neurological exam, and history of frequent seizures or medically refractory seizures prior to control. Conversely, factors associated with low risk for recurrent seizures include idiopathic epilepsy, normal EEG, onset in childhood, and seizures easily controlled with a single drug. The risk of recurrent seizures approximates 25% in low-risk individuals and exceeds 50% in high-risk individuals (Anonymous, 1996). Typically 80% of recurrences will occur within 4 months of discontinuing therapy. The clinician and patient must weigh the risk of recurrent seizure and the associated potential deleterious consequences (*e.g.*, loss of driving privileges) against the various implications of continuing medication including cost, unwanted effects, implications of diagnosis of epi-

lepsy, etc. Any taper ideally is performed slowly over a period of several months.

Simple and Complex Partial and Secondarily Generalized Tonic-Clonic Seizures. The efficacy and toxicity of carbamazepine, phenobarbital, and phenytoin for treatment of partial and secondarily generalized tonic-clonic seizures in adults have been examined in a double-blind prospective study (Mattson *et al.*, 1985). A subsequent double-blind prospective study compared carbamazepine with valproate (Mattson *et al.*, 1992). Carbamazepine and phenytoin were the most effective overall for single-drug therapy of partial or generalized tonic-clonic seizures. The choice between carbamazepine and phenytoin required assessment of toxic effects of each drug. Decreased libido and impotence were associated with all three drugs (carbamazepine 13%, phenobarbital 16%, and phenytoin 11%). The study comparing carbamazepine with valproate revealed that carbamazepine provided superior control of complex partial seizures. With respect to adverse effects, carbamazepine was more commonly associated with skin rash, but valproate was more commonly associated with tremor and weight gain. Overall, the data demonstrated that carbamazepine and phenytoin are preferable for treatment of partial seizures, but phenobarbital and valproic acid are also efficacious.

Control of secondarily generalized tonic-clonic seizures did not differ significantly with carbamazepine, phenobarbital, or phenytoin (Mattson *et al.*, 1985). Valproate was as effective as carbamazepine for control of secondarily generalized tonic-clonic seizures (Mattson *et al.*, 1992). Since secondarily generalized tonic-clonic seizures usually coexist with partial seizures, these data indicate that among drugs introduced before 1990, carbamazepine and phenytoin are the first-line drugs for these conditions.

One key issue confronting the treating physician is the optimal drug for initiating treatment in the patient newly diagnosed with partial or generalized onset epilepsy. At first glance, this issue may appear unimportant because approximately 50% of newly diagnosed patients become seizure free with the first drug, whether old or new drugs are used (Kwan and Brodie, 2000). However, responsive patients typically receive the initial drug for several years, underscoring the importance of proper drug selection. Among the drugs available before 1990, phenytoin, carbamazepine, and phenobarbital induce hepatic CYPs, thereby complicating use of multiple antiseizure drugs as well as impacting metabolism of oral contraceptives, warfarin, and many other drugs. These drugs also enhance metabolism of endogenous compounds including gonadal steroids and vitamin D, potentially impacting reproductive function and bone density. By contrast, most of the newer drugs have little if any effect on the CYPs. Factors arguing against use of recently introduced drugs include higher costs and less clinical experience with the compounds.

Ideally, a prospective study would systematically compare newly introduced antiseizure drugs with drugs available before 1990 in a study design adjusting dose as needed and observing responses for extended periods of time (*e.g.*, 2 years or more), in much the same manner as that used when comparing the older antiseizure drugs with one another as described above (Mattson *et al.*, 1985).

Unfortunately, such a study has not been performed. Many of the studies referenced in description of newer drugs did compare a new with an older antiseizure drug, but study design did not permit declaring a clearly superior drug; moreover, differences in study design and patient populations preclude comparing a new drug with multiple older drugs or with other new drugs. The use of recently introduced antiseizure drugs for newly diagnosed epilepsy was

thoughtfully considered following a comprehensive analysis of scientific literature conducted jointly by subcommittees of the American Academy of Neurology and the American Epilepsy Society (French *et al.*, 2004a; French *et al.*, 2004b); these authors concluded that available evidence supported the use of gabapentin, lamotrigine, and topiramate for newly diagnosed partial or mixed seizure disorders. None of these drugs, however, has been approved by the FDA for either of these indications. Insufficient evidence was available on the remaining newly introduced drugs to permit meaningful assessment of their effectiveness for this indication.

Absence Seizures. The best data indicate that ethosuximide and valproate are equally effective in the treatment of absence seizures (Mikati and Browne, 1988). Between 50% and 75% of newly diagnosed patients can be rendered free of seizures following therapy with either drug. In the event that tonic-clonic seizures are present or emerge during therapy, valproate is the agent of first choice. French and others concluded that available evidence indicates that lamotrigine is also effective for newly diagnosed absence epilepsy despite the fact that lamotrigine is not approved for this indication by the FDA.

Myoclonic Seizures. Valproic acid is the drug of choice for myoclonic seizures in the syndrome of juvenile myoclonic epilepsy, in which myoclonic seizures often coexist with tonic-clonic and also absence seizures. No trials have been conducted examining any of the newly introduced drugs for patients with juvenile myoclonic epilepsy or other idiopathic generalized epilepsy syndromes.

Febrile Convulsions. Two to four percent of children experience a convulsion associated with a febrile illness. From 25% to 33% of these children will have another febrile convulsion. Only 2% to 3% become epileptic in later years, a sixfold increase in risk compared with the general population. Several factors are associated with an increased risk of developing epilepsy: preexisting neurological disorder or developmental delay, a family history of epilepsy, or a complicated febrile seizure (*i.e.*, the febrile seizure lasted more than 15 minutes, was one-sided, or was followed by a second seizure in the same day). If all of these risk factors are present, the risk of developing epilepsy is approximately 10%.

Concern regarding the increased risk of developing epilepsy or other neurological sequelae led many physicians to prescribe antiseizure drugs prophylactically after a febrile seizure. Uncertainties regarding the efficacy of prophylaxis for reducing epilepsy combined with substantial side effects of phenobarbital prophylaxis (Farwell *et al.*, 1990) argue against the use of chronic therapy for prophylactic purposes (Freeman, 1992). For children at high risk of developing recurrent febrile seizures and epilepsy, rectally administered diazepam at the time of fever may prevent recurrent seizures and avoid side effects of chronic therapy.

Seizures in Infants and Young Children. Infantile spasms with hypsarrhythmia are refractory to the usual antiseizure agents; *corticotropin* or the glucocorticoids are commonly used. A randomized study found *vigabatrin* (γ -vinyl GABA) to be efficacious in comparison to placebo (Appleton *et al.*, 1999). Constriction of visual fields has been reported in some adults treated with vigabatrin (Miller *et al.*, 1999). The drug received orphan drug status for the treatment of infantile spasms in the United States in 2000 and also is available in other countries.

The Lennox-Gastaut syndrome is a severe form of epilepsy which usually begins in childhood and is characterized by cognitive impairments and multiple types of seizures including tonic-clonic, tonic, atonic, myoclonic, and atypical absence seizures. Addition of lamotrigine to other antiseizure drugs resulted in improved seizure control in comparison to placebo in a double-blind trial (Motte *et al.*, 1997), demonstrating lamotrigine to be an effective and well-tolerated drug for this treatment-resistant form of epilepsy. Felbamate also was found to be effective for seizures in this syndrome, but the occasional occurrence of aplastic anemia has limited its use (French *et al.*, 1999). Topiramate has also been demonstrated to be effective for Lennox-Gastaut syndrome (Sachdeo *et al.*, 1999).

Status Epilepticus and Other Convulsive Emergencies. Status epilepticus is a neurological emergency. Mortality for adults approximates 20% (Lowenstein and Alldredge, 1998). The goal of treatment is rapid termination of behavioral and electrical seizure activity; the longer the episode of status epilepticus is untreated, the more difficult it is to control and the greater the risk of permanent brain damage. Critical to the management is a clear plan, prompt treatment with effective drugs in adequate doses, and attention to hypoventilation and hypotension. Since hypoventilation may result from high doses of drugs used for treatment, it may be necessary to assist respiration temporarily. Drugs should be administered by the intravenous route only. Because of slow and unreliable absorption, the intramuscular route has no place in treatment of status epilepticus. To assess the optimal initial drug regimen, a double-blind, multicenter trial compared four intravenous treatments: diazepam followed by phenytoin; lorazepam; phenobarbital; and phenytoin alone (Treiman *et al.*, 1998). The treatments were shown to have similar efficacies, in that success rates ranged from 44% to 65%, but lorazepam alone was significantly better than phenytoin alone. No significant differences were found with respect to recurrences or adverse reactions.

Antiseizure Therapy and Pregnancy. Use of antiseizure drugs has diverse implications of great importance for the health of women, issues considered in guidelines articulated by the American Academy of Neurology (Morrell, 1998). These issues include interactions with oral contraceptives, potential teratogenic effects, and effects on vitamin K metabolism in pregnant women.

The effectiveness of oral contraceptives appears to be reduced by concomitant use of antiseizure drugs. The failure rate of oral contraceptives is 3.1/100 years in women receiving antiseizure drugs compared to a rate of 0.7/100 years in nonepileptic women. One attractive explanation of the increased failure rate is the increased rate of oral contraceptive metabolism caused by antiseizure drugs that induce hepatic enzymes (Table 19–2); particular caution is needed with antiseizure drugs that induce CYP3A4.

Epidemiological evidence suggests that antiseizure drugs have teratogenic effects. These teratogenic effects add to the deleterious consequences of oral contraceptive failure. Infants of epileptic mothers are at twofold greater risk of major congenital malformations than offspring of nonepileptic mothers (4% to 8% compared to 2% to 4%). These malformations include congenital heart defects, neural tube defects, and others. Inferring causality from the associations found in large epidemiological studies with many uncontrolled variables can be hazardous, but a causal role for antiseizure drugs is suggested by association of congenital defects with higher concentrations of a drug or with polytherapy compared to monotherapy. Phenytoin, carbamazepine, valproate, and phenobarbital all have

been associated with teratogenic effects. The antiseizure drugs introduced after 1990 have teratogenic effects in animals but whether such effects occur in humans is yet uncertain. One consideration for a woman with epilepsy who wishes to become pregnant is a trial free of antiseizure drug; monotherapy with careful attention to drug levels is another alternative. Polytherapy with toxic levels should be avoided. Folate supplementation (0.4 mg/day) has been recommended by the U.S. Public Health Service for all women of childbearing age to reduce the likelihood of neural tube defects, and this is appropriate for epileptic women as well.

Antiseizure drugs that induce CYPs have been associated with vitamin K deficiency in the newborn, which can result in a coagulopathy and intracerebral hemorrhage. Treatment with vitamin K₁, 10 mg/day during the last month of gestation, has been recommended for prophylaxis.

TREATMENT OF CENTRAL NERVOUS SYSTEM DEGENERATIVE DISORDERS

David G. Standaert and Anne B. Young

Neurodegenerative disorders are characterized by progressive and irreversible loss of neurons from specific regions of the brain. Prototypical neurodegenerative disorders include Parkinson's disease (PD) and Huntington's disease (HD), where loss of neurons from structures of the basal ganglia results in abnormalities in the control of movement; Alzheimer's disease (AD), where the loss of hippocampal and cortical neurons leads to impairment of memory and cognitive ability; and amyotrophic lateral sclerosis (ALS), where muscular weakness results from the degeneration of spinal, bulbar, and cortical motor neurons. As a group, these disorders are relatively common and represent a substantial medical and societal problem. They are primarily disorders of later life, developing in individuals who are neurologically normal, although childhood-onset forms of each of the disorders are recognized. PD is observed in more than 1% of individuals over the age of 65 (Tanner, 1992), whereas AD affects as many as 10% of the same population (Evans *et al.*, 1989). HD, which is a genetically determined autosomal dominant disorder, is less frequent in the population as a whole but affects, on average, 50% of each generation in families carrying the gene. ALS also is relatively rare but often leads rapidly to disability and death (Kurtzke, 1982).

At present, the pharmacological therapy of neurodegenerative disorders is limited mostly to symptomatic treatments that do not alter the course of the underlying disease. Symptomatic treatment for PD, where the neurochemical deficit produced by the disease is well defined, is, in general, relatively successful, and a number of effective agents are available. The available treatments for AD, HD, and ALS are much more limited in effectiveness, and the need for new strategies is particularly acute.

SELECTIVE VULNERABILITY AND NEUROPROTECTIVE STRATEGIES

Selective Vulnerability. The most striking feature of this group of disorders is the exquisite specificity of the disease processes for particular types of neurons. For example, in PD there is extensive destruction of the dopaminergic neurons of the substantia nigra, whereas neurons in the cortex and many other areas of the brain are unaffected (Gibb, 1992; Fearnley and Lees, 1994). In contrast, neural injury in AD is most severe in the hippocampus and neocortex, and even within the cortex, the loss of neurons is not uniform but varies dramatically in different functional regions (Arnold *et al.*, 1991). Even more striking is the observation that in HD the mutant gene responsible for the disorder is expressed throughout the brain and in many other organs, yet the pathological changes are most prominent in the neostriatum (Vonsattel *et al.*, 1985; Landwehrmeyer *et al.*, 1995). In ALS, there is loss of spinal motor neurons and the cortical neurons that provide their descending input (Tandan and Bradley, 1985). The diversity of these patterns of neural degeneration has led to the proposal that the process of neural injury must be viewed as the interaction of genetic and environmental influences with the intrinsic physiological characteristics of the affected populations of neurons. These intrinsic factors may include susceptibility to excitotoxic injury, regional variation in capacity for oxidative metabolism, and the production of toxic free radicals as by-products of cellular metabolism (Figure 20–1). The factors that convey selective vulnerability may prove to be important targets for neuroprotective agents to slow the progression of neurodegenerative disorders.

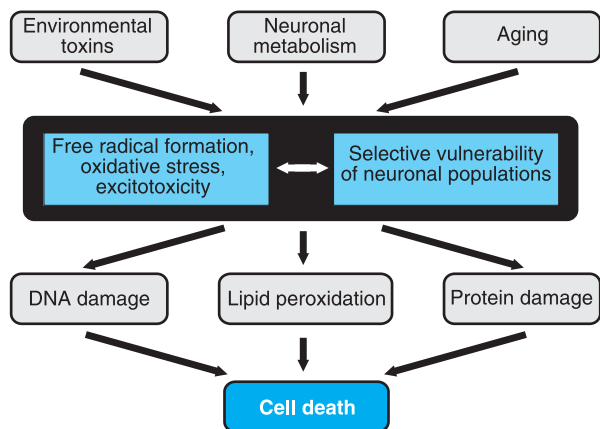

Figure 20–1. Mechanisms of selective neuronal vulnerability in neurodegenerative diseases.

Genetics. It has long been suspected that genetic predisposition plays an important role in the etiology of neurodegenerative disorders, and some of the responsible mechanisms have now been discovered. HD is transmitted by autosomal dominant inheritance, and the molecular nature of the genetic defect has been defined (*discussed below*). Most cases of PD, AD, or ALS are sporadic, but families with a high incidence of each of these diseases have been identified, and these studies have begun to yield important clues to the pathogenesis of the disorders. In the case of PD, mutations in four different proteins can lead to genetically determined forms of the disease: α -synuclein, an abundant synaptic protein; parkin, a ubiquitin hydrolase; UCHL1, which also participates in ubiquitin-mediated degradation of proteins in the brain; and DJ-1, a protein thought to be involved in the neuronal response to stress (Gwinn-Hardy, 2002). In AD, mutations in the genes coding for the amyloid precursor protein (APP) and proteins known as the presenilins, which may be involved in APP processing, lead to inherited forms of the disease (Selkoe, 2002). Mutations in the gene coding for copper-zinc superoxide dismutase (*SOD1*) account for about 2% of the cases of adult-onset ALS (Cudkovicz and Brown, 1996). Although these mutations are rare, their importance extends beyond the families that carry them because they point to pathways and mechanisms that also may underlie the more common, sporadic cases of these diseases.

Genetically determined cases of PD, AD, and ALS are infrequent, but it is likely that an individual's genetic background has an important role in determining the probability of acquiring these diseases. Apolipoprotein E (apo E) has been identified as the first of what are likely to be many genetic risk factors for AD. Four distinct isoforms of this protein, which is well known to be involved

in transport of cholesterol and lipids in blood, exist. Although all the isoforms carry out their primary role in lipid metabolism equally well, individuals who are homozygous for the apo E 4 allele ("4/4") have a much higher lifetime risk of AD than do those homozygous for the apo E 2 allele ("2/2"). The mechanism by which the apo E 4 protein increases the risk of AD is not known, but a secondary function of the protein in β -amyloid aggregation or processing of APP has been suggested (Roses, 1997).

Environmental Triggers. Infectious agents, environmental toxins, and acquired brain injury have been proposed to have a role in the etiology of neurodegenerative disorders. The role of infection is best documented in the numerous cases of PD that developed following the epidemic of encephalitis lethargica (Von Economo's encephalitis) in the early part of the 20th century. Most contemporary cases of PD are not preceded by encephalitis, and there is no convincing evidence for an infectious contribution to HD, AD, or ALS. Traumatic brain injury has been suggested as a trigger for neurodegenerative disorders, and in the case of AD there is some evidence to support this view (Cummings *et al.*, 1998). At least one toxin, *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP; *discussed below*), can induce a condition closely resembling PD. More recently, the widely used agricultural pesticide rotenone has been shown to induce a parkinsonian condition in rodents, but sustained parenteral treatment was required (Betarbet, 2002). Whether environmental exposure to these or similar agents may contribute to human PD is unknown.

Excitotoxicity. The term *excitotoxicity* was coined by Olney (1969) to describe the neural injury that results from the presence of excess glutamate in the brain. Glutamate is used as a neurotransmitter by many different neural systems and is believed to mediate most excitatory synaptic transmission in the mammalian brain (*see* Chapter 12). Although glutamate is required for normal brain function, the presence of excessive amounts of glutamate can lead to excitotoxic cell death (Lipton and Rosenberg, 1994). The destructive effects of glutamate are mediated by glutamate receptors, particularly those of the *N*-methyl-D-aspartate (NMDA) type. Unlike other glutamate-gated ion channels, which primarily regulate the flow of Na^+ , activated NMDA-receptor channels allow an influx of Ca^{2+} , which in excess can activate a variety of potentially destructive processes. The activity of NMDA-receptor channels is regulated not only by the concentration of glutamate in the synaptic space but also by a voltage-dependent blockade of the channel by Mg^{2+} ; thus entry of Ca^{2+} into neurons through NMDA-receptor chan-

nels requires binding of glutamate to NMDA receptors as well as depolarization of the neuron (e.g., by the activity of glutamate at non-NMDA receptors), which relieves the blockade of NMDA-receptor channels by extracellular Mg^{2+} . Excitotoxic injury is thought to make an important contribution to the neural death that occurs in acute processes such as stroke and head trauma (Choi and Rothman, 1990). In the chronic neurodegenerative disorders, the role of excitotoxicity is less certain; regional and cellular differences in susceptibility to excitotoxic injury, conveyed, for example, by differences in types of glutamate receptors, may contribute to selective vulnerability.

Energy Metabolism and Aging. The excitotoxic hypothesis provides a link between selective patterns of neuronal injury, the effects of aging, and observations on the metabolic capacities of neurons (Beal *et al.*, 1993). Since blockade of the NMDA-receptor channel by Mg^{2+} depends on the membrane potential, disturbances that impair the metabolic capacity of neurons will tend to relieve Mg^{2+} blockade and predispose to excitotoxic injury. The capacity of neurons for oxidative metabolism declines progressively with age perhaps in part because of a progressive accumulation of mutations in the mitochondrial genome (Wallace, 1992). Patients with PD exhibit several defects in energy metabolism that are even greater than expected for their age, most notably a reduction in the function of complex I of the mitochondrial electron-transport chain (Schapira *et al.*, 1990). Additional evidence for the role of metabolic defects in the etiology of neural degeneration comes from the study of patients who inadvertently self-administered MPTP, a “designer drug” that resulted in symptoms of severe and irreversible parkinsonism (Ballard *et al.*, 1985). Subsequent studies have shown that a metabolite of MPTP induces degeneration of neurons similar to that observed in idiopathic PD and that its mechanism of action appears to be related to an ability to impair mitochondrial energy metabolism in dopaminergic neurons (Przedborski and Jackson-Lewis, 1998). The pesticide rotenone, which also can induce dopaminergic injury, has a similar mechanism of action (Beterbet *et al.*, 2002). In rodents, neural degeneration similar to that observed in HD can be produced either by direct administration of large doses of NMDA-receptor agonists or by more chronic administration of inhibitors of mitochondrial oxidative metabolism, suggesting that disturbances of energy metabolism may underlie the selective pathology of HD as well (Beal *et al.*, 1986, 1993).

Oxidative Stress. Although neurons depend on oxidative metabolism for survival, a consequence of this pro-

cess is the production of reactive compounds such as hydrogen peroxide and oxyradicals (Cohen and Werner, 1994). Unchecked, these reactive species can lead to DNA damage, peroxidation of membrane lipids, and neuronal death. Several mechanisms serve to limit this *oxidative stress*, including the presence of reducing compounds such as ascorbate and glutathione and enzymatic mechanisms such as superoxide dismutase, which catalyzes the reduction of superoxide radicals. Oxidative stress also may be relieved by aminosteroid agents that serve as free radical scavengers. In PD, attention has focused on the possibility that oxidative stress induced by the metabolism of dopamine may underlie the selective vulnerability of dopaminergic neurons (Jenner, 1998). The primary catabolic pathway of dopamine to 3,4-dihydroxyphenylacetic acid (DOPAC) is catalyzed by monoamine oxidase (MAO) and generates hydrogen peroxide. Hydrogen peroxide, in the presence of ferrous ion, which is relatively abundant in the basal ganglia, can generate hydroxyl free radicals (the Fenton reaction) (Figure 20–2). If the protective mechanisms are inadequate because of inherited or acquired deficiency, the oxyradicals could cause degeneration of dopaminergic neurons. This hypothesis has led to several proposals for therapeutic agents to retard neuronal loss in PD. Two candidates, the free radical scavenger *tocopherol* (vitamin E) and the MAO inhibitor *selegiline* (discussed below), have been tested in a large-scale clinical trial, but neither was shown to have a substantial neuroprotective effect (Parkinson Study Group, 1993).

PARKINSON'S DISEASE (PD)

Clinical Overview. Parkinsonism is a clinical syndrome consisting of four cardinal features: bradykinesia (slowness and poverty of movement), muscular rigidity, resting tremor (which usually abates during voluntary movement), and an impairment of postural balance leading to disturbances of gait and falling (Lang, 1998). The most common cause of parkinsonism is idiopathic PD, first described by James Parkinson in 1817 as *paralysis agitans*, or the “shaking palsy.” The pathological hallmark of PD is a loss of the pigmented, dopaminergic neurons of the substantia nigra pars compacta, with the appearance of intracellular inclusions known as *Lewy bodies* (Gibb, 1992; Fearnley and Less, 1994). Progressive loss of dopamine-containing neurons is a feature of normal aging; however, most people do not lose the 70% to 80% of dopaminergic neurons required to cause symptomatic PD. Without treatment, PD progresses over 5 to 10 years to a

Figure 20–2. Production of free radicals by the metabolism of dopamine. Dopamine is converted by monoamine oxidase (MAO) and aldehyde dehydrogenase (AD) to 3,4-dihydroxyphenylacetic acid (DOPAC), producing hydrogen peroxide (H_2O_2). In the presence of ferrous iron, H_2O_2 undergoes spontaneous conversion, forming a hydroxyl free radical (the Fenton reaction).

rigid, akinetic state in which patients are incapable of caring for themselves. Death frequently results from complications of immobility, including aspiration pneumonia or pulmonary embolism. The availability of effective pharmacological treatment has altered radically the prognosis of PD; in most cases, good functional mobility can be maintained for many years, and the life expectancy of adequately treated patients is increased substantially. It is important to recognize that several disorders other than PD also may produce parkinsonism, including some relatively rare neurodegenerative disorders, stroke, and intoxication with dopamine-receptor antagonists. Drugs in common clinical use that may cause parkinsonism include antipsychotics such as *haloperidol* and *thorazine* (see Chapter 18) and antiemetics such as *prochlorperazine* and *metoclopramide* (see Chapter 37). Although a complete discussion of the clinical diagnostic approach to parkinsonism exceeds the scope of this chapter, the distinction between PD and other causes of parkinsonism is important because parkinsonism arising from other causes usually is refractory to all forms of treatment.

Pathophysiology. The primary deficit in PD is a loss of the neurons in the substantia nigra pars compacta that provide dopaminergic innervation to the striatum (caudate and putamen). The current understanding of the pathophysiology of PD can be traced to neurochemical investigations that demonstrated a reduction in the striatal dopamine content in excess of 80%. This paralleled the loss of neurons from the substantia nigra, suggesting that replacement of dopamine could restore function (Cotzias *et al.*, 1969; Hornykiewicz, 1973). These fundamental observations led to an extensive investigative effort to understand the metabolism and actions of dopamine and to learn how a deficit in dopamine gives rise to the clinical features of PD. We now have a model of the function of the basal ganglia that, while incomplete, is still useful.

Dopamine Synthesis and Metabolism. Dopamine, a catecholamine, is synthesized in the terminals of dopaminergic neurons from

tyrosine and stored, released, and metabolized by processes described in Chapter 6 and summarized in Figures 20–3 and 20–4.

Dopamine Receptors. The actions of dopamine in the brain are mediated by a family of dopamine-receptor proteins (Figure 20–5).

Figure 20–3. Dopaminergic terminal. Dopamine (DA) is synthesized in neuronal terminals from tyrosine by the sequential actions of tyrosine hydroxylase (TH), producing the intermediary L-dihydroxyphenylalanine (L-DOPA), and aromatic L-amino acid decarboxylase (AAD). In the terminal, DA is transported into storage vesicles by a vesicular membrane transporter (T). Release, triggered by depolarization and entry of Ca^{2+} , allows dopamine to act on a variety of postsynaptic GPCRs for DA. The D_1 and D_2 receptors are important in brain regions involved in PD. The differential actions of DA on postsynaptic targets bearing different types of DA receptors have important implications for the function of neural circuits. The actions of DA are terminated by reuptake into the nerve terminal (where DA may be stored or metabolized) or uptake into the postsynaptic cell (where DA is metabolized). Metabolism occurs by the sequential actions of the enzymes catechol-*O*-methyltransferase (COMT), monoamine oxidase (MAO), and aldehyde dehydrogenase (AD). 3MT, 3-methoxytyramine; DOPAC, 3,4-dihydroxyphenylacetic acid; HVA, 3-methoxy-4-hydroxy-phenylacetic acid (see Figure 20–4). In humans, HVA is the principal metabolite of DA. (From Cooper *et al.*, 1996, with permission.)

Figure 20–4. Metabolism of levodopa (L-DOPA). AD, aldehyde dehydrogenase; COMT, catechol-O-methyltransferase; DβH, dopamine β-hydroxylase; AAD, aromatic L-amino acid decarboxylase; MAO, monoamine oxidase.

Two types of dopamine receptors were identified in the mammalian brain using pharmacological techniques: D₁ receptors, which stimulate the synthesis of the intracellular second messenger cyclic AMP, and D₂ receptors, which inhibit cyclic AMP synthesis as well as suppress Ca²⁺ currents and activate receptor-operated K⁺ currents. Application of molecular genetics to the study of dopamine receptors has revealed a more complex receptor situation than envisioned

originally. At present, five distinct dopamine receptors are known (see Missale *et al.*, 1998, and Chapter 12). All the dopamine receptors are heptahelical G protein-coupled receptors (GPCRs) (see Chapter 1).

The five dopamine receptors can be divided into two groups on the basis of their pharmacological and structural properties (Figure 20–5). The D₁ and D₅ proteins have a long intracellular carboxy-terminal tail and are members of the class defined pharmacologically as D₁; they stimulate the formation of cyclic AMP and phosphatidylinositol hydrolysis. The D₂, D₃, and D₄ receptors share a large third intracellular loop and are of the D₂ class. They decrease cyclic AMP formation and modulate K⁺ and Ca²⁺ currents. Each of the five dopamine receptor proteins has a distinct anatomical pattern of expression in the brain. The D₁ and D₂ proteins are abundant in the striatum and are the most important receptor sites with regard to the causes and treatment of PD. The D₄ and D₅ proteins are largely extrastriatal, whereas D₃ expression is low in the caudate and putamen but more abundant in the nucleus accumbens and olfactory tubercle.

Neural Mechanism of Parkinsonism. Considerable effort has been devoted to understanding how the loss of dopaminergic input to the neurons of the neostriatum gives rise to the clinical features of PD (for review, see Albin *et al.*, 1989; Mink and Thach, 1993; and Wichmann and DeLong, 1993). The basal ganglia can be viewed as a modulatory side loop that regulates the flow of information from the cerebral cortex to the motor neurons of the spinal cord (Figure 20–6). The neostriatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of the cortex. Most neurons within the striatum are projection neurons that innervate other basal ganglia structures. A small but important subgroup of striatal neurons consists of interneurons that connect neurons within the striatum but do not project beyond its borders. Acetylcholine and neuropeptides are used as transmitters by these striatal interneurons.

The outflow of the striatum proceeds along two distinct routes, termed the *direct* and *indirect pathways*. The direct pathway is

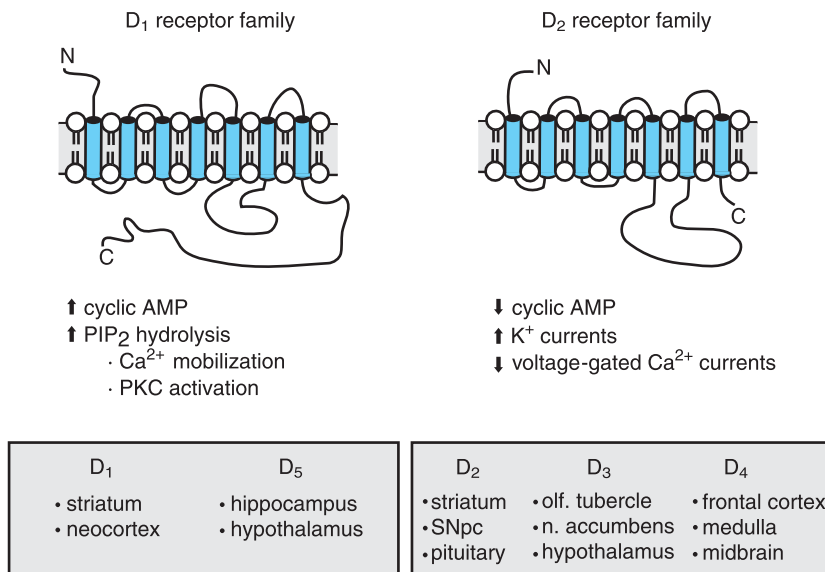

Figure 20–5. Distribution and characteristics of dopamine receptors in the central nervous system. SNpc, substantia nigra pars compacta.

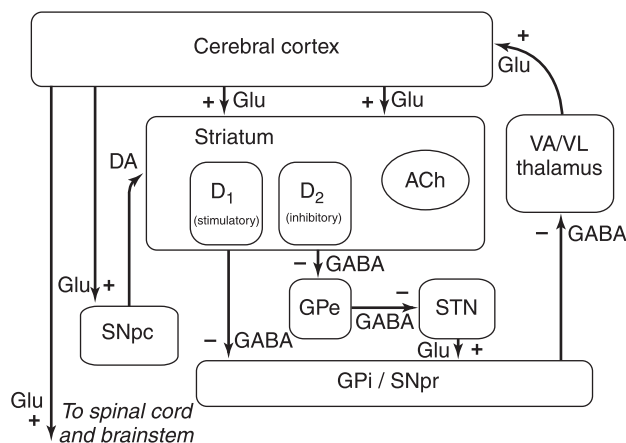

Figure 20–6. Schematic wiring diagram of the basal ganglia. The striatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of cerebral cortex. The striatum contains projection neurons expressing predominantly D₁ or D₂ dopamine receptors, as well as interneurons that use acetylcholine (ACh) as a neurotransmitter. Outflow from the striatum proceeds along two routes. The direct pathway, from the striatum to the substantia nigra pars reticulata (SNpr) and globus pallidus interna (GPI), uses the inhibitory transmitter GABA. The indirect pathway, from the striatum through the globus pallidus externa (GPe) and the subthalamic nucleus (STN) to the SNpr and GPI consists of two inhibitory GABAergic links and one excitatory glutamatergic projection (Glu). The substantia nigra pars compacta (SNpc) provides dopaminergic innervation to the striatal neurons, giving rise to both the direct and indirect pathways, and regulates the relative activity of these two paths. The SNpr and GPI are the output structures of the basal ganglia and provide feedback to the cerebral cortex through the ventroanterior and ventrolateral nuclei of the thalamus (VA/VL).

formed by neurons in the striatum that project directly to the output stages of the basal ganglia, the substantia nigra pars reticulata (SNpr) and the globus pallidus interna (GPI); these, in turn, relay to the ventroanterior and ventrolateral thalamus, which provides excitatory input to the cortex. The neurotransmitter of both links of the direct pathway is γ -aminobutyric acid (GABA), which is inhibitory, so that the net effect of stimulation of the direct pathway at the level of the striatum is to increase the excitatory outflow from the thalamus to the cortex. The indirect pathway is composed of striatal neurons that project to the globus pallidus externa (GPe). This structure, in turn, innervates the subthalamic nucleus (STN), which provides outflow to the SNpr and GPI output stage. As in the direct pathway, the first two links—the projections from striatum to GPe and GPe to STN—use the inhibitory transmitter GABA; however, the final link—the projection from STN to SNpr and GPI—is an excitatory glutamatergic pathway. Thus the net effect of stimulating the indirect pathway at the level of the striatum is to reduce the excitatory outflow from the thalamus to the cerebral cortex.

The key feature of this model of basal ganglia function, which accounts for the symptoms observed in PD as a result of loss of

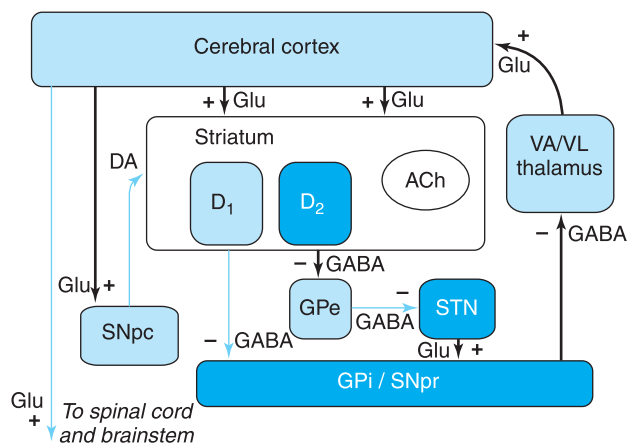

Figure 20–7. The basal ganglia in Parkinson's disease. The primary defect is destruction of the dopaminergic neurons of the SNpc. The striatal neurons that form the direct pathway from the striatum to the SNpr and GPI express primarily the *excitatory* D₁ dopamine receptor, whereas the striatal neurons that project to the GPe and form the indirect pathway express the *inhibitory* D₂ dopamine receptor. Thus, loss of the dopaminergic input to the striatum has a differential effect on the two outflow pathways; the direct pathway to the SNpr and GPI is less active (*structures in light blue*), whereas the activity in the indirect pathway is increased (*structures in dark blue*). The net effect is that neurons in the SNpr and GPI become more active. This leads to increased inhibition of the VA/VL thalamus and reduced excitatory input to the cortex. (See legend to Figure 20–6 for definitions of anatomical abbreviations.)

dopaminergic neurons, is the differential effect of dopamine on the direct and indirect pathways (Figure 20–7). The dopaminergic neurons of the substantia nigra pars compacta (SNpc) innervate all parts of the striatum; however, the target striatal neurons express distinct types of dopamine receptors. The striatal neurons giving rise to the direct pathway express primarily the *excitatory* D₁ dopamine receptor protein, whereas the striatal neurons forming the indirect pathway express primarily the *inhibitory* D₂ type. Thus dopamine released in the striatum tends to increase the activity of the direct pathway and reduce the activity of the indirect pathway, whereas the depletion that occurs in PD has the opposite effect. The net effect of the reduced dopaminergic input in PD is to increase markedly the inhibitory outflow from the SNpr and GPI to the thalamus and reduce excitation of the motor cortex.

There are several limitations of this model of basal ganglia function (Parent and Ciccetti, 1998). In particular, recent work has shown that the anatomical connections are considerably more complex than envisioned originally. In addition, many of the pathways involved use not just one but several neurotransmitters. For example, the neuropeptides substance P and dynorphin are found predominantly in striatal neurons making up the direct pathway, whereas most of the indirect pathway neurons express enkephalin. These transmitters are expected to have slow modulatory effects on signaling, in contrast to the rapid effects of glutamate and GABA, but the functional significance of these modulatory effects remains unclear. Nevertheless, the model is useful and has important implications for

Table 20–1
Commonly Used Medications for the Treatment of Parkinson’s Disease

AGENT	TYPICAL INITIAL DOSE	TOTAL DAILY DOSE— USEFUL RANGE	COMMENTS
Carbidopa/levodopa	25 mg carbidopa + 100 mg levodopa (“25/100” tablet), twice or three times a day	200–1200 mg levodopa	
Carbidopa/levodopa sustained release	50 mg carbidopa + 200 mg levodopa (“50/200 sustained release” tablet) twice a day	200–1200 mg levodopa	Bioavailability 75% of immediate release form
Bromocriptine	1.25 mg twice a day	3.75–40 mg	Titrate slowly
Pergolide	0.05 mg once a day	0.75–5 mg	Titrate slowly
Ropinirole	0.25 mg three times a day	1.5–24 mg	
Pramipexole	0.125 mg three times a day	1.5–4.5 mg	
Entacapone	200 mg with each dose of levodopa/carbidopa	600–2000 mg	
Tolcapone	100 mg twice a day or three times a day	200–600 mg	May be hepatotoxic; requires monitoring of liver enzymes
Selegiline	5 mg twice a day	2.5–10 mg	
Amantadine	100 mg twice a day	100–200 mg	
Trihexyphenidyl HCl	1 mg twice a day	2–15 mg	

the rational design and use of pharmacological agents in PD. First, it suggests that to restore the balance of the system through stimulation of dopamine receptors, the complementary effect of actions at both D₁ and D₂ receptors, as well as the possibility of adverse effects that may be mediated by D₃, D₄, or D₅ receptors, must be considered. Second, it explains why replacement of dopamine is not the only approach to the treatment of PD. Drugs that inhibit cholinergic receptors have long been used for treatment of parkinsonism. Although their mechanisms of action are not completely understood, it seems likely that their effect is mediated at the level of the striatal projection neurons, which normally receive cholinergic input from striatal cholinergic interneurons. Few clinically useful drugs for parkinsonism are presently available based on actions through GABA and glutamate receptors, even though both have crucial roles in the circuitry of the basal ganglia. However, they represent a promising avenue for drug development (Hallet and Standaert, 2004).

TREATMENT OF PARKINSON’S DISEASE

Commonly used medications for the treatment of PD are summarized in Table 20–1.

Levodopa

Levodopa (L-DOPA, LARODOPA, L-3,4-dihydroxyphenylalanine), the metabolic precursor of dopamine, is the single most effective agent in the treatment of PD.

Levodopa is itself largely inert; both its therapeutic and adverse effects result from the decarboxylation of levodopa to dopamine. When administered orally, levodopa is absorbed rapidly from the small bowel by the transport system for aromatic amino acids. Concentrations of the drug in plasma usually peak between 0.5 and 2 hours after an oral dose. The half-life in plasma is short (1 to 3 hours). The rate and extent of absorption of levodopa depends on the rate of gastric emptying, the pH of gastric juice, and the length of time the drug is exposed to the degradative enzymes of the gastric and intestinal mucosa. Competition for absorption sites in the small bowel from dietary amino acids also may have a marked effect on the absorption of levodopa; administration of levodopa with meals delays absorption and reduces peak plasma concentrations. Entry of the drug into the central nervous system (CNS) across the blood–brain barrier also is mediated by a membrane transporter for aromatic amino acids, and competition between dietary protein and levodopa may occur at this level. In the brain, levodopa is converted to dopamine by decarboxylation primarily within the presynaptic terminals of dopaminergic neurons in the striatum. The dopamine produced is responsible for the therapeutic effectiveness of the drug in PD; after release, it is either transported back into dopaminergic terminals by the presynaptic uptake mechanism or

metabolized by the actions of MAO and catechol-*O*-methyltransferase (COMT) (Figure 20–4).

In practice, levodopa is almost always administered in combination with a peripherally acting inhibitor of aromatic L-amino acid decarboxylase, such as *carbidopa* or *benserazide* (available outside the United States), that do not penetrate well into the CNS. If levodopa is administered alone, the drug is largely decarboxylated by enzymes in the intestinal mucosa and other peripheral sites so that relatively little unchanged drug reaches the cerebral circulation and probably less than 1% penetrates the CNS. In addition, dopamine release into the circulation by peripheral conversion of levodopa produces undesirable effects, particularly nausea. Inhibition of peripheral decarboxylase markedly increases the fraction of administered levodopa that remains unmetabolized and available to cross the blood–brain barrier (see Figure 20–9) and reduces the incidence of gastrointestinal side effects. In most individuals, a daily dose of 75 mg carbidopa is sufficient to prevent the development of nausea. For this reason, the most commonly prescribed form of carbidopa/levodopa (SINEMET, ATAMET) is the 25/100 form, containing 25 mg carbidopa and 100 mg levodopa. With this formulation, dosage schedules of three or more tablets daily provide acceptable inhibition of decarboxylase in most individuals. Occasionally, individuals will require larger doses of carbidopa to minimize gastrointestinal side effects, and administration of supplemental carbidopa (LODOSYN) alone may be beneficial.

Levodopa therapy can have a dramatic effect on all the signs and symptoms of PD. Early in the course of the disease, the degree of improvement in tremor, rigidity, and bradykinesia may be nearly complete. In early PD, the duration of the beneficial effects of levodopa may exceed the plasma lifetime of the drug, suggesting that the nigrostriatal dopamine system retains some capacity to store and release dopamine. A principal limitation of the long-term use of levodopa therapy is that with time this apparent “buffering” capacity is lost, and the patient’s motor state may fluctuate dramatically with each dose of levodopa. A common problem is the development of the “wearing off” phenomenon: each dose of levodopa effectively improves mobility for a period of time, perhaps 1 to 2 hours, but rigidity and akinesia return rapidly at the end of the dosing interval. Increasing the dose and frequency of administration can improve this situation, but this often is limited by the development of *dyskinesias*, excessive and abnormal involuntary movements. Dyskinesias are observed most often when the plasma levodopa concentration is high, although in some individuals dyskinesias or dystonia may be triggered when the level is rising or falling. These movements can be as uncomfortable and disabling

as the rigidity and akinesia of PD. In the later stages of PD, patients may fluctuate rapidly between being “off,” having no beneficial effects from their medications, and being “on” but with disabling dyskinesias, a situation called the *on/off phenomenon*.

Recent evidence has indicated that induction of the on/off phenomena and dyskinesias may be the result of an active process of adaptation to variations in brain and plasma levodopa levels. This process of adaptation is apparently complex, involving not only alterations in the function of dopamine receptors but also downstream changes in the postsynaptic striatal neurons, including modification of NMDA glutamate receptors (Mouradian and Chase, 1994; Chase, 1998, Hallett and Standaert, 2004). When levodopa levels are maintained constant by intravenous infusion, dyskinesias and fluctuations are greatly reduced, and the clinical improvement is maintained for up to several days after returning to oral levodopa dosing (Mouradian *et al.*, 1990). A sustained-release formulation consisting of carbidopa/levodopa in an erodable wax matrix (SINEMET CR) has been marketed in an attempt to produce more stable plasma levodopa levels than can be obtained with oral administration of standard carbidopa/levodopa formulations. This formulation is helpful in some cases, but absorption of the sustained-release formulation is not entirely predictable. Another technique used to overcome the on/off phenomenon is to sum the total daily dose of carbidopa/levodopa and give equal amounts every 2 hours rather than every 4 or 6 hours.

An important unanswered question regarding the use of levodopa in PD is whether this medication alters the course of the underlying disease or merely modifies the symptoms. Two aspects of levodopa treatment and the outcome of PD are of concern. First, if the production of free radicals as a result of dopamine metabolism contributes to the death of nigrostriatal neurons, then the addition of levodopa actually might accelerate the process, although no convincing evidence for such an effect has yet been obtained. Second, it is well established that the undesirable on/off fluctuations and wearing off phenomena are observed almost exclusively in patients treated with levodopa, but it is not known if delaying treatment with levodopa will delay the appearance of these effects. In view of these uncertainties, most practitioners have adopted a pragmatic approach, using levodopa only when the symptoms of PD cause functional impairment.

In addition to motor fluctuations and nausea, several other adverse effects may be observed with levodopa treatment. A common and troubling adverse effect is the induction of hallucinations and confusion; these effects are particularly common in the elderly and in those with pre-existing cognitive dysfunction and often limit the ability to treat parkinsonian symptoms adequately. Conventional antipsychotic agents, such as the phenothiazines, are effective against levodopa-induced psychosis but may cause marked worsening of parkinsonism, probably through actions at the D₂ dopamine receptor. A recent approach has been to use the “atypical” antipsychotic agents, which are effective in the treatment of psychosis but do not cause or worsen parkinsonism (see Chapter 18). The most effective of these are *clozapine* and *quetiapine* (Friedman and Factor, 2000).

Peripheral decarboxylation of levodopa and release of dopamine into the circulation may activate vascular dopamine receptors and produce orthostatic hypotension. The actions of dopamine at α and β adrenergic receptors may induce cardiac arrhythmias, especially

in patients with pre-existing conduction disturbances. Administration of levodopa with nonspecific inhibitors of MAO, such as *phenelzine* and *tranylcypromine*, markedly accentuates the actions of levodopa and may precipitate life-threatening hypertensive crisis and hyperpyrexia; nonspecific MAO inhibitors always should be discontinued at least 14 days before levodopa is administered (note that this prohibition does not include the MAO-B subtype-specific inhibitor *selegiline*, which, as discussed below, often is administered safely in combination with levodopa). Abrupt withdrawal of levodopa or other dopaminergic medications may precipitate the *neuroleptic malignant syndrome* more commonly observed after treatment with dopamine antagonists.

Dopamine-Receptor Agonists. An alternative to levodopa is the use of drugs that are direct agonists of striatal dopamine receptors, an approach that offers several potential advantages. Since enzymatic conversion of these drugs is not required for activity, they do not depend on the functional capacities of the nigrostriatal neurons. Most dopamine-receptor agonists in clinical use have durations of action substantially longer than that of levodopa and often are useful in the management of dose-related fluctuations in motor state. Finally, if the hypothesis that free radical formation as a result of dopamine metabolism contributes to neuronal death is correct, then dopamine-receptor agonists may have the potential to modify the course of the disease by reducing endogenous release of dopamine as well as the need for exogenous levodopa.

Four orally administered dopamine-receptor agonists are available for treatment of PD: two older agents, *bromocriptine* (PARLODEL) and *pergolide* (PERMAX); and two newer, more selective compounds, *ropinirole* (REQUIP) and *pramipexole* (MIRPEX). Bromocriptine and pergolide both are ergot derivatives and share a similar spectrum of therapeutic actions and adverse effects. Bromocriptine is a strong agonist of the D₂ class of dopamine receptors and a partial antagonist of the D₁ receptors, whereas pergolide is an agonist of both classes. Ropinirole and pramipexole (Figure 20–8) have selective activity at D₂ class sites (specifically at the D₂ and D₃ receptor proteins) and little or no activity at D₁ class sites. All four of the drugs are well absorbed orally and have similar therapeutic actions. Like levodopa, they can relieve the clinical symptoms of PD. The duration of action of the dopamine agonists (8 to 24 hours) often is longer than that of levodopa (6 to 8 hours), and they are particularly effective in the treatment of patients who have developed on/off phenomena. All four also may produce hallucinosis or confusion, similar to that observed with levodopa, and may worsen orthostatic hypotension.

The principal distinction between the newer, more selective agents and the older ergot derivatives is in their tolerability and speed of titration. Initial treatment with bro-

Figure 20–8. Structures of selective dopamine D₂-receptor agonists.

mocriptine or pergolide may cause profound hypotension, so they should be initiated at low dosage. The ergot derivatives also often induce nausea and fatigue with initial treatment. Symptoms usually are transient, but they require slow upward adjustment of the dose over a period of weeks to months. Ropinirole and pramipexole can be initiated more quickly, achieving therapeutically useful doses in a week or less. They generally cause less gastrointestinal disturbance than do the ergot derivatives, but they can produce nausea and somnolence. The somnolence in some cases may be quite severe, and several instances of sudden attacks of irresistible sleepiness leading to motor vehicle accidents have been reported (Frucht *et al.*, 1999). This effect seems to be uncommon, but it is prudent to advise patients of this possibility and to switch to another treatment if sleepiness interferes with the activities of daily life. Recent reports have associated long-term use of pergolide with significant cardiac valvular disease. If these reports are confirmed, this may be another important factor favoring the use of the nonergot agents.

The introduction of pramipexole and ropinirole has led to a substantial change in the clinical use of dopamine agonists in PD. Because these selective agonists are well tolerated, they are used increasingly as initial treatment for PD rather than as adjuncts to levodopa. This change has been driven by two factors: (1) the belief that because of their longer duration of action, dopamine agonists may be less likely than levodopa to induce on/off effects and dyskinesias and (2) the concern that levodopa may contribute to oxidative stress, thereby accelerating loss of dopaminergic neurons. Two large controlled clinical trials comparing levodopa with pramipexole or ropinirole as initial treatment of PD have provided convincing evidence for a reduced rate of motor fluctuation in patients treated with these agonists. This benefit was accompanied by an increased rate of adverse effects in both stud-

ies, especially somnolence and hallucinations (Parkinson Study Group, 2000; Rascol *et al.*, 2000). At present, many experts favor dopamine agonists as initial therapy in younger patients with PD and levodopa as the initial treatment in older patients who may be more vulnerable to the adverse cognitive effects of the agonists.

Apomorphine (APOKYN) is a dopaminergic agonist that can be administered by subcutaneous injection. It has high affinity for D₄ receptors; moderate affinity for D₂, D₃, D₅, and adrenergic α 1D, α 2B, and α 2C receptors; and low affinity for D₁ receptors. Apomorphine has been used in Europe for many years and was approved recently by the U.S. Food and Drug Administration (FDA) as a “rescue therapy” for the acute intermittent treatment of “off” episodes in patients with a fluctuating response to dopaminergic therapy. In addition to being associated with the side effects discussed earlier for the oral dopamine agonists, apomorphine also is highly emetogenic and requires pre- and post-treatment antiemetic therapy. It is recommended that oral trimethobenzamide (TIGAN), at a dose of 300 mg three times daily, be started three days prior to the initial dose of apomorphine and continued at least during the first 2 months of therapy. Based on reports of profound hypotension and loss of consciousness when apomorphine was administered with ondansetron, the concomitant use of apomorphine with antiemetic drugs of the 5-HT₃ antagonist class is contraindicated. Other potentially serious side effects of apomorphine include QT prolongation, injection-site reactions, and the development of a pattern of abuse characterized by increasingly frequent dosing leading to hallucinations, dyskinesia, and abnormal behavior. Because of these potential adverse effects, use of apomorphine is appropriate only when other measures, such as oral dopamine agonists or COMT inhibitors, have failed to control the “off” episodes. Apomorphine therapy should be initiated in a setting where the patient can be monitored carefully, beginning with a 2-mg test dose. If this is tolerated, it can be titrated slowly up to a maximum dosage of 6 mg. For effective control of symptoms, patients may require three or more injections daily.

Catechol-O-Methyltransferase (COMT) Inhibitors. A recently developed class of drugs for the treatment of PD consists of inhibitors of COMT. COMT and MAO are responsible for the catabolism of levodopa as well as dopamine. COMT transfers a methyl group from the donor S-adenosyl-L-methionine, producing the pharmacologically inactive compounds 3-O-methyl DOPA (from levodopa) and 3-methoxytyramine (from dopamine) (Figure 20–9). When levodopa is administered orally, nearly 99% of the drug is catabolized and does not reach the brain. Most is

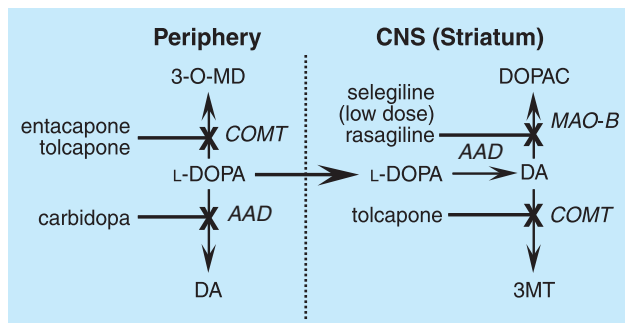

Figure 20–9. Pharmacological preservation of L-DOPA and striatal dopamine. The principal site of action of inhibitors of catechol-O-methyltransferase (COMT) (such as tolcapone and entacapone) is in the peripheral circulation. They block the O-methylation of levodopa (L-DOPA) and increase the fraction of the drug available for delivery to the brain. Tolcapone also has effects in the CNS. Inhibitors of MAO-B, such as low-dose selegiline and rasagiline, will act within the CNS to reduce oxidative deamination of DA, thereby enhancing vesicular stores. AAD, aromatic L-amino acid decarboxylase; DA, dopamine; DOPAC, 3,4-dihydroxyphenylacetic acid; MAO, monoamine oxidase; 3MT, 3-methoxytyramine; 3-O-MD, 3-O-methyl DOPA.

converted by aromatic L-amino acid decarboxylase (AAD) to dopamine, which causes nausea and hypotension. Addition of an AAD inhibitor such as carbidopa reduces the formation of dopamine but increases the fraction of levodopa that is methylated by COMT. The principal therapeutic action of the COMT inhibitors is to block this peripheral conversion of levodopa to 3-O-methyl DOPA, increasing both the plasma half-life of levodopa as well as the fraction of each dose that reaches the CNS.

Two COMT inhibitors presently are available for this use in the United States, *tolcapone* (TASMAR) and *entacapone* (COMTAN). Both these agents have been shown in double-blind trials to reduce the clinical symptoms of “wearing off” in patients treated with levodopa/carbidopa (Parkinson Study Group, 1997; Kurth *et al.*, 1997). Although the magnitude of their clinical effects and mechanisms of action are similar, they differ with respect to pharmacokinetic properties and adverse effects. Tolcapone has a relatively long duration of action, allowing for administration two to three times a day, and appears to act by both central and peripheral inhibition of COMT. The duration of action of entacapone is short, around 2 hours, so it usually is administered simultaneously with each dose of levodopa/carbidopa. The action of entacapone is attributable principally to peripheral inhibition of COMT. The common adverse effects of these agents are similar to those observed in patients treated with levodopa/carbidopa alone and include nausea, orthostatic

hypotension, vivid dreams, confusion, and hallucinations. An important adverse effect associated with tolcapone is hepatotoxicity. In clinical trials, up to 2% of the patients treated had increases in serum alanine aminotransferase and aspartate transaminase; after marketing, three fatal cases of fulminant hepatic failure in patients taking tolcapone were observed, leading to addition of a warning to the label. At present, tolcapone should be used only in patients who have not responded to other therapies and with appropriate monitoring for hepatic injury. Entacapone has not been associated with hepatotoxicity and requires no special monitoring. Entacapone also is available in fixed-dose combinations with levodopa/carbidopa (STALEVO).

Selective MAO-B Inhibitors. Two isoenzymes of MAO oxidize monoamines. While both isoenzymes (MAO-A and MAO-B) are present in the periphery and inactivate monoamines of intestinal origin, the isoenzyme MAO-B is the predominant form in the striatum and is responsible for most of the oxidative metabolism of dopamine in the brain. At low to moderate doses (10 mg/day or less), *selegiline* (ELDEPRYL) is a selective inhibitor of MAO-B, leading to irreversible inhibition of the enzyme (Olanow, 1993). Unlike nonspecific inhibitors of MAO (such as phenelzine, tranylcypromine, and isocarboxazid), selegiline does not inhibit peripheral metabolism of catecholamines; thus it can be taken safely with levodopa. Selegiline also does not cause the lethal potentiation of catecholamine action observed when patients taking nonspecific MAO inhibitors ingest indirectly acting sympathomimetic amines such as the tyramine found in certain cheeses and wine. Doses of selegiline higher than 10 mg daily can produce inhibition of MAO-A and should be avoided.

Selegiline has been used for several years as a symptomatic treatment for PD, although its benefit is modest. The basis of the efficacy of selegiline is presumed to be its capacity to retard the breakdown of dopamine in the striatum. With the recent emergence of interest in the potential role of free radicals and oxidative stress in the pathogenesis of PD, it has been proposed that the ability of selegiline to retard the metabolism of dopamine might confer neuroprotective properties. In support of this idea, selegiline can protect animals from MPTP-induced parkinsonism by blocking the conversion of MPTP to its toxic metabolite (1-methyl-4-phenylpyridium ion), a transformation mediated by MAO-B. The potential protective role of selegiline in idiopathic PD was evaluated in multicenter randomized trials; these studies showed a symptomatic effect of selegiline in PD, but longer follow-up failed to provide

any definite evidence of ability to retard the loss of dopaminergic neurons (Parkinson Study Group, 1993).

Selegiline is generally well tolerated in patients with early or mild PD. In patients with more advanced PD or underlying cognitive impairment, selegiline may accentuate the adverse motor and cognitive effects of levodopa therapy. Metabolites of selegiline include amphetamine and methamphetamine, which may cause anxiety, insomnia, and other adverse symptoms. A related compound, rasagiline, also acts through inhibition of MAO-B but does not form these undesirable metabolites. Rasagiline has shown efficacy in both early and advanced PD but is not yet approved for use in the United States. Interestingly, selegiline, like the nonspecific MAO inhibitors, can lead to the development of stupor, rigidity, agitation, and hyperthermia after administration of the analgesic meperidine; the basis of this interaction is uncertain. There also have been case reports of adverse effects resulting from interactions between selegiline and tricyclic antidepressants and between selegiline and serotonin-reuptake inhibitors. The combination of selegiline and serotonin-reuptake inhibitors seems well tolerated in patients with PD, and many patients do take these combinations of medications without apparent adverse interaction; nonetheless, concomitant administration of selegiline and serotonergic drugs should be done with caution.

Muscarinic Receptor Antagonists. Antagonists of muscarinic acetylcholine receptors were used widely for the treatment of PD before the discovery of levodopa. The biological basis for the therapeutic actions of anticholinergics is not completely understood. It seems likely that they act within the neostriatum through the receptors that normally mediate the response to intrinsic cholinergic innervation of this structure, which arises primarily from cholinergic striatal interneurons. Several muscarinic cholinergic receptors have been cloned (*see* Chapters 7 and 12); like the dopamine receptors, these are GPCRs. Five subtypes of muscarinic receptors have been identified; at least four and probably all five subtypes are present in the striatum, although each has a distinct distribution (Hersch *et al.*, 1994). Several drugs with anticholinergic properties currently are used in the treatment of PD, including *trihexyphenidyl* (ARTANE, 2 to 4 mg three times per day), *benztropine mesylate* (COGENTIN, 1 to 4 mg two times per day), and *diphenhydramine hydrochloride* (BENADRYL, 25 to 50 mg three to four times per day). *Diphenhydramine* also is a histamine H₁ antagonist (*see* Chapter 24). All have modest antiparkinsonian activity that is useful in the treatment of early PD or as an adjunct to dopaminergic therapy. The adverse effects of these drugs are a result of

their anticholinergic properties. Most troublesome are sedation and mental confusion. They also may produce constipation, urinary retention, and blurred vision through cycloplegia; they must be used with caution in patients with narrow-angle glaucoma.

Amantadine. *Amantadine* (SYMMETREL), an antiviral agent used for the prophylaxis and treatment of influenza A (see Chapter 49), has antiparkinsonian activity. Amantadine has several pharmacological effects; it is not clear which properties are responsible for its antiparkinsonian actions. Amantadine appears to alter dopamine release in the striatum and also has anticholinergic properties. The most significant action of amantadine may be its ability to block NMDA glutamate receptors (Hallett and Standaert, 2004). In any case, the effects of amantadine in PD are modest. It is used as initial therapy of mild PD. It also may be helpful as an adjunct in patients on levodopa with dose-related fluctuations and dyskinesias. The antidyskinetic properties of amantadine have been attributed to actions at NMDA receptors, although the closely related NMDA receptor antagonist *memantine* (discussed below) does not seem to have this effect. Amantadine usually is administered in a dose of 100 mg twice a day and is well tolerated. Dizziness, lethargy, anticholinergic effects, and sleep disturbance, as well as nausea and vomiting, have been observed occasionally, but even when present, these effects are mild and reversible.

Neuroprotective Treatments for Parkinson's Disease. It would be desirable to identify a treatment that modifies the progressive degeneration that underlies PD rather than simply controlling the symptoms. Current research strategies are based on the mechanistic approaches described earlier (e.g., energy metabolism, oxidative stress, environmental triggers, and excitotoxicity) and on discoveries related to the genetics of PD (Cantuti-Castelvetri and Standaert, 2004). Some of the strongest evidence for a neuroprotective action has emerged from long-term studies of the effects of the dopamine agonists pramipexole and ropinirole. The therapeutic effects of these are related to actions at postsynaptic dopamine receptors, but they also can activate presynaptic autoreceptors found on dopamine terminals, which are principally of the D₂ class. By stimulating presynaptic receptors, pramipexole and ropinirole may reduce endogenous dopamine production and release and thereby diminish oxidative stress. Two trials have attempted to examine the effect of pramipexole or ropinirole on neurodegeneration in PD (Whone *et al.*, 2003; Parkinson Study Group, 2002). Both trials observed that in patients treated with one of these agonists, there

was a reduced rate of loss of markers of dopaminergic neurotransmission measured by brain imaging compared with a similar group of patients treated with levodopa. These intriguing data should be viewed cautiously, particularly because there is considerable uncertainty about the relationship of the imaging techniques used and the true rate of neurodegeneration (Albin and Frey, 2003). Another strategy under study is the use of compounds that augment cellular energy metabolism such coenzyme Q10, a cofactor required for the mitochondrial electron-transport chain. A small study has demonstrated that this drug is well tolerated in PD and has suggested that coenzyme Q10 may slow the course of the disease (Shults *et al.*, 2002).

ALZHEIMER'S DISEASE (AD)

Clinical Overview. AD produces an impairment of cognitive abilities that is gradual in onset but relentless in progression. Impairment of short-term memory usually is the first clinical feature, whereas retrieval of distant memories is preserved relatively well into the course of the disease. As the condition progresses, additional cognitive abilities are impaired, among them the ability to calculate, exercise visuospatial skills, and use common objects and tools (ideomotor apraxia). The level of arousal or alertness of the patient is not affected until the condition is very advanced, nor is there motor weakness, although muscular contractures are an almost universal feature of advanced stages of the disease. Death, most often from a complication of immobility such as pneumonia or pulmonary embolism, usually ensues within 6 to 12 years of onset. The diagnosis of AD is based on careful clinical assessment of the patient and appropriate laboratory tests to exclude other disorders that may mimic AD; at present, no direct antemortem confirmatory test exists.

Pathophysiology. AD is characterized by marked atrophy of the cerebral cortex and loss of cortical and subcortical neurons. The pathological hallmarks of AD are senile plaques, which are spherical accumulations of the protein β -amyloid accompanied by degenerating neuronal processes, and neurofibrillary tangles, composed of paired helical filaments and other proteins (Arnold *et al.*, 1991; Braak and Braak, 1994). Although small numbers of senile plaques and neurofibrillary tangles can be observed in intellectually normal individuals, they are far more abundant in patients with AD, and the abundance of tangles is roughly proportional to the severity of cognitive impairment. In advanced AD, senile plaques and neurofibrillary tangles are numerous and most abundant in the hippocampus and associative regions of the cortex, whereas areas such as the visual and motor cortices are relatively spared. This corresponds to the clinical features of marked impairment of memory and abstract reasoning, with preservation of vision and movement. The factors

underlying the selective vulnerability of particular cortical neurons to the pathological effects of AD are not known.

Neurochemistry. The neurochemical disturbances that arise in AD have been studied intensively (Johnston, 1992). Direct analysis of neurotransmitter content in the cerebral cortex shows a reduction of many transmitter substances that parallels neuronal loss; there is a striking and disproportionate deficiency of acetylcholine. The anatomical basis of the cholinergic deficit is the atrophy and degeneration of subcortical cholinergic neurons, particularly those in the basal forebrain (nucleus basalis of Meynert), that provide cholinergic innervation to the whole cerebral cortex. The selective deficiency of acetylcholine in AD, as well as the observation that central cholinergic antagonists such as atropine can induce a confusional state that bears some resemblance to the dementia of AD, has given rise to the “cholinergic hypothesis,” which proposes that a deficiency of acetylcholine is critical in the genesis of the symptoms of AD (Perry, 1986). Although the conceptualization of AD as a “cholinergic deficiency syndrome” in parallel with the “dopaminergic deficiency syndrome” of PD provides a useful framework, it is important to note that the deficit in AD is far more complex, involving multiple neurotransmitter systems, including serotonin, glutamate, and neuropeptides, and that in AD there is destruction of not only cholinergic neurons but also the cortical and hippocampal targets that receive cholinergic input.

Role of β -Amyloid. The presence of aggregates of β -amyloid is a constant feature of AD. Until recently, it was not clear whether the amyloid protein was causally linked to the disease process or merely a by-product of neuronal death. The application of molecular genetics has shed some light on this question. β -amyloid from affected brains and found to be a short polypeptide of 42 to 43 amino acids. This information led to cloning of amyloid precursor protein (APP), a much larger protein of more than 700 amino acids, which is expressed widely by neurons throughout the brain in normal individuals as well as in those with AD. The function of APP is unknown, although the structural features of the protein suggest that it may serve as a cell surface receptor for an as-yet-unidentified ligand. The production of β -amyloid from APP appears to result from abnormal proteolytic cleavage of APP by the β -site APP-cleaving enzyme BACE. This may be an important target of future therapies (Vassar *et al.*, 1999).

Analysis of APP gene structure in pedigrees exhibiting autosomal dominant inheritance of AD has shown that in some families, mutations of the β -amyloid-forming region of APP are present, whereas in others, mutations of proteins involved in the processing of APP are implicated (Selkoe, 2002). These results suggest that it is possible for abnormalities in APP or its processing to cause AD. The vast majority of cases of AD, however, are not familial, and structural abnormality of APP or related proteins has not been observed consistently in these sporadic cases of AD. As noted earlier, common alleles of the apo E protein have been found to influence the probability of developing AD. Many investigators believe that modifying the metabolism of APP might alter the course of AD in both familial and sporadic cases, but no clinically practical strategies have been developed.

Treatment of Alzheimer’s Disease. A major approach to the treatment of AD has involved attempts to augment the cholinergic function of the brain (Johnston, 1992). An early approach was the use of precursors of acetylcholine

synthesis, such as *choline chloride* and *phosphatidyl choline (lecithin)*. Although these supplements generally are well tolerated, randomized trials have failed to demonstrate any clinically significant efficacy.

A somewhat more successful strategy has been the use of inhibitors of acetylcholinesterase (AChE), the catabolic enzyme for acetylcholine (*see* Chapter 8). *Physostigmine*, a rapidly acting, reversible AChE inhibitor, produces improved responses in animal models of learning, and some studies have demonstrated mild transitory improvement in memory following physostigmine treatment in patients with AD. The use of physostigmine has been limited because of its short half-life and tendency to produce symptoms of systemic cholinergic excess at therapeutic doses.

Four inhibitors of AChE currently are approved by the FDA for treatment of Alzheimer’s disease: *tacrine* (1,2,3,4-tetrahydro-9-aminoacridine; COGNEX), *donepezil* (ARICEPT), *rivastigmine* (EXCELON), and *galantamine* (RAZADYNE) (Mayeux and Sano, 1999). Tacrine is a potent centrally acting inhibitor of AChE (Freeman and Dawson, 1991). Studies of oral tacrine in combination with lecithin have confirmed that there is indeed an effect of tacrine on some measures of memory performance, but the magnitude of improvement observed with the combination of lecithin and tacrine is modest at best (Chatellier and Lacomblez, 1990). The side effects of tacrine often are significant and dose-limiting; abdominal cramping, anorexia, nausea, vomiting, and diarrhea are observed in up to one-third of patients receiving therapeutic doses, and elevations of serum transaminases are observed in up to 50% of those treated. Because of significant side effects, tacrine is not used widely clinically. Donepezil is a selective inhibitor of AChE in the CNS with little effect on AChE in peripheral tissues. It produces modest improvements in cognitive scores in Alzheimer’s disease patients (Rogers and Friedhoff, 1998) and has a long half-life (*see* Appendix II), allowing once-daily dosing. Rivastigmine and galantamine are dosed twice daily and produce a similar degree of cognitive improvement. Adverse effects associated with donepezil, rivastigmine, and galantamine are similar in character but generally less frequent and less severe than those observed with tacrine; they include nausea, diarrhea, vomiting, and insomnia. Donepezil, rivastigmine, and galantamine are not associated with the hepatotoxicity that limits the use of tacrine.

An alternative strategy for the treatment of AD is the use of the NMDA glutamate-receptor antagonist memantine (NAMENDA). Memantine produces a use-dependent blockade of NMDA receptors. In patients with moderate to severe AD, use of memantine is associated with a

reduced rate of clinical deterioration (Reisberg *et al.*, 2003). Whether this is due to a true disease-modifying effect, possibly reduced excitotoxicity, or is a symptomatic effect of the drug is unclear. Adverse effects of memantine usually are mild and reversible and may include headache or dizziness.

HUNTINGTON'S DISEASE

Clinical Features. HD is a dominantly inherited disorder characterized by the gradual onset of motor incoordination and cognitive decline in midlife. Symptoms develop insidiously, either as a movement disorder manifest by brief, jerklke movements of the extremities, trunk, face, and neck (chorea) or as personality changes or both. Fine motor incoordination and impairment of rapid eye movements are early features. Occasionally, especially when the onset of symptoms occurs before age 20, choreic movements are less prominent; instead, bradykinesia and dystonia predominate. As the disorder progresses, the involuntary movements become more severe, dysarthria and dysphagia develop, and balance is impaired. The cognitive disorder manifests first as slowness of mental processing and difficulty in organizing complex tasks. Memory is affected, but affected persons rarely lose their memory of family, friends, and the immediate situation. Such persons often become irritable, anxious, and depressed. Less frequently, paranoia and delusional states are manifest. The outcome of HD is invariably fatal; over a course of 15 to 30 years, the affected person becomes totally disabled and unable to communicate, requiring full-time care; death ensues from the complications of immobility (Hayden, 1981; Harper, 1991).

Pathology and Pathophysiology. HD is characterized by prominent neuronal loss in the striatum (caudate/putamen) of the brain (Vonsattel *et al.*, 1985). Atrophy of these structures proceeds in an orderly fashion, first affecting the tail of the caudate nucleus and then proceeding anteriorly from mediodorsal to ventrolateral. Other areas of the brain also are affected, although much less severely; morphometric analyses indicate that there are fewer neurons in cerebral cortex, hypothalamus, and thalamus. Even within the striatum, the neuronal degeneration of HD is selective. Interneurons and afferent terminals are largely spared, whereas the striatal projection neurons (the medium spiny neurons) are severely affected. This leads to large decreases in striatal GABA concentrations, whereas somatostatin and dopamine concentrations are relatively preserved (Ferrante *et al.*, 1987).

Selective vulnerability also appears to underlie the most conspicuous clinical feature of HD, the development of chorea. In most adult-onset cases, the medium spiny neurons that project to the GPi and SNpr (the indirect pathway) appear to be affected earlier than

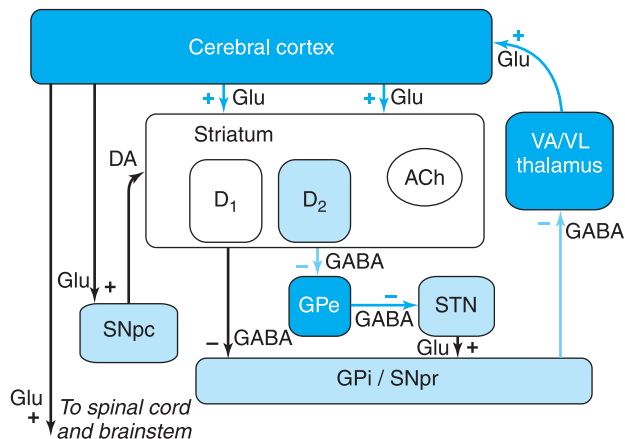

Figure 20–10. The basal ganglia in Huntington's disease. HD is characterized by loss of neurons from the striatum. The neurons that project from the striatum to the GPe and form the indirect pathway are affected earlier in the course of the disease than those which project to the GPi. This leads to a loss of inhibition of the GPe. The increased activity in this structure, in turn, inhibits the STN, SNpr, and GPi, resulting in a loss of inhibition to the VA/VL thalamus and increased thalamocortical excitatory drive. Structures in light blue have reduced activity in HD, whereas structures in dark blue have increased activity. (See legend to Figure 20–6 for definitions of anatomical abbreviations.)

those projecting to the GPe (the direct pathway) (Albin *et al.*, 1992). The disproportionate impairment of the indirect pathway increases excitatory drive to the neocortex, producing involuntary choreiform movements (Figure 20–10). In some individuals, rigidity rather than chorea is the predominant clinical feature; this is especially common in juvenile-onset cases. In these cases the striatal neurons giving rise to both the direct and indirect pathways are impaired to a comparable degree.

Genetics. HD is an autosomal dominant disorder with nearly complete penetrance. The average age of onset is between 35 and 45 years, but the range varies from as early as age 2 to as late as the middle 80s. Although the disease is inherited equally from mother and father, more than 80% of those developing symptoms before age 20 inherit the defect from the father. This is an example of *anticipation*, or the tendency for the age of onset of a disease to decline with each succeeding generation, which also is observed in other neurodegenerative diseases with similar genetic mechanisms. Known homozygotes for HD show clinical characteristics identical to the typical HD heterozygote, indicating that the unaffected chromosome does not attenuate the disease symptomatology. Until the discovery of the genetic defect responsible for HD, *de novo* mutations causing HD were thought to be unusual; but it is now clear that the disease can arise from unaffected parents, especially when one carries an “intermediate allele,” as described below.

The discovery of the genetic mutation responsible for Huntington's disease was the product of an arduous 10-year, multi-investigator collaborative effort. In 1993, a region near the end of the short arm of chromosome 4 was found to contain a polymorphic (CAG)_n trinucleotide repeat that was significantly expanded in all individu-

als with HD (Huntington's Disease Collaborative Research Group, 1993). The expansion of this trinucleotide repeat is the genetic alteration responsible for HD. The range of CAG repeat length in normal individuals is between 9 and 34 triplets, with a median repeat length on normal chromosomes of 19. The repeat length in HD varies from 40 to over 100. Repeat lengths of 35 to 39 represent intermediate alleles; some of these individuals develop HD late in life, whereas others are not affected. Repeat length is correlated inversely with age of onset. The younger the age of onset, the higher is the probability of a large repeat number. This correlation is most powerful in individuals with onset before age 30; with onset above age 30, the correlation is weaker. Thus, repeat length cannot serve as an adequate predictor of age of onset in most individuals. Several other neurodegenerative diseases also arise through expansion of a CAG repeat, including hereditary spinocerebellar ataxias and Kennedy's disease, a rare inherited disorder of motor neurons.

Selective Vulnerability. The mechanism by which the expanded trinucleotide repeat leads to the clinical and pathological features of HD is unknown. The HD mutation lies within a gene designated *IT15*. The *IT15* gene is very large (10 kilobases) and encodes a protein of approximately 348,000 daltons or 3144 amino acids. The trinucleotide repeat, which encodes the amino acid glutamine, occurs at the 5 end of *IT15* and is followed directly by a second, shorter repeat of (CCG)_n that encodes proline. The protein, named *huntingtin*, does not resemble any other known protein, and the normal function of the protein has not been identified. Mice with a genetic knockout of huntingtin die early in embryonic life, so it must have an essential cellular function. It is thought that the mutation results in a *gain of function*; i.e., the mutant protein acquires a new function or property not found in the normal protein.

The HD gene is expressed widely throughout the body. High levels of expression are present in brain, pancreas, intestine, muscle, liver, adrenals, and testes. In brain, expression of *IT15* does not correlate with neuron vulnerability: Although the striatum is most severely affected, neurons in all regions of the brain express similar levels of *IT15* mRNA (Landwehrmeyer *et al.*, 1995).

The ability of the HD mutation to produce selective neural degeneration despite nearly universal expression of the gene among neurons may be related to metabolic or excitotoxic mechanisms. For many years it has been noted that HD patients are thin, suggesting the presence of a systemic disturbance of energy metabolism. In animal models, agonists for the NMDA subtype of excitatory amino acid receptor can cause pathology similar to that seen in HD when they are injected into the striatum (Beal *et al.*, 1986). Interestingly, inhibitors of complex II of the mitochondrial respiratory chain also can produce HD-like striatal lesions—even when given systemically (Beal *et al.*, 1993). Furthermore, this pathology can be diminished by NMDA-receptor antagonists, suggesting that this is an example of a metabolic impairment giving rise to excitotoxic neuronal injury. Thus the link between the widespread expression of the gene for the abnormal *IT15* protein in HD and the selective vulnerability of neurons in the disease may arise from the interaction of a widespread defect in energy metabolism with the intrinsic properties of striatal neurons, including their capacity and need for oxidative metabolism, as well as the types of glutamate receptors present.

An alternative mechanism for the neurodegeneration observed in HD has arisen from studies of effects of the disease on gene expression. In both the human disease and animal models there are striking and selective alterations in patterns of gene expression. This has led to the “transcriptional hypothesis” that suggests that the abnormal

function of mutant huntingtin may be an ability to alter or interfere with mechanisms of gene transcription (Cha, 2000).

These two hypotheses have given rise to trials of several different types of therapies in animal models and patients with HD, addressing on the one hand, metabolic defects and energy defects through treatment with agents such as coenzyme Q10 and, on the other hand, drugs that alter gene transcription. None of these approaches is yet established to be effective in altering the course of the disease.

Symptomatic Treatment of Huntington's Disease. Practical treatment for symptomatic HD emphasizes the selective use of medications (Shoulson, 1992). No current medication slows the progression of the disease, and many medications can impair function because of side effects. Treatment is needed for patients who are depressed, irritable, paranoid, excessively anxious, or psychotic. Depression can be treated effectively with standard antidepressant drugs with the caveat that drugs with substantial anticholinergic profiles can exacerbate chorea. *Fluoxetine* (see Chapter 17) is effective treatment for both the depression and the irritability manifest in symptomatic HD. *Carbamazepine* (see Chapter 19) also has been found to be effective for depression. Paranoia, delusional states, and psychosis usually require treatment with antipsychotic drugs, but the doses required often are lower than those usually used in primary psychiatric disorders. These agents also reduce cognitive function and impair mobility and thus should be used in the lowest doses possible and should be discontinued when the psychiatric symptoms resolve. In individuals with predominantly rigid HD, *clozapine*, *quetiapine* (see Chapter 18), or carbamazepine may be more effective for treatment of paranoia and psychosis.

The movement disorder of HD *per se* only rarely justifies pharmacological therapy. For those with large-amplitude chorea causing frequent falls and injury, dopamine-depleting agents such as *tetrabenazine* and *reserpine* (see Chapter 32) can be tried, although patients must be monitored for hypotension and depression. Antipsychotic agents also can be used, but these often do not improve overall function because they decrease fine motor coordination and increase rigidity. Many HD patients exhibit worsening of involuntary movements as a result of anxiety or stress. In these situations, judicious use of sedative or anxiolytic benzodiazepines can be very helpful. In juvenile-onset cases where rigidity rather than chorea predominates, dopamine agonists have had variable success in the improvement of rigidity. These individuals also occasionally develop myoclonus and seizures that can be responsive to *clonazepam*, *valproic acid*, and other anticonvulsants.

AMYOTROPHIC LATERAL SCLEROSIS (ALS)

Clinical Features and Pathology. ALS is a disorder of the motor neurons of the ventral horn of the spinal cord and the cortical neurons that provide their afferent input. The ratio of males to females affected is approximately 1.5:1 (Kurtzke, 1982). The disorder is characterized by rapidly progressive weakness, muscle atrophy and fasciculations, spasticity, dysarthria, dysphagia, and respiratory compromise. Sensory function generally is spared, as is cognitive, autonomic, and oculomotor activity. ALS usually is progressive and fatal, with most affected patients dying of respiratory compromise and pneumonia after 2 to 3 years, although occasional individuals have a more indolent course and survive for many years. The pathology of ALS corresponds closely to the clinical features: There is prominent loss of the spinal and brainstem motor neurons that project to striated muscles (although the oculomotor neurons are spared), as well as loss of the large pyramidal motor neurons in layer V of motor cortex, which are the origin of the descending corticospinal tracts. In familial cases, Clarke's column and the dorsal horns sometimes are affected (Rowland, 1994).

Etiology. About 10% of ALS cases are familial (FALS), usually with an autosomal dominant pattern of inheritance. Most of the mutations responsible have not been identified, but an important subset of FALS patients are families with a mutation in the gene for the enzyme SOD1 (Rosen *et al.*, 1993). Mutations in this protein account for about 20% of cases of FALS. Most of the mutations are alterations of single amino acids, but more than 30 different alleles have been found in different kindreds. Transgenic mice expressing mutant human SOD1 develop a progressive degeneration of motor neurons that closely mimics the human disease, providing an important animal model for research and pharmaceutical trials. Interestingly, many of the mutations of SOD1 that can cause disease do not reduce the capacity of the enzyme to perform its primary function, the catabolism of superoxide radicals. Thus, as may be the case in HD, mutations in SOD1 may confer a toxic "gain of function," the precise nature of which is unclear.

More than 90% of ALS cases are sporadic and are not associated with abnormalities of SOD1 or any other known gene. The cause of the motor neuron loss in sporadic ALS is unknown, but theories include autoimmunity, excitotoxicity, free radical toxicity, and viral infection (Rowland, 1994; Cleveland, 1999). Most of these ideas are not well supported by available data, but there is evidence that glutamate reuptake may be abnormal in the disease, leading to accumulation of glutamate and excitotoxic injury (Rothstein *et al.*, 1992). The only currently approved therapy for ALS, *riluzole*, is based on these observations.

Treatment of ALS with Riluzole. Riluzole (2-amino-6-[trifluoromethoxy]benzothiazole; RILUTEK) is an agent

with complex actions in the nervous system (Bryson *et al.*, 1996). Its structure is as follows:

Riluzole is absorbed orally and is highly protein bound. It undergoes extensive metabolism in the liver by both cytochrome P450-mediated hydroxylation and glucuronidation. Its half-life is about 12 hours. *In vitro* studies have shown that riluzole has both presynaptic and postsynaptic effects. It inhibits glutamate release, but it also blocks postsynaptic NMDA- and kainate-type glutamate receptors and inhibits voltage-dependent sodium channels. Some of the effects of riluzole *in vitro* are blocked by pertussis toxin, implicating the drug's interaction with an as-yet-unidentified GPCR. In clinical trials riluzole has modest but genuine effects on the survival of patients with ALS. In the largest trial conducted to date, with nearly 1000 patients, the median duration of survival was extended by about 60 days (Lacomblez *et al.*, 1996). The recommended dose is 50 mg every 12 hours, taken 1 hour before or 2 hours after a meal. Riluzole usually is well tolerated, although nausea or diarrhea may occur. Rarely, riluzole may produce hepatic injury with elevations of serum transaminases, and periodic monitoring of these is recommended. Although the magnitude of the effect of riluzole on ALS is small, it represents a significant therapeutic milestone in the treatment of a disease refractory to all previous treatments.

Symptomatic Therapy of ALS: Spasticity. Spasticity is an important component of the clinical features of ALS in that the presence of spasticity often leads to considerable pain and discomfort and reduces mobility, which already is compromised by weakness. Furthermore, spasticity is the feature of ALS that is most amenable to present forms of treatment. *Spasticity* is defined as an increase in muscle tone characterized by an initial resistance to passive displacement of a limb at a joint, followed by a sudden relaxation (the so-called clasped-knife phenomenon). Spasticity is the result of the loss of descending inputs to the spinal motor neurons, and the character of the spasticity depends on which nervous system pathways are affected (Davidoff, 1990). Whole repertoires of movement can be generated directly at the spinal cord level; it is beyond the scope of this chapter to describe these in detail. The monosynaptic tendon-stretch reflex is the simplest of the

spinal mechanisms contributing to spasticity. Primary Ia afferents from muscle spindles, activated when the muscle is stretched rapidly, synapse directly on motor neurons going to the stretched muscle, causing it to contract and resist the movement. A collateral of the primary Ia afferent synapses on a “Ia-coupled interneuron” that inhibits the motor neurons innervating the antagonist of the stretched muscle, allowing contraction of the muscle to be unopposed. Upper motor neurons from the cerebral cortex (the pyramidal neurons) suppress spinal reflexes and the lower motor neurons indirectly by activating the spinal cord inhibitory interneuron pools. The pyramidal neurons use glutamate as a neurotransmitter. When the pyramidal influences are removed, the reflexes are released from inhibition and become more active, leading to hyperreflexia. Other descending pathways from the brainstem, including the rubro-, reticulo-, and vestibulospinal pathways and the descending catecholamine pathways, also influence spinal reflex activity. When just the pyramidal pathway is affected, extensor tone in the legs and flexor tone in the arms are increased. When the vestibulospinal and catecholamine pathways are impaired, increased flexion of all extremities is observed, and light cutaneous stimulation can lead to disabling whole-body spasms. In ALS, pyramidal pathways are impaired with relative preservation of the other descending pathways, resulting in hyperactive deep-tendon reflexes, impaired fine motor coordination, increased extensor tone in the legs, and increased flexor tone in the arms. The gag reflex often is overactive as well.

The most useful agent for the symptomatic treatment of spasticity in ALS is *baclofen* (LIORESAL), a GABA_B-receptor agonist. Initial doses of 5 to 10 mg/day are recommended, but the dose can be increased to as much as 200 mg/day if necessary. If weakness occurs, the dose should be lowered. In addition to oral administration, baclofen also can be delivered directly into the space around the spinal cord by use of a surgically implanted pump and an intrathecal catheter. This approach minimizes the adverse effects of the drug, especially sedation, but it carries the risk of potentially life-threatening CNS depression and should be only used by physicians trained in delivering chronic intrathecal therapy. *Tizanidine* (ZANFLEX) is an agonist of α_2 adrenergic receptors in the CNS. It reduces muscle spasticity and is assumed to act by increasing presynaptic inhibition of motor neurons. Tizanidine is used most widely in the treatment of spasticity in multiple sclerosis or after stroke, but it also may be effective in patients with ALS. Treatment should be initiated at a low dose of 2 to 4 mg at bedtime and titrated upward gradually. Drowsiness, asthenia, and dizziness may limit

the dose that can be administered. *Benzodiazepines* (see Chapter 16) such as *clonazepam* (KLONIPIN) are effective antispasmodics, but they may contribute to respiratory depression in patients with advanced ALS. *Dantrolene* (DANTRIUM) also is approved in the United States for the treatment of muscle spasm. In contrast to the other agents discussed, dantrolene acts directly on skeletal muscle fibers, impairing calcium ion flux across the sarcoplasmic reticulum. Because it can exacerbate muscular weakness, it is not used in ALS but is effective in treating spasticity associated with stroke or spinal cord injury and in treating malignant hyperthermia (see Chapter 9). Dantrolene may cause hepatotoxicity, so it is important to perform liver function tests before and during therapy with the drug.

CLINICAL SUMMARY

The shared characteristic of all neurodegenerative disorders is the selective and progressive loss of neurons in specific brain structures. At the present time there are effective symptomatic therapies for several of the disorders, but few treatments that can substantially slow the underlying degenerative processes.

PD is characterized by the progressive loss of dopaminergic neurons in the substantia nigra pars compacta, producing abnormalities in the control of movement. The symptomatic therapy of PD is often very successful, producing effective control of many of the signs and symptoms. The single most effective therapy is levodopa, but long-term use of this agent is associated with undesirable side effects, wearing off, and dyskinesias. There also is uncertainty about the impact of levodopa on progression of the disease. An alternative to treatment with levodopa is the use of dopamine agonists such as pramipexole or ropinirole. There are also useful adjunctive therapies for PD, including inhibitors of the enzyme COMT, that prolong the action of levodopa, as well as drugs acting at acetylcholine receptors and other sites.

AD is associated with accumulation of abnormal aggregates of the protein β -amyloid, as well as neuronal degeneration with neurofibrillary tangles, and leads to progressive impairment of memory and cognition. Many different brain regions are affected, but there is particularly severe degeneration of cholinergic neurons in the basal forebrain. Most current therapies are based on augmenting cholinergic transmission through inhibition of acetylcholinesterase. This approach is modestly effective, producing partial improvement in memory and behavioral symptoms that may improve the quality of life of affected patients significantly.

HD is an autosomal dominant disorder caused by a mutation in the protein huntingtin. The defect leads to progressive motor and cognitive symptoms. At present there is no effective treatment for the primary disorder, although antidepressant and antipsychotic medications may be useful to control specific symptoms.

ALS (or Lou Gehrig's disease) is a progressive degenerative disease of spinal motor neurons leading to weakness and eventually paralysis. It is the most rapidly progressive of the common neurodegenerative disorders and often is fatal within 2 to 3 years of onset. The only therapy established to alter the course of ALS is the drug riluzole, which acts through inhibition of glutamate release as well as other mechanisms. The effect of this treatment is modest, prolonging survival by about 3 months.

An important goal of much current research in the pharmacology of neurodegenerative disorders is identification of drugs that can slow the underlying degenerative process. A number of candidate mechanisms have been identified that are shared among these disease, and there are clinical trials currently in progress seeking evidence of efficacy.

OPIOID ANALGESICS

Howard B. Gutstein and Huda Akil

OVERVIEW

Opioids have been the mainstay of pain treatment for thousands of years, and they remain so today. Opioids such as *heroin* and *morphine* exert their effects by mimicking naturally occurring substances, called *endogenous opioid peptides* or *endorphins*. Much now is known about the basic biology of the endogenous opioid system and its molecular and biochemical complexity, widespread anatomy, and diversity. The diverse functions of this system include the best known sensory role, prominent in inhibiting responses to painful stimuli; a modulatory role in gastrointestinal, endocrine, and autonomic functions; an emotional role, evident in the powerful rewarding and addicting properties of opioids; and a cognitive role in the modulation of learning and memory. The endogenous opioid system is complex and subtle, with a great diversity in endogenous ligands (more than a dozen) yet with only four major receptor types. This chapter presents key facts about the biochemical and functional nature of the opioid system that then are used to understand the actions of clinically used opioid drugs and strategies for pain treatment.

Terminology. The term *opioid* refers broadly to all compounds related to opium. The word *opium* is derived from *opos*, the Greek word for “juice,” the drug being derived from the juice of the opium poppy, *Papaver somniferum*. *Opiates* are drugs derived from opium, and they include the natural products *morphine*, *codeine*, and *thebaine*, and many semisynthetic derivatives. *Endogenous opioid peptides* are the naturally occurring ligands for opioid receptors. The term *endorphin* is used synonymously with endogenous opioid peptides but also refers to a specific endogenous opioid, β -endorphin. The term *narcotic* was derived from the Greek word for “stupor.” At one time, the term referred to any drug that induced sleep, but then it became associated with opioids. It often is used in a legal context to refer to a variety of substances with abuse or addictive potential.

History. The first undisputed reference to opium is found in the writings of Theophrastus in the third century B.C. Arab physicians

were well versed in the uses of opium; Arab traders introduced the drug to the Orient, where it was employed mainly for the control of dysenteries. During the Middle Ages, many of the uses of opium were appreciated. In 1680, Sydenham wrote: “Among the remedies which it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and so efficacious as opium.”

Opium contains more than 20 distinct alkaloids. In 1806, Sertürner reported the isolation of a pure substance in opium that he named *morphine*, after Morpheus, the Greek god of dreams. The discovery of other alkaloids in opium quickly followed—codeine by Robiquet in 1832 and *papaverine* by Merck in 1848. By the middle of the nineteenth century, the use of pure alkaloids in place of crude opium preparations began to spread throughout the medical world.

In addition to the remarkable beneficial effects of opioids, the toxic side effects and addictive potential of these drugs also have been known for centuries. These problems stimulated a search for potent synthetic opioid analgesics free of addictive potential and other side effects. Unfortunately, all synthetic compounds that have been introduced into clinical use share the liabilities of classical opioids. However, the search for new opioid agonists led to the synthesis of opioid antagonists and compounds with mixed agonist–antagonist properties, which expanded therapeutic options and provided important tools for exploring mechanisms of opioid actions.

Until the early 1970s, the endogenous opioid system was totally unknown. The actions of morphine, heroin, and other opioids as antinociceptive and addictive agents, while well described, typically were studied in the context of interactions with other neurotransmitter systems, such as monoaminergic and cholinergic. Some investigators suggested the existence of a specific opioid receptor because of the unique structural requirements of opiate ligands, but the presence of an opiate-like system in the brain remained unproven. A particularly misleading observation was that the administration of the opioid antagonist *naloxone* to a normal animal produced little effect, although the drug was effective in reversing or preventing the effects of exogenous opiates. The first physiological evidence suggesting an endogenous opioid system was the demonstration that analgesia produced by electrical stimulation of certain brain regions was reversed by naloxone (Akil *et al.*, 1972, 1976). Pharmacological evidence for an opiate receptor also was building. In 1973, investigators in three laboratories demonstrated opiate-binding sites in the brain (Pert and Snyder, 1973; Simon *et al.*, 1973; Terenius, 1973). This was the first use of radioligand-binding assays to demonstrate the presence of membrane-associated neurotransmitter receptors in the brain.

Stimulation-produced analgesia, its naloxone reversibility, and the discovery of opioid receptors strongly pointed to the existence of endogenous opioids. In 1975, Hughes and associates identified an endogenous opiate-like factor that they called *enkephalin* (from the head). Soon after, two more classes of endogenous opioid peptides were isolated, the *dynorphins* and *endorphins*. Details of these discoveries and the unique properties of the opioid peptides have been reviewed (Akil *et al.*, 1984).

Given the large number of endogenous ligands, it was not surprising that multiple classes of opioid receptors also were found. The concept of opioid receptor multiplicity arose shortly after the initial demonstration of opiate-binding sites. Based on *in vivo* studies in dogs, Martin and colleagues postulated the existence of multiple types of opiate receptors (Martin *et al.*, 1976). Receptor-binding studies and subsequent cloning confirmed the existence of three main receptor types: μ , δ , and κ . A fourth member of the opioid peptide receptor family, the *nociceptin/orphanin FQ* (N/OFQ) receptor, was cloned in 1994. This latter receptor is not, strictly speaking, opioid in its function, in that it does not interact with any of the classical opiate ligands, but it is part of the opioid family based on extensive sequence homology. In addition to these four major receptor classes, a number of subtypes have been proposed, such as ϵ , often based on bioassays from different species (Schulz *et al.*, 1979), ι (Oka, 1980), λ (Grevel and Sadée, 1983), and ζ (Zagon *et al.*, 1989). In 2000, the Committee on Receptor Nomenclature and Drug Classification of the International Union of Pharmacology adopted the terms *MOP*, *DOP*, and *KOP* to indicate μ , δ , and κ opioid peptide receptors, respectively. The original Greek letter designations are used in this and other chapters. The committee also recommended the term *NOP* for the N/OFQ receptor.

ENDOGENOUS OPIOID PEPTIDES

Three distinct families of classical opioid peptides have been identified: the *enkephalins*, *endorphins*, and *dynorphins*. Each family derives from a distinct precursor protein and has a characteristic anatomical distribution. These precursors, prepro-opiomelanocortin (POMC), preproenkephalin, and preprodynorphin, respectively, are encoded by three corresponding genes. Each precursor is subject to complex cleavages and post-translational modifications resulting in the synthesis of multiple active peptides. The opioid peptides share the common amino-terminal sequence of Tyr-Gly-Gly-Phe-(Met or Leu), which has been called the *opioid motif*. This motif is followed by various C-terminal extensions yielding peptides ranging from 5 to 31 residues (Table 21–1).

The major opioid peptide derived from POMC is β -endorphin. Although β -endorphin contains the sequence for met-enkephalin at its amino terminus, it is not converted to this peptide; met-enkephalin is derived from the processing of preproenkephalin. In addition to β -endorphin, the POMC precursor also is processed into the non-opioid peptides adrenocorticotrophic hormone (ACTH),

melanocyte-stimulating hormone (α -MSH), and β -lipotropin (β -LPH). Previous biochemical work had suggested a common precursor for the stress hormone ACTH and the opioid peptide β -endorphin. This association implied a close physiological linkage between the stress axis and opioid systems, which was validated by many studies of the phenomenon of stress-induced analgesia (Akil *et al.*, 1986). Proenkephalin contains multiple copies of met-enkephalin, as well as a single copy of leu-enkephalin. Prodynorphin contains three peptides of differing lengths that all begin with the leu-enkephalin sequence: dynorphin A, dynorphin B, and neoendorphin (Figure 21–1). The anatomical distribution of these peptides in the CNS has been reviewed (Mansour *et al.*, 1988).

A novel endogenous opioid peptide was cloned in 1995 (Meunier *et al.*, 1995; Reinscheid *et al.*, 1995). This peptide has a significant sequence homology to dynorphin A, with an identical length of 17 amino acids, identical carboxy-terminal residues, and a slight modification of the amino-terminal opioid core (Phe-Gly-Gly-Phe instead of Tyr-Gly-Gly-Phe) (Table 21–1). The removal of this single hydroxyl group is sufficient to abolish interactions with the three classical opioid peptide receptors. This peptide was called *orphanin FQ* (OFQ) by one group of investigators and *nociceptin* (N) by another because it lowered pain threshold under certain conditions. Like the opioid precursors, the structure of the N/OFQ precursor (Figure 21–2) suggests that it may encode other biologically active peptides (Nothacker *et al.*, 1996). Immediately downstream of N/OFQ is a 17-amino-acid peptide (orphanin-2), which also starts with phenylalanine and ends with glutamine but is otherwise distinct from N/OFQ, as well as a putative peptide upstream from N/OFQ, which may be liberated on post-translational processing (*nocistatin*). The N/OFQ system represents a new neuropeptide system with a high degree of sequence identity to the opioid peptides. Indeed, it appears to be derived from a common opioid precursor that contains OFQ and enkephalin-like structures (Danielson *et al.*, 2001). However, the slight structural changes profoundly alter function. The common precursor apparently diverged through evolution to give rise to the opioid and the nonopioid branches of this family (Danielson *et al.*, 2001). Thus, N/OFQ has behavioral and pain modulatory properties distinct from those of the three classical opioid peptides (*see below*).

The anatomical distribution of POMC-producing cells is relatively limited within the CNS, occurring mainly in the arcuate nucleus and nucleus tractus solitarius. These neurons project widely

to limbic and brainstem areas and to the spinal cord (Lewis *et al.*, 1987). There also is evidence of POMC production in the spinal cord (Gutstein *et al.*, 1992). The distribution of POMC corresponds to areas of the human brain where electrical stimulation can relieve pain (Pilcher *et al.*, 1988). Peptides from POMC occur in the anterior and intermediate lobes of the pituitary and also are contained in pancreatic islet cells. The peptides from prodynorphin and proenkephalin are distributed widely throughout the CNS and frequently are found together. Although each family of peptides typically is located in different groups of neurons, occasionally more than one family is expressed within the same neuron (Weihe *et al.*, 1988). Of particular note, proenkephalin peptides are present in areas of the CNS that are presumed to be related to the perception of pain (*e.g.*, laminae I and II of the spinal cord, the spinal trigeminal nucleus, and the periaqueductal gray), to the modulation of affective behavior (*e.g.*, amygdala, hippocampus, locus ceruleus, and the frontal cerebral cortex), to the modulation of motor control (*e.g.*, caudate nucleus and globus pallidus), to the regulation of the autonomic nervous system (*e.g.*, medulla oblongata), and to neuroendocrinological functions (*e.g.*, median eminence). Although there are a few long

enkephalinergic fiber tracts, these peptides are contained primarily in interneurons with short axons. The peptides from proenkephalin also are found in the adrenal medulla and in nerve plexuses and exocrine glands of the stomach and intestine.

The N/OFQ precursor has a unique anatomical distribution (Neal *et al.*, 1999b) that suggests important roles in hippocampus, cortex, and numerous sensory sites. N/OFQ produces a complex behavioral profile, including effects on drug reward and reinforcement (Bertorelli *et al.*, 2000), stress responsiveness (Devine *et al.*, 2001; Koster *et al.*, 1999), feeding behavior (Olszewski and Levine, 2004) and interplay with the stress system (Nicholson *et al.*, 2002), and learning and memory processes (Koster *et al.*, 1999). Studies of the effect of N/OFQ on pain sensitivity have produced conflicting results, perhaps because the effects of N/OFQ on pain sensitivity depend on the underlying behavioral state of the animal (Pan *et al.*, 2000) (*see below*). Analogous mechanisms also could explain some of the conflicting results with other physiological processes. However, more studies are needed before a general role can be ascribed to the N/OFQ system, including the investigation of other active peptides that may be derived from the precursor (Figure 21–2). For example, nocistatin

has been tested behaviorally and found to produce effects opposite to those of N/OFQ (Okuda-Ashitaka *et al.*, 1998). These findings, coupled with the extensive anatomy of the system, suggest that the N/OFQ precursor plays a complex role in the brain and that it interacts with many of the functions of the classical endogenous opioids, sometimes in a complementary but often in an opposing fashion. Not all cells that make a given precursor polypeptide store and release the same mixture of active opioid peptides because of differential processing secondary to variations in the cellular complement of pepti-

dases that produce and degrade the active opioid fragments (Akil *et al.*, 1984). In addition, processing of these peptides is altered by physiological demands, leading to a different mix of peptides being released by the same cell under different conditions. For example, chronic morphine treatment (Bronstein *et al.*, 1990) or stress (Akil *et al.*, 1985) can alter the forms of β -endorphin released by cells, which could underlie some observed physiological adaptations. Although the endogenous opioid peptides appear to function as neurotransmitters, modulators of neurotransmission, or neurohormones, the full extent of their physiological role is not completely understood (Akil *et al.*, 1988). The elucidation of the physiological roles of the opioid peptides has been made more difficult by their frequent coexistence with other putative neurotransmitters within a given neuron.

OPIOID RECEPTORS

Three classical opioid receptor types, μ , δ , and κ , have been studied extensively (Waldhoer *et al.*, 2004). The more recently discovered N/OFQ receptor, initially called the *opioid-receptor-like 1* (ORL-1) receptor or “orphan” opioid receptor, has added a dimension to the study of opioids.

Table 21–2

Classification of Opioid Receptor Subtypes and Actions from Animal Models

	RECEPTOR SUBTYPE	ACTIONS OF:	
		<i>Agonist</i>	<i>Antagonist</i>
Analgesia			
Supraspinal	μ, κ, δ	Analgesic	No effect
Spinal	μ, κ, δ	Analgesic	No effect
Respiratory function	μ	Decrease	No effect
Gastrointestinal tract	μ, κ	Decrease transit	No effect
Psychotomimesis	κ	Increase	No effect
Feeding	μ, κ, δ	Increase feeding	Decrease feeding
Sedation	μ, κ	Increase	No effect
Diuresis	κ	Increase	
Hormone regulation			
Prolactin	μ	Increase release	Decrease release
Growth hormone	μ and/or δ	Increase release	Decrease release
Neurotransmitter release			
Acetylcholine	μ	Inhibit	
Dopamine	μ, δ	Inhibit	
Isolated organ bioassays			
Guinea pig ileum	μ	Decrease contraction	No effect
Mouse vas deferens	d	Decrease contraction	No effect

The actions listed for antagonists are seen with the antagonist alone. All the correlations in this table are based on studies in rats and mice, which occasionally show species differences. Thus, any extensions of these associations to humans are tentative. Clinical studies do indicate that μ receptors elicit analgesia spinally and supraspinally. Preliminary work with a synthetic opioid peptide, [D-Ala²,D-Leu⁵]enkephalin, suggests that intrathecal δ agonists are analgesic in humans. Modified from Pasternak (1993).

Highly selective ligands that allowed for type-specific labeling of the three classical opioid receptors (e.g., DAMGO for μ , DPDPE for δ , and U-50,488 and U-69,593 for κ) (Handa *et al.*, 1981; Mosberg *et al.*, 1983; Vonvoightlander *et al.*, 1983) became available in the early 1980s. These tools made possible the definition of ligand-binding characteristics of each of the receptor types and the determination of anatomical distribution of the receptors using autoradiographic techniques. Each major opioid receptor has a unique anatomical distribution in brain, spinal cord, and the periphery (Mansour *et al.*, 1988; Neal *et al.*, 1999b). These distinctive localization patterns suggested possible functions that subsequently have been investigated in pharmacological and behavioral studies.

The study of the biological functions of opioid receptors *in vivo* was aided by the synthesis of selective antagonists and agonists. Among the most commonly used antagonists are cyclic analogs of *somatostatin* such as CTOP as μ -receptor antagonists, a derivative of naloxone called *naltrindole* as a δ -receptor antagonist, and a bivalent derivative of *naltrexone* called *binaltorphimine* (nor-

BNI) as a κ -receptor antagonist (Gulya *et al.*, 1986; Portoghese *et al.*, 1987, 1988). In general, functional studies using selective agonists and antagonists have revealed substantial parallels between μ and δ receptors and dramatic contrasts between μ/δ and κ receptors. *In vivo* infusions of selective antagonists and agonists also were used to establish the receptor types involved in mediating various opioid effects (Table 21–2).

Most of the clinically used opioids are relatively selective for μ receptors, reflecting their similarity to morphine (Tables 21–3 and 21–4). However, it is important to note that drugs that are relatively selective at standard doses will interact with additional receptor subtypes when given at sufficiently high doses, leading to possible changes in their pharmacological profile. This is especially true as doses are escalated to overcome tolerance. Some drugs, particularly mixed agonist–antagonist agents, interact with more than one receptor class at usual clinical doses. The actions of these drugs are particularly interesting because they may act as an agonist at one receptor and an antagonist at another.

Activities of drugs are given at the receptors for which the agent has reasonable affinity. +, agonist; -, antagonist; P, partial agonist; DAMGO, CTOP, DPDPE, DSLET, see Table 21–1. The number of symbols is an indication of potency; the ratio for a given drug denotes selectivity. These values were obtained primarily from animal studies and should be extrapolated to human beings with caution. Both β -funaltrexamine and naloxonazine are irreversible μ antagonists, but β -funaltrexamine also has reversible κ agonist activity.

There is little agreement regarding the exact classification of opioid receptor subtypes. Pharmacological studies have suggested the existence of multiple subtypes of each receptor. The complex literature on κ -opioid receptor subtypes (Akil and Watson, 1994) strongly suggests the presence of at least one additional subtype with high affinity for the benzomorphan class of opiate alkaloids. The data for δ -opioid receptor subtypes are intriguing. While early support for the possibility of multiple δ receptors came from radioligand-binding studies, the strongest evidence derives from behavioral studies (Jiang *et al.*, 1991), which led to the proposal that two δ -receptor sites exist, δ_1 and δ_2 . In the case of the μ receptor, behavioral and pharmacological studies led to the proposal of μ_1 and μ_2 subtypes (Pasternak, 1986). The μ_1 site is proposed to be a very high affinity receptor with little discrimination between μ and δ ligands. A parallel hypothesis (Rothman *et al.*, 1988) holds that there is a high-affinity μ/δ complex rather than a distinct μ site. Although molecular cloning studies have not readily supported the existence of these subtypes as distinct molecules, recent findings (*see below*) regarding modified specificity for opioid ligands owing to heterodimerization of receptors may explain the observed pharmacological diversity.

Molecular Studies of Opioid Receptors and Their Ligands

For many years, the study of multiple opioid receptors greatly profited from the availability of a rich array of natural and synthetic ligands but was limited by the absence of opioid receptor clones. In 1992, the mouse δ receptor was cloned from the NG-108 cell line (Evans *et al.*, 1992). Subsequently, the other two major types of classical opioid receptors were cloned from various rodent species (Meng *et al.*, 1993; Thompson *et al.*, 1993). The N/OFQ receptor was cloned as a result of searches for novel types or subtypes of opioid receptors. The coding regions for the opioid peptide receptors subsequently were isolated and chromosomally assigned. In the case of μ , the cloned sequence is the classical morphine-like receptor rather than the proposed μ_1 . With δ no differentiation between the two proposed types by binding appears possible, and the cloned receptor recognizes all δ -selective ligands regardless of their behavioral assignment as δ_1 or δ_2 . For κ , the cloned receptor is the classical receptor rather than the proposed benzomorphan-binding site. All four opioid receptors belong to the GPCR family (*see Chapter 1*) and share extensive sequence homologies (Figure 21–3). The N/OFQ receptor has high structural homology with the classical opioid receptors, but it has very low or no affinity for binding conventional opioid ligands. The structural similarities of the N/OFQ receptor and the three classical opioid receptors are highest in the transmembrane regions and cytoplasmic domains and lowest in the extracellular domains critical for ligand selectivity (Meng *et al.*, 1998) (Figure 21–3B).

Further cloning experiments may identify unique genes encoding opioid receptor subtypes; if multiple opioid receptor subtypes exist, however, they may derive from a single gene, and multiple mechanisms may provide distinct pharmacological profiles. Two potential pathways to opioid receptor diversity are alternative splicing of receptor RNA and dimerization of receptor proteins.

Alternative splicing of receptor heteronuclear RNA (*e.g.*, exon skipping and intron retention) is thought to play an important role in producing *in vivo* diversity within many members of the GPCR superfamily (Kilpatrick *et al.*, 1999). Splice variants may exist within each of the three opioid receptor families, and this alternative splicing of receptor transcripts may be crucial for the diversity of opioid receptors. A technique used widely to identify potential sites of alternative splicing is antisense oligodeoxynucleotide (ODN)

mapping. The ability of antisense ODNs to target specific regions of cDNA permits the systematic evaluation of the contribution of individual exons to observed receptor properties. Use of this approach has demonstrated that antisense ODNs targeting of exon 1 of μ -opioid receptors blocks morphine analgesia, whereas administration of antisense ODNs targeting exon 2 does not block morphine analgesia but prevents the analgesia produced by heroin, *fentanyl*, and the morphine metabolite morphine-6-glucuronide (Pasternak, 2001). These results, which imply that unique μ -receptor mechanisms mediate the analgesic effects of a variety of opioids, are consistent with the proposal that unique receptor mechanisms are achieved through alternative splicing. The use of antisense ODNs and real-time polymerase chain reaction techniques also has led to the identification of potential sites for splice variation in the κ - and δ -opioid receptors (Wei *et al.*, 2004). Central to the claim that these results reflect the existence of splice variants is the *in vivo* isolation of such variants. A μ opioid receptor splice variant has been identified that differs considerably from the native receptor within its C terminus (Zimprich *et al.*, 1995). This variant exhibits a binding profile similar to that of the cloned μ opioid receptor but does not readily undergo the desensitization frequently observed after exposure to agonist. Thus, the existence of this splice variant cannot explain the differential analgesic sensitivities described earlier. Studies are investigating the *in vivo* relevance of putative splice variants.

The interaction of two receptors to form a unique structure (dimerization) also has been accorded an important role in regulating receptor function (Agnati *et al.*, 2003, Milligan, 2004). κ and δ opioid receptors have been shown to exist as homodimers (Levac *et al.*, 2002). However, the most interesting findings have been generated by studies showing dimerization between different opioid receptor types. κ and δ opioid receptors, as well as μ and δ opioid receptors, can exist as heterodimers in heterologous expression systems and *in vivo* (Devi, 2001). The dimerization of these receptors profoundly alters their pharmacological properties. The affinity of the heterodimers for highly selective agonists and antagonists is

reduced greatly. Instead, the heterodimers show greatest affinity for partially selective agonists such as *bremazocine* and some endogenous opioid peptides (Levac *et al.*, 2002). *In vivo* responses to morphine also may be altered (Gomes *et al.*, 2004), suggesting novel strategies for pain treatment. Receptor heterodimerization may explain, at least in part, the discrepancies between molecular and pharmacological properties of opioid receptors. Heterodimerization also may occur between opioid receptors and other types of GPCRs (Pfeiffer *et al.*, 2003), but the physiological significance of these interactions is not clear.

Given the existence of four families of endogenous ligands and cloned receptors, it seems reasonable to ask if there is a one-to-one correspondence among them. Previous studies using brain homogenates demonstrated that an orderly pattern of association between a set of opioid gene products and a given receptor does not exist. Although proenkephalin products generally are associated with δ receptors and prodynorphin products with κ receptors, much “cross-talk” is present (Mansour *et al.*, 1995). The cloning of the opioid receptors allowed this question to be addressed more systematically because each receptor could be expressed separately and then compared under identical conditions (Mansour *et al.*, 1997). The κ receptor exhibits the most selectivity across endogenous ligands, with affinities ranging from 0.1 nM for dynorphin A to approximately 100 nM for leu-enkephalin. In contrast, μ and δ receptors show only a tenfold difference between the most and least preferred ligand, with a majority of endogenous ligands exhibiting greater affinity for δ than for μ receptors. The limited selectivity of μ and δ receptors suggests that the μ and δ receptors recognize principally the Tyr-Gly-Gly-Phe core of the endogenous peptide, whereas the κ receptor requires this core *and* the arginine in position 6 of dynorphin A and other prodynorphin products (Table 21–1). Interestingly, proenkephalin products with arginine in position 6 (*i.e.*, met-enkephalin-Arg-Phe and met-enkephalin-Arg-Gly-Leu) are equally good κ -receptor ligands, arguing against the idea of a unique association between a given receptor and a given opioid precursor family.

Figure 21-3. A. Structural homology among the three opioid receptors. B. Structural homology among the three opioid receptors and the N/OFQ receptor. Numbers indicate the percent of identical amino acids in the segment. (From Akil *et al.*, 1998, with permission.)

In sum, high-affinity interactions are possible between each of the peptide precursor families and each of the three receptor types, the only exception being the lack of high-affinity interaction between POMC-derived peptides and opioid receptors. Otherwise, at least one peptide product from each of the families exhibits high affinity (low nanomolar or subnanomolar) for each receptor. The relatively unimpressive affinity of the μ receptor toward all known endogenous ligands suggests that its most avid and selective ligand has not been identified, a notion being tested (*see below*).

Molecular Basis for Opioid Receptor Selectivity and Affinity. Previous studies of other peptide receptors suggested that peptides and small molecules may bind to GPCRs differently. Mutagenesis studies of small-ligand receptors (*e.g.*, adrenergic and dopamine receptors) showed that charged amino acid residues in the transmembrane domains were important in receptor binding and activation (Mansour *et al.*, 1992). This observation places the bound ligands within the receptor core formed by the transmembrane helices. On the other hand, studies with peptidergic receptors have demonstrated a critical role for extracellular loops in ligand recognition (Xie *et al.*, 1990). All three classical opioid receptors appear to combine both properties: Charged residues in transmembrane domains have been implicated in the high-affinity binding of most opioid ligands, whether alkaloid or peptide (Mansour *et al.*, 1997). However, criti-

cal interactions of opioid peptides with the extracellular domains also have been shown.

The opioid peptide Tyr-Gly-Gly-Phe core, sometimes called the *message*, appears to be necessary for interaction with the receptor-binding pocket; however, peptide *selectivity* resides in the carboxy-terminal extension beyond the tetrapeptide core, providing the *address* (Schwyzer, 1986). When the carboxy-terminal domain is long, it may interact with extracellular loops of the receptors, contributing to selectivity in a way that cannot be achieved by the much smaller alkaloids. Indeed, dynorphin A selectivity depends on the second extracellular loop of the κ receptor (Meng *et al.*, 1995), whereas δ - and μ -selective ligands have more complex mechanisms of selectivity that depend on multiple extracellular loops. These findings have led to the proposal that high selectivity is achieved by attraction to the most favored receptor and repulsion by the less favored receptor (Meng *et al.*, 1995). For example, the N/OFQ receptor does not bind any of the classical endogenous opioid peptides. However, mutating as few as four amino acids endows the N/OFQ receptor with the ability to recognize prodynorphin-derived peptides while retaining recognition of N/OFQ (Meng *et al.*, 1996), suggesting that unique mechanisms have evolved to ensure selectivity of the N/OFQ receptor for N/OFQ and against classical opioid peptides. Mechanisms involved in selectivity can be difficult to separate from mechanisms involved in affinity because the extracellular

domains not only may allow interactions with the peptide ligands but also may be important in stabilizing these interactions.

Results of the research discussed above imply that the alkaloids are small enough to fit completely inside or near the mouth of the receptor core, whereas peptides bind to the extracellular loops and simultaneously extend to the receptor core to activate the common binding site. That one can truly separate the binding of peptides and alkaloids is demonstrated most clearly by a genetically engineered κ receptor (Coward *et al.*, 1998) that does not recognize endogenous peptide ligands yet retains full affinity and efficacy for small synthetic κ -receptor ligands, such as *spiradoline*. Given these differences in binding interactions with the receptor, it is possible that unique classes of ligands may activate the opioid receptor differently, leading to conformational changes of distinct quality or duration that may result in varying magnitudes and possibly different second-messenger events (Kenakin, 2002). This hypothesis is being tested (Quillan *et al.*, 2002; Alvarez *et al.*, 2002) and, if validated, may lead to novel strategies for differentially altering the interactions between the opioid receptors and signal-transduction cascades. The likely presence of receptor heterodimers that may have unique profiles and signaling properties provides a number of new directions for discovery of drugs that may target receptors in particular states (Bouvier, 2001; Wang *et al.*, 2005).

Opioid Receptor Signaling and Consequent Intracellular Events

Coupling of Opioid Receptors to Second Messengers. The μ , δ , and κ receptors in endogenous neuronal settings are coupled, *via* pertussis toxin-sensitive G proteins, to inhibition of adenylyl cyclase activity (Herz, 1993), activation of receptor-linked K^+ currents, and suppression of voltage-gated Ca^{2+} currents (Duggan and North, 1983). The hyperpolarization of the membrane potential by K^+ -current activation and the limiting of Ca^{2+} entry by suppression of Ca^{2+} currents are tenable but unproven mechanisms for explaining blockade by opioids of neurotransmitter release and pain transmission in varying neuronal pathways. Studies with cloned receptors have shown that opioid receptors may couple to an array of other second-messenger systems, including activation of the MAP kinases and the phospholipase C (PLC)-mediated cascade leading to the formation of inositol triphosphate and diacylglycerol (Akil *et al.*, 1997). Prolonged exposure to opioids results in adaptations at multiple levels within these signaling cascades. The significance of these cellular-level adaptations lies in the causal relationship that may exist between them and adaptations seen at the organismic level, such as tolerance, sensitization, and withdrawal (Waldhoer *et al.*, 2004).

Receptor Desensitization, Internalization, and Sequestration after Chronic Exposure to Opioids. Transient administration of opioids leads to a phenomenon called *acute tolerance*, whereas sustained administration leads to the development of *classical* or *chronic tolerance*. *Tolerance* simply refers to a decrease in effectiveness of a drug with its repeated administration (*see* Chapter 23). Several studies have focused on putative cellular mechanisms of acute tolerance. Short-term receptor desensitization, which may underlie the development of tolerance, probably involves phosphorylation of the μ and δ receptors by PKC (Mestek *et al.*, 1995). A number of other kinases have been implicated in receptor desensitization, including PKA and β adrenergic receptor kinase (β ARK) (Pei *et al.*, 1995; Wang *et al.*, 1994) (*see* below).

Like other GPCRs, μ and δ receptors can undergo rapid agonist-mediated internalization *via* a classic endocytic pathway (Gaudriault *et al.*, 1997), whereas κ receptors do not internalize after prolonged agonist exposure (Chu *et al.*, 1997). Interestingly, internalization of the μ and δ receptors apparently occurs *via* partially distinct endocytic pathways, suggesting *receptor-specific* interactions with different mediators of intracellular trafficking (Gaudriault *et al.*, 1997). It also is intriguing that these processes may be induced differentially as a function of the structure of the *ligand*. For example, certain agonists, such as *etorphine* and *enkephalins*, cause rapid internalization of the μ receptor, whereas morphine does not cause μ -receptor internalization, even though it decreases adenylyl cyclase activity equally well (Keith *et al.*, 1996). In addition, a truncated μ receptor with normal G protein coupling was shown to recycle constitutively from the membrane to cytosol (Segredo *et al.*, 1997), further indicating that activation of signal transduction and internalization are controlled by distinct molecular mechanisms. These studies also support the hypothesis that different ligands induce different conformational changes in the receptor that result in divergent intracellular events, and they may provide an explanation for differences in the efficacy and abuse potential of various opioids. One of the most interesting studies to evaluate the relevance of these alterations in signaling to the adaptations seen in response to opioid exposure *in vivo* was the demonstration that acute morphine-induced analgesia was enhanced in mice lacking β -arrestin 2 (Bohn *et al.*, 1999). Opioid-receptor internalization is mediated, at least in part, by the actions of GPCR kinases (GRKs). GRKs selectively phosphorylate agonist-bound receptors, thereby promoting interactions with β -arrestins, which interfere with G protein coupling and promote receptor internalization (Bohn *et al.*, 1999). Enhanced analgesia in mice lacking β -arrestin 2 is consistent with a role for the GRKs and arrestins in regulating responsivity to opioids *in vivo*. This result is even more intriguing given the inability of morphine to support arrestin translocation and receptor internalization *in vitro* (Whistler and von Zastrow, 1998) (*see* below).

Traditionally, long-term tolerance has been thought to be associated with increases in adenylyl cyclase activity—a counter-regulation to the decrease in cyclic AMP levels seen after acute opioid administration (Sharma *et al.*, 1977). Chronic treatment with μ -receptor opioids causes superactivation of adenylyl cyclase (Avidor-Reiss *et al.*, 1996). This effect is prevented by pretreatment with *pertussis toxin*, demonstrating involvement of $G_{i/o}$ proteins, and also by cotransfection with scavengers of G protein- $\beta\gamma$ dimers, indicating a role for this complex in superactivation. Alterations in levels of cyclic AMP clearly bring about numerous secondary changes (Nestler and Aghajanian, 1997).

Exciting recent findings suggest that the classic hypothesis of opioid tolerance development may need to be modified. For example, it appears that morphine does not efficiently promote μ -receptor internalization or receptor phosphorylation and desensitization (von Zastrow *et al.*, 2003; Koch *et al.*, 2005). When other μ agonists are subjected to similar analyses, widely divergent biochemical responses are observed. Unlike morphine, some opioids are very effective at cellular desensitization (Kovoor *et al.*, 1998). Some opioids rapidly induce receptor internalization, whereas morphine and other low-efficacy agonists do not (Whistler *et al.*, 1999). These studies collectively suggest that μ receptor desensitization and down-regulation are agonist-dependent, and they imply that different active receptor conformations caused by differing ligands produce a range of signaling responses (Kenakin, 2002). Concurrent studies of other GPCRs also have revealed that endocytosis and sequestration of receptors do not

invariably lead to receptor degradation but also can result in receptor dephosphorylation and recycling to the surface of the cell (Krupnick and Benovic, 1998). Thus, receptor internalization may have divergent consequences, either reducing signaling by receptor inactivation and degradation or enhancing signaling by reactivating desensitized receptors.

Taken together, these findings suggest a novel hypothesis, namely, that opioid tolerance may not be related to receptor desensitization but rather to a lack of desensitization. Agonists that rapidly internalize opioid receptors also would rapidly desensitize signaling, but this desensitization would be at least partially reset by recycling of “reactivated” opioid receptors. It has been proposed that the lack of desensitization caused by morphine may result in prolonged receptor signaling, which, even though less efficient than that observed with other agonists, would lead to further downstream cellular adaptations that increase tolerance development (Borgland, 2001). Whistler and colleagues (1999) also have suggested that the measurement of relative agonist signaling *versus* endocytosis (RAVE) for opioid agonists could be predictive of the potential for tolerance development (Waldhoer *et al.*, 2004). A study by He and colleagues (2002) provides additional support for this concept, demonstrating that DAMGO, a μ agonist that alone causes receptor internalization, also will cause internalization of μ receptors in the presence of morphine, even when administered in concentrations that normally do not cause receptor internalization. In addition, these low concentrations of DAMGO inhibited the development of adenylyl cyclase supersensitivity by morphine. These intriguing *in vitro* findings were supported further by *in vivo* data demonstrating that coadministration of subthreshold amounts of DAMGO with morphine intraspinally in rats induced μ receptor endocytosis in the presence of morphine and markedly inhibited the development of morphine tolerance (He *et al.*, 2002). However, recent findings evaluating various aspects of this hypothesis *in vitro* have not confirmed these findings (Contet *et al.*, 2004). Further studies are needed to evaluate this new hypothesis.

An “Apparent Paradox.” A paradox in evaluating the function of endogenous opioid systems is that a large number of endogenous ligands activate a small number of opioid receptors. This pattern is different from that of many other neurotransmitter systems, where a single ligand interacts with a large number of receptors having different structures and second messengers. Is this richness and complexity at the presynaptic level lost as multiple opioid ligands derived from different genes converge on only three receptors, or is this richness preserved through means yet to be discovered? One possibility is that molecular cloning has not revealed all opioid receptors. The complete sequence of the human and mouse genomes makes this less likely. Other options include splice variants, dimerization, and post-translational modification, as discussed previously. Even assuming that other receptors and variants will be found, the binding of many endogenous ligands to the three cloned classical receptors suggests a great deal of convergence. However, this convergence may be only apparent, since multiple mechanisms for achieving distinctive responses in the context of the biology described earlier may exist. Some issues to consider are:

1. The *duration of action* of endogenous ligands may be a crucial variable that has been overlooked and that may have clinical relevance.
2. The *pattern or profile of activation of multiple receptors by a ligand*, rather than activation of a single receptor, may be a crucial determinant of effect.

3. *Opioid genes may give rise to multiple active peptides with unique profiles of activity.* This patterning may be very complex and regulated by various stimuli.
4. *Differences in patterns and/or efficacy of intracellular signaling* produced by endogenous ligands at opioid receptors are under investigation. This issue may be particularly relevant for understanding physiological alterations after chronic administration of exogenous opioids.
5. *Intracellular trafficking of the receptors* may vary as a function of the receptor and of the ligand. This could have interesting implications for long-term adaptations during sustained treatment with opioids and after their withdrawal.

Understanding the complexity of endogenous opioid peptides and their patterns of interaction with multiple opioid receptors may help to define the similarities and differences between the endogenous modulation of these systems and their activation by drugs. These insights could be important in devising treatment strategies that maximize beneficial properties of opioids (*e.g.*, pain relief) while limiting their undesirable side effects, such as tolerance, dependence, and addiction.

EFFECTS OF CLINICALLY USED OPIOIDS

Morphine and most other clinically used opioid agonists exert their effects through μ opioid receptors. These drugs affect a wide range of physiological systems. They produce analgesia, affect mood and rewarding behavior (*see* Chapter 23), and alter respiratory, cardiovascular, gastrointestinal, and neuroendocrine function. δ Opioid receptor agonists also are potent analgesics in animals, and in some cases they have proved useful in humans (Moulin *et al.*, 1985). Agonists selective for κ receptors produce analgesia that has been shown in animals to be mediated primarily at spinal sites. Respiratory depression and miosis may be less severe with κ agonists. Instead of euphoria, κ receptor agonists produce dysphoric and psychotomimetic effects (Pfeiffer *et al.*, 1986). In neural circuitry mediating reward and analgesia, μ and κ agonists have been shown to have antagonistic effects (*see* below).

Mixed agonist–antagonist compounds were developed with the hope that they would have less addictive potential and less respiratory depression than morphine and related drugs. In practice, however, it has turned out that for the same degree of analgesia, the same intensity of side effects will occur. A “ceiling effect,” limiting the amount of analgesia attainable, often is seen with these drugs. Some mixed agonist–antagonist drugs, such as *pentazocine* and *nalorphine*, can produce severe psychotomimetic effects that are not reversible with naloxone (suggesting that these undesirable side effects are not mediated through classical opioid receptors). Also, pentazocine and nalorphine can precipitate withdrawal in opioid-

tolerant patients. For these reasons, the clinical use of these mixed agonist–antagonist drugs is limited.

Analgesia

In humans, morphine-like drugs produce analgesia, drowsiness, changes in mood, and mental clouding. A significant feature of the analgesia is that it occurs without loss of consciousness. When therapeutic doses of morphine are given to patients with pain, they report that the pain is less intense, less discomforting, or entirely gone; drowsiness commonly occurs. In addition to relief of distress, some patients experience euphoria.

When morphine in the same dose is given to a normal, pain-free individual, the experience may be unpleasant. Nausea is common, and vomiting may occur. There may be feelings of drowsiness, difficulty in mentation, apathy, and lessened physical activity. As the dose is increased, the subjective, analgesic, and toxic effects, including respiratory depression, become more pronounced. Morphine does not have anticonvulsant activity and usually does not cause slurred speech, emotional lability, or significant motor incoordination.

The relief of pain by morphine-like opioids is relatively selective, in that other sensory modalities are not affected. Patients frequently report that the pain is still present but that they feel more comfortable (*see* Therapeutic Uses of Opioid Analgesics, below). Continuous dull pain is relieved more effectively than sharp intermittent pain, but with sufficient amounts of opioid it is possible to relieve even the severe pain associated with renal or biliary colic.

Any meaningful discussion of the action of analgesic agents must include some distinction between *pain as a specific sensation*, subserved by distinct neurophysiological structures, and *pain as suffering* (the original sensation plus the reactions evoked by the sensation). It generally is agreed that all types of painful experiences, whether produced experimentally or occurring clinically as a result of pathology, include the original sensation and the reaction to that sensation. It also is important to distinguish between pain caused by stimulation of nociceptive receptors and transmitted over intact neural pathways (*nociceptive* pain) and pain that is caused by damage to neural structures, often involving neural supersensitivity (*neuropathic* pain). Although nociceptive pain usually is responsive to opioid analgesics, neuropathic pain typically responds poorly to opioid analgesics and may require higher doses of drug (McQuay, 1988).

In clinical situations, pain cannot be terminated at will, and the meaning of the sensation and the distress it engenders are markedly affected by the individual's previous experiences and current expectations. In experimentally produced pain, measurements of the effects of morphine on pain threshold have not always been consistent; some workers find that opioids reliably elevate the threshold, whereas many others do not obtain consistent changes. In contrast, moderate doses of morphine-like analgesics are effective in relieving clinical pain and increasing the capacity to tolerate experimen-

tally induced pain. Not only is the sensation of pain altered by opioid analgesics, but the affective response is changed as well. This latter effect is best assessed by asking patients with clinical pain about the degree of relief produced by the drug administered. When pain does not evoke its usual responses (anxiety, fear, panic, and suffering), a patient's ability to tolerate the pain may be markedly increased even when the capacity to perceive the sensation is relatively unaltered. It is clear, however, that alteration of the emotional reaction to painful stimuli is not the sole mechanism of analgesia. Intrathecal administration of opioids can produce profound segmental analgesia without causing significant alteration of motor or sensory function or subjective effects (Yaksh, 1988).

Mechanisms and Sites of Opioid-Induced Analgesia. While cellular and molecular studies of opioid receptors are invaluable in understanding their function, it is crucial to place them in their anatomical and physiological context to fully understand the opioid system. Pain control by opioids must be considered in the context of brain circuits modulating analgesia and the functions of the various receptor types in these circuits (Fields *et al.*, 1991).

It is well established that the analgesic effects of opioids arise from their ability to directly inhibit the ascending transmission of nociceptive information from the spinal cord dorsal horn and to activate pain control circuits that descend from the midbrain *via* the rostral ventromedial medulla to the spinal cord dorsal horn. Opioid peptides and their receptors are found throughout these descending pain control circuits (Mansour *et al.*, 1995; Gutstein *et al.*, 1998). μ -Opioid receptor mRNA and/or ligand binding is seen throughout the periaqueductal gray (PAG), pontine reticular formation, median raphe, nucleus raphe magnus, and adjacent gigantocellular reticular nucleus in the rostral ventromedial medulla (RVM) and spinal cord. Evaluation of discrepancies between levels of ligand binding and mRNA expression provides important insights into the mechanisms of μ -opioid receptor-mediated analgesia. For instance, the presence of significant μ -opioid receptor ligand binding in the superficial dorsal horn but scarcity of mRNA expression (Mansour *et al.*, 1995) suggests that the majority of these spinal μ -receptor ligand-binding sites are located presynaptically on the terminals of primary afferent nociceptors. This conclusion is consistent with the high levels of μ -opioid receptor mRNA observed in dorsal root ganglia (DRG). A similar mismatch between μ -receptor ligand binding and mRNA expression is seen in the dorsolateral PAG (a high level of binding and sparse mRNA) (Gutstein *et al.*, 1998). δ -Opioid receptor mRNA and ligand binding have been demonstrated in the ventral and ventrolateral quadrants of the PAG, the pontine reticular formation, and the gigantocellular reticular nucleus, but only low levels are seen in the median raphe and nucleus raphe magnus. As with the μ -opioid receptor, there are significant numbers of δ -opioid receptor-binding sites in the dorsal horn but no detectable mRNA expression, suggesting an important role for presynaptic actions of the δ -opioid receptor in spinal analgesia. κ -Opioid receptor mRNA and ligand binding are widespread throughout the PAG, pontine reticular formation, median raphe, nucleus raphe magnus, and adjacent gigantocellular reticular nucleus. Again, κ -receptor ligand binding but minimal mRNA have been found in the dorsal horn. Although all three receptor mRNAs are found in the DRG, they are localized on different types of primary afferent cells. μ -Opioid receptor mRNA is present in medium- and large-diameter DRG cells, δ -opioid receptor mRNA in large-diameter cells, and κ -opioid receptor mRNA in small- and medium-diameter cells (Mansour *et al.*, 1995). This differential localization may be linked to functional differences in pain modulation.

The distribution of opioid receptors in descending pain control circuits indicates substantial overlap between μ and κ receptors. μ Receptors and κ receptors are most anatomically distinct from the δ -opioid receptor in the PAG, median raphe, and nucleus raphe magnus (Gutstein *et al.*, 1998). A similar differentiation of μ and κ receptors from δ is seen in the thalamus, suggesting that interactions between the κ and μ receptors may be important for modulating nociceptive transmission from higher nociceptive centers, as well as in the spinal cord dorsal horn. The actions of μ -receptor agonists are invariably analgesic, whereas those of κ -receptor agonists can be either analgesic or antianalgesic. Consistent with the anatomical overlap between the μ and κ receptors, the antianalgesic actions of the κ -receptor agonists appear to be mediated by functional antagonism of the actions of μ receptor agonists. The μ receptor produces analgesia within descending pain control circuits, at least in part, by the removal of γ aminobutyric acid (GABA)-mediated inhibition of RVM-projecting neurons in the PAG and spinally projecting neurons in the RVM (Fields *et al.*, 1991). The pain-modulating effects of the κ receptor agonists in the brainstem appear to oppose those of μ receptor agonists. Application of a κ opioid agonist hyperpolarizes the same RVM neurons that are depolarized by a μ opioid agonist, and microinjections of a κ receptor agonist into the RVM antagonize the analgesia produced by microinjections of μ agonists into this region (Pan *et al.*, 1997). This is the strongest evidence to date demonstrating that opioids can have antianalgesic and analgesic effects, which may explain behavioral evidence for the reduction in hyperalgesia that follows injections of naloxone under certain circumstances.

As mentioned earlier, there is significant opioid-receptor ligand binding and little detectable receptor mRNA expression in the spinal cord dorsal horn but high levels of opioid-receptor mRNA in DRG. This distribution may suggest that the actions of opioid-receptor agonists relevant to analgesia at the spinal level are predominantly presynaptic. At least one presynaptic mechanism with potential clinical significance is inhibition of spinal tachykinin signaling. It is well known that opioids decrease the pain-evoked release of tachykinins from primary afferent nociceptors. Recently, the significance of this effect has been questioned. Trafton and colleagues (1999) have demonstrated that at least 80% of tachykinin signaling in response to noxious stimulation remains intact after the intrathecal administration of large doses of opioids. These results suggest that while opioid administration may reduce tachykinin release from primary afferent nociceptors, this reduction has little functional impact on the actions of tachykinins on postsynaptic pain-transmitting neurons. This implies either that tachykinins are not central to pain signaling and/or opioid-induced analgesia at the spinal level or that, contrary to the conclusions suggested by anatomical studies, presynaptic opioid actions may be of little analgesic significance.

Paralleling the important insights into mechanisms of opioid-induced analgesia at the brainstem and spinal levels, progress also has been made in understanding forebrain mechanisms. The actions of opioids in bulbospinal pathways are crucial in their analgesic efficacy, but the precise role of forebrain actions of opioids and whether these actions are independent of those in bulbospinal pathways are less well defined. Opioid actions in the forebrain clearly contribute to analgesia because decerebration prevents analgesia when rats are tested for pain sensitivity using the formalin test (Mathies and Franklin, 1992), and microinjection of opioids into several forebrain regions is analgesic in this test (Manning *et al.*, 1994). However, because these manipulations frequently do not change the analgesic efficacy of opioids in measures of acute-phasic nocicep-

tion, such as the tailflick test, a distinction has been made between forebrain-dependent mechanisms for morphine-induced analgesia in the presence of tissue injury and bulbospinal mechanisms for this analgesia in the absence of tissue injury. Manning and Mayer (1995a, 1995b) have shown that this distinction is not absolute. Analgesia induced by systemic administration of morphine in both the tailflick and formalin tests was disrupted either by lesioning or by reversibly inactivating the central nucleus of the amygdala, demonstrating that opioid actions in the forebrain contribute to analgesia in measures of tissue damage, as well as acute-phasic nociception.

Simultaneous administration of morphine at spinal and supraspinal sites results in synergy in analgesic response, with a tenfold reduction in the total dose of morphine necessary to produce equivalent analgesia at either site alone. The mechanisms responsible for spinal/supraspinal synergy are readily distinguished from those involved with supraspinal analgesia (Pick *et al.*, 1992). In addition to the well-described spinal/supraspinal synergy, synergistic μ/μ - and μ/δ -agonist interactions also have been observed within the brainstem between the PAG, locus coeruleus, and nucleus raphe magnus (Rossi *et al.*, 1993).

Opioids also can produce analgesia when administered peripherally. Opioid receptors are present on peripheral nerves and will respond to peripherally applied opioids and locally released endogenous opioid compounds when up-regulated during inflammatory pain states (Stein, 1993). During inflammation, immune cells capable of releasing endogenous opioids are present near sensory nerves, and a perineural defect allows opioids access to the nerves (Stein, 1993). This also may occur in neuropathic pain models (Kayser *et al.*, 1995), perhaps because of the presence of immune cells near damaged nerves (Monaco *et al.*, 1992) and perineural defects extant in these conditions.

The Role of N/OFQ and Its Receptor in Pain Modulation. N/OFQ mRNA and peptides are present throughout descending pain control circuits. For instance, N/OFQ-containing neurons are present in the PAG, the median raphe, throughout the RVM, and in the superficial dorsal horn (Neal *et al.*, 1999b). This distribution overlaps with that of opioid peptides, but the extent of colocalization is unclear. N/OFQ-receptor ligand binding and mRNA are seen in the PAG, median raphe, and RVM (Neal *et al.*, 1999a). Spinally, there is stronger N/OFQ-receptor mRNA expression in the ventral horn than in the dorsal horn but higher levels of ligand binding in the dorsal horn. There also are high N/OFQ-receptor mRNA levels in the DRG.

Despite clear anatomical evidence for a role of the N/OFQ system in pain modulation, its function is unclear. Targeted disruption of the N/OFQ receptor in mice had little effect on basal pain sensitivity in several measures, whereas targeted disruption of the N/OFQ precursor consistently elevated basal responses in the tailflick test, suggesting an important role for N/OFQ in regulating basal pain sensitivity (Koster *et al.*, 1999). Intrathecal injections of N/OFQ are analgesic (Xu *et al.*, 1996); however, supraspinal administration has produced either hyperalgesia, antiopioid effects, or a biphasic hyperalgesic/analgesic response (Mogil and Pasternak, 2001). These conflicting findings may be explained in part by a study in which it was shown that N/OFQ inhibits pain-facilitating and analgesia-facilitating neurons in the RVM (Pan *et al.*, 2000). Activation of endogenous analgesic circuitry was blocked by administration of N/OFQ. If the animal was hyperalgesic, the enhanced pain sensitivity also was blocked by N/OFQ. Thus, the effects of N/OFQ on pain responses appear to depend on the pre-

existing state of pain in the animal and the specific neural circuitry inhibited by N/OFQ (Heinricher, 2003).

Mood Alterations and Rewarding Properties

The mechanisms by which opioids produce euphoria, tranquility, and other alterations of mood (including rewarding properties) are not entirely clear. However, the neural systems that mediate opioid reinforcement are distinct from those involved in physical dependence and analgesia (Koob and Bloom, 1988). Behavioral and pharmacological data point to the role of dopaminergic pathways, particularly involving the nucleus accumbens (NAcc), in drug-induced reward. There is ample evidence for interactions between opioids and *dopamine* in mediating opioid-induced reward (see Chapter 23).

A full appreciation of mechanisms of drug-induced reward requires a more complete understanding of the NAcc and related structures at the anatomical level, as well as a careful examination of the interface between the opioid system and dopamine receptors. The NAcc, portions of the olfactory tubercle, and the ventral and medial portions of the caudate putamen constitute an area referred to as the *ventral striatum* (Heimer *et al.*, 1982). The ventral striatum is implicated in motivation and affect (limbic functions), whereas the dorsal striatum is involved in sensorimotor and cognitive functions (Willner *et al.*, 1991). The dorsal and ventral striata are heterogeneous structures that can be subdivided into distinct compartments. In the middle and caudal third of the NAcc, the characteristic distribution of neuroactive substances results in two unique compartments called the *core* and the *shell* (Heimer *et al.*, 1991). It is important to note that other reward-relevant brain regions (*e.g.*, the lateral hypothalamus and the medial prefrontal cortex) implicated with a variety of abused drugs are connected reciprocally to the shell of the NAcc. Thus the *shell of the NAcc* is the site that may be involved directly in the emotional and motivational aspects of drug-induced reward.

Prodynorphin- and proenkephalin-derived opioid peptides are expressed primarily in *output neurons* of the striatum and NAcc. All three opioid receptor types are present in the NAcc (Mansour *et al.*, 1988) and are thought to mediate, at least in part, the motivational effects of opiate drugs. Selective μ and δ receptor agonists are rewarding when defined by place preference (Shippenberg *et al.*, 1992) and intracranial self-administration (Devine and Wise, 1994) paradigms. Conversely, selective κ receptor agonists produce aversive effects (Cooper, 1991; Shippenberg *et al.*, 1992). Naloxone and selective μ antagonists also produce aversive effects (Cooper, 1991). Positive motivational effects of opioids are mediated partially by dopamine release at the level of the NAcc. Thus κ -receptor activation in these circuits inhibits dopamine release (Mulder and Schoffelmeier, 1993), whereas μ and δ receptor activation increases dopamine release (Devine *et al.*, 1993). Distinctive cell clusters in the shell of the NAcc contain proenkephalin, prodynorphin, μ receptors, and κ receptors, as well as dopamine receptors. These clusters may constitute a region where the motivational properties of dopaminergic and opioid drugs are processed.

The locus ceruleus (LC) contains noradrenergic neurons and high concentrations of opioid receptors and is postulated to play a

crucial role in feelings of alarm, panic, fear, and anxiety. Neural activity in the LC is inhibited by exogenous opioids and endogenous opioidlike peptides.

Other CNS Effects

Whereas opioids are used clinically primarily for their pain-relieving properties, they produce a host of other effects. This is not surprising in view of the wide distribution of opioids and their receptors in the brain and the periphery. A brief summary of some of these effects is presented below. High doses of opioids can produce muscular rigidity in humans. Chest wall rigidity severe enough to compromise respiration is not uncommon during anesthesia with fentanyl, *alfentanil*, *remifentanil*, and *sufentanil* (Monk *et al.*, 1988). Opioids and endogenous peptides cause catalepsy, circling, and stereotypical behavior in rats and other animals.

Effects on the Hypothalamus. Opioids alter the equilibrium point of the hypothalamic heat-regulatory mechanisms such that body temperature usually falls slightly. However, chronic high dosage may increase body temperature (Martin, 1983).

Neuroendocrine Effects. Morphine acts in the hypothalamus to inhibit the release of gonadotropin-releasing hormone (GnRH) and corticotropin-releasing hormone (CRH), thus decreasing circulating concentrations of luteinizing hormone (LH), follicle-stimulating hormone (FSH), ACTH, and β -endorphin; the last two peptides usually are released simultaneously from corticotropes in the pituitary. As a result of the decreased concentrations of pituitary trophic hormones, the plasma concentrations of testosterone and cortisol decline. Secretion of thyrotropin is relatively unaffected.

The administration of μ agonists increases the concentration of prolactin in plasma probably by reducing the dopaminergic inhibition of its secretion. Although some opioids enhance the secretion of growth hormone, the administration of morphine or β -endorphin has little effect on the concentration of the hormone in plasma. With chronic administration, tolerance develops to the effects of morphine on hypothalamic-releasing factors. Patients maintained on *methadone* reflect this phenomenon; in women, menstrual cycles that had been disrupted by intermittent use of heroin return to normal; in men, circulating concentrations of LH and testosterone usually are within the normal range.

Although κ -receptor agonists inhibit the release of antidiuretic hormone and cause diuresis, the administration of μ -opioid receptor agonists tends to produce antidiuretic effects in humans.

Miosis. Morphine and most μ and κ agonists cause constriction of the pupil by an excitatory action on the parasympathetic nerve innervating the pupil. After toxic doses of μ agonists, *the miosis is marked, and pinpoint pupils are pathognomonic*; however, marked mydriasis occurs when asphyxia intervenes. Some tolerance to the miotic effect develops, but addicts with high circulating concentrations of opioids continue to have constricted pupils.

Therapeutic doses of morphine increase accommodative power and lower intraocular tension in normal and glaucomatous eyes.

Convulsions. In animals, high doses of morphine and related opioids produce convulsions. Several mechanisms appear to be involved, and different types of opioids produce seizures with different characteristics. Morphine-like drugs excite certain groups of neurons, especially hippocampal pyramidal cells; these excitatory effects probably result from inhibition of the release of GABA by interneurons (McGinty and Friedman, 1988). Selective δ agonists produce similar effects. These actions may contribute to the seizures that are produced by some agents at doses only moderately higher than those required for analgesia, especially in children. However, with most opioids, convulsions occur only at doses far in excess of those required to produce profound analgesia, and seizures are not seen when potent μ agonists are used to produce anesthesia. Naloxone is more potent in antagonizing convulsions produced by some opioids (e.g., morphine, methadone, and propoxyphene) than those produced by others (e.g., meperidine). The production of convulsant metabolites of the latter agent may be partially responsible (see below). Anticonvulsant agents may not always be effective in suppressing opioid-induced seizures (see Chapter 19).

Respiration. Morphine-like opioids depress respiration at least in part by virtue of a direct effect on the brainstem respiratory centers. The respiratory depression is discernible even with doses too small to disturb consciousness and increases progressively as the dose is increased. In humans, death from morphine poisoning is nearly always due to respiratory arrest. Therapeutic doses of morphine in humans depress all phases of respiratory activity (rate, minute volume, and tidal exchange) and also may produce irregular and periodic breathing. The diminished respiratory volume is due primarily to a slower rate of breathing, and with toxic amounts, the rate may fall to three or four breaths per minute. Although effects on respiration are readily demonstrated, clinically significant respiratory depression rarely occurs with standard morphine doses in the absence of underlying pulmonary dysfunction. One important exception is when opioids are administered parenterally to women within 2 to 4 hours of delivery, which can lead to transient respiratory depression in the neonate because of transplacental passage of opioids. However, the combination of opioids with other medications, such as general anesthetics, tranquilizers, alcohol, or sedative-hypnotics, may present a greater risk of respiratory depression. Maximal respiratory depression occurs

within 5 to 10 minutes of intravenous administration of morphine or within 30 or 90 minutes of intramuscular or subcutaneous administration, respectively.

Maximal respiratory depressant effects occur more rapidly with more lipid-soluble agents. After therapeutic doses, respiratory minute volume may be reduced for as long as 4 to 5 hours. The primary mechanism of respiratory depression by opioids involves a reduction in the responsiveness of the brainstem respiratory centers to carbon dioxide. Opioids also depress the pontine and medullary centers involved in regulating respiratory rhythmicity and the responsiveness of medullary respiratory centers to electrical stimulation (Martin, 1983).

Hypoxic stimulation of chemoreceptors still may be effective when opioids have decreased the responsiveness to CO_2 , and the inhalation of O_2 thus may produce apnea. After large doses of morphine or other μ agonists, patients will breathe if instructed to do so, but without such instruction, they may remain relatively apneic.

Because of the accumulation of CO_2 , respiratory rate and sometimes even minute volume can be unreliable indicators of the degree of respiratory depression that has been produced by morphine. Natural sleep also produces a decrease in the sensitivity of the medullary center to CO_2 , and the effects of morphine and sleep are additive.

Numerous studies have compared morphine and morphine-like opioids with respect to their ratios of analgesic to respiratory-depressant activities, and most have found that when equianalgesic doses are used, there is no significant difference. Severe respiratory depression is less likely after the administration of large doses of selective κ agonists. High concentrations of opioid receptors and endogenous peptides are found in the medullary areas believed to be important in ventilatory control.

Cough. Morphine and related opioids also depress the cough reflex at least in part by a direct effect on a cough center in the medulla. There is, however, no obligatory relationship between depression of respiration and depression of coughing, and effective antitussive agents are available that do not depress respiration (see below). Suppression of cough by such agents appears to involve receptors in the medulla that are less sensitive to naloxone than those responsible for analgesia.

Nauseant and Emetic Effects. Nausea and vomiting produced by morphine-like drugs are side effects caused by direct stimulation of the chemoreceptor trigger zone for emesis in the area postrema of the medulla. Certain individuals never vomit after morphine, whereas others do so each time the drug is administered.

Nausea and vomiting are relatively uncommon in recumbent patients given therapeutic doses of morphine, but nausea occurs in approximately 40% and vomiting in 15% of ambulatory patients given 15 mg of the drug subcutaneously. This suggests that a vestibular component also is operative. Indeed, the nauseant and emetic

effects of morphine are markedly enhanced by vestibular stimulation, and morphine and related synthetic analgesics produce an increase in vestibular sensitivity. All clinically useful μ agonists produce some degree of nausea and vomiting. Careful, controlled clinical studies usually demonstrate that, in equianalgesic dosage, the incidence of such side effects is not significantly lower than that seen with morphine. Antagonists to the 5-HT₃ serotonin receptor have supplanted phenothiazines and drugs used for motion sickness as the drugs of choice for the treatment of opioid-induced nausea and vomiting. Gastric prokinetic agents such as *metoclopramide* also are useful anti-nausea and antiemetic drugs (*see* Chapter 37).

Cardiovascular System. In the supine patient, therapeutic doses of morphinelike opioids have no major effect on blood pressure or cardiac rate and rhythm. Such doses do produce peripheral vasodilation, reduced peripheral resistance, and an inhibition of baroreceptor reflexes. Therefore, when supine patients assume the head-up position, orthostatic hypotension and fainting may occur. The peripheral arteriolar and venous dilation produced by morphine involves several mechanisms. Morphine and some other opioids provoke release of histamine, which sometimes plays a large role in the hypotension. However, vasodilation usually is only partially blocked by H₁ antagonists, but it is effectively reversed by naloxone. Morphine also blunts the reflex vasoconstriction caused by increased PCO₂ (*see* Chapter 15).

Effects on the myocardium are not significant in normal individuals. In patients with coronary artery disease but no acute medical problems, 8 to 15 mg morphine administered intravenously produces a decrease in oxygen consumption, left ventricular end-diastolic pressure, and cardiac work; effects on cardiac index usually are slight. In patients with acute myocardial infarction, the cardiovascular responses to morphine may be more variable than in normal subjects, and the magnitude of changes (*e.g.*, the decrease in blood pressure) may be more pronounced (Roth *et al.*, 1988).

Morphine may exert its well-known therapeutic effect in the treatment of angina pectoris and acute myocardial infarction by decreasing preload, inotropy, and chronotropy, thus favorably altering determinants of myocardial oxygen consumption and helping to relieve ischemia. It is not clear whether the analgesic properties of morphine in this situation are due to the reversal of acidosis that may stimulate local acid-sensing ion channels (McCleskey and Gold, 1999) or to a direct analgesic effect on nociceptive afferents from the heart.

When administered before experimental ischemia, morphine has been shown to produce cardioprotective effects. Morphine can mimic the phenomenon of ischemic preconditioning, where a short ischemic episode paradoxically protects the heart against further ischemia. This effect appears to be mediated through δ receptors signaling through a mitochondrial ATP-sensitive potassium channel in cardiac myocytes; the effect also is produced by other GPCRs signaling through G_i (Fryer *et al.*, 2000). It also has been suggested recently that δ opioids can be antiarrhythmic and antifibrillatory during and after periods of ischemia (Fryer *et al.*, 2000), although other data suggest that δ opioids can be arrhythmogenic (McIntosh *et al.*, 1992).

Very large doses of morphine can be used to produce anesthesia; however, decreased peripheral resistance and blood pressure are troublesome. Fentanyl and sufentanil, which are potent and selective μ agonists, are less likely to cause hemodynamic instability during surgery in part because they do not cause the release of histamine (Monk *et al.*, 1988).

Morphine-like opioids should be used with caution in patients who have a decreased blood volume because these agents can aggravate hypovolemic shock. Morphine should be used with great care in patients with cor pulmonale because deaths after ordinary therapeutic doses have been reported. The concurrent use of certain phenothiazines may increase the risk of morphine-induced hypotension.

Cerebral circulation is not affected directly by therapeutic doses of morphine. However, opioid-induced respiratory depression and CO₂ retention can result in cerebral vasodilation and an increase in cerebrospinal fluid pressure; the pressure increase does not occur when PCO₂ is maintained at normal levels by artificial ventilation.

Gastrointestinal Tract. Stomach. Morphine and other μ agonists usually decrease the secretion of hydrochloric acid, although stimulation sometimes is evident. Activation of opioid receptors on parietal cells enhances secretion, but indirect effects, including increased secretion of somatostatin from the pancreas and reduced release of acetylcholine, appear to be dominant in most circumstances (Kromer, 1988). Relatively low doses of morphine decrease gastric motility, thereby prolonging gastric emptying time; this can increase the likelihood of esophageal reflux. The tone of the antral portion of the stomach and of the first part of the duodenum is increased, which often makes therapeutic intubation of the duodenum more difficult. Passage of the gastric contents through the duodenum may be delayed by as much as 12 hours, and the absorption of orally administered drugs is retarded.

Small Intestine. Morphine diminishes biliary, pancreatic, and intestinal secretions (De Luca and Coupar, 1996) and delays digestion of food in the small intestine. Resting tone is increased, and periodic spasms are observed. The amplitude of the nonpropulsive type of rhythmic, segmental contractions usually is enhanced, but propulsive contractions are decreased markedly. The upper part of the small intestine, particularly the duodenum, is affected more than the ileum. A period of relative atony may follow the hypertonicity. Water is absorbed more completely because of the delayed passage of bowel contents, and intestinal secretion is decreased; this increases the viscosity of the bowel contents.

In the presence of intestinal hypersecretion that may be associated with diarrhea, morphine-like drugs inhibit the transfer of fluid and electrolytes into the lumen by naloxone-sensitive actions on the intestinal mucosa and within the CNS (De Luca and Coupar, 1996; Kromer, 1988). Enteric muscle cells also may possess opioid receptors (Holzer, 2004). However, it is clear that opioids exert important effects on the submucosal plexus that lead to a decrease in the basal

secretion by enterocytes and inhibition of the stimulatory effects of acetylcholine, prostaglandin E₂, and vasoactive intestinal peptide. The effects of opioids initiated either in the CNS or in the submucosal plexus may be mediated in large part by the release of norepinephrine and stimulation of α_2 adrenergic receptors on enterocytes.

Large Intestine. Propulsive peristaltic waves in the colon are diminished or abolished after administration of morphine, and tone is increased to the point of spasm. The resulting delay in the passage of bowel contents causes considerable desiccation of the feces, which, in turn, retards their advance through the colon. The amplitude of the nonpropulsive type of rhythmic contractions of the colon usually is enhanced. The tone of the anal sphincter is augmented greatly, and reflex relaxation in response to rectal distension is reduced. These actions, combined with inattention to the normal sensory stimuli for defecation reflex owing to the central actions of the drug, contribute to morphine-induced constipation.

Mechanism of Action on the Bowel. The usual gastrointestinal effects of morphine primarily are mediated by μ and δ opioid receptors in the bowel. However, injection of opioids into the cerebral ventricles or in the vicinity of the spinal cord can inhibit gastrointestinal propulsive activity as long as the extrinsic innervation to the bowel is intact. The relatively poor penetration of morphine into the CNS may explain how preparations such as *paregoric* can produce constipation at less than analgesic doses and may account for troublesome gastrointestinal side effects during the use of oral morphine for the treatment of cancer pain. Although some tolerance develops to the effects of opioids on gastrointestinal motility, patients who take opioids chronically remain constipated.

Biliary Tract. After the subcutaneous injection of 10 mg *morphine sulfate*, the sphincter of Oddi constricts, and the pressure in the common bile duct may rise more than tenfold within 15 minutes; this effect may persist for 2 hours or more. Fluid pressure also may increase in the gallbladder and produce symptoms that may vary from epigastric distress to typical biliary colic.

Some patients with biliary colic experience exacerbation rather than relief of pain when given opioids. Spasm of the sphincter of Oddi probably is responsible for elevations of plasma amylase and lipase that occur sometimes after morphine administration. All opioids can cause biliary spasm. *Atropine* only partially prevents morphine-induced biliary spasm, but opioid antagonists prevent or relieve it. *Nitroglycerin* (0.6 to 1.2 mg) administered sublingually also decreases the elevated intrabiliary pressure (Staritz, 1988).

Other Smooth Muscle. Ureter and Urinary Bladder. Therapeutic doses of morphine may increase the tone and amplitude of contractions of the ureter, although the response is variable. When the antidiuretic effects of the drug are prominent and urine flow decreases, the ureter may become quiescent.

Morphine inhibits the urinary voiding reflex and increases the tone of the external sphincter and the volume of the bladder; cath-

eterization sometimes is required after therapeutic doses of morphine. Stimulation of either μ or δ receptors in the brain or in the spinal cord exerts similar actions on bladder motility (Dray and Nunan, 1987). Tolerance develops to these effects of opioids on the bladder.

Uterus. If the uterus has been made hyperactive by oxytocics, morphine tends to restore the tone, frequency, and amplitude of contractions to normal.

Skin. Therapeutic doses of morphine cause dilation of cutaneous blood vessels. The skin of the face, neck, and upper thorax frequently becomes flushed. These changes may be due in part to the release of histamine and may be responsible for the sweating and some of the pruritus that occasionally follow the systemic administration of morphine (*see below*). Histamine release probably accounts for the urticaria commonly seen at the site of injection, which is not mediated by opioid receptors and is not blocked by naloxone. It is seen with morphine and meperidine but not with *oxymorphone*, methadone, fentanyl, or sufentanil.

Pruritus is a common and potentially disabling complication of opioid use. It can be caused by intraspinal and systemic injections of opioids, but it appears to be more intense after intraspinal administration (Ballantyne *et al.*, 1988). The effect appears to be mediated largely by dorsal horn neurons and is reversed by naloxone (Thomas *et al.*, 1992).

Immune System. The effects of opioids on the immune system are complex. Opioids modulate immune function by direct effects on cells of the immune system and indirectly *via* centrally mediated neuronal mechanisms (Sharp and Yaksh, 1997). The acute central immunomodulatory effects of opioids may be mediated by activation of the sympathetic nervous system, whereas the chronic effects of opioids may involve modulation of the hypothalamic–pituitary–adrenal (HPA) axis (Mellon and Bayer, 1998). Direct effects on immune cells may involve unique, incompletely characterized variants of the classical neuronal opioid receptors, with δ -receptor variants being most prominent (Sharp and Yaksh, 1997). Atypical receptors could account for the fact that it has been very difficult to demonstrate significant opioid binding on immune cells despite the observance of robust functional effects. In contrast, morphine-induced immune suppression largely is abolished in knockout mice lacking the μ receptor gene, suggesting that the μ receptor is a major target of morphine's actions on the immune system (Gaveriaux-Ruff *et al.*, 1998). A proposed mechanism for the immune suppressive effects of morphine on neutrophils is through a nitric oxide–dependent inhibition of NF- κ B activation (Welters *et al.*, 2000). Others have proposed that the induction and activation of MAP kinase also may play a role (Chuang *et al.*, 1997).

The overall effects of opioids appear to be immunosuppressive, and increased susceptibility to infection and tumor spread have been observed. Infusion of the μ -receptor antagonist naloxone has been shown to improve survival after experimentally induced sepsis (Risdaal *et al.*, 1998). Such effects have been inconsistent in clinical situations possibly because of the use of confounding therapies and necessary opioid analgesics. In some situations, immune effects appear more prominent with acute administration than with chronic administration, which could have important implications for the care of the critically ill (Sharp and Yaksh, 1997). In contrast, opioids have been shown to reverse pain-induced immunosuppression and increase tumor metastatic potential in animal models (Page and Ben-Eliyahu, 1997). Therefore, opioids may

either inhibit or augment immune function depending on the context in which they are used. These studies also indicate that withholding opioids in the presence of pain in immunocompromised patients actually could worsen immune function. An intriguing paper indicated that the partial μ -receptor agonist *buprenorphine* (see below) did not alter immune function when injected centrally into the mesencephalic PAG, whereas morphine did (Gomez-Flores and Weber, 2000). Taken together, these studies indicate that opioid-induced immune suppression may be clinically relevant both to the treatment of severe pain and in the susceptibility of opioid addicts to infection [e.g., human immunodeficiency virus (HIV) infection and tuberculosis]. Different opioid agonists also may have unique immunomodulatory properties. Better understanding of these properties eventually should help to guide the rational use of opioids in patients with cancer or at risk for infection or immune compromise.

Tolerance and Physical Dependence

The development of tolerance and physical dependence with repeated use is a characteristic feature of all the opioid drugs. *Tolerance* to the effect of opioids or other drugs simply means that, over time, the drug loses its effectiveness and an increased dose is required to produce the same physiological response. *Dependence* refers to a complex and poorly understood set of changes in the homeostasis of an organism that causes a disturbance of the homeostatic set point of the organism if the drug is stopped. This disturbance often is revealed when administration of an opioid is stopped abruptly, resulting in *withdrawal*. *Addiction* is a behavioral pattern characterized by compulsive use of a drug and overwhelming involvement with its procurement and use. Tolerance and dependence are physiological responses seen in all patients and are not predictors of addiction (see Chapter 23). These processes appear to be quite distinct. For example, cancer pain often requires prolonged treatment with high doses of opioids, leading to tolerance and dependence. Yet abuse in this setting is very unusual (Foley, 1993). Neither the presence of tolerance and dependence nor the fear that they may develop should ever interfere with the appropriate use of opioids. Opioids can be discontinued in dependent patients once the need for analgesics is gone without subjecting them to withdrawal (see Chapter 23). Clinically, the dose can be decreased by 10% to 20% every other day and eventually stopped without signs and symptoms of withdrawal.

In vivo studies in animal models demonstrate the importance of neurotransmitters and their interactions with opioid pathways in the development of tolerance to morphine. Blockade of glutamate actions by NMDA (*N*-methyl-D-aspartate)-receptor antagonists blocks morphine tolerance (Trujillo and Akil, 1991). Since NMDA antagonists have no effect on the potency of morphine in naive animals, their effect cannot be attributed to poten-

tiation of opioid actions. Interestingly, the antitussive *dextromethorphan* (see below) has been shown to function as an NMDA antagonist. In animals, it can attenuate opioid tolerance development and reverse established tolerance (Elliott *et al.*, 1994). Nitric oxide production, possibly induced by NMDA-receptor activation, also has been implicated in tolerance because inhibition of nitric oxide synthase (NOS) also blocks morphine tolerance development (Kolesnikov *et al.*, 1993). Administering NOS inhibitors to morphine-tolerant animals also may reverse tolerance in certain circumstances. Although NMDA antagonists and nitric oxide synthase inhibitors are effective against tolerance to morphine and δ agonists such as DPDPE, they have little effect against tolerance to the κ agonists. Morphine dependence was thought to be closely related to tolerance because some treatments that block tolerance to morphine also block dependence. Nonetheless, it now is believed that distinct mechanisms underlie these two effects. The deletion of β -arrestin-2 inhibits the development of tolerance to morphine but does not inhibit the development of physical dependence (Bohn *et al.*, 2000). Deletion of GRK3 inhibits the development of tolerance to fentanyl but has no effect on the development of morphine tolerance (Terman *et al.*, 2004). GRK3 deletion also did not affect physical dependence. Taken together, these findings suggest that the signaling mechanisms underlying the development of opioid tolerance and physical dependence also may be agonist-dependent.

MORPHINE AND RELATED OPIOID AGONISTS

There are now many compounds with pharmacological properties similar to those of morphine, yet morphine remains the standard against which new analgesics are measured. However, responses of an individual patient may vary dramatically with different μ -opioid receptor agonists. For example, some patients unable to tolerate morphine may have no problems with an equianalgesic dose of methadone, whereas others can tolerate morphine and not methadone. If problems are encountered with one drug, another should be tried. Mechanisms underlying variations in individual responses to morphine-like agonists are poorly understood.

Source and Composition of Opium. Because the synthesis of morphine is difficult, the drug still is obtained from opium or extracted from poppy straw. Opium is obtained from the unripe seed capsules of the poppy plant, *Papaver somniferum*. The milky juice is dried and powdered to make powdered opium, which contains a number of alkaloids. Only a few—morphine, codeine, and papaverine—have clinical usefulness. These alkaloids can be divided into two distinct chemical classes, *phenanthrenes* and *benzylisoquinolines*. The principal phenanthrenes are morphine (10% of opium), codeine (0.5%), and thebaine (0.2%). The principal benzylisoquinolines are papaverine (1%), which is a smooth muscle relaxant (see the seventh and earlier editions of this book), and *noscapine* (6%).

Chemistry of Morphine and Related Opioids. The structure of morphine is shown in Table 21–5. Many semisynthetic derivatives are made by relatively simple modifications of morphine or thebaine. Codeine is methylmorphine, the methyl substitution being on the phenolic hydroxyl group. Thebaine differs from morphine only in that both hydroxyl groups are methylated and that the ring has two double bonds ($\Delta^{6,7}$, $\Delta^{8,14}$). Thebaine has little analgesic action but is a precursor of several important 14-OH compounds, such as *oxycodone* and *naloxone*. Certain derivatives of thebaine are more than 1000 times as potent as morphine (*e.g.*, *etorphine*). *Diacetylmorphine*, or heroin, is made from morphine by acetylation at the 3 and 6 positions. *Apomorphine*, which also can be prepared from morphine, is a potent emetic and dopaminergic agonist (*see* Chapter 20). *Hydromorphone*, *oxymorphone*, *hydrocodone*, and *oxycodone* also are made by modifying the morphine molecule. The structural relationships between morphine and some of its surrogates and antagonists are shown in Table 21–5.

Structure–Activity Relationship of the Morphine-like Opioids.

In addition to morphine, codeine, and the semisynthetic derivatives of the natural opium alkaloids, a number of other structurally distinct chemical classes of drugs have pharmacological actions similar to those of morphine. Clinically useful compounds include the morphinans, benzomorphans, methadones, phenylpiperidines, and propionanilides. Although the two-dimensional representations of these chemically diverse compounds appear to be quite different, molecular models show certain common characteristics, as indicated by the heavy lines in the structure of morphine shown in Table 21–5. Among the important properties of the opioids that can be altered by structural modification are their affinities for various species of opioid receptors, their activities as agonists *versus* antagonists, their lipid solubilities, and their resistance to metabolic breakdown. For example, blockade of the phenolic hydroxyl at position 3, as in codeine and heroin, drastically reduces binding to μ receptors; these compounds are converted *in vivo* to the potent analgesics morphine and 6-acetyl morphine, respectively.

Absorption, Distribution, Fate, and Excretion. **Absorption.** In general, the opioids are absorbed readily from the gastrointestinal tract; absorption through the rectal mucosa is adequate, and a few agents (*e.g.*, morphine, hydromorphone) are available in suppositories. The more lipophilic opioids also are absorbed readily through the nasal or buccal mucosa (Weinberg *et al.*, 1988). Those with the greatest lipid solubility also can be absorbed transdermally (Portenoy *et al.*, 1993). Opioids are absorbed readily after subcutaneous or intramuscular injection and can penetrate the spinal cord adequately after epidural or intrathecal administration. Small amounts of morphine introduced epidurally or intrathecally into the spinal canal can produce profound analgesia that may last 12 to 24 hours. However, because of the hydrophilic nature of morphine, there is rostral spread of the drug in spinal fluid, and side effects, especially respiratory depression, can emerge up to 24 hours later as the opioid reaches supraspinal respiratory control centers. With highly lipophilic agents such as hydromorphone or fen-

tanyl, rapid absorption by spinal neural tissues produces very localized effects and segmental analgesia. The duration of action is shorter because of distribution of the drug in the systemic circulation, and the severity of respiratory depression may be more directly proportional to its concentration in plasma owing to a lesser degree of rostral spread (Gustafsson and Wiesenfeld-Hallin, 1988). However, patients receiving epidural or intrathecal fentanyl still should be monitored for respiratory depression.

With most opioids, including morphine, the effect of a given dose is less after oral than after parenteral administration because of variable but significant first-pass metabolism in the liver. For example, the bioavailability of oral preparations of morphine is only about 25%. The shape of the time–effect curve also varies with the route of administration, so the duration of action often is somewhat longer with the oral route. If adjustment is made for variability of first-pass metabolism and clearance, adequate relief of pain can be achieved with oral administration of morphine. Satisfactory analgesia in cancer patients is associated with a very broad range of steady-state concentrations of morphine in plasma (16 to 364 ng/ml) (Neumann *et al.*, 1982).

When morphine and most opioids are given intravenously, they act promptly. However, the more lipid-soluble compounds act more rapidly than morphine after subcutaneous administration because of differences in the rates of absorption and entry into the CNS. Compared with more lipid-soluble opioids such as codeine, heroin, and methadone, morphine crosses the blood–brain barrier at a considerably lower rate.

Distribution and Fate. About one-third of morphine in the plasma is protein-bound after a therapeutic dose. Morphine itself does not persist in tissues, and 24 hours after the last dose, tissue concentrations are low.

The major pathway for the metabolism of morphine is conjugation with glucuronic acid. The two major metabolites formed are *morphine-6-glucuronide* and *morphine-3-glucuronide*. Small amounts of morphine-3,6-diglucuronide also may be formed. Although the 3- and 6-glucuronides are quite polar, both still can cross the blood–brain barrier to exert significant clinical effects (Christup, 1997). Morphine-6-glucuronide has pharmacological actions indistinguishable from those of morphine. Morphine-6-glucuronide given systemically is approximately twice as potent as morphine in animal models (Paul *et al.*, 1989) and in humans (Osborne *et al.*, 1988). With chronic administration, it accounts for a significant portion of morphine’s analgesic actions (Osborne *et al.*, 1988). Indeed, with chronic oral dosing, the blood levels

*The numbers 3, 6, and 17 refer to positions in the morphine molecule, as shown above. †Other changes in the morphine molecule are: (1) Single instead of double bond between C7 and C8; (2) OH added to C14; (3) No oxygen between C4 and C5; (4) *Endo*etheno bridge between C6 and C14; 1-hydroxy-1,2,2-trimethylpropyl substitution on C7.

of morphine-6-glucuronide typically exceed those of morphine. Given its greater potency and its higher concentration, morphine-6-glucuronide may be responsible for most of morphine's analgesic activity in patients receiving chronic oral morphine. Morphine-6-glucuronide is excreted by the kidney. In renal failure, the levels of morphine-6-glucuronide can accumulate, perhaps explaining

morphine's potency and long duration in patients with compromised renal function. In adults, the half-life of morphine is about 2 hours; the half-life of morphine-6-glucuronide is somewhat longer. Children achieve adult renal function values by 6 months of age. In elderly patients, lower doses of morphine are recommended based on its smaller volume of distribution (Owen *et al.*,

1983) and the general decline in renal function in the elderly. Morphine-3-glucuronide, another important metabolite (Milne *et al.*, 1996), has little affinity for opioid receptors but may contribute to excitatory effects of morphine (Smith, 2000). Some investigators have shown that morphine-3-glucuronide can antagonize morphine-induced analgesia (Smith *et al.*, 1990), but this finding is not universal (Christup, 1997). *N*-Demethylation of morphine to normorphine is a minor metabolic pathway in humans but is more prominent in rodents (Yeh *et al.*, 1977). *N*-Dealkylation also is important in the metabolism of some congeners of morphine.

Excretion. Very little morphine is excreted unchanged. It is eliminated by glomerular filtration, primarily as morphine-3-glucuronide; 90% of the total excretion takes place during the first day. Enterohepatic circulation of morphine and its glucuronides occurs, which accounts for the presence of small amounts of morphine in the feces and in the urine for several days after the last dose.

Codeine. In contrast to morphine, codeine is approximately 60% as effective orally as parenterally as an analgesic and as a respiratory depressant. Codeine analogs such as *levorphanol*, oxycodone, and methadone have a high ratio of oral-to-parenteral potency. The greater oral efficacy of these drugs reflects lower first-pass metabolism in the liver. Once absorbed, codeine is metabolized by the liver, and its metabolites are excreted chiefly as inactive forms in the urine. A small fraction (approximately 10%) of administered codeine is *O*-demethylated to morphine, and free and conjugated morphine can be found in the urine after therapeutic doses of codeine. Codeine has an exceptionally low affinity for opioid receptors, and the analgesic effect of codeine is due to its conversion to morphine. However, its antitussive actions may involve distinct receptors that bind codeine itself. The half-life of codeine in plasma is 2 to 4 hours.

The conversion of codeine to morphine is effected by the CYP2D6. Well-characterized genetic polymorphisms in CYP2D6 lead to the inability to convert codeine to morphine, thus making codeine ineffective as an analgesic for about 10% of the Caucasian population (Eichelbaum and Evert, 1996). Other polymorphisms can lead to enhanced metabolism and thus increased sensitivity to codeine's effects (Eichelbaum and Evert, 1996). Interestingly, there appears to be variation in metabolic efficiency among ethnic groups. For example, Chinese produce less morphine from codeine than do Caucasians and also are less sensitive to morphine's effects. The reduced sensitivity to morphine may be due to decreased production of morphine-6-glucuronide (Caraco *et al.*, 1999). Thus, it is important to consider the possibility of metabolic enzyme polymorphism in any patient who does not receive adequate analgesia from

codeine or an adequate response to other administered opioid prodrugs.

Tramadol. Tramadol (ULTRAM) is a synthetic codeine analog that is a weak μ -opioid receptor agonist. Part of its analgesic effect is produced by inhibition of uptake of norepinephrine and serotonin. In the treatment of mild-to-moderate pain, tramadol is as effective as morphine or meperidine. However, for the treatment of severe or chronic pain, tramadol is less effective. Tramadol is as effective as meperidine in the treatment of labor pain and may cause less neonatal respiratory depression.

Tramadol is 68% bioavailable after a single oral dose and 100% available when administered intramuscularly. Its affinity for the μ -opioid receptor is only 1/6000 that of morphine. However, the primary *O*-demethylated metabolite of tramadol is two to four times as potent as the parent drug and may account for part of the analgesic effect. Tramadol is supplied as a racemic mixture, which is more effective than either enantiomer alone. The (+)-enantiomer binds to the μ receptor and inhibits serotonin uptake. The (–)-enantiomer inhibits norepinephrine uptake and stimulates α_2 adrenergic receptors (Lewis and Han, 1997). The compound undergoes hepatic metabolism and renal excretion, with an elimination half-life of 6 hours for tramadol and 7.5 hours for its active metabolite. Analgesia begins within an hour of oral dosing and peaks within 2 to 3 hours. The duration of analgesia is about 6 hours. The maximum recommended daily dose is 400 mg.

Common side effects of tramadol include nausea, vomiting, dizziness, dry mouth, sedation, and headache. Respiratory depression appears to be less than with equianalgesic doses of morphine, and the degree of constipation is less than that seen after equivalent doses of codeine (Duthie, 1998). Tramadol can cause seizures and possibly exacerbate seizures in patients with predisposing factors. While tramadol-induced analgesia is not entirely reversible by naloxone, tramadol-induced respiratory depression can be reversed by naloxone. However, the use of naloxone increases the risk of seizure. Physical dependence on and abuse of tramadol have been reported. Although its abuse potential is unclear, tramadol probably should be avoided in patients with a history of addiction. Because of its inhibitory effect on serotonin uptake, tramadol should not be used in patients taking monoamine oxidase (MAO) inhibitors (Lewis and Han, 1997) (*see* section on interaction of meperidine with other drugs below).

Heroin. Heroin (diacetylmorphine) is rapidly hydrolyzed to 6-monoacetylmorphine (6-MAM), which, in turn, is hydrolyzed to morphine. Heroin and 6-MAM are more lipid soluble than morphine and enter the brain more readily. Evidence suggests that morphine and 6-MAM are responsible for the pharmacological actions of heroin. Heroin is excreted mainly in the urine largely as free and conjugated morphine.

Untoward Effects and Precautions. Morphine and related opioids produce a wide spectrum of unwanted effects,

including respiratory depression, nausea, vomiting, dizziness, mental clouding, dysphoria, pruritus, constipation, increased pressure in the biliary tract, urinary retention, and hypotension. The bases of these effects were described earlier. Rarely, a patient may develop delirium. Increased sensitivity to pain after analgesia has worn off also may occur.

A number of factors may alter a patient's sensitivity to opioid analgesics, including the integrity of the blood-brain barrier. For example, when morphine is administered to a newborn infant in weight-appropriate doses extrapolated from adults, unexpectedly profound analgesia and respiratory depression may be observed. This is due to the immaturity of the blood-brain barrier in neonates. As mentioned previously, morphine is hydrophilic, so proportionately less morphine normally crosses into the CNS than with more lipophilic opioids. In neonates or when the blood-brain barrier is compromised, lipophilic opioids may give more predictable clinical results than morphine. In adults, the *duration* of the analgesia produced by morphine increases progressively with age; however, the *degree* of analgesia that is obtained with a given dose changes little. Changes in pharmacokinetic parameters only partially explain these observations. The patient with severe pain may tolerate larger doses of morphine. However, as the pain subsides, the patient may exhibit sedation and even respiratory depression as the stimulatory effects of pain are diminished. The reasons for this effect are unclear.

All opioid analgesics are metabolized by the liver and should be used with caution in patients with hepatic disease because increased bioavailability after oral administration or cumulative effects may occur. Renal disease also significantly alters the pharmacokinetics of morphine, codeine, *dihydrocodeine*, meperidine, and propoxyphene. Although single doses of morphine are well tolerated, the active metabolite, morphine-6-glucuronide, may accumulate with continued dosing, and symptoms of opioid overdose may result (Chan and Matzke, 1987). This metabolite also may accumulate during repeated administration of codeine to patients with impaired renal function. When repeated doses of meperidine are given to such patients, the accumulation of normeperidine may cause tremor and seizures (Kaiko *et al.*, 1983). Similarly, the repeated administration of propoxyphene may lead to naloxone-insensitive cardiac toxicity caused by the accumulation of norpropoxyphene (Chan and Matzke, 1987).

Morphine and related opioids must be used cautiously in patients with compromised respiratory function (*e.g.*, emphysema, kyphoscoliosis, or severe obesi-

ty). In patients with cor pulmonale, death has occurred after therapeutic doses of morphine. Although many patients with such conditions seem to be functioning within normal limits, they are already using compensatory mechanisms, such as increased respiratory rate. Many have chronically elevated levels of plasma CO₂ and may be less sensitive to the stimulating actions of CO₂. The further imposition of the depressant effects of opioids and the related capacity to elevate intracranial pressure must be considered in the presence of head injury or an already elevated intracranial pressure. While head injury *per se* does not constitute an absolute contraindication to the use of opioids, the possibility of exaggerated depression of respiration and the potential need to control ventilation of the patient must be considered. Finally, since opioids may produce mental clouding and side effects such as miosis and vomiting, which are important signs in following the clinical course of patients with head injuries, the advisability of their use must be weighed carefully against these risks.

Morphine causes histamine release, which can cause bronchoconstriction and vasodilation. Morphine has the potential to precipitate or exacerbate asthmatic attacks and should be avoided in patients with a history of asthma. Other μ receptor agonists that do not release histamine, such as the fentanyl derivatives, may be better choices for such patients.

Patients with reduced blood volume are considerably more susceptible to the vasodilatory effects of morphine and related drugs, and these agents must be used cautiously in patients with hypotension from any cause.

Allergic phenomena occur with opioid analgesics but are uncommon. They usually are manifested as urticaria and other types of skin rashes such as fixed eruptions; contact dermatitis in nurses and pharmaceutical workers also occurs. Wheals at the site of injection of morphine, codeine, and related drugs are probably secondary to histamine release. Anaphylactoid reactions have been reported after intravenous administration of codeine and morphine, but such reactions are rare. Such reactions may be responsible for some of the sudden deaths, episodes of pulmonary edema, and other complications that occur among addicts who use heroin intravenously (*see* Chapter 23).

Interactions with Other Drugs. The depressant effects of some opioids may be exaggerated and prolonged by phenothiazines, MOA inhibitors, and tricyclic antidepressants; the mechanisms of these supra-additive effects are not understood fully but may involve alterations in the rate of metabolic transformation of the opioid or alterations in neurotransmitters involved in the actions of opioids. Some, but not all, phenothiazines reduce the amount of opioid required to produce a given level of analgesia. Depending

on the specific agent, the respiratory-depressant effects also seem to be enhanced, the degree of sedation is increased, and the hypotensive effects of phenothiazines become an additional complication. Some phenothiazine derivatives enhance the sedative effects but at the same time seem to be antianalgesic and increase the amount of opioid required to produce satisfactory relief from pain. Small doses of *amphetamine* substantially increase the analgesic and euphoriant effects of morphine and may decrease its sedative side effects. A number of antihistamines exhibit modest analgesic actions; some (*e.g.*, *hydroxyzine*) enhance the analgesic effects of low doses of opioids (Rumore and Schlichting, 1986). Antidepressants such as *desipramine* and *amitriptyline* are used in the treatment of chronic neuropathic pain but have limited intrinsic analgesic actions in acute pain. However, antidepressants may enhance morphine-induced analgesia (Levine *et al.*, 1986). The analgesic synergism between opioids and aspirinlike drugs is discussed below and in Chapter 26.

OTHER μ RECEPTOR AGONISTS

Levorphanol

Levorphanol (LEVO-DRORMORAN) is the only commercially available opioid agonist of the morphinan series. The D-isomer (dextrorphan) is relatively devoid of analgesic action but may have inhibitory effects at NMDA receptors. The structure of levorphanol is shown in Table 21–5.

The pharmacological effects of levorphanol closely parallel those of morphine. However, clinical reports suggest that it may produce less nausea and vomiting. Levorphanol is metabolized less rapidly than morphine and has a half-life of about 12 to 16 hours; repeated administration at short intervals may thus lead to accumulation of the drug in plasma.

Meperidine and Congeners

The structural formulas of meperidine, a *phenylpiperidine*, and some of its congeners are shown in Figure 21–4. Meperidine is predominantly a μ receptor agonist, and it exerts its chief pharmacological action on the CNS and the neural elements in the bowel. Meperidine is no longer recommended for the treatment of chronic pain because of concerns over metabolite toxicity. It should not be used for longer than 48 hours or in doses greater than 600 mg/day (Agency for Health Care Policy and Research, 1992a).

Pharmacological Properties. Central Nervous System. Meperidine produces a *pattern* of effects similar but not identical to that described for morphine.

Analgesia. The analgesic effects of meperidine are detectable about 15 minutes after oral administration, peak in about 1 to 2 hours, and subside gradually. The onset of analgesic effect is faster (within 10 minutes) after subcutaneous or intramuscular administration, and the effect reaches a peak in about 1 hour that corresponds closely to peak concentrations in plasma. In clinical use, the duration of effective analgesia is approximately 1.5 to 3 hours. In general, 75 to 100 mg meperidine hydrochloride (*pethidine*, DEMEROL) given parenterally is approximately equivalent to 10 mg morphine, and in equianalgesic doses, meperidine produces as much sedation, respiratory depression, and euphoria as does morphine. In terms of total analgesic effect, meperidine is about one-third as effective when given orally as when administered parenterally. A few patients may experience dysphoria.

Other CNS Actions. Peak respiratory depression is observed within 1 hour of intramuscular administration, and there is a return toward normal starting at about 2 hours. Like other opioids, meperidine causes pupillary constriction, increases the sensitivity of the labyrinthine apparatus, and has effects on the secretion of pituitary hormones similar to those of morphine. Meperidine sometimes causes CNS excitation, characterized by tremors, muscle twitches, and seizures; these effects are due largely to accumulation of a metabolite, *normeperidine* (*see below*). As with morphine, respiratory depression is responsible for an accumulation of CO₂, which, in turn, leads to cerebrovascular dilation, increased cerebral blood flow, and elevation of cerebrospinal fluid pressure.

Cardiovascular System. The effects of meperidine on the cardiovascular system generally resemble those of morphine, including the ability to release histamine on parenteral administration. Intramuscular administration of meperidine does not affect heart rate significantly, but intravenous administration frequently produces a marked increase in heart rate.

Smooth Muscle. Meperidine has effects on certain smooth muscles qualitatively similar to those observed with other opioids. Meperidine does not cause as much constipation as does morphine even when given over prolonged periods of time; this may be related to its greater ability to enter the CNS, thereby producing analgesia at lower systemic concentrations. As with other opioids, clinical doses of meperidine slow gastric emptying sufficiently to delay absorption of other drugs significantly.

The uterus of a nonpregnant woman usually is mildly stimulated by meperidine. Administered before an oxytocic, meperidine does not exert any antagonistic effect. Therapeutic doses given during active labor do not delay the birth process; in fact, the frequency, duration, and amplitude of uterine contraction sometimes may be increased (Zimmer *et al.*, 1988). The drug does not interfere with normal postpartum contraction or involution of the uterus, and it does not increase the incidence of postpartum hemorrhage.

Figure 21-4. Chemical structures of piperidine and phenylpiperidine analgesics.

Absorption, Fate, and Excretion. Meperidine is absorbed by all routes of administration, but the rate of absorption may be erratic after intramuscular injection. The peak plasma concentration usually occurs at about 45 minutes, but the range is wide. After oral administration, only about 50% of the drug escapes first-pass metabolism to

enter the circulation, and peak concentrations in plasma usually are observed in 1 to 2 hours.

In humans, meperidine is hydrolyzed to meperidinic acid, which, in turn, is partially conjugated. Meperidine also is *N*-demethylated to normeperidine, which then may be hydrolyzed to normeperidinic acid and subsequently

conjugated. The clinical significance of the formation of normeperidine is discussed further below. Meperidine is metabolized chiefly in the liver, with a half-life of about 3 hours. In patients with cirrhosis, the bioavailability of meperidine is increased to as much as 80%, and the half-lives of both meperidine and normeperidine are prolonged. Approximately 60% of meperidine in plasma is protein-bound. Only a small amount of meperidine is excreted unchanged.

Untoward Effects, Precautions, and Contraindications. The pattern and overall incidence of untoward effects that follow the use of meperidine are similar to those observed after equianalgesic doses of morphine, except that constipation and urinary retention may be less common. Patients who experience nausea and vomiting with morphine may not do so with meperidine; the converse also may be true. As with other opioids, tolerance develops to some of these effects. The contraindications generally are the same as for other opioids. In patients or addicts who are tolerant to the depressant effects of meperidine, large doses repeated at short intervals may produce an excitatory syndrome including hallucinations, tremors, muscle twitches, dilated pupils, hyperactive reflexes, and convulsions. These excitatory symptoms are due to the accumulation of normeperidine, which has a half-life of 15 to 20 hours compared with 3 hours for meperidine. Opioid antagonists can block the convulsant effect of normeperidine in the mouse. Since normeperidine is eliminated by the kidney and the liver, decreased renal or hepatic function increases the likelihood of such toxicity (Kaiko *et al.*, 1983).

Interactions with Other Drugs. Severe reactions may follow the administration of meperidine to patients being treated with MAO inhibitors. Two basic types of interactions can be observed. The most prominent is an excitatory reaction (“serotonin syndrome”) with delirium, hyperthermia, headache, hyper- or hypotension, rigidity, convulsions, coma, and death. This reaction may be due to the ability of meperidine to block neuronal reuptake of serotonin and the resulting serotonergic overactivity (Stack *et al.*, 1988). Therefore, meperidine and its congeners should not be used in patients taking MAO inhibitors. Dextromethorphan also inhibits neuronal serotonin uptake and should be avoided in these patients. As discussed earlier, tramadol inhibits uptake of norepinephrine and serotonin and should not be used concomitantly with MAO inhibitors. Similar interactions with other opioids have not been observed clinically. Another type of interaction, a potentiation of opioid effect owing to inhibition of hepatic CYPs, also can be observed in patients taking MAO inhibitors, necessitating a reduction in the doses of opioids.

Chlorpromazine increases the respiratory-depressant effects of meperidine, as do tricyclic antidepressants; this is not true of *diazepam*. Concurrent administration of drugs such as *promethazine* or *chlorpromazine* also may greatly enhance meperidine-induced sedation without slowing clearance of the drug. Treatment with *phe-*

nobarbital or *phenytoin* increases systemic clearance and decreases oral bioavailability of meperidine; this is associated with an elevation of the concentration of normeperidine in plasma (Edwards *et al.*, 1982). As with morphine, concomitant administration of amphetamine has been reported to enhance the analgesic effects of meperidine and its congeners while counteracting sedation.

Therapeutic Uses. The major use of meperidine is for analgesia. Unlike morphine and its congeners, meperidine is not used for the treatment of cough or diarrhea. Single doses of meperidine also appear to be effective in the treatment of postanesthetic shivering. Meperidine, 25 to 50 mg, is used frequently with antihistamines, corticosteroids, *acetaminophen*, or nonsteroidal antiinflammatory drugs (NSAIDs) to prevent or ameliorate infusion-related rigors and shaking chills that accompany the intravenous administration of *amphotericin B*, *aldesleukin* (interleukin-2), *trastuzumab*, and *alemtuzumab*.

Meperidine crosses the placental barrier and even in reasonable analgesic doses causes a significant increase in the percentage of babies who show delayed respiration, decreased respiratory minute volume, or decreased oxygen saturation or who require resuscitation. Fetal and maternal respiratory depression induced by meperidine can be treated with naloxone. The fraction of drug that is bound to protein is lower in the fetus; concentrations of free drug thus may be considerably higher than in the mother. Nevertheless, meperidine produces less respiratory depression in the newborn than does an equianalgesic dose of morphine or methadone (Fishburne, 1982).

Congeners of Meperidine. Diphenoxylate. *Diphenoxylate* is a meperidine congener that has a definite constipating effect in humans. Its only approved use is in the treatment of diarrhea (*see* Chapter 37). Although single doses in the therapeutic range (*see* below) produce little or no morphine-like subjective effects, at high doses (40 to 60 mg) the drug shows typical opioid activity, including euphoria, suppression of morphine abstinence, and a morphine-like physical dependence after chronic administration. *Diphenoxylate* is unusual in that even its salts are virtually insoluble in aqueous solution, thus obviating the possibility of abuse by the parenteral route. *Diphenoxylate hydrochloride* is available only in combination with atropine sulfate (LOMOTIL, others). The recommended daily dosage of diphenoxylate for the treatment of diarrhea in adults is 20 mg in divided doses. *Difenoxin* (MOTOFEN), a metabolite of diphenoxylate, has actions similar to those of the parent compound.

Loperamide. *Loperamide* (IMODIUM, others), like diphenoxylate, is a piperidine derivative (Figure 21–3). It slows gastrointestinal motility by effects on the circular and longitudinal muscles of the intestine presumably as a result of its interactions with opioid receptors in the intestine. Some part of its antidiarrheal effect may be due to a reduction of gastrointestinal secretion (*see* above) (Kromer, 1988). In controlling chronic diarrhea, loperamide is as effective as diphenoxylate. In clinical studies, the most common side effect is abdominal cramps. Little tolerance develops to its constipating effect.

In human volunteers taking large doses of loperamide, concentrations of drug in plasma peak about 4 hours after ingestion; this

long latency may be due to inhibition of gastrointestinal motility and to enterohepatic circulation of the drug. The apparent elimination half-life is 7 to 14 hours. Loperamide is poorly absorbed after oral administration and, in addition, apparently does not penetrate well into the brain because of P-glycoprotein transporter widely expressed in the brain endothelium (Sadeque *et al.*, 2000). Mice with deletions of one of the genes encoding the P-glycoprotein transporter have much higher brain levels and significant central effects after administration of loperamide (Schinkel *et al.*, 1996). Inhibition of P-glycoprotein by many clinically used drugs, such as *quinidine* and *verapamil*, possibly could lead to enhanced central effects of loperamide.

In general, loperamide is unlikely to be abused parenterally because of its low solubility; large doses of loperamide given to human volunteers do not elicit pleasurable effects typical of opioids. The usual dosage is 4 to 8 mg/day; the daily dose should not exceed 16 mg.

Fentanyl and Congeners

Fentanyl is a synthetic opioid related to the phenylpiperidines (Figure 21–3). The actions of fentanyl and its congeners, sufentanil, remifentanil, and alfentanil, are similar to those of other μ -receptor agonists. Alfentanil is seldom used now, and information concerning this drug can be found in the 10th edition of this text. Fentanyl is a popular drug in anesthetic practice because of its relatively shorter time to peak analgesic effect, rapid termination of effect after small bolus doses, and relative cardiovascular stability (*see* Chapter 13).

Pharmacological Properties. Analgesia. The analgesic effects of fentanyl and sufentanil are similar to those of morphine and other μ opioids. Fentanyl is approximately 100 times more potent than morphine, and sufentanil is approximately 1000 times more potent than morphine. These drugs are most commonly administered intravenously, although both also are commonly administered epidurally and intrathecally for acute postoperative and chronic pain management. Fentanyl and sufentanil are far more lipid soluble than morphine; thus the risk of delayed respiratory depression from rostral spread of intraspinally administered narcotic to respiratory centers is greatly reduced. The time to peak analgesic effect after intravenous administration of fentanyl and sufentanil is less than that for morphine and meperidine, with peak analgesia being reached after about 5 minutes, as opposed to approximately 15 minutes. Recovery from analgesic effects also occurs more quickly. However, with larger doses or prolonged infusions, the effects of these drugs become more lasting, with durations of action becoming similar to those of longer-acting opioids (*see* below).

Other CNS Effects. As with other μ opioids, nausea, vomiting, and itching can be observed with fentanyl. Muscle rigidity, while possible after all narcotics, appears to be more common after administration of bolus doses of fentanyl or its congeners. This effect is felt to be centrally mediated and may be due in part to their increased potency relative to morphine. Rigidity can be mitigated by avoiding bolus dosing, slower administration of boluses, and pretreatment with a nonopioid anesthetic induction agent. Rigidity can be treated with depolarizing or nondepolarizing neuromuscular blocking agents while controlling the patient's ventilation. Care must be taken to make sure that the patient is not simply immobilized but aware. Respiratory depression is similar to that observed with other μ receptor agonists, but the onset is more rapid. As with

analgesia, respiratory depression after small doses is of shorter duration than with morphine but of similar duration after large doses or long infusions. As with morphine and meperidine, delayed respiratory depression also can be seen after the use of fentanyl or sufentanil, possibly owing to enterohepatic circulation. High doses of fentanyl can cause neuroexcitation and, rarely, seizure-like activity in humans (Bailey and Stanley, 1994). Fentanyl has minimal effects on intracranial pressure when ventilation is controlled and the arterial CO_2 concentration is not allowed to rise.

Cardiovascular System. Fentanyl and its derivatives decrease the heart rate and can mildly decrease blood pressure. However, these drugs do not release histamine and, in general, provide a marked degree of cardiovascular stability. Direct depressant effects on the myocardium are minimal. For this reason, high doses of fentanyl or sufentanil are commonly used as the primary anesthetic for patients undergoing cardiovascular surgery or for patients with poor cardiac function.

Absorption, Fate, and Excretion. These agents are highly lipid soluble and rapidly cross the blood–brain barrier. This is reflected in the half-life for equilibration between the plasma and cerebrospinal fluid of approximately 5 minutes for fentanyl and sufentanil. The levels in plasma and cerebrospinal fluid decline rapidly owing to redistribution of fentanyl from highly perfused tissue groups to other tissues, such as muscle and fat. As saturation of less well-perfused tissue occurs, the duration of effect of fentanyl and sufentanil approaches the length of their elimination half-lives of between 3 and 4 hours. Fentanyl and sufentanil undergo hepatic metabolism and renal excretion. Therefore, with the use of higher doses or prolonged infusions, fentanyl and sufentanil become longer acting.

Therapeutic Uses. *Fentanyl citrate* (SUBLIMAZE) and *sufentanil citrate* (SUFENTA) have gained widespread popularity as anesthetic adjuvants (*see* Chapter 13). They are used commonly either intravenously, epidurally, or intrathecally. Epidural use of fentanyl and sufentanil for postoperative or labor analgesia has gained increasing popularity. A combination of epidural opioids with local anesthetics permits reduction in the dosage of both components, minimizing the side effects of the local anesthetic (*i.e.*, motor blockade) and the opioid (*i.e.*, urinary retention, itching, and delayed respiratory depression in the case of morphine). Intravenous use of fentanyl and sufentanil for postoperative pain has been effective but limited by clinical concerns about muscle rigidity. However, the use of fentanyl and sufentanil in chronic pain treatment has become more widespread. Epidural and intrathecal infusions, both with and without local anesthetic, are used in the management of chronic malignant pain and selected cases of nonmalignant pain. Also, the development of novel, less invasive routes of administration for fentanyl has facilitated the use of these compounds in chronic pain management. Transdermal patches (DURAGESIC) that provide sustained release of fentanyl for 48 hours or more are available. However, factors promoting increased absorption (*e.g.*, fever) can lead to relative overdose and increased side effects (*see* the section on alternative routes of administration, below). Also, the FENTANYL ORALET, a formulation that permits rapid absorption of fentanyl through the buccal mucosa (much like a lollipop), was tried as an anesthetic premedicant but did not gain wide acceptance owing to undesirable side effects in opioid-naïve patients (nausea, vomiting, pruritus, and respiratory depression). This dosage form has been discontinued in the United States. A similar fentanyl product, ACTIQ, is available in

higher strengths and is used for relief of breakthrough cancer pain (Ashburn *et al.*, 1989).

Remifentanil. This compound was developed in an effort to create an analgesic with a more rapid onset and predictable termination of effect. The potency of remifentanil is approximately equal to that of fentanyl. The pharmacological properties of remifentanil are similar to those of fentanyl and sufentanil. They have similar incidences of nausea, vomiting, and dose-dependent muscle rigidity. Nausea, vomiting, itching, and headaches have been reported when remifentanil has been used for conscious analgesia for painful procedures. Intracranial pressure changes are minimal when ventilation is controlled. Seizures after remifentanil administration have been reported.

Absorption, Fate, and Excretion. Remifentanil has a more rapid onset of analgesic action than fentanyl or sufentanil. Analgesic effects occur within 1 to 1.5 minutes. Remifentanil is unique in that it is metabolized by plasma esterases (Burkle *et al.*, 1996). Elimination is independent of hepatic metabolism or renal excretion, and the elimination half-life is 8 to 20 minutes. There is no prolongation of effect with repeated dosing or prolonged infusion. Age and weight can affect clearance of remifentanil, requiring that dosage be reduced in the elderly and based on lean body mass. However, neither of these conditions causes major changes in duration of effect. After 3- to 5-hour infusions of remifentanil, recovery of respiratory function can be seen within 3 to 5 minutes, whereas full recovery from all effects of remifentanil is observed within 15 minutes (Glass *et al.*, 1999). The primary metabolite, remifentanil acid, is 2000 to 4000 times less potent than remifentanil and is excreted renally. Peak respiratory depression after bolus doses of remifentanil occurs after 5 minutes (Patel and Spencer, 1996).

Therapeutic Uses. Remifentanil hydrochloride (ULTIVA) is useful for short, painful procedures that require intense analgesia and blunting of stress responses. The titratability of remifentanil and its consistent, rapid offset make it ideally suited for short surgical procedures where rapid recovery is desirable. Remifentanil also has been used successfully for longer neurosurgical procedures, where rapid emergence from anesthesia is important. However, in cases where postprocedural analgesia is required, remifentanil alone is a poor choice. In this situation, either a longer-acting opioid or another analgesic modality should be combined with remifentanil for prolonged analgesia, or another opioid should be used. Remifentanil is not used intraspinally because glycine in the drug vehicle can cause temporary motor paralysis. It generally is given by continuous intravenous infusion because its short duration of action makes bolus administration impractical.

Methadone and Congeners

Methadone is a long-acting μ -receptor agonist with pharmacological properties qualitatively similar to those of morphine.

Chemistry. Methadone has the following structural formula:

The analgesic activity of the racemate is almost entirely the result of its content of L-methadone, which is 8 to 50 times more potent than the D isomer; D-methadone also lacks significant respiratory depressant action and addiction liability, but it does possess antitussive activity.

Pharmacological Actions. The outstanding properties of methadone are its analgesic activity, its efficacy by the oral route, its extended duration of action in suppressing withdrawal symptoms in physically dependent individuals, and its tendency to show persistent effects with repeated administration. Miotic and respiratory-depressant effects can be detected for more than 24 hours after a single dose, and on repeated administration, marked sedation is seen in some patients. Effects on cough, bowel motility, biliary tone, and the secretion of pituitary hormones are qualitatively similar to those of morphine.

Absorption, Fate, and Excretion. Methadone is absorbed well from the gastrointestinal tract and can be detected in plasma within 30 minutes of oral ingestion; it reaches peak concentrations at about 4 hours. After therapeutic doses, about 90% of methadone is bound to plasma proteins. Peak concentrations occur in the brain within 1 or 2 hours of subcutaneous or intramuscular administration, and this correlates well with the intensity and duration of analgesia. Methadone also can be absorbed from the buccal mucosa (Weinberg *et al.*, 1988).

Methadone undergoes extensive biotransformation in the liver. The major metabolites, the results of *N*-demethylation and cyclization to form pyrrolidines and pyrroline, are excreted in the urine and the bile along with small amounts of unchanged drug. The amount of methadone excreted in the urine is increased when the urine is acidified. The half-life of methadone is approximately 15 to 40 hours.

Methadone appears to be firmly bound to protein in various tissues, including brain. After repeated administration, there is gradual accumulation in tissues. When administration is discontinued, low concentrations are maintained in plasma by slow release from extravascular binding sites; this process probably accounts for the relatively mild but protracted withdrawal syndrome.

Side Effects, Toxicity, Drug Interactions, and Precautions. Side effects, toxicity, and conditions that alter sensitivity, as well as the treatment of acute intoxication, are similar to those described for morphine. During long-term administration, there may be excessive sweating, lymphocytosis, and increased concentrations of prolactin, albumin, and globulins in the plasma. *Rifampin* and phenytoin accelerate the metabolism of methadone and can precipitate withdrawal symptoms.

Tolerance and Physical Dependence. Volunteer postaddicts who receive subcutaneous or oral methadone daily develop partial tolerance to the nauseant, anorectic, miotic, sedative, respiratory-depres-

sant, and cardiovascular effects of methadone. Tolerance develops more slowly to methadone than to morphine in some patients, especially with respect to the depressant effects; this may be related in part to cumulative effects of the drug or its metabolites. Tolerance to the constipating effect of methadone does not develop as fully as does tolerance to other effects. The behavior of addicts who use methadone parenterally is strikingly similar to that of morphine addicts, but many former heroin users treated with oral methadone show virtually no overt behavioral effects.

Development of physical dependence during the long-term administration of methadone can be demonstrated by drug withdrawal or by administration of an opioid antagonist. Subcutaneous administration of 10 to 20 mg methadone to former opioid addicts produces definite euphoria equal in duration to that caused by morphine, and its overall abuse potential is comparable with that of morphine.

Therapeutic Uses. The primary uses of *methadone hydrochloride* (DOLOPHINE, others) are relief of chronic pain, treatment of opioid abstinence syndromes, and treatment of heroin users. It is not used widely as an antiperistaltic agent. It should not be used in labor.

Analgesia. The onset of analgesia occurs 10 to 20 minutes after parenteral administration and 30 to 60 minutes after oral medication. The average minimal effective analgesic concentration in blood is about 30 ng/ml (Gourlay *et al.*, 1986). The typical oral dose is 2.5 to 15 mg depending on the severity of the pain and the response of the patient. The initial parenteral dose is usually 2.5 to 10 mg. Care must be taken when escalating the dosage because of the prolonged half-life of the drug and its tendency to accumulate over a period of several days with repeated dosing. Despite its longer plasma half-life, the duration of the analgesic action of single doses is essentially the same as that of morphine. With repeated use, cumulative effects are seen, so either lower dosages or longer intervals between doses become possible. In contrast to morphine, methadone and many of its congeners retain a considerable degree of their effectiveness when given orally. In terms of total analgesic effects, methadone given orally is about 50% as effective as the same dose administered intramuscularly; however, the oral-parenteral potency ratio is considerably lower when peak analgesic effect is considered. In equianalgesic doses, the pattern and incidence of untoward effects caused by methadone and morphine are similar.

Propoxyphene

Propoxyphene is structurally related to methadone (*see below*). Its analgesic effect resides in the D-isomer, D-propoxyphene (*dextro-propoxyphene*). However, *levopropoxyphene* seems to have some antitussive activity. The structure of propoxyphene is as follows:

Pharmacological Actions. Although slightly less selective than morphine, propoxyphene binds primarily to μ opioid receptors and produces analgesia and other CNS effects that are similar to those seen with morphine-like opioids. It is likely that at equianalgesic doses the incidence of side effects such as nausea, anorexia, constipation, abdominal pain, and drowsiness are similar to those of codeine.

As an analgesic, propoxyphene is about one-half to two-thirds as potent as codeine given orally. A dose of 90 to 120 mg of *propoxyphene hydrochloride* administered orally would equal the analgesic effects of 60 mg codeine, a dose that usually produces about as much analgesia as 600 mg *aspirin*. Combinations of propoxyphene and aspirin, like combinations of codeine and aspirin, afford a higher level of analgesia than does either agent given alone (Beaver, 1988).

Absorption, Fate, and Excretion. After oral administration, concentrations of propoxyphene in plasma reach their highest values at 1 to 2 hours. There is great variability between subjects in the rate of clearance and the plasma concentrations that are achieved. The average half-life of propoxyphene in plasma after a single dose is 6 to 12 hours, which is longer than that of codeine. In humans, the major route of metabolism is *N*-demethylation to yield *norpropoxyphene*. The half-life of norpropoxyphene is about 30 hours, and its accumulation with repeated doses may be responsible for some of the observed toxicity (Chan and Matzke, 1987).

Toxicity. Given orally, propoxyphene is approximately one-third as potent as orally administered codeine in depressing respiration. Moderately toxic doses usually produce CNS and respiratory depression, but with still larger doses the clinical picture may be complicated by convulsions in addition to respiratory depression. Delusions, hallucinations, confusion, cardiotoxicity, and pulmonary edema also have been noted. Respiratory-depressant effects are significantly enhanced when ethanol or sedative-hypnotics are ingested concurrently. Naloxone antagonizes the respiratory-depressant, convulsant, and some of the cardiotoxic effects of propoxyphene.

Tolerance and Dependence. Very large doses [800 mg propoxyphene hydrochloride (DARVON, others) or 1200 mg of the *napsylate* (DARVON-N) per day] reduce the intensity of the morphine withdrawal syndrome somewhat less effectively than do 1500-mg doses of codeine. Maximal tolerated doses are equivalent to daily doses of 20 to 25 mg morphine given subcutaneously. The use of higher doses of propoxyphene is prevented by untoward side effects and the occurrence of toxic psychoses. Very large doses produce some respiratory depression in morphine-tolerant addicts, suggesting that cross-tolerance between propoxyphene and morphine is incomplete. Abrupt discontinuation of chronically administered propoxyphene hydrochloride (up to 800 mg/day given for almost 2 months) results in mild abstinence phenomena, and large oral doses (300 to 600 mg) produce subjective effects that are considered pleasurable by postaddicts. The drug is quite irritating when administered either intravenously or subcutaneously, so abuse by these routes results in severe damage to veins and soft tissues.

Therapeutic Uses. Propoxyphene is recommended for the treatment of mild-to-moderate pain. Given acutely, the commonly prescribed combination of 32 mg propoxyphene with aspirin may not produce more analgesia than aspirin alone, and doses of 65 mg of the hydrochloride or 100 mg of the napsylate are suggested. Propoxyphene is given most often in combination with aspirin or *acetaminophen*.

The wide popularity of propoxyphene is largely a result of unrealistic overconcern about the addictive potential of codeine.

ACUTE OPIOID TOXICITY

Acute opioid toxicity may result from clinical overdosage, accidental overdosage in addicts, or attempts at suicide. Occasionally, a delayed type of toxicity may occur from the injection of an opioid into chilled skin areas or in patients with low blood pressure and shock. The drug is not fully absorbed, and therefore, a subsequent dose may be given. When normal circulation is restored, an excessive amount may be absorbed suddenly. It is difficult to define the exact amount of any opioid that is toxic or lethal to humans. Recent experiences with methadone indicate that in nontolerant individuals, serious toxicity may follow the oral ingestion of 40 to 60 mg. Older literature suggests that in the case of morphine, a normal, pain-free adult is not likely to die after oral doses of less than 120 mg or to have serious toxicity with less than 30 mg parenterally.

Symptoms and Diagnosis. The patient who has taken an overdose of an opioid usually is stuporous or, if a large overdose has been taken, may be in a profound coma. The respiratory rate will be very low, or the patient may be apneic, and cyanosis may be present. As respiratory exchange decreases, blood pressure, at first likely to be near normal, will fall progressively. If adequate oxygenation is restored early, the blood pressure will improve; if hypoxia persists untreated, there may be capillary damage, and measures to combat shock may be required. The pupils will be symmetrical and pinpoint in size; however, if hypoxia is severe, they may be dilated. Urine formation is depressed. Body temperature falls, and the skin becomes cold and clammy. The skeletal muscles are flaccid, the jaw is relaxed, and the tongue may fall back and block the airway. Frank convulsions occasionally may be noted in infants and children. When death occurs, it is nearly always from respiratory failure. Even if respiration is restored, death still may occur as a result of complications that develop during the period of coma, such as pneumonia or shock. Noncardiogenic pulmonary edema is seen commonly with opioid poisoning. It probably is not due to contaminants or to anaphylactoid reactions, and it has been observed after toxic doses of morphine, methadone, propoxyphene, and uncontaminated heroin.

The triad of coma, pinpoint pupils, and depressed respiration strongly suggests opioid poisoning. The finding of needle marks suggestive of addiction further supports the diagnosis. Mixed poisonings, however, are not uncommon. Examination of the urine and gastric contents for drugs may aid in diagnosis, but the results usually become available too late to influence treatment.

Treatment. The first step is to establish a patent airway and ventilate the patient. Opioid antagonists (*see below*)

can produce dramatic reversal of the severe respiratory depression, and the antagonist naloxone (*see below*) is the treatment of choice. However, care should be taken to avoid precipitating withdrawal in dependent patients, who may be extremely sensitive to antagonists. The safest approach is to dilute the standard naloxone dose (0.4 mg) and slowly administer it intravenously, monitoring arousal and respiratory function. With care, it usually is possible to reverse the respiratory depression without precipitating a major withdrawal syndrome. If no response is seen with the first dose, additional doses can be given. Patients should be observed for rebound increases in sympathetic nervous system activity, which may result in cardiac arrhythmias and pulmonary edema. For reversing opioid poisoning in children, the initial dose of naloxone is 0.01 mg/kg. If no effect is seen after a total dose of 10 mg, one can reasonably question the accuracy of the diagnosis. Pulmonary edema sometimes associated with opioid overdosage may be countered by positive-pressure respiration. Tonic-clonic seizures, occasionally seen as part of the toxic syndrome with meperidine and propoxyphene, are ameliorated by treatment with naloxone.

The presence of general CNS depressants does not prevent the salutary effect of naloxone, and in cases of mixed intoxications, the situation will be improved largely owing to antagonism of the respiratory-depressant effects of the opioid. However, some evidence indicates that naloxone and naltrexone also may antagonize some of the depressant actions of sedative-hypnotics (*see below*). One need not attempt to restore the patient to full consciousness. The duration of action of the available antagonists is shorter than that of many opioids; hence patients can slip back into coma. This is particularly important when the overdosage is due to methadone. The depressant effects of these drugs may persist for 24 to 72 hours, and fatalities have occurred as a result of premature discontinuation of naloxone. In cases of overdoses of these drugs, a continuous infusion of naloxone should be considered. Toxicity owing to overdose of pentazocine and other opioids with mixed actions may require higher doses of naloxone. The pharmacological actions of opioid antagonists are discussed in more detail below.

OPIOID AGONIST/ANTAGONISTS AND PARTIAL AGONISTS

The drugs described in this section differ from clinically used μ -opioid receptor agonists. Drugs such as *nalbuphine* and *butorphanol* are competitive μ -receptor antagonists but exert their analgesic actions by acting as agonists at κ receptors. Pentazocine qualitatively resembles these drugs, but it may be a weaker μ -receptor antagonist or partial agonist while retaining its κ -agonist activity. Buprenorphine, on the other hand, is a partial agonist at μ receptors.

The stimulus for the development of mixed agonist–antagonist drugs was a need for analgesics with less respiratory depression and addictive potential. The clinical use of these compounds is limited by undesirable side effects and limited analgesic effects.

Pentazocine

Pentazocine was synthesized as part of a deliberate effort to develop an effective analgesic with little or no abuse potential. It has agonistic actions and weak opioid antagonistic activity.

Pharmacological Actions. The pattern of CNS effects produced by pentazocine generally is similar to that of the morphine-like opioids, including analgesia, sedation, and respiratory depression. The analgesic effects of pentazocine are due to agonistic actions at κ opioid receptors. Higher doses of pentazocine (60 to 90 mg) elicit dysphoric and psychotomimetic effects. The mechanisms responsible for these side effects are not known but might involve activation of supraspinal κ receptors because it has been suggested that these untoward effects may be reversible by naloxone.

The cardiovascular responses to pentazocine differ from those seen with typical μ receptor agonists, in that high doses cause an increase in blood pressure and heart rate. Pentazocine acts as a weak antagonist or partial agonist at μ opioid receptors. Pentazocine does not antagonize the respiratory depression produced by morphine. However, when given to patients dependent on morphine or other μ -receptor agonists, pentazocine may precipitate withdrawal. Ceiling effects for analgesia and respiratory depression are observed above 50 to 100 mg pentazocine (Bailey and Stanley, 1994).

Tablets for oral use now contain *pentazocine hydrochloride* (equivalent to 50 mg of the base) and *naloxone hydrochloride* (equivalent to 0.5 mg of the base; TALWIN NX), which reduces the potential use of tablets as a source of injectable pentazocine. After oral ingestion, naloxone is destroyed rapidly by the liver; however, if the material is dissolved and injected, the naloxone produces aversive effects in subjects dependent on opioids. An oral dose of about 50 mg pentazocine results in analgesia equivalent to that produced by 60 mg codeine orally.

Nalbuphine

Nalbuphine is related structurally to naloxone and oxymorphone (Table 21–5). It is an agonist–antagonist opioid with a spectrum of effects that qualitatively resembles that of pentazocine; however, nalbuphine is a more potent antagonist at μ receptors and is less likely to produce dysphoric side effects than is pentazocine.

Pharmacological Actions and Side Effects. An intramuscular dose of 10 mg nalbuphine is equianalgesic to 10 mg morphine, with similar onset and duration of analgesic and subjective effects. Nalbuphine depresses respiration as much as do equianalgesic doses of morphine. However, nalbuphine exhibits a ceiling effect such that increases in dosage beyond 30 mg produce no further respiratory depression. However, a ceiling effect for analgesia also is reached at this point. In contrast to pentazocine and butorphanol, 10 mg nalbuphine given to patients with stable coronary artery disease does not produce an increase in cardiac index, pulmonary arterial pressure, or cardiac work, and systemic blood pressure is not significantly altered; these indices also are relatively stable when nalbuphine is

given to patients with acute myocardial infarction (Roth *et al.*, 1988). Its gastrointestinal effects probably are similar to those of pentazocine. Nalbuphine produces few side effects at doses of 10 mg or less; sedation, sweating, and headache are the most common. At much higher doses (70 mg), psychotomimetic side effects (*e.g.*, dysphoria, racing thoughts, and distortions of body image) can occur. Nalbuphine is metabolized in the liver and has a half-life in plasma of 2 to 3 hours. Given orally, nalbuphine is 20% to 25% as potent as when given intramuscularly.

Tolerance and Physical Dependence. In subjects dependent on low doses of morphine (60 mg/day), nalbuphine precipitates an abstinence syndrome. Prolonged administration of nalbuphine can produce physical dependence. The withdrawal syndrome is similar in intensity to that seen with pentazocine. The potential for abuse of parenteral nalbuphine in subjects not dependent on μ receptor agonists probably is similar to that for parenteral pentazocine.

Therapeutic Uses. *Nalbuphine hydrochloride* (NUBAIN) is used to produce analgesia. Because it is an agonist–antagonist, administration to patients who have been receiving morphine-like opioids may create difficulties unless a brief drug-free interval is interposed. The usual adult dose is 10 mg parenterally every 3 to 6 hours; this may be increased to 20 mg in nontolerant individuals.

Butorphanol

Butorphanol is a morphinan congener with a profile of actions similar to those of pentazocine. The structural formula of butorphanol is shown in Table 21–5.

Pharmacological Actions and Side Effects. In postoperative patients, a parenteral dose of 2 to 3 mg butorphanol produces analgesia and respiratory depression approximately equal to that produced by 10 mg morphine or 80 to 100 mg meperidine; the onset, peak, and duration of action are similar to those that follow the administration of morphine. The plasma half-life of butorphanol is about 3 hours. Like pentazocine, analgesic doses of butorphanol produce an increase in pulmonary arterial pressure and in the work of the heart; systemic arterial pressure is slightly decreased (Popio *et al.*, 1978).

The major side effects of butorphanol are drowsiness, weakness, sweating, feelings of floating, and nausea. While the incidence of psychotomimetic side effects is lower than that with equianalgesic doses of pentazocine, they are qualitatively similar. Physical dependence on butorphanol can occur.

Therapeutic Uses. *Butorphanol tartrate* (STADOL) is better suited for the relief of acute pain than of chronic pain. Because of its side effects on the heart, it is less useful than morphine or meperidine in patients with congestive heart failure or myocardial infarction. The usual dose is between 1 and 4 mg of the tartrate given intramuscularly or 0.5 to 2 mg given intravenously every 3 to 4 hours. A nasal formulation (STADOL NS) is available and has proven to be effective. This formulation is particularly useful for patients with severe headaches who may be unresponsive to other forms of treatment.

Buprenorphine

Buprenorphine is a semisynthetic, highly lipophilic opioid derived from thebaine (Table 21–5). It is 25 to 50 times more potent than morphine.

Pharmacological Actions and Side Effects. Buprenorphine produces analgesia and other CNS effects that are qualitatively similar to those of morphine. About 0.4 mg buprenorphine is equianalgesic with 10 mg morphine given intramuscularly (Wallenstein *et al.*, 1986). Although variable, the duration of analgesia usually is longer than that of morphine. Some of the subjective and respiratory-depressant effects are unequivocally slower in onset and last longer than those of morphine. For example, peak miosis occurs about 6 hours after intramuscular injection, whereas maximal respiratory depression is observed at about 3 hours.

Buprenorphine appears to be a partial μ receptor agonist. Depending on the dose, buprenorphine may cause symptoms of abstinence in patients who have been receiving μ receptor agonists for several weeks. It antagonizes the respiratory depression produced by anesthetic doses of fentanyl about as well as does naloxone without completely reversing opioid pain relief (Boysen *et al.*, 1988). Although respiratory depression has not been a major problem, it is not clear whether there is a ceiling for this effect (as seen with nalbuphine and pentazocine). The respiratory depression and other effects of buprenorphine can be prevented by prior administration of naloxone, but they are not readily reversed by high doses of naloxone once the effects have been produced. This suggests that buprenorphine dissociates very slowly from opioid receptors. The half-life for dissociation from the μ receptor is 166 minutes for buprenorphine, as opposed to 7 minutes for fentanyl (Boas and Viliger, 1985). Therefore, plasma levels of buprenorphine may not parallel clinical effects. Cardiovascular and other side effects (*e.g.*, sedation, nausea, vomiting, dizziness, sweating, and headache) appear to be similar to those of morphine-like opioids.

Buprenorphine is relatively well absorbed by most routes. Administered sublingually, the drug (0.4 to 0.8 mg) produces satisfactory analgesia in postoperative patients. Concentrations in blood peak within 5 minutes of intramuscular injection and within 1 to 2 hours of oral or sublingual administration. While the half-life in plasma has been reported to be about 3 hours, this value bears little relationship to the rate of disappearance of effects (*see* above). Both *N*-dealkylated and conjugated metabolites are detected in the urine, but most of the drug is excreted unchanged in the feces. About 96% of the circulating drug is bound to protein.

Physical Dependence. When buprenorphine is discontinued, a withdrawal syndrome develops that is delayed in onset for 2 days to 2 weeks; this consists of typical but generally not very severe morphine-like withdrawal signs and symptoms, and it persists for about 1 to 2 weeks (Bickel *et al.*, 1988; Fudala *et al.*, 1989).

Therapeutic Uses. Buprenorphine (BUPRENEX; SUBUTEX) may be used as an analgesic and also has proven to be useful as a maintenance drug for opioid-dependent subjects (Johnson *et al.*, 2000). The usual intramuscular or intravenous dose for analgesia is 0.3 mg given every 6 hours. Sublingual doses of 0.4 to 0.8 mg also produce effective analgesia. Buprenorphine is metabolized to norbuprenorphine by CYP3A4. Thus care should be taken in treating patients who also are taking known inhibitors of CYP3A4 (*e.g.*, azole antifungals, macrolide antibiotics, and HIV protease inhibitors), as well as drugs that induce CYP3A4 activity (*e.g.*, anticonvulsants and *rifampin*).

Buprenorphine is approved by the Food and Drug Administration (FDA) for the treatment of opioid addiction. Treatment is initiated with buprenorphine alone administered sublingually, followed by maintenance therapy with a combination of buprenorphine and

naloxone (SUBOXONE) to minimize abuse potential. The partial agonist properties of buprenorphine limit its usefulness for the treatment of addicts who require high maintenance doses of opioids. However, conversion to maintenance treatment with higher doses of methadone, a full agonist, is possible (Kreek *et al.*, 2002).

OPIOID ANTAGONISTS

Under ordinary circumstances, the drugs discussed in this section produce few effects unless opioids with agonistic actions have been administered previously. However, when the endogenous opioid systems are activated, as in shock or certain forms of stress, the administration of an opioid antagonist alone may have visible consequences. These agents have obvious therapeutic utility in the treatment of opioid overdose. As the understanding of the role of endogenous opioid systems in pathophysiological states increases, additional therapeutic indications for these antagonists may develop.

Chemistry. Relatively minor changes in the structure of an opioid can convert a drug that is primarily an agonist into one with antagonistic actions at one or more types of opioid receptors. The most common such substitution is that of a larger moiety (*e.g.*, an allyl or methylcyclopropyl group) for the *N*-methyl group that is typical of the μ -receptor agonists. Such substitutions transform morphine to *nalorphine*, *levorphanol* to *levallorphan*, and oxymorphone to naloxone or naltrexone (Table 21-5). In some cases, congeners are produced that are competitive antagonists at μ receptors but that also have agonistic actions at κ receptors. Nalorphine and levallorphan have such properties. Other congeners, especially naloxone and naltrexone, appear to be devoid of agonistic actions and probably interact with all types of opioid receptors, albeit with widely different affinities (Martin, 1983).

Nalmefene (REVIX) is a relatively pure μ -receptor antagonist that is more potent than naloxone (Dixon *et al.*, 1986). A number of other nonpeptide antagonists have been developed that are relatively selective for individual types of opioid receptors. These include *cypripidime* and β -*funaltrexamine* (β -FNA) (μ), *naltrindole* (δ), and *norbinaltorphimine* (κ) (Portoghese, 1989).

Pharmacological Properties

If endogenous opioid systems have not been activated, the pharmacological actions of opioid antagonists depend on whether or not an opioid agonist has been administered previously, on the pharmacological profile of that opioid, and on the degree to which physical dependence on an opioid has developed.

Effects in the Absence of Opioid Drugs. Subcutaneous doses of naloxone (NARCAN) up to 12 mg produce no discernible subjective effects in humans, and 24 mg causes only slight drowsiness. Naltrexone (REVIA) also appears

to be a relatively pure antagonist but with higher oral efficacy and a longer duration of action. At doses in excess of 0.3 mg/kg naloxone, normal subjects show increased systolic blood pressure and decreased performance on tests of memory. High doses of naltrexone appeared to cause mild dysphoria in one study but almost no subjective effect in several others (Gonzalez and Brogden, 1988).

Although high doses of antagonists might be expected to alter the actions of endogenous opioid peptides, the detectable effects usually are both subtle and limited (Cannon and Liebeskind, 1987). Most likely this reflects the low levels of tonic activity of the opioid systems. In this regard, analgesic effects can be differentiated from endocrine effects, in which naloxone causes readily demonstrable changes in hormone levels (*see below*). It is interesting that naloxone appears to block the analgesic effects of placebo medications and acupuncture. In laboratory animals, the administration of naloxone will reverse or attenuate the hypotension associated with shock of diverse origins, including that caused by anaphylaxis, endotoxin, hypovolemia, and injury to the spinal cord; opioid agonists aggravate these conditions (Amir, 1988). Naloxone apparently acts to antagonize the actions of endogenous opioids that are mobilized by pain or stress and that are involved in the regulation of blood pressure by the CNS. Although neural damage that follows trauma to the spinal cord or cerebral ischemia also appears to involve endogenous opioids, it is not certain whether opioid antagonists can prevent damage to these or other organs and/or increase rates of survival. Nevertheless, opioid antagonists can reduce the extent of injury in some animal models, perhaps by blocking κ receptors (Faden, 1988).

As noted earlier, endogenous opioid peptides participate in the regulation of pituitary secretion apparently by exerting tonic inhibitory effects on the release of certain hypothalamic hormones (*see Chapter 55*). Thus, the administration of naloxone or naltrexone increases the secretion of gonadotropin-releasing hormone and corticotropin-releasing hormone and elevates the plasma concentrations of LH, FSH, and ACTH, as well as the steroid hormones produced by their target organs. Antagonists do not consistently alter basal or stress-induced concentrations of prolactin in plasma in men; paradoxically, naloxone *stimulates* the release of prolactin in women. Opioid antagonists augment the increases in plasma concentrations of cortisol and catecholamines that normally accompany stress or exercise. The neuroendocrine effects of opioid antagonists have been reviewed. Endogenous opioid peptides probably have some role in the regulation of feeding or energy metabolism because opioid antagonists increase energy expenditure and interrupt hibernation in appropriate species and induce weight loss in genetically obese rats. The antagonists also prevent stress-induced overeating and obesity in rats. These observations have led to the experimental use of opioid antagonists in the treatment of human obesity, especially that associated with stress-induced eating disorders. However, naltrexone does not accelerate weight loss in very obese subjects, even though short-term administration of opioid antagonists reduces food intake in lean and obese individuals (Atkinson, 1987).

Antagonistic Actions. Small doses (0.4 to 0.8 mg) of naloxone given intramuscularly or intravenously prevent or promptly reverse the effects of μ receptor agonists. In patients with respiratory depression, an increase in respiratory rate is seen within 1 or 2 minutes. Sedative effects are

reversed, and blood pressure, if depressed, returns to normal. Higher doses of naloxone are required to antagonize the respiratory-depressant effects of buprenorphine; 1 mg naloxone intravenously completely blocks the effects of 25 mg heroin. Naloxone reverses the psychotomimetic and dysphoric effects of agonist-antagonist agents such as pentazocine, but much higher doses (10 to 15 mg) are required. The duration of antagonistic effects depends on the dose but usually is 1 to 4 hours. Antagonism of opioid effects by naloxone often is accompanied by “overshoot” phenomena. For example, respiratory rate depressed by opioids transiently becomes higher than that before the period of depression. Rebound release of catecholamines may cause hypertension, tachycardia, and ventricular arrhythmias. Pulmonary edema also has been reported after naloxone administration.

Effects in Physical Dependence. In subjects who are dependent on morphine-like opioids, small subcutaneous doses of naloxone (0.5 mg) precipitate a moderate-to-severe withdrawal syndrome that is very similar to that seen after abrupt withdrawal of opioids, except that the syndrome appears within minutes of administration and subsides in about 2 hours. The severity and duration of the syndrome are related to the dose of the antagonist and to the degree and type of dependence. Higher doses of naloxone will precipitate a withdrawal syndrome in patients dependent on pentazocine, butorphanol, or nalbuphine. Naloxone produces overshoot phenomena suggestive of early acute physical dependence 6 to 24 hours after a single dose of a μ agonist (Heishman *et al.*, 1989).

Tolerance and Physical Dependence. Even after prolonged administration of high doses, discontinuation of naloxone is not followed by any recognizable withdrawal syndrome, and the withdrawal of naltrexone, another relatively pure antagonist, produces very few signs and symptoms. However, long-term administration of antagonists increases the density of opioid receptors in the brain and causes a temporary exaggeration of responses to the subsequent administration of opioid agonists (Yoburn *et al.*, 1988). Naltrexone and naloxone have little or no potential for abuse.

Absorption, Fate, and Excretion. Although absorbed readily from the gastrointestinal tract, naloxone is almost completely metabolized by the liver before reaching the systemic circulation and thus must be administered parenterally. The drug is absorbed rapidly from parenteral sites of injection and is metabolized in the liver primarily by conjugation with glucuronic acid; other metabolites are produced in small amounts. The half-life of naloxone is about 1 hour, but its clinically effective duration of action can be even less.

Compared with naloxone, naltrexone retains much more of its efficacy by the oral route, and its duration of action approaches 24 hours after moderate oral doses. Peak concentrations in plasma are reached within 1 to 2 hours and then decline with an apparent half-life of approximately 3 hours; this value does not change with long-term use. Naltrexone is metabolized to 6-naltrexol, which is a weaker antagonist but has a longer half-life of about 13 hours. Naltrexone is much more potent than naloxone, and 100-mg oral doses given to patients addicted to opioids produce concentrations in tissues sufficient to block the euphorogenic effects of 25-mg intravenous doses of heroin for 48 hours (Gonzalez and Brogden, 1988).

Therapeutic Uses

Opioid antagonists have established uses in the treatment of opioid-induced toxicity, especially respiratory depression; in the diagnosis of physical dependence on opioids; and as therapeutic agents in the treatment of compulsive users of opioids, as discussed in Chapter 23. Their potential utility in the treatment of shock, stroke, spinal cord and brain trauma, and other disorders that may involve mobilization of endogenous opioid peptides remains to be established. Naltrexone is approved by the FDA for treatment of alcoholism (*see* Chapters 22 and 23).

Treatment of Opioid Overdosage. Naloxone hydrochloride is used to treat opioid overdose. As discussed earlier, it acts rapidly to reverse the respiratory depression associated with high doses of opioids. However, it should be used cautiously because it also can precipitate withdrawal in dependent subjects and cause undesirable cardiovascular side effects. By carefully titrating the dose of naloxone, it usually is possible to antagonize the respiratory-depressant actions without eliciting a full withdrawal syndrome. The duration of action of naloxone is relatively short, and it often must be given repeatedly or by continuous infusion. Opioid antagonists also have been employed effectively to decrease neonatal respiratory depression secondary to the intravenous or intramuscular administration of opioids to the mother. In the neonate, the initial dose is 10 $\mu\text{g}/\text{kg}$ given intravenously, intramuscularly, or subcutaneously.

CENTRALLY ACTIVE ANTITUSSIVE AGENTS

Cough is a useful physiological mechanism that serves to clear the respiratory passages of foreign material and

excess secretions. It should not be suppressed indiscriminately. There are, however, many situations in which cough does not serve any useful purpose but may, instead, only annoy the patient or prevent rest and sleep. Chronic cough can contribute to fatigue, especially in elderly patients. In such situations, the physician should use a drug that will reduce the frequency or intensity of the coughing. The cough reflex is complex, involving the central and peripheral nervous systems, as well as the smooth muscle of the bronchial tree. It has been suggested that irritation of the bronchial mucosa causes bronchoconstriction, which, in turn, stimulates cough receptors (which probably represent a specialized type of stretch receptor) located in tracheobronchial passages. Afferent conduction from these receptors is *via* fibers in the vagus nerve; central components of the reflex probably include several mechanisms or centers that are distinct from the mechanisms involved in the regulation of respiration.

The drugs that directly or indirectly can affect this complex mechanism are diverse. For example, cough may be the first or only symptom in bronchial asthma or allergy, and in such cases, bronchodilators (*e.g.*, β_2 adrenergic receptor agonists; *see* Chapter 10) have been shown to reduce cough without having any significant central effects; other drugs act primarily on the central or peripheral nervous system components of the cough reflex.

A number of drugs reduce cough as a result of their central actions, although the exact mechanisms still are not entirely clear. Included among them are the opioid analgesics discussed earlier (codeine and hydrocodone are the opioids most commonly used to suppress cough), as well as a number of nonopioid agents. Cough suppression often occurs with lower doses of opioids than those needed for analgesia. A 10- or 20-mg oral dose of codeine, although ineffective for analgesia, produces a demonstrable antitussive effect, and higher doses produce even more suppression of chronic cough.

In selecting a specific centrally active agent for a particular patient, the significant considerations are its antitussive efficacy against pathological cough and the incidence and type of side effects to be expected. In the majority of situations requiring a cough suppressant, liability for abuse need not be a major consideration. Most of the nonopioid agents now offered as antitussives are effective against cough induced by a variety of experimental techniques. However, the ability of these tests to predict clinical efficacy is limited.

Dextromethorphan. Dextromethorphan (D-3-methoxy-N-methylmorphinan) is the D-isomer of the codeine analog methorphan; however, unlike the L-isomer, it has no

analgesic or addictive properties and does not act through opioid receptors. The drug acts centrally to elevate the threshold for coughing. Its effectiveness in patients with pathological cough has been demonstrated in controlled studies; its potency is nearly equal to that of codeine. Compared with codeine, dextromethorphan produces fewer subjective and gastrointestinal side effects (Matthys *et al.*, 1983). In therapeutic dosages, the drug does not inhibit ciliary activity, and its antitussive effects persist for 5 to 6 hours. Its toxicity is low, but extremely high doses may produce CNS depression.

Sites that bind dextromethorphan with high affinity have been identified in membranes from various regions of the brain (Craviso and Musacchio, 1983). Although dextromethorphan is known to function as an NMDA-receptor antagonist, the dextromethorphan-binding sites are not limited to the known distribution of NMDA receptors (Elliott *et al.*, 1994). Thus, the mechanism by which dextromethorphan exerts its antitussive effect still is not clear. Two other known antitussives, *carbetapentane* and *caramiphen*, also bind avidly to the dextromethorphan-binding sites, but codeine, levopropoxyphene, and other antitussive opioids (as well as naloxone) are not bound. Although *noscapine* (see below) enhances the affinity of dextromethorphan, it appears to interact with distinct binding sites (Karlsson *et al.*, 1988). The relationship of these binding sites to antitussive actions is not known; however, these observations, coupled with the ability of naloxone to antagonize the antitussive effects of codeine but not those of dextromethorphan, indicate that cough suppression can be achieved by a number of different mechanisms. The average adult dosage of *dextromethorphan hydrobromide* is 10 to 30 mg three to six times daily; however, as is the case with codeine, higher doses often are required. The drug generally is marketed for over-the-counter sale in numerous syrups and lozenges or in combinations with antihistamines and other agents.

Other Drugs. *Pholcodine* [3-*O*-(2-morpholinoethyl)morphine] is used clinically in many countries outside the United States. Although structurally related to the opioids, it has no opioid-like actions because the substitution at the 3-position is not removed by metabolism. Pholcodine is at least as effective as codeine as an antitussive; it has a long half-life and can be given once or twice daily.

Benzonate (TESSALON) is a long-chain polyglycol derivative chemically related to *procaine* and believed to exert its antitussive action on stretch or cough receptors in the lung, as well as by a central mechanism. It has been administered by all routes; the oral dosage is 100 mg three times daily, but higher doses have been used.

THERAPEUTIC USES OF OPIOID ANALGESICS

Sir William Osler called morphine “God’s own medicine.” Opioids still are the mainstay of pain treatment. However, the development of new analgesic compounds and new routes of administration have increased the

therapeutic options available to clinicians while at the same time helping to minimize undesirable side effects. This section provides guidelines for rational drug selection, discusses routes of administration other than the standard oral and parenteral methods, and outlines general principles for the use of opioids in acute and chronic pain states.

Extensive efforts by many individuals and organizations have resulted in the publication of many useful guidelines for the administration of opioids. These have been developed for a number of clinical situations, including treatment of acute pain, trauma, cancer, nonmalignant chronic pain, and pain in children (Agency for Health Care Policy and Research, 1992a, 1992b, 1994; International Association for the Study of Pain, 1992; American Pain Society, 2003; Grossman *et al.*, 1999; World Health Organization, 1998; Berde *et al.*, 1990). These guidelines provide comprehensive discussions of dosing regimens and drug selection and also provide protocols for the management of complex conditions. In the case of cancer pain, adherence to standardized protocols for cancer pain management (Agency for Health Care Policy and Research, 1994) has been shown to improve pain management significantly (Du Pen *et al.*, 1999). Guidelines for the oral and parenteral dosing of commonly used opioids are presented in Table 21–6.

These guidelines are for acute pain management in opioid-naïve patients. Adjustments will need to be made for use in opioid-tolerant patients and in chronic pain states. For children younger than 6 months of age, especially those who are ill or premature, expert consultation should be obtained. The pharmacokinetics and potency of opioids can be altered substantially in these patients, and in some cases there is a significant risk of apnea. It also should be noted that there is substantial individual variability in responses to opioids. A standard intramuscular dose of 10 mg morphine sulfate will relieve severe pain adequately in only two of three patients. Adjustments will have to be made based on clinical response.

In general, it is recommended that opioids always be combined with other analgesic agents, such as NSAIDs or acetaminophen. In this way, one can take advantage of additive analgesic effects and minimize the dose of opioids and thus undesirable side effects. In some situations, NSAIDs can provide analgesia equal to that produced by 60 mg codeine. Potentiation of opioid action by NSAIDs may be due to increased conversion of arachidonic acid to 12-lipoxygenase products that facilitate effects of opioids on K⁺ channels (Vaughan *et al.*, 1997). This “opioid sparing” strategy is the backbone of the “analgesic ladder” for pain management proposed by

Table 21–6

Dosing Data for Opioid Analgesics

DRUG	APPROXIMATE EQUIANALGESIC ORAL DOSE	APPROXIMATE EQUIANALGESIC PARENTERAL DOSE	RECOMMENDED STARTING DOSE (ADULTS MORE THAN 50 KG BODY WEIGHT)		RECOMMENDED STARTING DOSE (CHILDREN AND ADULTS LESS THAN 50 KG BODY WEIGHT) ¹		
			<i>Oral</i>	<i>Parenteral</i>	<i>Oral</i>	<i>Parenteral</i>	
Opioid Agonist							
Morphine ²	30 mg q3–4h (around-the-clock dosing) 60 mg q3–4h (single dose or intermittent dosing)	10 mg q3–4h	30 mg q3–4h	10 mg q3–4h	0.3 mg/kg q3–4h	0.1 mg/kg q3–4h	
Codeine ³	130 mg q3–4h	75 mg q3–4h	60 mg q3–4h	60 mg q2h (intramuscular/subcutaneous)	1 mg/kg q3–4h ⁴	Not recommended

Nalbuphine (NUBAIN)	Not available	10 mg q3–4h	Not available	10 mg q3–4h	Not available	0.1 mg/kg q3–4h	

NOTE: Published tables vary in the suggested doses that are equianalgesic to morphine. Clinical response is the criterion that must be applied for each patient; titration to clinical response is necessary. Because there is not complete cross tolerance among these drugs, it is usually necessary to use a lower than equianalgesic dose when changing drugs and to retitrate to response. *Caution:* Recommended doses do not apply to patients with renal or hepatic insufficiency or other conditions affecting drug metabolism and kinetics. ¹*Caution:* Doses listed for patients with body weight less than 50 kg cannot be used as initial starting doses in babies less than 6 months of age. Consult the *Clinical Practice Guideline for Acute Pain Management: Operative or Medical Procedures and Trauma* section on management of pain in neonates for recommendations. ²For morphine, hydromorphone, and oxymorphone, rectal administration is an alternate route for patients unable to take oral medications, but equianalgesic doses may differ from oral and parenteral doses because of pharmacokinetic differences. ³*Caution:* Codeine doses above 65 mg often are not appropriate due to diminishing incremental analgesia with increasing doses but continually increasing constipation and other side effects. ⁴*Caution:* Doses of aspirin and acetaminophen in combination opioid/NSAID preparations must also be adjusted to the patient's body weight. Maximum acetaminophen dose: 4 gm/day in adults, 90 mg/kg/day in children. ⁵Doses for moderate pain not necessarily equivalent to 30 mg oral or 10 mg parenteral morphine. ⁶Risk of seizures; parenteral formulation not available in the U.S. ⁷OXYCONTIN is an extended-release preparation containing up to 160 mg of oxycodone per tablet and recommended for use every 12 hours. It has been subject to substantial abuse. ABBREVIATION: q, every. Modified from Agency for Healthcare Policy and Research, 1992a, with permission.

the World Health Organization (1990). Weaker opioids can be supplanted by stronger opioids in cases of moderate and severe pain. In addition, analgesics always should be dosed in a continuous or “around the clock” fashion rather than on an as-needed basis for chronic severe pain. This provides more consistent analgesic levels and avoids unnecessary suffering.

Factors guiding the selection of specific opioid compounds for pain treatment include potency, pharmacokinetic characteristics, and the routes of administration available. A more potent compound could be useful when high doses of opioid are required so that the medicine can be given in a smaller volume. Duration of action also is an important consideration. For example, a long-acting opioid such as methadone may be appropriate when less frequent dosing is desired. For short, painful procedures, a quick-acting, fast-dissipating compound such as remifentanyl would be a useful choice. In special cases, where a lower addiction risk is required or in patients unable to tolerate other opioids, a partial agonist or mixed agonist–antagonist compound might be a rational choice. The properties of some commonly used orally administered opioids are discussed in more detail below.

Morphine is available for oral use in standard and controlled-release preparations. Owing to first-pass metabolism, morphine is two to six times less potent orally than it is parenterally. This is important to remember when converting a patient from parenteral to oral medication. There is wide variability in the first-pass metabolism, and the dose should be titrated to the patient’s needs. In children who weigh less than 50 kg, morphine can be given at 0.1 mg/kg every 3 to 4 hours parenterally or at 0.3 mg/kg orally.

Codeine is used widely owing to its high oral/parenteral potency ratio. Orally, codeine at 30 mg is approximately equianalgesic to 325 to 600 mg aspirin. Combinations of codeine with aspirin or acetaminophen usually provide additive actions, and at these doses, analgesic efficacy can exceed that of 60 mg codeine (Beaver, 1988). Many drugs can be used instead of either morphine or codeine, as shown in Table 21–6. Oxycodone, with its high oral/parenteral potency ratio, is used widely in combination with aspirin (PERCODAN, others) or acetaminophen (PERCOCET 2.5/325, others), although it is available alone (ROXICODINE, others). Oxycodone also is available in a sustained-release formulation for chronic pain management (OXYCONTIN). Unfortunately, this formulation has been subject to widespread abuse leading to serious consequences, including death, and the FDA has strengthened warnings for this drug (*see* Chapter 23).

Heroin (diacetylmorphine) is not available for therapeutic use in the United States, although it has been used in the United Kingdom. Given intramuscularly, it is approximately twice as potent as morphine. Pharmacologically, heroin is very similar to morphine and does not appear to have any unique therapeutic advantages over the available opioids (Sawynok, 1986).

It also may be helpful to employ other agents (adjuvants) that enhance opioid analgesia and that may add beneficial effects of their own. For example, the combination of an opioid with a small

dose of amphetamine may augment analgesia while reducing the sedative effects. Certain antidepressants, such as amitriptyline and desipramine, also may enhance opioid analgesia, and they may have analgesic actions in some types of neuropathic (deafferentation) pain (McQuay, 1988). Other potentially useful adjuvants include certain antihistamines, anticonvulsants such as *carbamazepine* and phenytoin, and glucocorticoids.

Alternative Routes of Administration

In addition to the traditional oral and parenteral formulations for opioids, many other methods of administration have been developed in an effort to improve therapeutic efficacy while minimizing side effects. These routes also improve the ease of use of opioids and increase patient satisfaction.

Patient-Controlled Analgesia (PCA). With this modality, the patient has limited control of the dosing of opioid from an infusion pump within tightly mandated parameters. PCA can be used for intravenous or epidural infusion. This technique avoids any delays in administration and permits greater dosing flexibility than other regimens, better adapting to individual differences in responsiveness to pain and to opioids. It also gives the patient a greater sense of control. With shorter-acting opioids, serious toxicity or excessive use rarely occurs. An early concern that self-administration of opioids would increase the probability of addiction has not materialized. PCA is suitable for adults and children, and it is preferred over intramuscular injections for postoperative pain control (Rodgers *et al.*, 1988).

Intraspinal Infusion. Administration of opioids into the epidural or intrathecal space provides more direct access to the first pain-processing synapse in the dorsal horn of the spinal cord. This permits the use of doses substantially lower than those required for oral or parenteral administration (Table 21–7). Systemic side effects thus are decreased. However, epidural opioids have their own dose-dependent side effects, such as itching, nausea, vomiting, respiratory depression, and urinary retention. The use of hydrophilic opioids such as preservative-free morphine (DURAMORPH, others) permits more rostral spread of the compound, allowing it to directly affect supraspinal sites. As a consequence, after intraspinal morphine, delayed respiratory depression can be observed for as long as 24 hours after a bolus dose. While the risk of delayed respiratory depression is reduced with more lipophilic opioids, it is not eliminated. Extreme vigilance and appropriate monitoring are required for all patients receiving intraspinal narcotics. Nausea and vomiting also are

Table 21-7
Intraspinal Opioids for the Treatment of Acute Pain

DRUG	SINGLE DOSE* (mg)	INFUSION RATE† (mg/h)	ONSET (MINUTES)	DURATION OF EFFECT OF A SINGLE DOSE‡ (HOURS)
Epidural				
Morphine	1–6	0.1–1.0	30	6–24
Meperidine	20–150	5–20	5	4–8
Methadone	1–10	0.3–0.5	10	6–10
Hydromorphone	1–2	0.1–0.2	15	10–16
Fentanyl	0.025–0.1	0.025–0.10	5	2–4
Sufentanil	0.01–0.06	0.01–0.05	5	2–4
Alfentanil	0.5–1	0.2	15	1–3
Subarachnoid				
Morphine	0.1–0.3		15	8–24+
Meperidine	10–30		?	10–24+
Fentanyl	0.005–0.025		5	3–6

*Low doses may be effective when administered to the elderly or when injected in the cervical or thoracic region. †If combining with a local anesthetic, consider using 0.0625% bupivacaine. ‡Duration of analgesia varies widely; higher doses produce longer duration. Adapted from International Association for the Study of Pain, 1992.

more prominent symptoms with intraspinal morphine. However, supraspinal analgesic centers also can be stimulated, possibly leading to synergistic analgesic effects.

Analogous to the relationship between systemic opioids and NSAIDs, intraspinal narcotics often are combined with local anesthetics. This permits the use of lower concentrations of both agents, minimizing local anesthetic-induced complications of motor blockade and the opioid-induced complications listed earlier. Epidural administration of opioids has become popular in the management of postoperative pain and for providing analgesia during labor and delivery. Lower systemic opioid levels are achieved with epidural opioids, leading to less placental transfer and less potential for respiratory depression of the newborn (Shnider and Levinson, 1987). Intrathecal administration of opioids as a single bolus (“spinal” anesthesia) also is popular for acute pain management. Chronic intrathecal infusions generally are reserved for use in chronic pain patients.

Peripheral Analgesia. As mentioned previously, opioid receptors on peripheral nerves have been shown to respond to locally applied opioids during inflammation (Stein, 1993). Peripheral analgesia permits the use of lower doses, applied locally, than those necessary to achieve a systemic effect. The effectiveness of this technique has been demonstrated in studies of postoperative pain (Stein, 1993). These studies also suggest that peripherally acting opioid compounds would be effective in other selected circumstances without entering the CNS to cause many undesirable side effects. Development of such compounds and expansion of clinical applications of this technique are active areas of research.

Rectal Administration. This route is an alternative for patients with difficulty swallowing or other oral pathology and who prefer a less invasive route than parenteral. This route is not well tolerated in most children. Onset of action is seen within 10 minutes. In the United States, morphine, hydromorphone, and oxycodone are available in rectal suppository formulations.

Administration by Inhalation. Opioids delivered by nebulizer can be an effective means of analgesic drug delivery (Worsley *et al.*, 1990). However, constant supervision is required when administering the drug, and variable delivery to the lungs can cause differences in therapeutic effect. In addition, possible environmental contamination is a concern.

Oral Transmucosal Administration. Opioids can be absorbed through the oral mucosa more rapidly than through the stomach. Bioavailability is greater owing to avoidance of first-pass metabolism, and lipophilic opioids are absorbed better by this route than are hydrophilic compounds such as morphine (Weinberg *et al.*, 1988). A transmucosal delivery system that suspends fentanyl in a dissolvable matrix has been approved for clinical use (ACTIQ). Its primary indication is for treatment of breakthrough cancer pain (Ashburn *et al.*, 1989). In this setting, transmucosal fentanyl relieves pain within 15 minutes, and patients easily can titrate the appropriate dose. Transmucosal fentanyl also has been studied as a premedicant for children. However, this technique has been largely abandoned owing to a substantial incidence of undesirable side effects such as respiratory depression, sedation, nausea, vomiting, and pruritus.

Transdermal or Iontophoretic Administration. Transdermal fentanyl patches are approved for use in sustained pain. The opioid permeates the skin, and a “depot” is established in the stratum corneum layer. Unlike other transdermal systems (*i.e.*, transdermal

scopolamine), anatomic position of the patch does not affect absorption. However, fever and external heat sources (heating pads, hot baths) can increase absorption of fentanyl and potentially lead to an overdose (Rose *et al.*, 1993). This modality is well suited for cancer pain treatment because of its ease of use, prolonged duration of action, and stable blood levels (Portenoy *et al.*, 1993). It may take up to 12 hours to develop analgesia and up to 16 hours to observe full clinical effect. Plasma levels stabilize after two sequential patch applications, and the kinetics do not appear to change with repeated applications (Portenoy *et al.*, 1993). However, there may be a great deal of variability in plasma levels after a given dose. The plasma half-life after patch removal is about 17 hours. Thus, if excessive sedation or respiratory depression is experienced, antagonist infusions may need to be maintained for an extended period. Dermatological side effects from the patches, such as rash and itching, usually are mild.

Iontophoresis is the transport of soluble ions through the skin by using a mild electric current. This technique has been employed with morphine (Ashburn *et al.*, 1992). Fentanyl and sufentanil have been chemically modified and applied by iontophoresis in rats (Thysman and Preat, 1993). Effective analgesia was achieved in less than 1 hour, suggesting that iontophoresis could be a promising modality for postoperative pain. It should be noted that increasing the applied current will increase drug delivery and could lead to overdose. However, unlike transdermal opioids, a drug reservoir does not build up in the skin, thus limiting the duration of both main and side effects.

Nonanalgesic Therapeutic Uses of Opioids. *Dyspnea.* Morphine is used to alleviate the dyspnea of acute left ventricular failure and pulmonary edema, and the response to intravenous morphine may be dramatic. The mechanism underlying this relief is not clear. It may involve an alteration of the patient's reaction to impaired respiratory function and an indirect reduction of the work of the heart owing to reduced fear and apprehension. However, it is more probable that the major benefit is due to cardiovascular effects, such as decreased peripheral resistance and an increased capacity of the peripheral and splanchnic vascular compartments (Vismara *et al.*, 1976). Nitroglycerin, which also causes vasodilation, may be superior to morphine in this condition (Hoffman and Reynolds, 1987). In patients with normal blood gases but severe breathlessness owing to chronic obstruction of airflow ("pink puffers"), dihydrocodeine, 15 mg orally before exercise, reduces the feeling of breathlessness and increases exercise tolerance (Johnson *et al.*, 1983). Nonetheless, opioids generally are contraindicated in pulmonary edema owing to respiratory irritants unless severe pain also is present; relative contraindications to the use of histamine-releasing opioids in asthma have been discussed.

Special Anesthesia. High doses of morphine or other opioids have been used as the primary anesthetic agents in certain surgical procedures. Although respiration is so depressed that physical assistance is required, patients can retain consciousness (*see* Chapter 13).

CLINICAL SUMMARY

Opioid analgesics provide symptomatic relief of pain, but the underlying disease remains. The clinician must weigh the benefits of this relief against any potential risk to the

patient, which may be quite different in an acute compared with a chronic disease.

In acute problems, opioids will reduce the intensity of pain. However, physical signs (such as abdominal rigidity) generally will remain. Relief of pain also can facilitate history taking, examination, and the patient's ability to tolerate diagnostic procedures. Patients should not be evaluated inadequately because of the physician's unwillingness to prescribe analgesics, nor in most cases should analgesics be withheld for fear of obscuring the progression of underlying disease.

The problems that arise in the relief of pain associated with chronic conditions are more complex. Repeated daily administration of opioid analgesics eventually will produce tolerance and some degree of physical dependence. The degree will depend on the particular drug, the frequency of administration, and the quantity administered. The decision to control any chronic symptom, especially pain, by the repeated administration of an opioid must be made carefully. When pain is due to chronic nonmalignant disease, measures other than opioid drugs should be employed to relieve chronic pain if they are effective and available. Such measures include the use of NSAIDs, local nerve blocks, antidepressant drugs, electrical stimulation, acupuncture, hypnosis, or behavioral modification. However, highly selected subpopulations of chronic nonmalignant pain patients can be maintained adequately on opioids for extended periods of time (Portenoy, 1990).

In the usual doses, morphine-like drugs relieve suffering by altering the emotional component of the painful experience, as well as by producing analgesia. Control of pain, especially chronic pain, must include attention to both psychological factors and the social impact of the illness that sometimes play dominant roles in determining the suffering experienced by the patient. In addition to emotional support, the physician also must consider the substantial variability in the patient's capacity to tolerate pain and the response to opioids. As a result, some patients may require considerably more than the average dose of a drug to experience any relief from pain; others may require dosing at shorter intervals. Some clinicians, out of an exaggerated concern for the possibility of inducing addiction, tend to prescribe initial doses of opioids that are too small or given too infrequently to alleviate pain and then respond to the patient's continued complaints with an even more exaggerated concern about drug dependence despite the high probability that the request for more drug is only the expected consequence of the inadequate dosage initially prescribed (Sriwatanakul *et al.*, 1983). It also is important to note that infants and children probably are more apt to receive inadequate treat-

ment for pain than are adults owing to communication difficulties, lack of familiarity with appropriate pain assessment methodologies, and inexperience with the use of strong opioids in children. If an illness or procedure causes pain for an adult, there is no reason to assume that it will produce less pain for a child (Yaster and Deshpande, 1988).

Pain of Terminal Illness and Cancer Pain. Opioids are not indicated in all cases of terminal illness, but the analgesia, tranquility, and even euphoria afforded by the use of opioids can make the final days far less distressing for the patient and family. Although physical dependence and tolerance may develop, this possibility should not in any way prevent physicians from fulfilling their primary obligation to ease the patient's discomfort. The physician should not wait until the pain becomes agonizing; *no patient should ever wish for death because of a physician's reluctance to use adequate amounts of effective opioids.* This sometimes may entail the regular use of opioid analgesics in substantial doses. Such patients, while they may be physically dependent, are not "addicts" even though they may need large doses on a regular basis. Physical dependence is not equivalent to addiction (*see* Chapter 23).

Most clinicians who are experienced in the management of chronic pain associated with malignant disease or terminal illness recommend that opioids be administered at sufficiently short, fixed intervals so that pain is continually under control and patients do not dread its return (Foley, 1993). Less drug is needed to prevent the recurrence of pain than to relieve it. Morphine remains the opioid of choice in most of these situations, and the route and dose should be adjusted to the needs of the individual patient. Many clinicians find that oral morphine is adequate in most situations. Sustained-release preparations of oral morphine and oxycodone are available that can be administered at 8-, 12- or 24-hour intervals (morphine) or 8- to 12-hour intervals (oxycodone). Superior control of pain often can be achieved with fewer side effects using the same daily dose; a decrease in the fluctuation of plasma concentrations of morphine may be partially responsible.

Constipation is an exceedingly common problem when opioids are used, and the use of stool softeners and laxatives should be initiated early. Amphetamines have demonstrable mood-elevating and analgesic effects and enhance opioid-induced analgesia. However, not all terminal patients require the euphoriant effects of amphetamine, and some experience side effects, such as anorexia. Controlled studies demonstrate no superiority of oral heroin over oral morphine. Similarly, after adjustment is

made for potency, parenteral heroin is not superior to morphine in terms of analgesia, effects on mood, or side effects (Sawynok, 1986). Although tolerance does develop to oral opioids, many patients obtain relief from the same dosage for weeks or months. In cases where one opioid loses effectiveness, switching to another may provide better pain relief. "Cross-tolerance" among opioids exists, but clinically and experimentally, cross-tolerance among related μ receptor agonists is not complete. The reasons for this are not clear but may relate to differences between agonists in receptor-binding characteristics and subsequent cellular signaling interactions, as discussed earlier in this chapter.

When opioids and other analgesics are no longer satisfactory, nerve block, chordotomy, or other types of neurosurgical interventions such as neurostimulation may be required if the nature of the disease permits. Epidural or intrathecal administration of opioids may be useful when administration of opioids by usual routes no longer yields adequate relief of pain (*see* above). This technique has been used with ambulatory patients over periods of weeks or months (Gustafsson and Wiesenfeld-Hallin, 1988). Moreover, portable devices have been developed that permit the patient to control the parenteral administration of an opioid while remaining ambulatory (Kerr *et al.*, 1988). These devices use a pump that infuses the drug from a reservoir at a rate that can be tailored to the needs of the patient, and they include mechanisms to limit dosage and/or allow the patient to self-administer an additional "rescue" dose if there is a transient change in the intensity of pain.

ETHANOL

Michael Fleming, S. John Mihic, and R. Adron Harris

The two-carbon alcohol *ethanol*, $\text{CH}_3\text{CH}_2\text{OH}$, is a CNS depressant that is widely available to adults; its use is legal and accepted in many societies, and its abuse is a societal problem. The relevant pharmacological properties of ethanol include effects on the gastrointestinal, cardiovascular, and central nervous systems, effects on disease processes, and effects on prenatal development. Ethanol disturbs the fine balance between excitatory and inhibitory influences in the brain, producing disinhibition, ataxia, and sedation. Tolerance to ethanol develops after chronic use, and physical dependence is demonstrated on alcohol withdrawal (see Chapter 23). Understanding the cellular and molecular mechanisms of these myriad effects of ethanol *in vivo* requires an integration of knowledge from multiple biomedical sciences.

HISTORY AND OVERVIEW

Alcoholic beverages are so strongly associated with human society that fermentation is said to have developed in parallel with civilization. Indeed, there is speculation that human alcohol use is linked evolutionarily to a preference for fermenting fruit, where the presence of ethanol signals that the fruit is ripe but not yet rotten (Dudley, 2000) (the terms *ethanol* and *alcohol* are used interchangeably in this chapter).

The Arabs developed distillation about 800 C.E., and the word *alcohol* is derived from the Arabic for “something subtle.” Alchemists of the Middle Ages were captivated by the invisible “spirit” that was distilled from wine and thought it to be a remedy for practically all diseases. The term *whiskey* is derived from *usquebaugh*, Gaelic for “water of life,” and alcohol became the major ingredient of widely marketed “tonics” and “elixirs.”

Although alcohol abuse and alcoholism are major health problems in many countries, the medical and social impacts of alcohol

abuse have not always been appreciated. The economic burden to the U.S. economy is about \$185 billion each year, and alcohol is responsible for more than 100,000 deaths annually. At least 14 million Americans meet the criteria for alcohol abuse or alcoholism, but medical diagnosis and treatment often are delayed until the disease is advanced and complicated by multiple social and health problems, making treatment difficult. Biological and genetic studies clearly place alcoholism among diseases with both genetic and environmental influences, but persistent stigmas and attribution to moral failure have impeded recognition and treatment of alcohol problems. A major challenge for physicians and researchers is to devise diagnostic and therapeutic approaches aimed at this major health problem.

Compared with other drugs, surprisingly large amounts of alcohol are required for physiological effects, resulting in its consumption more as a food than a drug. The alcohol content of beverages typically ranges from 4% to 6% (volume/volume) for beer, 10% to 15% for wine, and 40% and higher for distilled spirits (the “proof” of an alcoholic beverage is twice its percentage of alcohol; e.g., 40% alcohol is 80 proof). A glass of beer or wine, a mixed drink, or a shot of spirits contains about 14 g alcohol, or about 0.3 mol ethanol. Consumption of 1 to 2 mol over a few hours is not uncommon. Thus, alcohol is consumed in gram quantities, whereas most other drugs are taken in milligram or microgram doses. Since the ratio of ethanol in end-expiratory alveolar air and ethanol in the blood is relatively consistent, blood alcohol levels (BALs) in human beings can be estimated readily by the measurement of alcohol levels in expired air; the partition coefficient for ethanol between blood and alveolar air is approximately 2000:1. Because of the causal relationship between excessive alcohol consumption and vehicular accidents, there has been a near-universal adoption of laws attempting to limit the operation of vehicles while under the influence of alcohol. Legally allowed BALs typically are set at or below 80 mg% (80 mg ethanol per

100 ml blood; 0.08% w/v), which is equivalent to a concentration of 17 mM ethanol in blood. A 12-oz bottle of beer, a 5-oz glass of wine, and a 1.5-oz “shot” of 40% liquor each contains approximately 14 g ethanol, and the consumption of one of these beverages by a 70-kg person would produce a BAL of approximately 30 mg%. However, it is important to note that this is approximate because the BAL is determined by a number of factors, including the rate of drinking, sex, body weight and water percentage, and the rates of metabolism and stomach emptying (see “Acute Alcohol Intoxication” below).

PHARMACOLOGICAL PROPERTIES

Absorption, Distribution, and Metabolism

After oral administration, ethanol is absorbed rapidly into the bloodstream from the stomach and small intestine and

distributes into total-body water (0.5 to 0.7 L/kg). Peak blood levels occur about 30 minutes after ingestion of ethanol when the stomach is empty. Because absorption occurs more rapidly from the small intestine than from the stomach, delays in gastric emptying (owing, for example, to the presence of food) slow ethanol absorption. Because of first-pass metabolism by gastric and liver alcohol dehydrogenase (ADH), oral ingestion of ethanol leads to lower BALs than would be obtained if the same quantity were administered intravenously. Gastric metabolism of ethanol is lower in women than in men, which may contribute to the greater susceptibility of women to ethanol (Lieber, 2000). *Aspirin* increases ethanol bioavailability by inhibiting gastric ADH. Ethanol is metabolized largely by sequential hepatic oxidation, first to acetaldehyde by ADH and then to acetic acid by aldehyde dehydrogenase (ALDH) (Figure 22–1). Each metabolic step requires NAD^+ ; thus oxidation of 1 mol ethanol (46 g) to 1 mol acetic acid requires 2 mol NAD^+ (approximately 1.3 kg). This greatly exceeds the supply of NAD^+ in the liver; indeed, NAD^+ availability limits ethanol

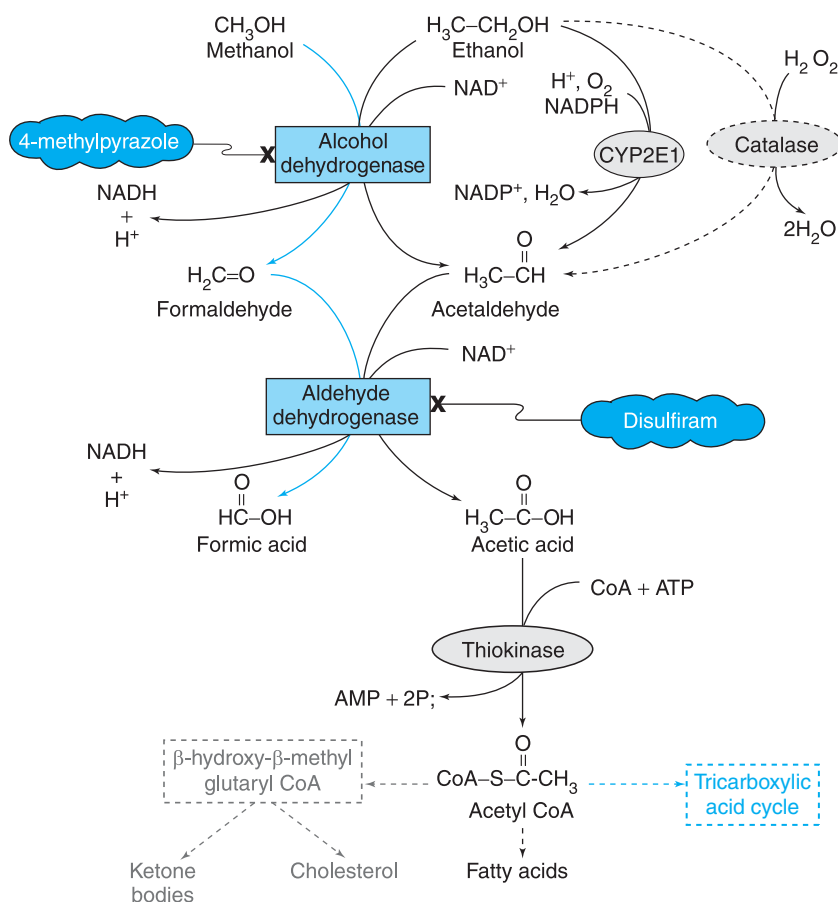

Figure 22–1. Metabolism of ethanol and methanol.

metabolism to about 8 g or 10 ml (approximately 170 mmol) per hour in a 70-kg adult, or approximately 120 mg/kg per hour. Thus, hepatic ethanol metabolism functionally saturates at relatively low blood levels compared with the high BALs achieved, and ethanol metabolism is a zero-order process (constant amount per unit time). Small amounts of ethanol are excreted in urine, sweat, and breath, but metabolism to acetate accounts for 90% to 98% of ingested ethanol, mostly owing to hepatic metabolism by ADH and ALDH. A hepatic cytochrome P450 enzyme, CYP2E1, also can contribute (Figure 22–1), especially at higher ethanol concentrations and under conditions such as alcoholism, where its activity may be induced. Catalase also can produce acetaldehyde from ethanol, but hepatic H₂O₂ availability usually is too low to support significant flux of ethanol through this pathway. Although CYP2E1 usually is not a major factor in ethanol metabolism, it can be an important site of interactions of ethanol with other drugs. CYP2E1 is induced by chronic consumption of ethanol, increasing the clearance of its substrates and activating certain toxins such as CCl₄. There can be decreased clearance of the same drugs, however, after acute consumption of ethanol because ethanol competes with them for oxidation by the enzyme system (*e.g.*, *phenytoin* and *warfarin*). The large increase in the hepatic NADH:NAD⁺ ratio during ethanol oxidation has profound consequences in addition to limiting the rate of ethanol metabolism. Enzymes requiring NAD⁺ are inhibited; thus lactate accumulates, activity of the tricarboxylic acid cycle is reduced, and acetyl coenzyme A (acetyl CoA) accumulates (and it is produced in quantity from ethanol-derived acetic acid; Figure 22-1). The combination of increased NADH and elevated acetyl CoA supports fatty acid synthesis and the storage and accumulation of triacylglycerides. Ketone bodies accrue, exacerbating lactic acidosis. Ethanol metabolism by the CYP2E1 pathway produces elevated NADP⁺, limiting the availability of NADPH for the regeneration of reduced glutathione (GSH), thereby enhancing oxidative stress.

The mechanisms underlying hepatic disease resulting from heavy ethanol use probably reflect a complex combination of these metabolic factors, CYP2E1 induction (and enhanced activation of toxins and production of H₂O₂ and oxygen radicals), and possibly enhanced release of endotoxin as a consequence of ethanol's effect on gram-negative flora in the gastrointestinal tract. Effects of heavy ethanol ingestion on various organs are summarized below; damage to tissues very likely reflects the poor nutritional status of alcoholics (malabsorption and lack of vitamins A and D and thiamine), suppression of immune function by ethanol, and a variety of other generalized effects.

The one-carbon alcohol *methanol* also is metabolized by ADH and ALDH, with damaging consequences (*see* below). Competition between methanol and ethanol for ADH forms the basis of the use of ethanol in methanol poisoning. Several drugs inhibit alcohol metabolism, including *4-methylprazole*, an ADH inhibitor useful in ethylene glycol poisoning, and *disulfiram*, an ALDH inhibitor used in treating alcoholism (*see* below). Ethanol also can competitively inhibit the metabolism of other substrates of ADH and CYP2E1, such as methanol and ethylene glycol, and therefore is an effective antidote.

EFFECTS OF ETHANOL ON PHYSIOLOGICAL SYSTEMS

William Shakespeare described the acute pharmacological effects of imbibing ethanol in the Porter scene (act 2, scene 3) of *Macbeth*. The Porter, awakened from an alcohol-induced sleep by Macduff, explains three effects of alcohol and then wrestles with a fourth effect that combines the contradictory aspects of soaring overconfidence with physical impairment:

Porter: . . . and drink, sir, is a great provoker of three things.

Macduff: What three things does drink especially provoke?

Porter: Marry, sir, nose-painting [cutaneous vasodilation], sleep [CNS depression], and urine [a consequence of the inhibition of antidiuretic hormone (vasopressin) secretion, exacerbated by volume loading]. Lechery, sir, it provokes and unprovokes: it provokes the desire but it takes away the performance. Therefore much drink may be said to be an equivocator with lechery: it makes him and it mars him; it sets him on and it takes him off; it persuades him and disheartens him, makes him stand to and not stand to [the imagination desires what the corpus cavernosum cannot deliver]; in conclusion, equivocates him in a sleep, and, giving him the lie, leaves him.

More recent research has added details to Shakespeare's enumeration—*see* the bracketed additions to the Porter's words above and the section on organ systems below—but the most noticeable consequences of the recreational use of ethanol still are well summarized by the gregarious and garrulous Porter, whose delighted and devilish demeanor demonstrates a frequently observed influence of modest concentrations of ethanol on the CNS. The sections below detail ethanol's effects on physiological systems.

Central Nervous System

Although the public often views alcoholic drinks as stimulating, ethanol primarily is a CNS depressant. Ingestion of moderate amounts of ethanol, like that of other depres-

sants such as barbiturates and benzodiazepines, can have anti-anxiety actions and produce behavioral disinhibition at a wide range of dosages. Individual signs of intoxication vary from expansive and vivacious affect to uncontrolled mood swings and emotional outbursts that may have violent components. With more severe intoxication, CNS function generally is impaired, and a condition of general anesthesia ultimately prevails. However, there is little margin between the anesthetic actions and lethal effects (usually owing to respiratory depression).

About 10% of alcohol drinkers progress to levels of consumption that are physically and socially detrimental. Chronic abuse is accompanied by tolerance, dependence, and craving for the drug (*see* below for a discussion of neuronal mechanisms; *see also* Chapter 23). Alcoholism is characterized by compulsive use despite clearly deleterious social and medical consequences. Alcoholism is a progressive illness, and brain damage from chronic alcohol abuse contributes to the deficits in cognitive functioning and judgment seen in alcoholics. Alcoholism is a leading cause of dementia in the United States (Oslin *et al.*, 1998). Chronic alcohol abuse results in shrinkage of the brain owing to loss of both white and gray matter (Kril and Halliday, 1999). The frontal lobes are particularly sensitive to damage by alcohol, and the extent of damage is determined by the amount and duration of alcohol consumption, with older alcoholics being more vulnerable than younger ones (Pfefferbaum *et al.*, 1998). It is important to note that ethanol itself is neurotoxic, and although malnutrition or vitamin deficiencies probably play roles in complications of alcoholism such as Wernicke's encephalopathy and Korsakoff's psychosis, most of the alcohol-induced brain damage in Western countries is due to alcohol itself. In addition to loss of brain tissue, alcohol abuse also reduces brain metabolism (as determined by positron-emission tomography), and this hypometabolic state rebounds to a level of increased metabolism during detoxification. The magnitude of decrease in metabolic state is determined by the number of years of alcohol use and the age of the patients (Volkow *et al.*, 1994; *see* "Mechanisms of CNS Actions" below).

Cardiovascular System

Serum Lipoproteins and Cardiovascular Effects. In most countries, the risk of mortality due to coronary heart disease (CHD) is correlated with a high dietary intake of saturated fat and elevated serum cholesterol levels. France is an exception to this rule, with relatively low mortality from CHD despite the consumption of high quantities of saturated fats by the French (the "French paradox"). Epidemiological studies suggest that widespread wine consumption (20 to 30 g ethanol per day) is one of the factors conferring a cardioprotective effect, with one to three drinks per day resulting in a 10% to 40% decreased risk of coronary heart disease compared with abstainers. In contrast, daily consumption of greater amounts of alcohol leads to an increased incidence of noncoronary causes of cardiovascular failure, such as arrhythmias, cardiomyopathy, and hemorrhagic stroke, offsetting the beneficial

effects of alcohol on coronary arteries; *i.e.*, alcohol has a J-shaped dose-mortality curve. Reduced risks for CHD are seen at intakes as low as one-half drink per day (Maclure, 1993). Young women and others at low risk for heart disease derive little benefit from light to moderate alcohol intake, whereas those of both sexes who are at high risk and who may have had a myocardial infarction clearly benefit. Data based on a number of prospective, cohort, cross-cultural, and case-control studies in diverse populations consistently reveal lower rates of angina pectoris, myocardial infarction, and peripheral artery disease in those consuming light (1 to 20 g/day) to moderate (21 to 40 g/day) amounts of alcohol.

One possible mechanism by which alcohol could reduce the risk of CHD is through its effects on blood lipids. Changes in plasma lipoprotein levels, particularly increases in high-density lipoprotein (HDL; *see* Chapter 35), have been associated with the protective effects of ethanol. HDL binds cholesterol and returns it to the liver for elimination or reprocessing, decreasing tissue cholesterol levels. Ethanol-induced increases in HDL-cholesterol thus could antagonize cholesterol accumulation in arterial walls, lessening the risk of infarction. Approximately half the risk reduction associated with ethanol consumption is explained by changes in total HDL levels (Langer *et al.*, 1992). HDL is found as two subfractions, named HDL_2 and HDL_3 . Increased levels of HDL_2 (and possibly also HDL_3) are associated with reduced risk of myocardial infarction. Levels of both subfractions are increased following alcohol consumption (Gaziano *et al.*, 1993) and decrease when alcohol consumption ceases. Apolipoproteins A-I and A-II are constituents of HDL; some HDL particles contain only the former, whereas others are composed of both. Increased levels of both apolipoproteins A-I and A-II are associated with individuals who are daily heavy drinkers. In contrast, there are reports of decreased serum apolipoprotein(a) levels following acute alcohol consumption. Elevated apolipoprotein(a) levels have been associated with an increased risk for the development of atherosclerosis.

Although the cardioprotective effects of ethanol initially were noted in wine drinkers, all forms of alcoholic beverages confer cardioprotection. A variety of alcoholic beverages increase HDL levels while decreasing the risk of myocardial infarction. The flavonoids found in red wine (and purple grape juice) may have an additional antiatherogenic role by protecting low-density lipoprotein (LDL) from oxidative damage. Oxidized LDL has been implicated in several steps of atherogenesis (Hillbom *et al.*, 1998). Another way in which alcohol consumption conceivably could play a cardioprotective role is by altering factors involved in blood clotting. The formation of clots is an important step in the genesis of myocardial infarctions, and a number of factors maintain a balance between bleeding and clot dissolution. Alcohol consumption elevates the levels of tissue plasminogen activator, a clot-dissolving enzyme (Ridker *et al.*, 1994; *see* Chapter 54), decreasing the likelihood of clot formation. Decreased fibrinogen concentrations seen following ethanol consumption also could be cardioprotective (Rimm *et al.*, 1999), and epidemiological studies have linked the moderate consumption of ethanol to an inhibition of platelet activation (Rubin, 1999).

Should abstainers from alcohol be advised to consume ethanol in moderate amounts? The answer is *no*. There

have been no randomized clinical trials to test the efficacy of daily alcohol use in reducing rates of coronary heart disease and mortality, and it is inappropriate for physicians to advocate alcohol ingestion solely to prevent heart disease. Many abstainers avoid alcohol because of a family history of alcoholism or for other health reasons, and it is imprudent to suggest that they begin drinking. Other lifestyle changes or medical treatments should be encouraged if patients are at risk for the development of CHD.

Hypertension. Heavy alcohol use can raise diastolic and systolic blood pressure (Klatsky, 1996). Studies indicate a positive, nonlinear association between alcohol use and hypertension that is unrelated to age, education, smoking status, or the use of oral contraceptives. Consumption above 30 g alcohol per day (more than two standard drinks) is associated with a 1.5 to 2.3 mm Hg rise in diastolic and systolic blood pressure. A time effect also has been demonstrated, with diastolic and systolic blood pressure elevation being greatest for persons who consumed alcohol within 24 hours of examination (Moreira *et al.*, 1998). Women may be at greater risk than men (Seppa *et al.*, 1996).

Several hypotheses have been proposed to explain the cause of alcohol-induced hypertension. One hypothesis holds that there is a direct pressor effect of alcohol caused by an unknown mechanism. Studies that have examined levels of renin, angiotensin, norepinephrine, antidiuretic hormone, cortisol, and other pressor mediators have been inconclusive. Newer hypotheses include increased intracellular Ca^{2+} levels with a subsequent increase in vascular reactivity, stimulation of the endothelium to release endothelin, and inhibition of endothelium-dependent NO production (Grogan and Kochar, 1994). Another hypothesis holds that there is an indirect effect. Some hypertensive alcoholic patients abstain before a physician visit (Iwase *et al.*, 1995), and as blood alcohol levels fall, acute withdrawal causes an elevation in blood pressure that is reflected in elevated blood pressure readings in the physician's office.

The prevalence of hypertension attributable to excess alcohol consumption is not known, but studies suggest a range of 5% to 11%. The prevalence probably is higher for men than for women because of higher alcohol consumption by men. A reduction in or cessation of alcohol use in heavy drinkers may reduce the need for antihypertensive medication or reduce the blood pressure to the normal range. A safe amount of alcohol consumption for hypertensive patients who are light drinkers (one to two drinks per occasion and less than 14 drinks per week) has not been determined. Factors to consider are a personal history of ischemic heart disease, a history of binge drinking, or a family history of alcoholism or of cerebrovascular accident. Hypertensive patients with any of these risk factors should abstain from alcohol use.

Cardiac Arrhythmias. Alcohol has a number of pharmacological effects on cardiac conduction, including prolongation of the QT interval, prolongation of ventricular repolarization, and sympathetic stimulation (Rossinen *et al.*, 1999; Kupari and Koskinen, 1998). Atrial arrhythmias associated

with chronic alcohol use include supraventricular tachycardia, atrial fibrillation, and atrial flutter. Some 15% to 20% of idiopathic cases of atrial fibrillation may be induced by chronic ethanol use (Braunwald, 1997). Ventricular tachycardia may be responsible for the increased risk of unexplained sudden death that has been observed in persons who are alcohol-dependent (Kupari and Koskinen, 1998). During continued alcohol use, treatment of these arrhythmias may be more resistant to cardioversion, digoxin, or Ca^{2+} channel blocking agents (*see* Chapter 34). Patients with recurrent or refractory atrial arrhythmias should be questioned carefully about alcohol use.

Cardiomyopathy. Ethanol is known to have dose-related toxic effects on both skeletal and cardiac muscle. Numerous studies have shown that alcohol can depress cardiac contractility and lead to cardiomyopathy (Thomas *et al.*, 1994). Echocardiography demonstrates global hypokinesis. Fatty acid ethyl esters (formed from the enzymatic reaction of ethanol with free fatty acids) appear to play a role in the development of this disorder (Beckmeier and Bora, 1998). Approximately half of all patients with idiopathic cardiomyopathy are alcohol-dependent. Although the clinical signs and symptoms of idiopathic and alcohol-induced cardiomyopathy are similar, alcohol-induced cardiomyopathy has a better prognosis if patients are able to stop drinking. Women are at greater risk of alcohol-induced cardiomyopathy than are men (Urban-Marquez *et al.*, 1995). Since 40% to 50% of persons with alcohol-induced cardiomyopathy who continue to drink die within 3 to 5 years, abstinence remains the primary treatment. Some patients respond to diuretics, angiotensin converting enzyme inhibitors, and vasodilators.

Stroke. Clinical studies indicate an increased incidence of hemorrhagic and ischemic stroke in persons who drink more than 40 to 60 g alcohol per day (Hansagi *et al.*, 1995). Many cases of stroke follow prolonged binge drinking, especially when stroke occurs in younger patients. Proposed etiological factors include alcohol-induced (1) cardiac arrhythmias and associated thrombus formation, (2) high blood pressure from chronic alcohol consumption and subsequent cerebral artery degeneration, (3) acute increases in systolic blood pressure and alterations in cerebral artery tone, and (4) head trauma. The effects on hemostasis, fibrinolysis, and blood clotting are variable and could prevent or precipitate acute stroke (Numminen *et al.*, 1996). The effects of alcohol on the formation of intracranial aneurysms are controversial, but the statistical association disappears when one controls for tobacco use and sex (Qureshi *et al.*, 1998).

Skeletal Muscle

Alcohol has a number of effects on skeletal muscle (Panzak *et al.*, 1998). Chronic, heavy, daily alcohol consumption is associated with decreased muscle strength, even when adjusted for other factors such as age, nicotine use, and chronic illness. Heavy doses of alcohol also can cause irreversible damage to muscle, reflected by a marked increase in the activity of creatine kinase in plasma. Muscle biopsies from heavy drinkers also reveal decreased glycogen stores and reduced pyruvate kinase activity (Vernet *et al.*, 1995). Approximately 50% of chronic heavy drinkers have evidence of type II fiber atrophy. These changes correlate with reductions in muscle protein synthesis and serum carnosinase activities (Wassif *et al.*, 1993). Most patients with chronic alcoholism show electromyographical changes, and many show evidence of a skeletal myopathy similar to alcoholic cardiomyopathy.

Body Temperature

Ingestion of ethanol causes a feeling of warmth because alcohol enhances cutaneous and gastric blood flow. Increased sweating also may occur. Heat, therefore, is lost more rapidly, and the internal body temperature falls. After consumption of large amounts of ethanol, the central temperature-regulating mechanism itself becomes depressed, and the fall in body temperature may become pronounced. The action of alcohol in lowering body temperature is greater and more dangerous when the ambient environmental temperature is low. Studies of deaths from hypothermia suggest that alcohol is a major risk factor in these events. Patients with ischemic limbs secondary to peripheral vascular disease are particularly susceptible to cold damage (Proano and Perbeck, 1994).

Diuresis

Alcohol inhibits the release of vasopressin (antidiuretic hormone; *see* Chapter 29) from the posterior pituitary gland, resulting in enhanced diuresis (Leppaluoto *et al.*, 1992). The volume loading that accompanies imbibing complements the diuresis that occurs as a result of reduced vasopressin secretion. Alcoholics have less urine output than do control subjects in response to a challenge dose with ethanol, suggesting that tolerance develops to the diuretic effects of ethanol (Collins *et al.*, 1992). Alcoholics withdrawing from alcohol exhibit increased vasopressin release and a consequent retention of water, as well as dilutional hyponatremia.

Gastrointestinal System

Esophagus. Alcohol frequently is either the primary etiologic factor or one of multiple causal factors associated with esophageal dysfunction. Ethanol also is associated with the development of esophageal reflux, Barrett's esophagus, traumatic rupture of the esophagus, Mallory-Weiss tears, and esophageal cancer. When compared with nonalcoholic nonsmokers, alcohol-dependent patients who smoke have a tenfold increased risk of developing cancer of the esophagus. There is little change in esophageal function at low blood alcohol concentrations, but at higher blood alcohol concentrations, a decrease in peristalsis and decreased lower esophageal sphincter pressure occur. Patients with chronic reflux esophagitis may respond to proton pump inhibitors (*see* Chapter 36) and abstinence from alcohol.

Stomach. Heavy alcohol use can disrupt the gastric mucosal barrier and cause acute and chronic gastritis. Ethanol appears to stimulate gastric secretions by exciting sensory nerves in the buccal and gastric mucosa and promoting the release of gastrin and histamine. Beverages containing more than 40% alcohol also have a direct toxic effect on gastric mucosa. While these effects are seen most often in chronic heavy drinkers, they can occur after moderate and short-term alcohol use. The diagnosis may not be clear because many patients have normal endoscopic examinations and upper gastrointestinal radiographs. Clinical symptoms include acute epigastric pain that is relieved with antacids or histamine H₂-receptor blockers (*see* Chapter 36).

Alcohol is not thought to play a role in the pathogenesis of peptic ulcer disease. Unlike acute and chronic gastritis, peptic ulcer disease is not more common in alcoholics. Nevertheless, alcohol exacerbates the clinical course and severity of ulcer symptoms. It appears to act synergistically with *Helicobacter pylori* to delay healing (Lieber, 1997a). Acute bleeding from the gastric mucosa, while uncommon, can be a life-threatening emergency. Upper gastrointestinal bleeding is associated more commonly with esophageal varices, traumatic rupture of the esophagus, and clotting abnormalities.

Intestines. Many alcoholics have chronic diarrhea as a result of malabsorption in the small intestine (Addolorato *et al.*, 1997). The major symptom is frequent loose stools. The rectal fissures and pruritus ani that frequently are associated with heavy drinking probably are related to chronic diarrhea. The diarrhea is caused by structural and functional changes in the small intestine (Papa *et al.*, 1998); the intestinal mucosa has flattened villi, and digestive enzyme levels often are decreased. These changes frequently are reversible after a period of abstinence. Treat-

ment is based on replacing essential vitamins and electrolytes, slowing transit time with an agent such as loperamide (see Chapter 38), and abstaining from all alcoholic beverages. Patients with severe magnesium deficiencies (serum magnesium < 1 mEq/L) or symptomatic patients (a positive Chvostek's sign or asterixis) should receive 1 g magnesium sulfate intravenously or intramuscularly every 4 hours until the serum magnesium concentration is greater than 1 mEq/L (Sikkink and Fleming, 1992).

Pancreas. Heavy alcohol use is the most common cause of both acute and chronic pancreatitis in the United States. While pancreatitis has been known to occur after a single episode of heavy alcohol use, prolonged heavy drinking is common in most cases. Acute alcoholic pancreatitis is characterized by the abrupt onset of abdominal pain, nausea, vomiting, and increased levels of serum or urine pancreatic enzymes. Computed tomography is being used increasingly for diagnostic testing. While most attacks are not fatal, hemorrhagic pancreatitis can develop and lead to shock, renal failure, respiratory failure, and death. Management usually involves intravenous fluid replacement—often with nasogastric suction—and opioid pain medication. The etiology of acute pancreatitis probably is related to a direct toxic metabolic effect of alcohol on pancreatic acinar cells. Fatty acid esters and cytokines appear to play a major role (Schenker and Montalvo, 1998).

Two-thirds of patients with recurrent alcoholic pancreatitis will develop chronic pancreatitis. Chronic pancreatitis is treated by replacing the endocrine and exocrine deficiencies that result from pancreatic insufficiency. The development of hyperglycemia often requires insulin for control of blood-sugar levels. Pancreatic enzyme capsules containing lipase, amylase, and proteases may be necessary to treat malabsorption (see Chapter 37). The average lipase dose is 4000 to 24,000 units with each meal and snack. Many patients with chronic pancreatitis develop a chronic pain syndrome. While opioids may be helpful, non-narcotic methods for pain relief such as antiinflammatory drugs, tricyclic antidepressants, exercise, relaxation techniques, and self-hypnosis are preferred treatments for this population because cross-dependence to other drugs is common among alcoholics. In particular, for patients receiving chronic opioid therapy for chronic pancreatitis, treatment contracts and frequent assessments for signs of addiction are important.

Liver. Ethanol produces a constellation of dose-related deleterious effects in the liver (Fickert and Zatloukal, 2000). The primary effects are fatty infiltration of the liver, hepatitis, and cirrhosis. Because of its intrinsic toxicity, alcohol can injure the liver in the absence of dietary deficiencies (Lieber, 1994). The accumulation of fat in the liver is an early event and can occur in normal individuals after the ingestion of relatively small amounts of ethanol. This accumulation results from inhibition of both the tri-

carboxylic acid cycle and the oxidation of fat, in part, owing to the generation of excess NADH produced by the actions of ADH and ALDH (see Figure 22–1).

Fibrosis, resulting from tissue necrosis and chronic inflammation, is the underlying cause of alcoholic cirrhosis. Normal liver tissue is replaced by fibrous tissue. Alcohol can affect stellate cells in the liver directly; chronic alcohol use is associated with transformation of stellate cells into collagen-producing, myofibroblast-like cells (Lieber, 1998), resulting in deposition of collagen around terminal hepatic venules (Worner and Lieber, 1985). The histological hallmark of alcoholic cirrhosis is the formation of Mallory bodies, which are thought to be related to an altered cyokeratin intermediate cytoskeleton (Denk *et al.*, 2000).

A number of molecular mechanisms for alcoholic cirrhosis have been proposed. In nonhuman primate models, alcohol alters phospholipid peroxidation. Ethanol decreases phosphatidylcholine levels in hepatic mitochondria, a change associated with decreased oxidase activity and oxygen consumption (Lieber *et al.*, 1994a,b). Cytokines, such as transforming growth factor β and tumor necrosis factor α , can increase rates of fibrinogenesis and fibrosis in the liver (McClain *et al.*, 1993). Acetaldehyde is thought to have a number of adverse effects, including depletion of glutathione (Lieber, 2000), depletion of vitamins and trace metals, and decreased transport and secretion of proteins owing to inhibition of tubulin polymerization (Lieber, 1997b). *Acetaminophen*-induced hepatic toxicity (see Chapter 26) has been associated with alcoholic cirrhosis as a result of alcohol-induced increases in microsomal production of toxic acetaminophen metabolites (Whitcomb and Block, 1994). Liver failure secondary to cirrhosis and resulting in impaired clearance of toxins such as ammonia (see discussion of lactulose in Chapter 38) also may contribute to alcohol-induced hepatic encephalopathy. Ethanol also appears to increase intracellular free hydroxy-ethyl radical formation (Mantle and Preedy, 1999), and there is evidence that endotoxins may play a role in the initiation and exacerbation of alcohol-induced liver disease. Hepatitis C appears to be an important cofactor in the development of end-stage alcoholic liver disease (Regev and Jeffers, 1999).

Several strategies to treat alcoholic liver disease have been evaluated. *Prednisolone* may improve survival in patients with hepatic encephalopathy (Lieber, 1998). Nutrients such as *S-adenosylmethionine* and *polyunsaturated lecithin* have been found to have beneficial effects in nonhuman primates and are undergoing clinical trials. Other medications that have been tested include *oxandrolone*, *propylthiouracil* (Orrego *et al.*, 1987), and *colchicine* (Lieber, 1997b). At present, however, none of these drugs is approved for use in the United States for the treatment of alcoholic liver disease. The current primary treatment for liver failure is transplantation in conjunction with abstinence from ethanol. Long-term outcome studies suggest that patients who are alcohol-dependent have survival rates similar to those of patients with other types of liver disease. Alcoholics with hepatitis C may respond to interferon-2 α (McCullough and O'Connor, 1998) (see Chapter 52).

Vitamins and Minerals

The almost complete lack of protein, vitamins, and most other nutrients in alcoholic beverages predisposes those

who consume large quantities of alcohol to nutritional deficiencies. Alcoholics often present with these deficiencies owing to decreased intake, decreased absorption, or impaired utilization of nutrients. The peripheral neuropathy, Korsakoff's psychosis, and Wernicke's encephalopathy seen in alcoholics probably are caused by deficiencies of the B complex of vitamins (particularly thiamine), although direct toxicity produced by alcohol itself has not been ruled out (Harper, 1998). Chronic alcohol abuse decreases the dietary intake of retinoids and carotenoids and enhances the metabolism of retinol by the induction of degradative enzymes (Leo and Lieber, 1999). Retinol and ethanol compete for metabolism by ADH; vitamin A supplementation therefore should be monitored carefully in alcoholics when they are consuming alcohol to avoid retinol-induced hepatotoxicity. The chronic consumption of alcohol inflicts an oxidative stress on the liver owing to the generation of free radicals, contributing to ethanol-induced liver injury. The antioxidant effects of α -tocopherol (vitamin E) may ameliorate some of this ethanol-induced toxicity in the liver (Nordmann, 1994). Plasma levels of α -tocopherol often are reduced in myopathic alcoholics compared with alcoholic patients without myopathy.

Chronic alcohol consumption has been implicated in osteoporosis (*see* Chapter 61). The reasons for this decreased bone mass remain unclear, although impaired osteoblastic activity has been implicated. Acute administration of ethanol produces an initial reduction in serum parathyroid hormone (PTH) and Ca^{2+} levels, followed by a rebound increase in PTH that does not restore Ca^{2+} levels to normal. The hypocalcemia observed after chronic alcohol intake also appears to be unrelated to effects of alcohol on PTH levels, and alcohol likely inhibits bone remodeling by a mechanism independent of Ca^{2+} -regulating hormones (Sampson, 1997). Vitamin D also may play a role. Since vitamin D requires hydroxylation in the liver for activation, alcohol-induced liver damage can indirectly affect the role of vitamin D in the intestinal and renal absorption of Ca^{2+} .

Alcoholics tend to have lowered serum and brain levels of magnesium, which may contribute to their predisposition to brain injuries such as stroke (Altura and Altura, 1999). Deficits in intracellular magnesium levels may disturb cytoplasmic and mitochondrial bioenergetic pathways, potentially leading to calcium overload and ischemia. Although there is general agreement that total magnesium levels are decreased in alcoholics, it is less clear that this also applies to ionized Mg^{2+} , the physiologically active form (Hristova *et al.*, 1997). Magnesium sulfate sometimes is used in the treatment of alcohol with-

drawal, but its efficacy has been questioned (Erstad and Cotugno, 1995).

Sexual Function

Despite the widespread belief that alcohol can enhance sexual activities, the opposite effect is noted more often. Many drugs of abuse, including alcohol, have disinhibiting effects that may lead initially to increased libido. With excessive, long-term use, however, alcohol often leads to a deterioration of sexual function. While alcohol cessation may reverse many sexual problems, patients with significant gonadal atrophy are less likely to respond to discontinuation of alcohol consumption (Sikkink and Fleming, 1992).

Both acute and chronic alcohol use can lead to impotence in men. Increased blood alcohol concentrations lead to decreased sexual arousal, increased ejaculatory latency, and decreased orgasmic pleasure. The incidence of impotence may be as high as 50% in patients with chronic alcoholism. Additionally, many chronic alcoholics develop testicular atrophy and decreased fertility. The mechanism involved in this is complex and likely involves altered hypothalamic function and a direct toxic effect of alcohol on Leydig cells. Testosterone levels may be depressed, but many men who are alcohol-dependent have normal testosterone and estrogen levels. Gynecomastia is associated with alcoholic liver disease and is related to increased cellular response to estrogen and to accelerated metabolism of testosterone.

Sexual function in alcohol-dependent women is less clearly understood. Many female alcoholics complain of decreased libido, decreased vaginal lubrication, and menstrual cycle abnormalities. Their ovaries often are small and without follicular development. Some data suggest that fertility rates are lower for alcoholic women. The presence of comorbid disorders such as anorexia nervosa or bulimia can aggravate the problem. The prognosis for men and women who become abstinent is favorable in the absence of significant hepatic or gonadal failure (O'Farrell *et al.*, 1997).

Hematological and Immunological Effects

Chronic alcohol use is associated with a number of anemias. Microcytic anemia can occur because of chronic blood loss and iron deficiency. Macrocytic anemias and increases in mean corpuscular volume are common and may occur in the absence of vitamin deficiencies. Normochromic anemias also can occur owing to effects of chronic illness on hematopoiesis. In the presence of severe liver disease, morphological changes can include the development of burr cells, schistocytes, and ringed sideroblasts. Alcohol-induced sideroblastic anemia may respond to vitamin B₆ replacement (Wartenberg, 1998). Alcohol use also is associated with reversible thrombocytopenia, although platelet counts under 20,000/mm³ are rare. Bleeding is uncommon unless there is an alteration in vitamin K₁-dependent clotting factors (*see* Chapter

54); proposed mechanisms have focused on platelet trapping in the spleen and marrow.

Alcohol also affects granulocytes and lymphocytes (Schirmer *et al.*, 2000). Effects include leukopenia, alteration of lymphocyte subsets, decreased T-cell mitogenesis, and changes in immunoglobulin production. These disorders may play a role in alcohol-related liver disease. In some patients, depressed leukocyte migration into inflamed areas may account in part for the poor resistance of alcoholics to some types of infection (*e.g.*, *Klebsiella pneumoniae*, listeriosis, and tuberculosis). Alcohol consumption also may alter the distribution and function of lymphoid cells by disrupting cytokine regulation, in particular that involving interleukin 2 (IL-2). Alcohol appears to play a role in the development of infection with the human immunodeficiency virus-1 (HIV). *In vitro* studies with human lymphocytes suggest that alcohol can suppress CD4 T-lymphocyte function and concanavalin A-stimulated IL-2 production and enhance *in vitro* replication of HIV. Moreover, persons who abuse alcohol have higher rates of high-risk sexual behavior.

ACUTE ETHANOL INTOXICATION

An increased reaction time, diminished fine motor control, impulsivity, and impaired judgment become evident when the concentration of ethanol in the blood is 20 to 30 mg/dl. More than 50% of persons are grossly intoxicated by a concentration of 150 mg/dl. In fatal cases, the average concentration is about 400 mg/dl, although alcohol-tolerant individuals often can withstand comparable blood alcohol levels. The definition of intoxication varies by state and country. In the United States, most states set the ethanol level defined as intoxication at 80 mg/dl. There is increasing evidence that lowering the limit to 50 to 80 mg/dl can reduce motor vehicle injuries and fatalities significantly. While alcohol can be measured in saliva, urine, sweat, and blood, measurement of levels in exhaled air remains the primary method of assessing the level of intoxication.

Many factors, such as body weight and composition and the rate of absorption from the gastrointestinal tract, determine the concentration of ethanol in the blood after ingestion of a given amount of ethanol. On average, the ingestion of three standard drinks (42 g ethanol) on an empty stomach results in a maximum blood concentration of 67 to 92 mg/dl in men. After a mixed meal, the maximal blood concentration from three drinks is 30 to 53 mg/dl in men. Concentrations of alcohol in blood will be

higher in women than in men consuming the same amount of alcohol because, on average, women are smaller than men, have less body water per unit of weight into which ethanol can distribute, and have less gastric ADH activity than men. For individuals with normal hepatic function, ethanol is metabolized at a rate of one standard drink every 60 to 90 minutes.

The characteristic signs and symptoms of alcohol intoxication are well known. Nevertheless, an erroneous diagnosis of drunkenness may occur with patients who appear inebriated but who have not ingested ethanol. Diabetic coma, for example, may be mistaken for severe alcoholic intoxication. Drug intoxication, cardiovascular accidents, and skull fractures also may be confused with alcohol intoxication. The odor of the breath of a person who has consumed ethanol is due not to ethanol vapor but to impurities in alcoholic beverages. Breath odor in a case of suspected intoxication can be misleading because there can be other causes of breath odor similar to that after alcohol consumption. Blood alcohol levels are necessary to confirm the presence or absence of alcohol intoxication (Schuckit, 1995).

The treatment of acute alcohol intoxication is based on the severity of respiratory and CNS depression. Acute alcohol intoxication can be a medical emergency, and a number of young people die every year from this disorder. Patients who are comatose and who exhibit evidence of respiratory depression should be intubated to protect the airway and to provide ventilatory assistance. The stomach may be lavaged, but care must be taken to prevent pulmonary aspiration of the return flow. Since ethanol is freely miscible with water, ethanol can be removed from blood by hemodialysis (Schuckit, 1995).

Acute alcohol intoxication is not always associated with coma, and careful observation is the primary treatment. Usual care involves observing the patient in the emergency room for 4 to 6 hours while the patient metabolizes the ingested ethanol. Blood alcohol levels will be reduced at a rate of about 15 mg/dl per hour. During this period, some individuals may display extremely violent behavior. Sedatives and antipsychotic agents have been employed to quiet such patients. Great care must be taken, however, when using sedatives to treat patients who have ingested an excessive amount of another CNS depressant, *i.e.*, ethanol, because of synergistic effects.

CLINICAL USES OF ETHANOL

Dehydrated alcohol may be injected in close proximity to nerves or sympathetic ganglia to relieve the long-lasting pain related to trigeminal neuralgia, inoperable carcinoma, and other conditions. Epidural, subarachnoid, and lumbar paravertebral injections of ethanol also

have been employed for inoperable pain. For example, lumbar paravertebral injections of ethanol may destroy sympathetic ganglia and thereby produce vasodilation, relieve pain, and promote healing of lesions in patients with vascular disease of the lower extremities.

Systemically administered ethanol is confined to the treatment of poisoning by methyl alcohol and ethylene glycol. The ingestion results in formation of methanol's metabolites, formaldehyde and formic acid (Figure 22–1). Formic acid causes nerve damage; its effects on the retina and optic nerve can cause blindness. Treatment consists of sodium bicarbonate to combat acidosis, hemodialysis, and the administration of ethanol, which slows formate production by competing with methanol for metabolism by alcohol dehydrogenase.

The use of alcohol to treat patients in alcohol withdrawal or obstetrical patients with premature contractions is no longer recommended. Some medical centers continue to use alcohol to prevent or reduce the risk of alcohol withdrawal in postoperative patients, but administering a combination of a benzodiazepine with haloperidol or clonidine may be more appropriate (Spies and Rommelspacher, 1999).

MECHANISMS OF CNS EFFECTS OF ETHANOL

Acute Intoxication

Alcohol perturbs the balance between excitatory and inhibitory influences in the brain, resulting in anxiolysis, ataxia, and sedation. This is accomplished by either enhancing inhibitory or antagonizing excitatory neurotransmission. Although ethanol was long thought to act nonspecifically by disordering lipids in cell membranes, it now is believed that proteins constitute the primary molecular sites of action for ethanol. A number of putative sites at which ethanol may act have been identified, and ethanol likely produces its effects by simultaneously altering the functioning of a number of proteins that can affect neuronal excitability. A key issue has been to identify proteins that determine neuronal excitability and are sensitive to ethanol at the concentrations (5 to 20 mM) that produce behavioral effects.

Ion Channels. A number of ion channels in the CNS are sensitive to ethanol, including representatives of the ligand-gated and G protein-coupled receptor families and voltage-gated ion channels. The primary mediators of inhibitory neurotransmission in the brain are the ligand-gated γ -aminobutyric acid A (GABA_A) receptors, whose function is markedly enhanced by a number of classes of sedative, hypnotic, and anesthetic agents, including barbiturates, benzodiazepines, and volatile anesthetics (see Chapter 12). Substantial biochemical, electrophysiological, and behavioral data implicate the GABA_A receptor as an important target for the *in vivo* actions of ethanol. *Bicuculline*, a GABA_A-receptor antagonist, and antagonists at the benzodiazepine-binding site on GABA_A receptors decrease alcohol consumption in animal models. Furthermore, administration of the GABA_A-receptor agonist *muscimol* into specific regions of

the limbic system in rats can substitute for ethanol in discrimination studies (Mihic, 1999). Subunit composition (especially δ) (Wallner *et al.*, 2003) and phosphorylation state (Kumar *et al.*, 2004) of the GABA_A receptor affect its sensitivity to ethanol.

Neuronal nicotinic acetylcholine receptors (see Chapter 8) also may be prominent molecular targets of alcohol (Narahashi *et al.*, 1999). Both enhancement and inhibition of nicotinic acetylcholine receptor function have been reported depending on receptor subunit concentration and the concentrations of ethanol tested. Effects of ethanol on these receptors may be particularly important because there is an association between nicotine exposure (smoking) and alcohol consumption in human beings. Furthermore, several studies indicate that nicotine increases alcohol consumption in animal models (Smith *et al.*, 1999).

Excitatory ionotropic glutamate receptors are divided into the *N*-methyl-D-aspartate (NMDA) and non-NMDA receptor classes, with the latter consisting of kainate- and AMPA-receptor subtypes (see Chapter 12). Ethanol inhibits the function of the NMDA- and kainate-receptor subtypes; AMPA receptors are largely resistant to alcohol (Carta *et al.*, 2003). As with the GABA_A receptors, phosphorylation of the glutamate receptor can determine sensitivity to ethanol. The tyrosine kinase Fyn phosphorylates NMDA receptors, rendering them less sensitive to inhibition by ethanol (Anders *et al.*, 1999) and perhaps explaining why knockout mice lacking Fyn display significantly greater sensitivity to the hypnotic effects of ethanol. A number of other types of channels are sensitive to alcohol at concentrations routinely achieved *in vivo*. Ethanol enhances the activity of large conductance, Ca²⁺-activated K⁺ channels in neurohypophyseal terminals (Dopico *et al.*, 1999), perhaps contributing to the reduced release of oxytocin and vasopressin after ethanol consumption. Ethanol also inhibits *N*- and *P/Q*-type Ca²⁺ channels in a manner that can be antagonized by channel phosphorylation by PKA (Solem *et al.*, 1997). BK potassium channels also are a target for alcohol action (Davies *et al.*, 2003). The diverse effects of ethanol on ion channels and other signaling proteins may be due to its ability to replace water in protein cavities (Trudell and Harris, 2004).

Protein Kinases and Signaling Enzymes. Phosphorylation by a number of protein kinases can affect the functioning of many receptors. The behavioral consequences of this were illustrated in knockout mice lacking the γ isoform of PKC; these mice display reduced effects of ethanol measured behaviorally and a loss of enhancement by ethanol of GABA's effects measured *in vitro* (Harris *et al.*, 1995). There is some uncertainty as to whether ethanol interacts directly with PKC. Intracellular signal-transduction cascades, such as those involving mitogen-activated protein kinase (MAPK), tyrosine kinases, and neurotrophic factor receptors, also are thought to be affected by ethanol (Valenzuela and Harris, 1997). Translocation of PKC and PKA between subcellular compartments also is sensitive to alcohol (Constantinescu *et al.*, 1999).

Ethanol enhances the activities of some of the nine isoforms of adenylyl cyclase, with the type VII isoform being the most sensitive (Tabakoff and Hoffman, 1998). This promotes increased production of cyclic AMP and thus increased activity of PKA. Ethanol's actions appear to be mediated by activation of G_s, as well as by promotion of the interaction between G_s and adenylyl cyclase. Decreased adenylyl cyclase activities have been reported in alcoholics and even in nondrinkers with family histories of alcoholism, suggesting that lowered adenylyl cyclase activity may be a trait marker for alcoholism (Menninger *et al.*, 1998).

Tolerance and Dependence

Tolerance is defined as a reduced behavioral or physiological response to the same dose of ethanol (*see* Chapter 23). There is a marked acute tolerance that is detectable soon after administration of ethanol. Acute tolerance can be demonstrated by measuring behavioral impairment at the same BALs on the ascending limb of the absorption phase of the BAL–time curve (minutes after ingestion of alcohol) and on the descending limb of the curve as BALs are lowered by metabolism (one or more hours after ingestion). Behavioral impairment and subjective feelings of intoxication are much greater at a given BAL on the ascending than on the descending limb. There also is a chronic tolerance that develops in the long-term heavy drinker. In contrast to acute tolerance, chronic tolerance often has a metabolic component owing to induction of alcohol-metabolizing enzymes.

Physical dependence is demonstrated by the elicitation of a withdrawal syndrome when alcohol consumption is terminated. The symptoms and severity are determined by the amount and duration of alcohol consumption and include sleep disruption, autonomic nervous system (sympathetic) activation, tremors, and in severe cases, seizures. In addition, two or more days after withdrawal, some individuals experience *delirium tremens*, characterized by hallucinations, delirium, fever, and tachycardia. Delirium tremens can be fatal. Another aspect of dependence is craving and drug-seeking behavior, often termed *psychological dependence*.

Ethanol tolerance and physical dependence are studied readily in animal models. Strains of mice with genetic differences in tolerance and dependence have been characterized, and a search for the relevant genes is under way (Crabbe, 2002). Neurobiological mechanisms of tolerance and dependence are not understood completely, but chronic alcohol consumption results in changes in synaptic and intracellular signaling likely owing to changes in gene expression. Most of the systems that are acutely affected by ethanol also are affected by chronic exposure, resulting in an adaptive or maladaptive response that can cause tolerance and dependence. In particular, chronic actions of ethanol likely require changes in signaling by glutamate and GABA receptors and intracellular systems such as PKC (Diamond and Gordon, 1997). There is an increase in NMDA-receptor function after chronic alcohol ingestion that may contribute to the CNS hyperexcitability and neurotoxicity seen during ethanol withdrawal (Chandler *et al.*, 1998). Arginine vasopressin, acting on V₁ receptors, maintains tolerance to ethanol in laboratory animals even after chronic ethanol administration has ceased (Hoffman *et al.*, 1990).

The neurobiological basis of the switch from controlled, volitional alcohol use to compulsive and uncontrolled addiction remains obscure. Impairment of the dopaminergic reward system and the resulting increase in alcohol consumption in an attempt to regain activation of the system is a possibility. In addition, the prefrontal cortex is particularly sensitive to damage from alcohol abuse and influences decision making and emotion, processes clearly compromised in the

alcoholic (Pfefferbaum *et al.*, 1998). Thus, impairment of executive function in cortical regions by chronic alcohol consumption may be responsible for some of the lack of judgment and control that is expressed as obsessive alcohol consumption. The loss of brain volume and impairment of function seen in the chronic alcoholic is at least partially reversible by abstinence but will worsen with continued drinking (Pfefferbaum *et al.*, 1998). Early diagnosis and treatment of alcoholism are important in limiting the brain damage that promotes the progression to severe addiction.

Genetic Influences

The concept of alcoholism as a disease was first articulated by Jellinek in 1960; the subsequent acceptance of alcoholism and addiction as “brain diseases” led to a search for biological causes. Studies of rats and mice carried out in Chile, Finland, and the United States showed significant heritabilities (roughly 60%) for many behavioral actions of alcohol, including sedation, ataxia, and most notably, consumption (Crabbe, 2002). It has long been appreciated that alcoholism “runs in families”; a series of adoption (cross-fostering) and twin studies showed that human alcohol dependence does, indeed, have a genetic component. Although the genetic contribution varies among studies, it generally is in the range of 40% to 60%, which means that environmental variables also are critical for individual susceptibility to alcoholism.

The search for the genes and alleles responsible for alcoholism is complicated by the polygenetic nature of the disease and the general difficulty in defining multiple genes responsible for complex diseases. One fruitful area of research has been the study of why some populations (mainly Asian) are protected from alcoholism. This has been attributed to genetic differences in alcohol- and aldehyde-metabolizing enzymes. Specifically, genetic variants of ADH that exhibit high activity and variants of ALDH that exhibit low activity protect against heavy drinking. This is so because alcohol consumption by individuals who have these variants results in accumulation of acetaldehyde, which produces a variety of unpleasant effects (Li, 2000). These effects are similar to those of disulfiram therapy (*see* below), but the prophylactic, genetic form of inhibition of alcohol consumption is more effective than the pharmacotherapeutic approach, which is applied after alcoholism has developed.

In contrast to these protective genetic variants, there are little consistent data about genes responsible for increased risk for alcoholism. Several large-scale genetic studies of alcoholism currently are in progress, and these efforts, together with genetic studies in laboratory animals, may lead to identification of genes influencing susceptibility to alcoholism. These studies also may allow genetic classification of subtypes of alcoholism and thereby resolve some of the inconsistencies among study populations. For example, antisocial alcoholism is linked with a polymorphism in a serotonin receptor (5-HT_{1B}), but there is no association of this gene with non-antisocial alcoholism (Lappalainen *et al.*, 1998).

Another approach to understanding the inherited biology of alcoholism is to ask what behavioral or functional differences exist between individuals with high and low genetic risks for alcoholism.

This may be accomplished by studying young social drinkers with many or few alcoholic relatives [family history–positive (FHP) and family history–negative (FHN)]. Brain imaging by positron-emission tomography has been used in this context. A family history of alcoholism is linked to lower cerebellar metabolism and a blunted effect of a benzodiazepine (lorazepam) on cerebellar metabolism (Volkow *et al.*, 1995). Because GABA_A receptors are the molecular site of benzodiazepine action, these results suggest that a genetic predisposition to alcoholism may be reflected in abnormal GABA_A receptor function.

Schuckit and colleagues have studied actions of alcohol in FHP college students and have followed the study subjects for almost 20 years to determine which ones will develop alcoholism or alcohol abuse. Remarkably, a blunted behavioral and physiological response to alcohol in the original test is associated with a significantly greater risk for later development of alcohol-related problems (Schuckit and Smith, 2000). Studies with twins indicate a common genetic vulnerability for alcohol and nicotine dependence (True *et al.*, 1999), which is consistent with the high rate of smoking among alcoholics.

TERATOGENIC EFFECTS: FETAL ALCOHOL SYNDROME

In 1968, French researchers noted that children born to alcoholic mothers displayed a common pattern of distinct dysmorphism that later came to be known as *fetal alcohol syndrome* (FAS) (Lemoine *et al.*, 1968; Jones and Smith, 1973). The diagnosis of FAS typically is based on the observance of a triad of abnormalities in the newborn, including (1) a cluster of craniofacial abnormalities, (2) CNS dysfunction, and (3) pre- and/or postnatal stunting of growth. Hearing, language, and speech disorders also may become evident as the child ages (Church and Kaltenbach, 1997). Children who do not meet all the criteria for a diagnosis of FAS still may show physical and mental deficits consistent with a partial phenotype, termed *fetal alcohol effects* (FAEs) or *alcohol-related neurodevelopmental disorders*. The incidence of FAS is believed to be in the range of 0.5 to 1 per 1000 live births in the general U.S. population, with rates as high as 2 to 3 per 1000 in African-American and Native-American populations. A lower socioeconomic status of the mother rather than racial background *per se* appears to be primarily responsible for the higher incidence of FAS observed in those groups (Abel, 1995). The incidence of FAEs is likely higher than that of FAS, making alcohol consumption during pregnancy a major public health problem.

Craniofacial abnormalities commonly observed in the diagnosis of FAS consist of a pattern of microcephaly, a long and smooth philtrum, shortened palpebral fissures, a flat midface, and epicanthal folds. Magnetic resonance imaging studies demonstrate decreased volumes in the basal ganglia, corpus callosum, cerebrum, and cerebellum (Mattson *et*

al., 1992). The severity of alcohol effects can vary greatly and depends on the drinking patterns and amount of alcohol consumed by the mother. Maternal drinking in the first trimester has been associated with craniofacial abnormalities; facial dysmorphism also is seen in mice exposed to ethanol at the equivalent time in gestation.

CNS dysfunction following *in utero* exposure to alcohol manifests in the form of hyperactivity, attention deficits, mental retardation, and learning disabilities. FAS is the most common cause of preventable mental retardation in the Western world (Abel and Sokol, 1987), with afflicted children consistently scoring lower than their peers on a variety of IQ tests. It now is clear that FAS represents the severe end of a spectrum of alcohol effects. A number of studies have documented intellectual deficits, including mental retardation, in children not displaying the craniofacial deformities or retarded growth seen in FAS. Although cognitive improvements are seen with time, decreased IQ scores of FAS children tend to persist as they mature, indicating that the deleterious prenatal effects of alcohol are irreversible. Although a correlation exists between the amount of alcohol consumed by the mother and infant scores on mental and motor performance tests, there is considerable variation in performance on such tests among children of mothers consuming similar quantities of alcohol. The peak BAL reached may be a critical factor in determining the severity of deficits seen in the offspring. Although the evidence is not conclusive, there is a suggestion that even moderate alcohol consumption (two drinks per day) in the second trimester of pregnancy is correlated with impaired academic performance of offspring at age 6 (Goldschmidt *et al.*, 1996). Maternal age also may be a factor. Pregnant women over age 30 who drink alcohol create greater risks to their children than do younger women who consume similar amounts of alcohol (Jacobson *et al.*, 1996).

Children exposed prenatally to alcohol most frequently present with attentional deficits and hyperactivity, even in the absence of intellectual deficits or craniofacial abnormalities. Furthermore, attentional problems have been observed in the absence of hyperactivity, suggesting that the two phenomena are not necessarily related. Fetal alcohol exposure also has been identified as a risk factor for alcohol abuse by adolescents (Baer *et al.*, 1998). Apart from the risk of FAS or FAEs to the child, the intake of high amounts of alcohol by a pregnant woman, particularly during the first trimester, greatly increases the chances of spontaneous abortion.

Studies with laboratory animals have demonstrated many of the consequences of *in utero* exposure to ethanol observed in human beings, including hyperactivity, motor dysfunction, and learning deficits. In animals, *in utero* exposure to ethanol alters the expression patterns of a wide variety of proteins, changes neuronal migration patterns, and results in brain region–specific and cell type–specific alterations in neuronal numbers. Indeed, specific periods of vulnerability may exist for particular neuronal populations in the brain. Genetics also may play a role in determining vulnerability to ethanol: There are differences among strains of rats in susceptibility to the prenatal effects of ethanol. Finally, multidrug abuse, such as the concomitant administration of cocaine with ethanol, enhances fetal damage and mortality.

PHARMACOTHERAPY OF ALCOHOLISM

Currently, three drugs are approved in the United States for treatment of alcoholism: *disulfiram* (ANTABUSE), *nal-*

traxone (REVIA), and *acamprosate*. Disulfiram has a long history of use but has fallen into disfavor because of its side effects and problems with patient adherence to therapy. Naltrexone and acamprosate were introduced more recently. The goal of these medications is to assist the patient in maintaining abstinence.

Naltrexone

Naltrexone was approved by the FDA for treatment of alcoholism in 1994. It is chemically related to the highly selective opioid-receptor antagonist *naloxone* (NARCAN) but has higher oral bioavailability and a longer duration of action. Neither drug has appreciable opioid-receptor agonist effects. These drugs were used initially in the treatment of opioid overdose and dependence because of their ability to antagonize all the actions of opioids (*see* Chapters 21 and 23). Animal research and clinical experience suggested that naltrexone might reduce alcohol consumption and craving; this was confirmed in clinical trials (*see* O'Malley *et al.*, 2000; Johnson and Ait-Daoud, 2000). There is evidence that naltrexone blocks activation by alcohol of dopaminergic pathways in the brain that are thought to be critical to reward.

Naltrexone helps to maintain abstinence by reducing the urge to drink and increasing control when a "slip" occurs. It is not a "cure" for alcoholism and does not prevent relapse in all patients. Naltrexone works best when used in conjunction with some form of psychosocial therapy, such as cognitive behavioral therapy (Anton *et al.*, 1999). It typically is administered after detoxification and given at a dose of 50 mg/day for several months. Adherence to the regimen is important to ensure the therapeutic value of naltrexone and has proven to be a problem for some patients (Johnson and Ait-Daoud, 2000). The most common side effect of naltrexone is nausea, which is more common in women than in men and subsides if the patients abstain from alcohol (O'Malley *et al.*, 2000). When given in excessive doses, naltrexone can cause liver damage. It is contraindicated in patients with liver failure or acute hepatitis and should be used only after careful consideration in patients with active liver disease.

Nalmefene (REVEX) is another opioid antagonist that appears promising in preliminary clinical tests (Mason *et al.*, 1999). It has a number of advantages over naltrexone, including greater oral bioavailability, longer duration of action, and lack of dose-dependent liver toxicity.

Disulfiram

Disulfiram (tetraethylthiuram disulfide; ANTABUSE) was taken in the course of an investigation of its potential anthelmintic efficacy by two Danish physicians, who became ill at a cocktail party and were quick to realize that the compound had altered their responses to alcohol. They initiated a series of pharmacological and clinical studies

that provided the basis for the use of disulfiram as an adjunct in the treatment of chronic alcoholism. Similar responses to alcohol ingestion are produced by various congeners of disulfiram, namely, *cyanamide*, the fungus *Coprinus atramentarius*, the hypoglycemic *sulfonylureas*, *metronidazole*, certain *cephalosporins*, and animal charcoal.

Disulfiram, given alone, is a relatively nontoxic substance, but it inhibits ALDH activity and causes the blood acetaldehyde concentration to rise to 5 to 10 times above the level achieved when ethanol is given to an individual not pretreated with disulfiram. Acetaldehyde, produced as a result of the oxidation of ethanol by ADH, ordinarily does not accumulate in the body because it is further oxidized almost as soon as it is formed primarily by ALDH. Following the administration of disulfiram, both cytosolic and mitochondrial forms of ALDH are irreversibly inactivated to varying degrees, and the concentration of acetaldehyde rises. It is unlikely that disulfiram itself is responsible for the enzyme inactivation *in vivo*; several active metabolites of the drug, especially diethylthiomethylcarbamate, behave as suicide-substrate inhibitors of ALDH *in vitro*. These metabolites reach significant concentrations in plasma following the administration of disulfiram (Johansson, 1992).

The ingestion of alcohol by individuals previously treated with disulfiram gives rise to marked signs and symptoms of acetaldehyde poisoning. Within 5 to 10 minutes, the face feels hot and soon afterward becomes flushed and scarlet in appearance. As the vasodilation spreads over the whole body, intense throbbing is felt in the head and neck, and a pulsating headache may develop. Respiratory difficulties, nausea, copious vomiting, sweating, thirst, chest pain, considerable hypotension, orthostatic syncope, marked uneasiness, weakness, vertigo, blurred vision, and confusion are observed. The facial flush is replaced by pallor, and the blood pressure may fall to shock levels.

Alarming reactions may result from the ingestion of even small amounts of alcohol in persons being treated with disulfiram. The use of disulfiram as a therapeutic agent thus is not without danger, and it should be attempted only under careful medical and nursing supervision. Patients must be warned that as long as they are taking disulfiram, the ingestion of alcohol in any form will make them sick and may endanger their lives. Patients must learn to avoid disguised forms of alcohol, as in sauces, fermented vinegar, cough syrups, and even after-shave lotions and back rubs.

The drug never should be administered until the patient has abstained from alcohol for at least 12 hours. In the initial phase of treatment, a maximal daily dose of 500 mg is given for 1 to 2 weeks. Maintenance dosage then ranges from 125 to 500 mg daily depending on tolerance to side effects. Unless sedation is prominent, the daily dose should be taken in the morning, the time when the resolve not to drink may be strongest. Sensitization to alcohol may last as long as 14 days after the last ingestion of disulfiram because of the slow rate of restoration of ALDH (Johansson, 1992).

Disulfiram and/or its metabolites can inhibit many enzymes with crucial sulfhydryl groups, and it thus has a wide spectrum of biological effects. It inhibits hepatic CYPs and thereby interferes with the metabolism of *phenytoin*, *chlordiazepoxide*, *barbiturates*, *warfarin*, and other drugs.

Disulfiram by itself usually is innocuous, but it may cause acne-form eruptions, urticaria, lassitude, tremor, restlessness, headache, dizziness, a garlic-like or metallic taste, and mild GI disturbances. Peripheral neuropathies, psychosis, and ketosis also have been reported.

Acamprosate

Acamprosate (*N*-acetylhomotaurine, calcium salt), an analogue of GABA, is used widely in Europe for the treatment of alcoholism and was approved recently for use in the United States. A number of double-blind, placebo-controlled studies have demonstrated that acamprosate decreases drinking frequency and reduces relapse drinking in abstinent alcoholics. It acts in a dose-dependent manner (1.3 to 2 g/day) (Paille *et al.*, 1995) and appears to have efficacy similar to that of naltrexone. Studies in laboratory animals have shown that acamprosate decreases alcohol intake without affecting food or water consumption. Acamprosate generally is well tolerated by patients, with diarrhea being the main side effect (Garbutt *et al.*, 1999). No abuse liability has been noted. The drug undergoes minimal metabolism in the liver, is excreted primarily by the kidneys, and has an elimination half-life of 18 hours after oral administration (Wilde and Wagstaff, 1997). Concomitant use of disulfiram appears to increase the effectiveness of acamprosate, without any adverse drug interactions being noted (Besson *et al.*, 1998). The mechanism of action of acamprosate is obscure, although there is some evidence that it modulates the function of NMDA receptors in brain (Johnson and Ait-Daoud, 2000).

Other Agents

Ondansetron, a 5-HT₃-receptor antagonist and antiemetic drug (see Chapters 11 and 37), reduces alcohol consumption in laboratory animals and currently is being tested in humans. Preliminary findings suggest that ondansetron is effective in the treatment of early-onset alcoholics, who respond poorly to psychosocial treatment alone, although the drug does not appear to work well in other types of alcoholics (Johnson and Ait-Daoud, 2000). Ondansetron administration lowers the amount of alcohol consumed, particularly by drinkers who consume fewer than 10 drinks per day (Sellers *et al.*, 1994). It also decreases the subjective effects of ethanol on 6 of 10 scales measured, including the desire to drink (Johnson *et al.*, 1993), while at the same time not having any effect on the pharmacokinetics of ethanol.

Topiramate, a drug used for treating seizure disorders (see Chapter 19), appears useful for treating alcohol dependence. Compared with the placebo group, patients taking topiramate achieved more abstinent days and a lower craving for alcohol (Johnson *et al.*, 2003). The mechanism of action of topiramate is not well understood but is distinct from that of other drugs used for the treatment of dependence (*e.g.*, opioid antagonists), suggesting that it may provide a new and unique approach to pharmacotherapy of alcoholism.

DRUG ADDICTION AND DRUG ABUSE

Charles P. O'Brien

DRUG DEPENDENCE

There are many misunderstandings about the origins and even the definitions of drug abuse and addiction. Although many physicians are concerned about “creating addicts,” relatively few individuals begin their drug addiction problems by misuse of prescription drugs. Confusion exists because the correct use of prescribed medications for pain, anxiety, and even hypertension commonly produces tolerance and physical dependence. These are *normal* physiological adaptations to repeated use of drugs from many different categories. Tolerance and physical dependence are explained in more detail later, but it must be emphasized that they *do not* imply abuse or addiction. This distinction is important because patients with pain sometimes are deprived of adequate opioid medication simply because they have shown evidence of tolerance or they exhibit withdrawal symptoms if the analgesic medication is stopped abruptly.

Definitions. Abuse and addiction have been defined and redefined by several organizations over the past 35 years. The reason for these revisions and disagreements is that abuse and addiction are behavioral syndromes that exist along a continuum from minimal use to abuse to addictive use. While tolerance and physical dependence are biological phenomena that can be defined precisely in the laboratory and diagnosed accurately in the clinic, there is an arbitrary aspect to the definitions of the overall behavioral syndromes of abuse and addiction. The most influential system of diagnosis for mental disorders is that published by the American Psychiatric Association (APA; *DSM IV*, 1994). The APA diagnostic system uses the term *substance dependence* instead of “addiction” for the overall behavioral syndrome. It also applies the same general cri-

teria to all types of drugs regardless of their pharmacological class. Although accepted widely, this terminology can lead to confusion between *physical dependence* and *psychological dependence*. The term *addiction*, when used here, refers to compulsive drug use, the entire substance-dependence syndrome as defined in *DSM IV*. This should not be confused with physical dependence alone, a common error among physicians. *Addiction* is not used as a pejorative term but rather for clarity of communication.

The APA defines *substance dependence* (addiction) as a cluster of symptoms indicating that the individual continues use of the substance despite significant substance-related problems. Evidence of tolerance and withdrawal symptoms are included in the list of symptoms, but neither tolerance nor withdrawal is necessary or sufficient for a diagnosis of substance dependence. Dependence (addiction) requires three or more of the symptoms, whereas abuse can be diagnosed when only one or two symptoms are present. The chronic, relapsing nature of dependence (addiction) fulfills criteria for a chronic disease (McLellan *et al.*, 2000), but because of the voluntary component at initiation, the disease concept is controversial.

Origins of Substance Dependence. Many variables operate simultaneously to influence the likelihood that a given person will become a drug abuser or an addict. These variables can be organized into three categories: agent (drug), host (user), and environment (Table 23–1).

Agent (Drug) Variables. Drugs vary in their capacity to produce immediate good feelings in the user. Drugs that reliably produce intensely pleasant feelings (euphoria) are more likely to be taken repeatedly. *Reinforcement* refers to the capacity of drugs to produce effects that make the user wish to take them again. The more strongly reinforcing a drug is, the greater is the likelihood that the drug will be abused. Reinforcing properties of a drug can

Table 23–1
Multiple Simultaneous Variables Affecting Onset and Continuation of Drug Abuse and Addiction

Agent (drug)

- Availability
- Cost
- Purity/potency
- Mode of administration
 - Chewing (absorption *via* oral mucous membranes)
 - Gastrointestinal
 - Intranasal
 - Subcutaneous and intramuscular
 - Intravenous
 - Inhalation
- Speed of onset and termination of effects (pharmacokinetics: combination of agent and host)

Host (user)

- Heredity
 - Innate tolerance
 - Speed of developing acquired tolerance
 - Likelihood of experiencing intoxication as pleasure
- Metabolism of the drug (nicotine and alcohol data already available)
- Psychiatric symptoms
- Prior experiences/expectations
- Propensity for risk-taking behavior

Environment

- Social setting
- Community attitudes
 - Peer influence, role models
- Availability of other reinforcers (sources of pleasure or recreation)
- Employment or educational opportunities
- Conditioned stimuli: Environmental cues become associated with drugs after repeated use in the same environment

be measured reliably in animals. Generally, animals such as rats or monkeys equipped with intravenous catheters connected to lever-regulated pumps will work to obtain injections of the same drugs in roughly the same order of potency that human beings will. Thus, medications can be screened for their potential for abuse in human beings by the use of animal models.

Reinforcing properties of drugs are associated with their capacity to increase neuronal activity in critical brain areas (*see* Chapter 12). Cocaine, amphetamine, ethanol, opioids, cannabinoids, and nicotine all reliably increase extracellular fluid dopamine levels in the ventral striatum, specifically the nucleus accumbens region. In experimental

animals, usually rats, brain microdialysis permits sampling of extracellular fluid while the animals are freely moving or receiving drugs. Smaller increases in dopamine in the nucleus accumbens also are observed when the rat is presented with sweet foods or a sexual partner. In contrast, drugs that block dopamine receptors generally produce bad feelings, *i.e.*, dysphoric effects. Neither animals nor human beings will take such drugs spontaneously. Despite strong correlative findings, a causal relationship between dopamine and euphoria/dysphoria has not been established, and other findings emphasize additional roles of serotonin, glutamine, norepinephrine, opiates, and γ -aminobutyric acid (GABA) in mediating the reinforcing effects of drugs.

The abuse liability of a drug is enhanced by rapidity of onset because effects that occur soon after administration are more likely to initiate the chain of events that leads to loss of control over drug taking. The pharmacokinetic variables that influence the time it takes the drug to reach critical receptor sites in the brain are explained in more detail in Chapter 1. The history of cocaine use illustrates the changes in abuse liability of the same compound, depending on the form and the route of administration.

When coca leaves are chewed, the cocaine is absorbed slowly through the buccal mucosa. This method produces low cocaine blood levels and correspondingly low levels in the brain. The mild stimulant effects produced by the chewing of coca leaves have a gradual onset, and this practice has produced little, if any, abuse or dependence despite use over thousands of years by natives of the Andes mountains. Beginning in the late 19th century, scientists isolated cocaine hydrochloride from coca leaves, and the extraction of pure cocaine became possible. Cocaine could be taken in higher doses by oral ingestion (GI absorption) or by absorption through the nasal mucosa, producing higher cocaine levels in the blood and a more rapid onset of stimulation. Subsequently, it was found that a solution of cocaine hydrochloride could be administered intravenously, giving a more rapid onset of stimulatory effects. Each newly available cocaine preparation that provided greater speed of onset and an increment in blood level was paralleled by a greater likelihood to produce addiction. In the 1980s, the availability of cocaine to the American public was increased further with the invention of crack cocaine. *Crack*, sold at a very low, albeit illegal, price (\$1 to \$3 per dose), is alkaloidal cocaine (free base), which can be readily vaporized by heating. Simply inhaling the vapors produces blood levels comparable with those resulting from intravenous cocaine owing to the large surface area for absorption into the pulmonary circulation following inhalation. The cocaine-containing blood then enters the left side of the heart and reaches the cerebral circulation without dilution by the systemic circulation. Inhalation of crack cocaine thus is much more likely to produce addiction than is chewing, drinking, or sniffing cocaine. This delivery method, with rapid drug brain levels, also is the preferred route for users of nicotine and cannabis.

Although the drug variables are important, they do not fully explain the development of abuse and addiction. Most people who experiment with drugs that have a high risk of producing addiction (addiction liability) do not intensify their drug use and lose control. The risk for

Table 23–2
Dependence among Users 1990–1992

AGENT	EVER USED* %	ADDICTION %	RISK OF ADDICTION %

*The ever-used and addiction percentages are those of the general population. The risk of addiction is specific to the drug indicated and refers to the percentage who met criteria for addiction among those who reported having used the agent at least once.

SOURCE: Anthony *et al.*, 1994, with permission.

developing addiction among those who try nicotine is about twice that for those who try cocaine (Table 23–2), but this does not imply that the pharmacological addiction liability of nicotine is twice that of cocaine. Rather, there are other variables listed in the categories of host factors and environmental conditions that influence the development of addiction.

Host (User) Variables. In general, effects of drugs vary among individuals. Even blood levels can show wide variation when the same dose of a drug on a milligram per kilogram basis is given to different people. Polymorphism of genes that encode enzymes involved in absorption, metabolism, and excretion and in receptor-mediated responses may contribute to the different degrees of reinforcement or euphoria observed among individuals (*see* Chapters 3 and 4).

Children of alcoholics show an increased likelihood of developing alcoholism, even when adopted at birth and raised by nonalcoholic parents. The studies of genetic influences in this disorder show only an *increased risk* for developing alcoholism, not a 100% determinism, consistent with a polygenic disorder that has multiple determinants. Even identical twins, who share the same genetic endowment, do not have 100% concordance when one twin is alcoholic. However, the concordance rate for identical twins is much higher than that for fraternal twins. The abuse of alcohol and other drugs tends to have some familial characteristics, suggesting that common mechanisms may be involved.

Innate tolerance to alcohol may represent a biological trait that contributes to the development of alcoholism. Data from a longitudinal study (Wilhelmsen *et al.*, 2003) show that sons of alcoholics have reduced sensitivity to alcohol when compared with other young men of the same age (22 years old) and drinking histories. Sensitivity to alcohol was measured as the effects of two different doses of ethanol in the laboratory on motor performance and subjective feelings of intoxication. When the men were re-examined 10 years later, those who had been most tolerant (insensitive) to alcohol at age 22 were the most likely to be diagnosed as alcohol dependent at age 32. The presence of tolerance predicted the development of alcoholism even in the group without a family history of alcoholism, but there were far fewer tolerant men in the negative-family-history group.

While innate tolerance increases vulnerability to alcoholism, impaired metabolism may *protect* against it. Ethanol is metabolized by sequential oxidation to acetaldehyde (by alcohol dehydrogenase) and then to acetic acid by aldehyde dehydrogenase (ALDH2) (*see* Figure 22–1). A common mutation in the ALDH2 gene results in a less effective enzyme. This allele has a high frequency in Asian populations and results in excess accumulation of acetaldehyde after the ingestion of alcohol. Those who are heterozygous for this allele experience a very unpleasant facial flushing reaction 5 to 10 minutes after ingesting alcohol; the reaction is more severe in individuals homozygous for the allele, and this genotype has not been found in alcoholics (Higuchi *et al.*, 1996). Similarly, individuals who inherit a gene associated with slow nicotine metabolism may experience unpleasant effects when beginning to smoke and reportedly have a lower probability of becoming nicotine dependent.

Psychiatric disorders constitute another category of host variables. Drugs may produce immediate, subjective effects that relieve preexisting symptoms. People with anxiety, depression, insomnia, or even subtle symptoms such as shyness may find, on experimentation or by accident, that certain drugs give them relief. However, the apparent beneficial effects are transient, and repeated use of the drug may lead to tolerance and eventually compulsive, uncontrolled drug use. While psychiatric symptoms are seen commonly in drug abusers presenting for treatment, most of these symptoms begin *after* the person starts abusing drugs. Thus, drugs of abuse appear to produce more psychiatric symptoms than they relieve.

Environmental Variables. Initiating and continuing illegal drug use appear to be influenced significantly by societal norms and peer pressure. Taking drugs may be seen initially as a form of rebellion against authority. In some communities, drug users and drug dealers are role models who seem to be successful and respected; thus, young people emulate them. There also may be a paucity of other options for pleasure, diversion, or income. These factors are particularly important in communities where educational levels are low and job opportunities scarce.

Pharmacological Phenomena. Tolerance. While abuse and addiction are complex conditions combining the many variables outlined earlier, there are a number of relevant pharmacological phenomena that occur independently of social and psychological dimensions. First are the changes in the way the body responds to a drug with repeated use. *Tolerance*, the most common response to

Figure 23–1. Shifts in a dose–response curve with tolerance and sensitization. With tolerance, there is a shift of the curve to the right such that doses higher than initial doses are required to achieve the same effects. With sensitization, there is a leftward shift of the dose–response curve such that for a given dose, there is a greater effect than seen after the initial dose.

repetitive use of the same drug, can be defined as the reduction in response to the drug after repeated administrations. Figure 23–1 shows an idealized dose–response curve for an administered drug. As the dose of the drug increases, the observed effect of the drug increases. With repeated use of the drug, however, the curve shifts to the right (tolerance). Thus a higher dose is required to produce the same effect that was once obtained at a lower dose. *Diazepam*, for example, typically produces sedation at doses of 5 to 10 mg in a first-time user, but those who repeatedly use it to produce a kind of “high” may become tolerant to doses of several hundreds of milligrams; some abusers have had documented tolerance to more than 1000 mg/day. As outlined in Table 23–3, there are many forms of tolerance likely arising *via* multiple mechanisms.

Table 23–3
Types of Tolerance

Innate (pre-existing sensitivity or insensitivity)
Acquired
Pharmacokinetic (dispositional or metabolic)
Pharmacodynamic
Learned tolerance
Behavioral
Conditioned
Acute tolerance
Reverse tolerance (sensitization)
Cross-tolerance

Tolerance develops to some drug effects much more rapidly than to other effects of the same drug. For example, tolerance develops rapidly to the euphoria produced by opioids such as heroin, and addicts tend to increase their dose in order to re-experience that elusive “high.” In contrast, tolerance to the gastrointestinal effects of opiates develops more slowly. The discrepancy between tolerance to euphoric effects (rapid) and tolerance to effects on vital functions (slow), such as respiration and blood pressure, can lead to potentially fatal accidents in sedative abusers.

Innate tolerance refers to genetically determined sensitivity (or lack of sensitivity) to a drug that is observed the first time that the drug is administered. Innate tolerance was discussed earlier as a host variable that influences the development of abuse or addiction.

Acquired tolerance can be divided into three major types: pharmacokinetic, pharmacodynamic, and learned tolerance, and includes acute, reverse, and cross-tolerance (Table 23–3).

Pharmacokinetic, or *dispositional*, *tolerance* refers to changes in the distribution or metabolism of a drug after repeated administrations such that a given dose produces a lower blood concentration than the same dose did on initial exposure (*see* Chapter 1). The most common mechanism is an increase in the rate of metabolism of the drug. For example, *barbiturates* stimulate the production of higher levels of hepatic CYPs, causing more rapid removal and breakdown of barbiturates from the circulation. Since the same enzymes metabolize many other drugs, they too are metabolized more quickly. This results in a decrease in their plasma levels as well and thus a reduction in their effects.

Pharmacodynamic tolerance refers to adaptive changes that have taken place within systems affected by the drug so that response to a given concentration of the drug is reduced. Examples include drug-induced changes in receptor density or efficiency of receptor coupling to signal-transduction pathways (*see* Chapters 1 and 12).

Learned tolerance refers to a reduction in the effects of a drug owing to compensatory mechanisms that are acquired by past experiences. One type of learned tolerance is called *behavioral tolerance*. This simply describes the skills that can be developed through repeated experiences with attempting to function despite a state of mild to moderate intoxication. A common example is learning to walk a straight line despite the motor impairment produced by alcohol intoxication. This probably involves both acquisition of motor skills and the learned awareness of one’s deficit, causing the person to walk more carefully. At higher levels of intoxication, behavioral tolerance is overcome, and the deficits are obvious.

Conditioned tolerance (situation-specific tolerance) develops when environmental cues such as sights, smells, or situations consistently are paired with the administration of a drug. When a drug affects homeostatic balance by producing sedation and changes in blood pressure, pulse rate, gut activity, etc., there is usually a reflexive counteraction or adaptation in the direction of maintaining the *status quo*. If a drug always is taken in the presence of specific environmental cues (*e.g.*, smell of drug preparation and sight of syringe), these cues begin to predict the effects of the drug, and the adaptations begin to occur even before the drug reaches its sites of action. If the drug always is preceded by the same cues, the adaptive response to the drug will be learned, and this will prevent the full manifestation of the drug’s effects (tolerance). This mechanism of conditioned tolerance production follows classical (pavlovian) principles of learning and results in drug tolerance under circumstances where the drug is “expected.” When the drug is received under novel or “unexpected” circumstances, conditioned tolerance does not occur, and drug effects are enhanced.

The term *acute tolerance* refers to rapid tolerance developing with repeated use on a single occasion, such as in a “binge.” For example, cocaine often is used in a binge, with repeated doses over one to several hours, sometimes longer, producing a decrease in response to subsequent doses of cocaine during the binge. This is the opposite of *sensitization*, observed with an intermittent dosing schedule, described below.

Sensitization. With stimulants such as cocaine or amphetamine, *reverse tolerance*, or *sensitization*, can occur. This refers to an increase in response with repetition of the same dose of the drug. Sensitization results in a shift to the left of the dose–response curve (Figure 23–1). For example, with repeated daily administration to rats of a dose of cocaine that produces increased motor activity, the effect increases over several days, even though the dose remains constant. A conditioned response also can be a part of sensitization to cocaine. Simply putting a rat into a cage where cocaine is expected or giving a placebo injection after several days of receiving cocaine under the same circumstances produces an increase in motor activity as though cocaine actually were given, *i.e.*, a conditioned response. Sensitization, in contrast to acute tolerance during a binge, requires a longer interval between doses, usually about 1 day.

Sensitization has been studied in rats equipped with microdialysis cannulas for monitoring extracellular dopamine (Kalivas and Duffy, 1990) (Figure 23–2). The initial response to 10 mg/kg of cocaine administered intraperitoneally is an increase in measured dopamine levels. After seven daily injections, the dopamine increase is significantly greater than on the first day, and the behavioral response also is greater. Figure 23–2 also provides an example of a conditioned response (learned drug effect) because injection of saline produced both an increase in dopamine levels and an increase in behavioral activity when administered 3 days after cocaine injections had stopped. Little research on sensitization has been conducted in human subjects, but the results suggest that the phenomenon can occur. It has been postulated that stimulant psychosis results from a sensitized response after long periods of use.

Cross-tolerance occurs when repeated use of a drug in a given category confers tolerance not only to that drug but also to other drugs in the same structural and mechanistic category. Understanding cross-tolerance is important in the medical management of persons dependent on any drug. **Detoxification** is a form of treatment for drug dependence that involves giving gradually decreasing doses of the drug to prevent withdrawal symptoms, thereby weaning the patient from the drug of dependence (*see* below). Detoxification can be accomplished with any medication in the same category as the initial drug of dependence. For example, users of heroin also are tolerant to other opioids. Thus, the detoxification of heroin-dependent patients can be accomplished with any medication that activates opiate receptors.

Physical Dependence

Physical dependence is a *state* that develops as a result of the adaptation (tolerance) produced by a resetting of homeostatic mechanisms in response to repeated drug use. Drugs can affect numerous systems that previously were in equilibrium; these systems find a new balance in the presence of inhibition or stimulation by a specific drug. A person in this adapted or physically dependent state

Figure 23–2. Changes in dopamine detected in the extracellular fluid of the nucleus accumbens of rats after daily injections of cocaine (10 mg/kg, *i.p.*). The first injection of cocaine produces a modest increase and the last, after 7 days, produces a much greater increase in dopamine release. The first saline injection produces no effect on dopamine levels, whereas the second, given 3 days after 7 days of cocaine injections, produces a significant rise in dopamine, presumably due to conditioning. (Adapted from Kalivas and Duffy, 1990, with permission.)

requires continued administration of the drug to maintain normal function. If administration of the drug is stopped abruptly, there is another imbalance, and the affected systems again must go through a process of readjusting to a new equilibrium without the drug.

Withdrawal Syndrome. The appearance of a withdrawal syndrome when administration of the drug is terminated is the only actual evidence of physical dependence. Withdrawal signs and symptoms occur when drug administration in a physically dependent person is terminated abruptly. Withdrawal symptoms have at least two origins: (1) removal of the drug of dependence and (2) CNS hyperarousal owing to readaptation to the absence of the drug of dependence. Pharmacokinetic variables are of considerable importance in the amplitude and duration of the withdrawal syndrome. Withdrawal symptoms are characteristic for a given category of drugs and tend to be *opposite* to the original effects produced by the drug before tolerance developed. Thus, abrupt termination of a drug (such as an opioid agonist) that produces miotic (constricted) pupils and slow heart rate will produce a withdrawal syndrome including dilated pupils and tachycardia. Tolerance, physical dependence, and withdrawal are

all biological phenomena. They are the natural consequences of drug use and can be produced in experimental animals and in any human being who takes certain medications repeatedly. These symptoms in themselves do not imply that the individual is involved in abuse or addiction. *Patients who take medicine for appropriate medical indications and in correct dosages still may show tolerance, physical dependence, and withdrawal symptoms if the drug is stopped abruptly rather than gradually.* For example, a hypertensive patient receiving a β adrenergic receptor blocker such as *metoprolol* may have a good therapeutic response, but if the drug is stopped abruptly, the patient may experience a withdrawal syndrome consisting of rebound increased blood pressure temporarily higher than that prior to beginning the medication.

Medical addict is a term used to describe a patient in treatment for a medical disorder who has become “addicted” to the available prescribed drugs; the patient begins taking them in excessive doses, out of control. An example would be a patient with chronic pain, anxiety, or insomnia who begins using the prescribed medication more often than directed by the physician. If the physician restricts the prescriptions, the patient may begin seeing several doctors without the knowledge of the primary physician. Such patients also may visit emergency rooms for the purpose of obtaining additional medication. This scenario is very uncommon, considering the large number of patients who receive medications capable of producing tolerance and physical dependence. *Fear of producing such medical addicts results in needless suffering among patients with pain* because physicians needlessly limit appropriate medications. Tolerance and physical dependence are inevitable consequences of chronic treatment with opioids and certain other drugs, but tolerance and physical dependence by themselves do not imply “addiction.”

CLINICAL ISSUES

The treatment of physically dependent individuals will be discussed with reference to the specific drug of abuse and dependence problems characteristic to each category: CNS depressants, including alcohol and other sedatives; nicotine and tobacco; opioids; psychostimulants, such as amphetamine and cocaine; cannabinoids; psychedelic drugs; and inhalants (volatile solvents, nitrous oxide, and ethyl ether). Abuse of combinations of drugs across these categories is common. Alcohol is so widely available that it is combined with practically all other categories. Some combinations reportedly are taken because of their interactive effects. An example is the combination of heroin and cocaine (“speedball”), which will be described with the opioid category. Alcohol and cocaine is another very common combination. When confronted with a patient exhibiting signs of overdose or withdrawal, the physician

must be aware of these possible combinations because each drug may require specific treatment.

CNS Depressants

Ethanol. Experimentation with ethanol is almost universal, and a high proportion of users finds the experience pleasant. More than 90% of American adults report experience with ethanol (commonly called *alcohol*), and approximately 70% report some level of current use. The lifetime prevalence of alcohol abuse and alcohol addiction (alcoholism) in this society is 5% to 10% for men and 3% to 5% for women.

Ethanol is classed as a depressant because it indeed produces sedation and sleep. However, the initial effects of alcohol, particularly at lower doses, often are perceived as stimulation owing to a suppression of inhibitory systems (see Chapter 22). Those who perceive only sedation from alcohol generally choose not to drink when evaluated in a test procedure (de Wit *et al.*, 1989).

Alcohol impairs recent memory and, in high doses, produces the phenomenon of “blackouts,” after which the drinker has no memory of his or her behavior while intoxicated. The effects of alcohol on memory are unclear, but evidence suggests that reports from patients about their reasons for drinking and their behavior during a binge are not reliable. Alcohol-dependent persons often say that they drink to relieve anxiety or depression. When allowed to drink under observation, however, alcoholics typically become more dysphoric as drinking continues (Mendelson and Mello, 1979), thus not supporting the idea that alcoholics drink to relieve tension.

Tolerance, Physical Dependence, and Withdrawal. Mild intoxication by alcohol is familiar to almost everyone, but the symptoms vary among individuals. Some simply experience motor incoordination and sleepiness. Others initially become stimulated and garrulous. As the blood level increases, the sedating effects increase, with eventual coma and death occurring at high alcohol levels. The initial sensitivity (innate tolerance) to alcohol varies greatly among individuals and is related to family history of alcoholism (Wilhelmsen *et al.*, 2003). Experience with alcohol can produce greater tolerance (acquired tolerance) such that extremely high blood levels (300 to 400 mg/dl) can be found in alcoholics who do not appear grossly sedated. In these cases, the lethal dose does not increase proportionately to the sedating dose, and thus the margin of safety (therapeutic index) is decreased.

Heavy consumers of alcohol not only acquire tolerance but also inevitably develop a state of physical dependence. This often leads to drinking in the morning to restore blood alcohol levels diminished during the night. Eventually, they may awaken during the night and take a drink to avoid the restlessness produced by falling alcohol levels. The alcohol-withdrawal syndrome (Table 23–4)

Table 23–4**Alcohol Withdrawal Syndrome**

Alcohol craving
Tremor, irritability
Nausea
Sleep disturbance
Tachycardia
Hypertension
Sweating
Perceptual distortion
Seizures (6 to 48 hours after last drink)
Visual (and occasionally auditory or tactile) hallucinations (12 to 48 hours after last drink)
Delirium tremens (48 to 96 hours after last drink; rare in uncomplicated withdrawal)
Severe agitation
Confusion
Fever, profuse sweating
Tachycardia
Nausea, diarrhea
Dilated pupils

generally depends on the size of the average daily dose and usually is “treated” by resumption of alcohol ingestion. Withdrawal symptoms are experienced frequently but usually are not severe or life-threatening until they occur in conjunction with other problems, such as infection, trauma, malnutrition, or electrolyte imbalance. In the setting of such complications, the syndrome of *delirium tremens* becomes likely (Table 23–4).

Alcohol produces cross-tolerance to other sedatives such as *benzodiazepines*. This tolerance is operative in abstinent alcoholics, but while the alcoholic is drinking, the sedating effects of alcohol add to those of other sedatives, making the combination more dangerous. This is particularly true for benzodiazepines, which are relatively safe in overdose when given alone but potentially are lethal in combination with alcohol.

The chronic use of alcohol and other sedatives is associated with the development of depression (McLellan *et al.*, 1979), and the risk of suicide among alcoholics is one of the highest of any diagnostic category. Cognitive deficits have been reported in alcoholics tested while sober. These deficits usually improve after weeks to months of abstinence. More severe recent memory impairment is associated with specific brain damage caused by nutritional deficiencies common in alcoholics, e.g., thiamine deficiency.

Alcohol is toxic to many organ systems. As a result, the medical complications of alcohol abuse and depen-

dence include liver disease, cardiovascular disease, endocrine and gastrointestinal effects, and malnutrition, in addition to the CNS dysfunctions outlined earlier. Ethanol readily crosses the placental barrier, producing the *fetal alcohol syndrome*, a major cause of mental retardation (see Chapter 22).

Pharmacological Interventions. Detoxification. A patient who presents in a medical setting with an alcohol-withdrawal syndrome should be considered to have a potentially lethal condition. Although most mild cases of alcohol withdrawal never come to medical attention, severe cases require general evaluation; attention to hydration and electrolytes; vitamins, especially high-dose thiamine; and a sedating medication that has cross-tolerance with alcohol. To block or diminish the symptoms described in Table 23–4, a short-acting benzodiazepine such as *oxazepam* (SERAX) can be used at a dose of 15 to 30 mg every 4 to 6 hours according to the stage and severity of withdrawal; some authorities recommend a long-acting benzodiazepine unless there is demonstrated liver impairment. Anticonvulsants such as *carbamazepine* have been shown to be effective in alcohol withdrawal, although they appear not to relieve subjective symptoms as well as benzodiazepines. After medical evaluation, uncomplicated alcohol withdrawal can be treated effectively on an outpatient basis. When there are medical problems or a history of seizures, hospitalization is required.

Other Measures. Detoxification is only the first step of treatment. Complete abstinence is the objective of long-term treatment, and this is accomplished mainly by behavioral approaches. Medications that aid in the prevention of relapse are under development. *Disulfiram* (ANTABUSE; see Chapter 22) has been useful in some programs that focus behavioral efforts on ingestion of the medication. Disulfiram blocks aldehyde dehydrogenase, the second step in ethanol metabolism, resulting in the accumulation of acetaldehyde, which produces an unpleasant flushing reaction when alcohol is ingested. Knowledge of this unpleasant reaction helps the patient to resist taking a drink. Although quite effective pharmacologically, disulfiram has not been found to be effective in controlled clinical trials because so many patients failed to ingest the medication.

An FDA-approved medication used as an adjunct in the treatment of alcoholism is *naltrexone* (REVIA; see Chapter 22). This opiate-receptor antagonist has been shown to block some of the reinforcing properties of alcohol and has resulted in a decreased rate of relapse to alcohol drinking in the majority of published double-blind clinical trials. It works best in combination with

behavioral treatment programs that encourage adherence to medication and to remaining abstinent from alcohol. A depot preparation with a duration of 30 days is currently under review by the FDA and would improve medication adherence, the major problem with the use of medications in alcoholism. One recent study linked abstinence in response to naltrexone therapy with a specific polymorphism in the gene encoding the μ opioid receptor (Oslin *et al.*, 2003), which has been linked to the reinforcing properties of alcohol and differential responses to μ -receptor antagonists. To the extent that these findings are confirmed, they may facilitate the identification of patients who are more likely to respond to pharmacotherapy with naltrexone.

Recently, the FDA approved another medication as an adjunct in the treatment of alcoholism. *Acamprosate* (Mason, 2003) is a competitive inhibitor of the *N*-methyl-D-aspartate (NMDA)-type glutamate receptor that is proposed to normalize the dysregulated neurotransmission associated with chronic ethanol intake and thereby to attenuate one of the mechanisms that lead to relapse. In several European studies, acamprosate has been shown to promote abstinence either alone or in combination with naltrexone.

Benzodiazepines. Benzodiazepines are among the most commonly prescribed drugs worldwide; they are used mainly for the treatment of anxiety disorders and insomnia (*see* Chapters 16 and 17). Considering their widespread use, intentional abuse of prescription benzodiazepines is relatively rare. When a benzodiazepine is taken for up to several weeks, there is little tolerance and no difficulty in stopping the medication when the condition no longer warrants its use. After several months, the proportion of patients who become tolerant increases, and reducing the dose or stopping the medication produces withdrawal symptoms (Table 23–5). It can be difficult to distinguish withdrawal symptoms from the reappearance of the anxiety symptoms for which the benzodiazepine was prescribed initially. Some patients may increase their dose over time because tolerance definitely develops to the sedative effects. Many patients and their physicians, however, contend that antianxiety benefits continue to occur long after tolerance to the sedating effects. Moreover, these patients continue to take the medication for years according to medical directions without increasing their dose and are able to function very effectively as long as they take the benzodiazepine. The degree to which tolerance develops to the anxiolytic effects of benzodiazepines is a subject of controversy. There is, however, good evidence that significant tolerance does not develop

Table 23–5
Benzodiazepine Withdrawal Symptoms

Following moderate dose usage

Delirium

to all benzodiazepine actions because some effects of acute doses on memory persist in patients who have taken benzodiazepines for years. According to a task force that reviewed the issues and published guidelines on the proper medical use of benzodiazepines (American Psychiatric Association, 1990), intermittent use only when symptoms occur retards the development of tolerance and therefore is preferable to daily use. Patients with a history of alcohol- or other drug-abuse problems have an increased risk for the development of benzodiazepine abuse and should rarely, if ever, be treated with benzodiazepines on a chronic basis.

While relatively few patients who receive benzodiazepines for medical indications abuse their medication, there are individuals who specifically seek benzodiazepines for their ability to produce a “high.” Among these abusers, there are differences in drug popularity; benzodiazepines that have a rapid onset, such as *diazepam* and *alprazolam*, tend to be the most desirable. The drugs may be obtained by simulating a medical condition and deceiving physicians or simply through illicit channels. Unsupervised use can lead to self-administration of large doses and therefore tolerance to the benzodiazepine’s sedating effects. For example, while 5 to 20 mg/day of diazepam is a typical dose for a patient receiving prescribed medication, abusers may take over 1000 mg/day and not appear grossly sedated.

Abusers may combine benzodiazepines with other drugs to increase the effect. For example, it is part of the “street lore” that taking diazepam 30 minutes after an oral dose of *methadone* will produce an augmented high not obtainable with either drug alone.

While there is some illicit use of benzodiazepines as a primary drug of abuse, most of the unsupervised use seems to be by abusers of other drugs who are attempting to self-medicate the side effects or withdrawal effects of their primary drug of abuse. Thus, cocaine addicts often take diazepam to relieve the irritability and agitation produced by cocaine binges, and opioid addicts find that diazepam and other benzodiazepines relieve some of the anxiety symptoms of opioid withdrawal when they are unable to obtain their preferred drug.

Pharmacological Interventions. If patients receiving long-term benzodiazepine treatment by prescription wish to stop their medication, the process may take months of gradual dose reduction. Withdrawal symptoms (Table 23–5) may occur during this outpatient detoxification, but in most cases the symptoms are mild. If anxiety symptoms return, a nonbenzodiazepine such as *bupirone* may be prescribed, but this agent usually is less effective than benzodiazepines for treatment of anxiety in these patients. Some authorities recommend transferring the patient to a long-half-life benzodiazepine during detoxification; other recommended medications include the anticonvulsants *carbamazepine* and *phenobarbital*. Controlled studies comparing different treatment regimens are lacking. Since patients who have been on low doses of benzodiazepines for years usually have no adverse effects, the physician and patient should decide jointly whether detoxification and possible transfer to a new anxiolytic is worth the effort.

The specific benzodiazepine receptor antagonist *flumazenil* has been found useful in the treatment of overdose and in reversing the effects of long-acting benzodiazepines used in anesthesia (see Chapter 16). It has been tried in the treatment of persistent withdrawal symptoms after cessation of long-term benzodiazepine treatment.

Deliberate abusers of high doses of benzodiazepines usually require inpatient detoxification. Frequently, benzodiazepine abuse is part of a combined dependence involving alcohol, opioids, and cocaine. Detoxification can be a complex clinical pharmacological problem requiring knowledge of the pharmacokinetics of each drug. The patient's history may be unreliable not simply because of lying but also because the patient frequently does not *know* the true identity of drugs purchased on the street. Medication for detoxification should not be prescribed by the “cookbook” approach but by careful titration and patient observation. The withdrawal syndrome from diazepam, for example, may not become evident until the patient develops a seizure in the second week of hospitalization. One approach to complex detoxification is to focus on the CNS-depressant drug and temporarily hold the opioid component constant with a low dose of methadone. Opioid detoxification can begin later. A long-acting benzodiazepine such as diazepam or *clorazepate* (TRANXENE) or a long-acting barbiturate such as *phenobarbital* can be used to block the sedative withdrawal symptoms. The phenobarbital dose should be determined by a series of test doses and subsequent observations to determine the level of tolerance. Most complex detoxifications can be accomplished using this phenobarbital loading-dose strategy (see Robinson *et al.*, 1981).

After detoxification, the prevention of relapse requires a long-term outpatient rehabilitation program similar to the treatment of alcoholism. No specific medications have been found to be useful in the rehabilitation of sedative abusers, but, of course, specific psychiatric disorders such as depression or schizophrenia, if present, require appropriate medications.

Barbiturates and Nonbenzodiazepine Sedatives. The use of barbiturates and other nonbenzodiazepine sedating medications has declined greatly in recent years owing to

the increased safety and efficacy of newer medications (see Chapters 16 and 17). Abuse problems with barbiturates resemble those seen with benzodiazepines in many ways. Treatment of abuse and addiction should be handled similarly to interventions for the abuse of alcohol and benzodiazepines. Because drugs in this category frequently are prescribed as hypnotics for patients complaining of insomnia, physicians should be aware of the problems that can develop when the hypnotic agent is withdrawn. Insomnia rarely should be treated with medication as a primary disorder except when produced by short-term stressful situations. Insomnia often is a symptom of an underlying chronic problem, such as depression or respiratory dysfunction, or may be due simply to a change in sleep requirements with age. Prescription of sedative medications, however, can change the physiology of sleep with subsequent tolerance to these medication effects. When the sedative is stopped, there is a rebound effect with worsened insomnia. This medication-induced insomnia requires detoxification by gradual dose reduction.

Nicotine

The basic pharmacology of nicotine is discussed in Chapter 9. Because nicotine provides the reinforcement for cigarette smoking, the most common cause of preventable death and disease in the United States, it is arguably the most dangerous dependence-producing drug. The dependence produced by nicotine can be extremely durable, as exemplified by the high failure rate among smokers who try to quit. Although more than 80% of smokers express a desire to quit, only 35% try to stop each year, and fewer than 5% are successful in unaided attempts to quit (American Psychiatric Association, 1994).

Cigarette (nicotine) addiction is influenced by multiple variables. Nicotine itself produces reinforcement; users compare nicotine to stimulants such as cocaine or amphetamine, although its effects are of lower magnitude. While there are many casual users of alcohol and cocaine, few individuals who smoke cigarettes smoke a small enough quantity (5 cigarettes or fewer per day) to avoid dependence. Nicotine is absorbed readily through the skin, mucous membranes, and lungs. The pulmonary route produces discernible CNS effects in as little as 7 seconds. Thus each puff produces some discrete reinforcement. With 10 puffs per cigarette, the one-pack-per-day smoker reinforces the habit 200 times daily. The timing, setting, situation, and preparation all become associated repetitively with the effects of nicotine.

Nicotine has both stimulant and depressant actions. The smoker feels alert, yet there is some muscle relaxation. Nicotine activates the nucleus accumbens reward system in the brain, discussed earlier;

Table 23–6**Nicotine Withdrawal Symptoms**

Irritability, impatience, hostility
 Anxiety
 Dysphoric or depressed mood
 Difficulty concentrating
 Restlessness
 Decreased heart rate
 Increased appetite or weight gain

increased extracellular dopamine has been found in this region after nicotine injections in rats. Nicotine affects other systems as well, including the release of endogenous opioids and glucocorticoids.

There is evidence for tolerance to the subjective effects of nicotine. Smokers typically report that the first cigarette of the day after a night of abstinence gives the “best” feeling. Smokers who return to cigarettes after a period of abstinence may experience nausea if they return immediately to their previous dose. Persons naive to the effects of nicotine will experience nausea at low nicotine blood levels, and smokers will experience nausea if nicotine levels are raised above their accustomed levels.

Negative reinforcement refers to the benefits obtained from the termination of an unpleasant state. In dependent smokers, there is evidence that the urge to smoke correlates with a low blood nicotine level, as though smoking were a means to achieve a certain nicotine level and thus avoid withdrawal symptoms. Some smokers even awaken during the night to have a cigarette, which ameliorates the effect of low nicotine blood levels that could disrupt sleep. If the nicotine level is maintained artificially by a slow intravenous infusion, there is a decrease in the number of cigarettes smoked and in the number of puffs. Thus, smokers may be smoking to achieve the reward of nicotine effects, to avoid the pain of nicotine withdrawal, or most likely a combination of the two. Nicotine withdrawal symptoms are listed in Table 23–6.

Depressed mood (dysthymic disorder, affective disorder) is associated with nicotine dependence, but it is not known whether depression predisposes one to begin smoking or depression develops during the course of nicotine dependence. Depression increases significantly during smoking withdrawal, and this is cited as one reason for relapse.

Pharmacological Interventions. The nicotine withdrawal syndrome can be alleviated by nicotine-replacement therapy, available with (*e.g.*, NICOTROL INHALER and NICOTROL NASAL SPRAY) or without (*e.g.*, NICORETTE GUM and others and NICODERM TRANSDERMAL PATCH, NICOTROL TRANSDERMAL PATCH, and others) a prescription. Figure 23–3 shows the blood nicotine concentrations achieved by different methods of nicotine delivery. Because nicotine gum and a nicotine patch do not achieve the *peak levels* seen with cigarettes, they do not produce the same magnitude of subjective effects as nicotine. These methods do, however, suppress the symptoms of nicotine withdrawal. Thus smokers should be able to

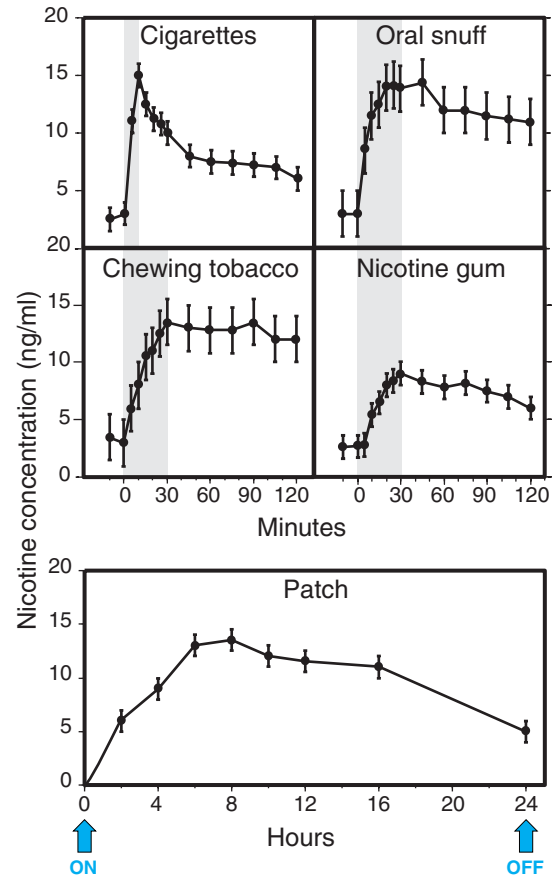

Figure 23–3. Nicotine concentrations in blood resulting from five different nicotine delivery systems. Shaded areas (upper panel) indicate the periods of exposure to nicotine. Arrows (lower panel) indicate when the nicotine patch was put on and taken off. (From Benowitz *et al.*, 1988, and Srivastava *et al.*, 1991, with permission.)

transfer their dependence to the alternative delivery system and gradually reduce the daily nicotine dose with minimal symptoms. Although this results in more smokers achieving abstinence, most resume smoking over the ensuing weeks or months. Comparisons with placebo treatment show large benefits of nicotine replacement at 6 weeks, but the effect diminishes with time. The nicotine patch produces a steady blood level (Figure 23–3) and seems to have better patient compliance than that observed with nicotine gum. Verified abstinence rates at 12 months are reported to be in the range of 20%, which is worse than the success rate for any other addiction. The necessary goal of complete abstinence contributes to the poor success rate; when ex-smokers “slip” and begin smoking a little, they usually relapse quickly to their prior level of dependence. A sustained-release preparation of the antidepressant *bupropion* (*see* Chapter 17), improves

abstinence rates among smokers. Newer agents such as the cannabinoid (CB-1) receptor antagonist *rimonabant* also have been reported to increase abstinence rates in clinical trials and are progressing through the FDA approval process. A combination of behavioral treatment with nicotine replacement to ease withdrawal and an anti-craving medication to reduce relapse is currently considered the treatment of choice.

Opioids

Opioid drugs are used primarily for the treatment of pain (see Chapter 21). Some of the CNS mechanisms that reduce the perception of pain also produce a state of well-being or euphoria. Thus opioid drugs also are taken outside medical channels for the purpose of obtaining the effects on mood. This potential for abuse has generated much research on separating the mechanism of analgesia from that of euphoria in the hope of eventually developing a potent analgesic that does not activate brain reward systems. Although this research has led to advances in understanding the physiology of pain, the standard medications for severe pain remain the derivatives of the opium poppy (opiates) and synthetic drugs that activate the same receptors (opioids). Drugs modeled after the endogenous opioid peptides may one day provide more specific treatment, but none of these currently is available for clinical use. Medications that do not act at opiate receptors, such as the *nonsteroidal antiinflammatory drugs* (NSAIDs), have an important role in certain types of pain, especially chronic pain, but for acute pain and for severe chronic pain, the opioid drugs are most effective. Progress in pain control stems from a greater understanding of the mechanism of tolerance to μ opiate receptor-mediated analgesia, which involves NMDA receptors (Trujillo and Akil, 1991). By combining morphine with dextromethorphan, an NMDA-receptor antagonist, tolerance is impaired and analgesia is enhanced without an increase in the dose of opioid.

The subjective effects of opioid drugs are useful in the management of acute pain. This is particularly true in high-anxiety situations, such as the crushing chest pain of myocardial infarction, when the relaxing, anxiolytic effects complement the analgesia. Normal volunteers with no pain given opioids in the laboratory may report the effects as unpleasant because of side effects such as nausea, vomiting, and sedation. Patients with pain rarely develop abuse or addiction problems. Of course, patients receiving opioids over time develop tolerance routinely, and if the medication is stopped abruptly, they will show the signs of an opioid-withdrawal syndrome, the evidence for physical dependence.

Opioids never should be withheld from patients with cancer out of fear of producing addiction. If chronic opioid medication is indi-

cated, it is preferable to prescribe an orally active, slow-onset opioid with a long duration of action. These qualities reduce the likelihood of producing euphoria at onset and withdrawal symptoms as the medication wears off. *Methadone* is an excellent choice for the management of chronic severe pain. Controlled-release oral *morphine* (MS CONTIN, AVINZA) and controlled-release *oxycodone* (OXYCONTIN) are other possibilities. Rapid-onset, short-duration opioids are excellent for acute short-term use, such as during the postoperative period. As tolerance and physical dependence develop, however, the patient may experience the early symptoms of withdrawal between doses, and during withdrawal, the threshold for pain decreases. Thus, for chronic administration, the long-acting opioids are recommended. While methadone is long acting because of its metabolism to active metabolites, the long-acting version of oxycodone has been formulated to release slowly, thus changing a short-acting opioid into a long-acting one. Unfortunately, this mechanism can be subverted by breaking the tablet and making the full dose of oxycodone immediately available. This has led to diversion of oxycodone to illicit traffic because high-dose oxycodone produces euphoria that is sought by opiate abusers. The diversion of prescription opioids such as oxycodone and hydrocodone to illegal markets has become an important source of opiate abuse in the United States.

The major risk for abuse or addiction occurs in patients complaining of pain with no clear physical explanation or with evidence of a chronic disorder that is not life-threatening. Examples are chronic headaches, backaches, abdominal pain, or peripheral neuropathy. Even in these cases, an opioid may be considered as a brief emergency treatment, but long-term treatment with opioids should be used only after other alternatives have been exhausted. In the relatively rare patients who develop abuse, the transition from legitimate use to abuse often begins with patients returning to their physician earlier than scheduled to get a new prescription or visiting emergency rooms of different hospitals complaining of acute pain and asking for an opioid injection.

Heroin is the most important opiate that is abused. There is no legal supply of heroin for clinical use in the United States. Despite claims that heroin has unique analgesic properties for the treatment of severe pain, double-blind trials have found it to be no more effective than hydromorphone. However, heroin is widely available on the illicit market, and its price dropped sharply in the 1990s, continuing to the present, with purity increased tenfold. Previously, street heroin in the United States was highly diluted: Each 100-mg bag of powder had only about 4 mg heroin (range 0 to 8 mg), and the rest was filler such as quinine. In the mid-1990s, street heroin reached 45% to 75% purity in many large cities, with some samples testing as high as 90%. This means that the level of physical dependence among heroin addicts is relatively high and that users who interrupt regular dosing will develop more severe withdrawal symptoms. Whereas heroin previously required intravenous injection, the more potent supplies can be smoked or administered nasally (snorted), thus making the initiation of heroin use accessible to people who would not insert a needle into their veins. There is no accurate way to count the number of

heroin addicts, but based on extrapolation from overdose deaths, number of applicants for treatment, and number of heroin addicts arrested, the estimates range from 800,000 to 1 million in the United States. Based on a stratified national sample of adults in the United States, approximately 1 in 4 individuals who report any use of heroin become addicted (Anthony *et al.*, 1994).

Tolerance, Dependence, and Withdrawal. Injection of a heroin solution produces a variety of sensations described as warmth, taste, or high and intense pleasure (“rush”) often compared with sexual orgasm. There are some differences among the opioids in their acute effects, with *morphine* producing more of a histamine-releasing effect and *meperidine* producing more excitation or confusion. Even experienced opioid addicts, however, cannot distinguish between heroin and hydromorphone in double-blind tests. Thus, the popularity of heroin may be due to its availability on the illicit market and its rapid onset. After intravenous injection, the effects begin in less than a minute. Heroin has high lipid solubility, crosses the blood–brain barrier quickly, and is deacetylated to the active metabolites 6-monoacetyl morphine and morphine. After the intense euphoria, which lasts from 45 seconds to several minutes, there is a period of sedation and tranquility (“on the nod”) lasting up to an hour. The effects of heroin wear off in 3 to 5 hours, depending on the dose. Experienced users may inject two to four times per day. Thus, the heroin addict is constantly oscillating between being “high” and feeling the sickness of early withdrawal (Figure 23–4). This produces many problems in the homeostatic systems regulated at least in part by endogenous opioids. For example, the hypothalamic–pituitary–gonadal axis and the hypothalamic–pituitary–adrenal axis are abnormal in heroin addicts. Women on heroin have irregular menses, and men have a variety of sexual performance problems. Mood also is affected. Heroin addicts are relatively docile and compliant after taking heroin, but during withdrawal, they become irritable and aggressive.

Based on patient reports, tolerance develops early to the euphoria-producing effects of opioids. There also is tolerance to the respiratory depressant, analgesic, sedative, and emetic properties. Heroin users tend to increase their daily dose, depending on their financial resources and the availability of the drug. If a supply is available, the dose can be increased progressively 100 times. Even in highly tolerant individuals, the possibility of overdose remains if tolerance is exceeded. Overdose is likely to occur when potency of the street sample is unexpectedly high or when the heroin is mixed with a far more potent opioid, such as *fentanyl* (SUBLIMAZE, others).

Figure 23–4. Differences in responses to heroin and methadone. A person who injects heroin (↑) several times per day oscillates between being sick and being high. In contrast, the typical methadone patient remains in the “normal” range (indicated in gray) with little fluctuation after dosing once per day. The ordinate values represent the subject’s mental and physical state, not plasma levels of the drug.

Addiction to heroin or other short-acting opioids produces behavioral disruptions and usually becomes incompatible with a productive life. There is a significant risk for opioid abuse and dependence among physicians and other health care workers who have access to potent opioids, thus tempting them toward unsupervised experimentation. Physicians often begin by assuming that they can manage their own dose, and they may rationalize their behavior based on the beneficial effects of the drug. Over time, however, the typical unsupervised opioid user loses control, and behavioral changes are observed by family and coworkers. Apart from the behavioral changes and the risk of overdose, especially with very potent opioids, chronic use of opioids is relatively nontoxic.

Opioids frequently are used in combinations with other drugs. A common combination is heroin and cocaine (“speedball”). Users report an improved euphoria because of the combination, and there is evidence of an interaction, because cocaine reduces the signs of opiate withdrawal, and heroin may reduce the irritability seen in chronic cocaine users.

The mortality rate for street heroin users is very high. Early death comes from involvement in crime to support the habit; from uncertainty about the dose, the purity, and even the identity of what is purchased on the street; and from serious infections associated with nonsterile drugs and sharing of injection paraphernalia. Heroin users commonly

Table 23–7
Characteristics of Opioid Withdrawal

SYMPTOMS	SIGNS
Regular withdrawal	
Craving for opioids	Pupillary dilation
Restlessness, irritability	Sweating
Increased sensitivity to pain	Piloerection (“gooseflesh”)
Nausea, cramps	Tachycardia
Muscle aches	Vomiting, diarrhea
Dysphoric mood	Increased blood pressure
Insomnia, anxiety	Yawning
	Fever
Protracted withdrawal	
Anxiety	Cyclic changes in weight,
Insomnia	pupil size, respiratory
Drug craving	center sensitivity

acquire bacterial infections producing skin abscesses; endocarditis; pulmonary infections, especially tuberculosis; and viral infections producing hepatitis C and acquired immune deficiency syndrome (AIDS).

As with other addictions, the first stage of treatment addresses physical dependence and consists of detoxification (Kosten and O’Conner, 2003). The opioid-withdrawal syndrome (Table 23–7) is very unpleasant but not life-threatening. It begins within 6 to 12 hours after the last dose of a short-acting opioid and as long as 72 to 84 hours after a very long-acting opioid medication. Heroin addicts go through early stages of this syndrome frequently when heroin is scarce or expensive. Some therapeutic communities as a matter of policy elect not to treat withdrawal so that the addict can experience the suffering while being given group support. The duration and intensity of the syndrome are related to the clearance of the individual drug. Heroin withdrawal is brief (5 to 10 days) and intense. *Methadone* withdrawal is slower in onset and lasts longer. Protracted withdrawal also is likely to be longer with methadone. (See more detailed discussions of protracted withdrawal under “Long-Term Management” below.)

Pharmacological Interventions. Opioid withdrawal signs and symptoms can be treated by three different approaches. The first and most commonly used approach depends on cross-tolerance and consists of transfer to a prescription opioid medication and then gradual dose reduction. The same principles of detoxification apply as for other types of physical dependence. It is convenient to change the patient from a short-acting opioid such as heroin to a long-acting one such as methadone. The initial dose of

methadone is typically 20 to 30 mg. This is a test dose to determine the level needed to reduce observed withdrawal symptoms. The first day’s total dose then can be calculated depending on the response and then reduced by 20% per day during the course of detoxification.

A second approach to detoxification involves the use of oral *clonidine* (CATAPRES, others), a medication approved only for the treatment of hypertension (see Chapter 32). Clonidine is an α_2 adrenergic agonist that decreases adrenergic neurotransmission from the locus ceruleus. Many of the autonomic symptoms of opioid withdrawal such as nausea, vomiting, cramps, sweating, tachycardia, and hypertension result from the loss of opioid suppression of the locus ceruleus system during the abstinence syndrome. Clonidine, acting *via* distinct receptors but by cellular mechanisms that mimic opioid effects, can alleviate many of the symptoms of opioid withdrawal. However, clonidine does not alleviate generalized aches and opioid craving characteristic of opioid withdrawal. When using clonidine to treat withdrawal, the dose must be titrated according to the stage and severity of withdrawal, beginning with 0.2 mg orally. Postural hypotension commonly occurs when clonidine treatment is used for withdrawal. A similar drug, *lofexidine* (not yet available in the United States), has greater selectivity for α_{2A} adrenergic receptors and is associated with less of the hypotension that limits the usefulness of clonidine in this setting.

A third method of treating opioid withdrawal involves activation of the endogenous opioid system without medication. The techniques proposed include acupuncture and several methods of CNS activation using transcutaneous electrical stimulation. While attractive theoretically, this has not yet been found to be practical. Rapid antagonist-precipitated opioid detoxification under general anesthesia has received considerable publicity because it promises detoxification in several hours while the patient is unconscious and thus not experiencing withdrawal discomfort. A mixture of medications has been used, but morbidity and mortality as reported in the lay press are unacceptable, with no demonstrated advantage in long-term outcome.

Long-Term Management. If patients are simply discharged from the hospital after withdrawal from opioids, there is a high probability of a quick return to compulsive opioid use. Addiction is a chronic disorder that requires long-term treatment. Numerous factors influence relapse. One factor is that the withdrawal syndrome does not end in 5 to 7 days. There are subtle signs and symptoms often called the *protracted withdrawal syndrome* (Table 23–7) that persist for up to 6 months. Physiological measures tend to oscillate as though a new set point were being established; during this phase, outpatient drug-free treatment has a low probability of success, even when the patient has received intensive prior treatment while protected from relapse in a residential program.

The most successful treatment for heroin addiction consists of stabilization on methadone. Patients who relapse repeatedly during drug-free treatment can be transferred directly to methadone without requiring detoxification. The dose of methadone must be sufficient to prevent withdrawal symptoms for at least 24 hours. The introduction of *buprenorphine*, a partial agonist at μ opioid receptors (see

Chapter 21), represents a major change in the treatment of opiate addiction. This drug produces minimal withdrawal symptoms and has a low potential for overdose, a long duration of action, and the ability to block heroin effects. The laws governing the prescription of opioids for addicts were changed so that trained physicians could treat up to 30 patients with maintenance buprenorphine to prevent relapse to opiate addiction. Treatment can take place in the physician's private office rather than in a special center, as required for methadone. When taken sublingually, buprenorphine (SUBUTEX) is active, but it also has the potential to be dissolved and injected (abused). Thus, a buprenorphine-*naloxone* combination (SUBOXONE) is also available. When taken orally (sublingually), the naloxone moiety is not effective, but if the patient abuses the medication by injecting, the naloxone will block the mild subjective high that could be produced by buprenorphine alone.

Agonist or Partial-Agonist Maintenance. Patients receiving methadone or buprenorphine will not experience the ups and downs experienced while on heroin (Figure 23-4). Drug craving diminishes and may disappear. Neuroendocrine rhythms eventually are restored (Kreek *et al.*, 2002). Because of cross-tolerance (from methadone to heroin), patients who inject street heroin report a reduced effect from usual heroin doses. This cross-tolerance effect is dose-related, so higher methadone maintenance doses result in less illicit opioid use, as determined by random urine testing. Buprenorphine, as a partial agonist, has a ceiling effect at about 16 mg of the sublingual tablet equaling no more than 60 mg methadone. If the patient has a higher level of physical dependence, methadone, a full agonist, must be used. Patients become tolerant to the sedating effects of methadone and become able to attend school or function in a job. Opioids also have a persistent, mild, stimulating effect noticeable after tolerance to the sedating effect, such that reaction time is quicker and vigilance is increased while on a stable dose of methadone.

Antagonist Treatment. Another pharmacological option is opioid antagonist treatment. *Naltrexone* (REVIA; see Chapter 21) is an antagonist with a high affinity for the μ opioid receptor (MOR); it will competitively block the effects of heroin or other MOR agonists. Naltrexone has almost no agonist effects of its own and will not satisfy craving or relieve protracted withdrawal symptoms. For these reasons, naltrexone treatment does not appeal to the average heroin addict, but it can be used after detoxification for patients with high motivation to remain opioid-free. Physicians, nurses, and pharmacists who have frequent access to opioid drugs make excellent candidates for this treatment approach. A depot formulation of naltrexone that provides 30 days of medication after a single injection is in clinical trials. This formulation would eliminate the necessity of daily pill-taking and prevent relapse when the recently detoxified patient leaves a protected environment.

Cocaine and Other Psychostimulants

Cocaine. More than 23 million Americans are estimated to have used cocaine at some time, but the number of current users declined from an estimated 8.6 million occasional users and 5.8 million regular users to 3.6 million who are currently estimated to be chronic cocaine users. The number of frequent users (at least weekly) has remained steady since 1991 at about 640,000. Not all users become addicts, and the variables that influence this

risk are discussed at the beginning of this chapter. A key factor is the widespread availability of relatively inexpensive cocaine in the alkaloidal form (free base, "crack") suitable for smoking and the hydrochloride powder form suitable for nasal or intravenous use. Drug abuse in men occurs about twice as frequently as in women. However, smoked cocaine use is particularly common in young women of childbearing age, who may use cocaine in this manner as commonly as do men.

The reinforcing effects of cocaine and cocaine analogs correlate best with their effectiveness in blocking the transporter that recovers dopamine from the synapse. This leads to increased dopamine concentrations at critical brain sites (Ritz *et al.*, 1987). However, cocaine also blocks both norepinephrine (NE) and serotonin (5-HT) reuptake, and chronic use of cocaine produces changes in these neurotransmitter systems, as measured by reductions in the neurotransmitter metabolites 3-methoxy-4-hydroxyphenylethyleneglycol (MOPEG or MHPG) and 5-hydroxyindoleacetic acid (5-HIAA).

The general pharmacology and legitimate use of cocaine are discussed in Chapter 14. Cocaine produces a dose-dependent increase in heart rate and blood pressure accompanied by increased arousal, improved performance on tasks of vigilance and alertness, and a sense of self-confidence and well-being. Higher doses produce euphoria, which has a brief duration and often is followed by a desire for more drug. Involuntary motor activity, stereotyped behavior, and paranoia may occur after repeated doses. Irritability and increased risk of violence are found among heavy chronic users. The half-life of cocaine in plasma is about 50 minutes, but inhalant (crack) users typically desire more cocaine after 10 to 30 minutes. Intranasal and intravenous uses also result in a high of shorter duration than would be predicted by plasma cocaine levels, suggesting that a declining plasma concentration is associated with termination of the high and resumption of cocaine seeking. This theory is supported by positron-emission tomographic imaging studies using ^{11}C -labeled cocaine, which show that the time course of subjective euphoria parallels the uptake and displacement of the drug in the corpus striatum (Volkow *et al.*, 1999). The major route for cocaine metabolism involves hydrolysis of each of its two ester groups. Benzoyllecgonine, produced on loss of the methyl group, represents the major urinary metabolite and can be found in the urine for 2 to 5 days after a binge. As a result, benzoyllecgonine tests are useful for detecting cocaine use; heavy users have detectable amounts of the metabolite in their urine for up to 10 days following a binge. Cocaine frequently is used in combination with other drugs. The cocaine-heroin combination was discussed earlier in the opioid section. Alcohol is another drug that cocaine users take to

reduce the irritability experienced during heavy cocaine use. Some develop alcohol addiction in addition to their cocaine problem. An important metabolic interaction occurs when cocaine and alcohol are taken concurrently. Some cocaine is transesterified to cocaethylene, which is equipotent to cocaine in blocking dopamine reuptake (Hearn *et al.*, 1991).

Addiction is the most common complication of cocaine use. Some users, especially intranasal users, can continue intermittent use for years. Others become compulsive users despite elaborate methods to maintain control. Stimulants tend to be used much more irregularly than opioids, nicotine, and alcohol. Binge use is very common, and a binge may last hours to days, terminating only when supplies of the drug are exhausted.

Toxicity. Other risks of cocaine use, beyond the potential for addiction, involve cardiac arrhythmias, myocardial ischemia, myocarditis, aortic dissection, cerebral vasoconstriction, and seizures. Death from trauma also is associated with cocaine use. Pregnant cocaine users may experience premature labor and abruptio placentae (Chasnoff *et al.*, 1989). Attributing the developmental abnormalities reported in infants born to cocaine-using women simply to cocaine use is confounded by the infant's prematurity, multiple-drug exposure, and overall poor pre- and postnatal care.

Cocaine has been reported to produce a prolonged and intense orgasm if taken prior to intercourse, and its use is associated with compulsive and promiscuous sexual activity. Long-term cocaine use, however, usually results in reduced sexual drive; complaints of sexual problems are common among cocaine users presenting for treatment. Psychiatric disorders, including anxiety, depression, and psychosis, are common in cocaine users who request treatment. While some of these psychiatric disorders undoubtedly existed prior to the stimulant use, many develop during the course of the drug abuse (McLellan *et al.*, 1979).

Tolerance, Dependence, and Withdrawal. Sensitization is a consistent finding in animal studies of cocaine and other stimulants. Sensitization is produced by intermittent use and typically is measured by behavioral hyperactivity. In human cocaine users, sensitization for the euphoric effect typically is not seen. On the contrary, most experienced users report requiring more cocaine over time to obtain euphoria, *i.e.*, tolerance. In the laboratory, tachyphylaxis (rapid tolerance) has been observed with reduced effects when the same dose is given repeatedly in one session. Sensitization may involve conditioning (Figure 23–2). Cocaine users often report a strong response on seeing cocaine before it is administered, consisting of physiological arousal and increased drug craving with concomitant activation of brain limbic structures (Childress *et al.*, 1999). Sensitization in human beings has been linked to paranoid, psychotic manifestations of cocaine use based on the observation that cocaine-induced hallucinations and paranoia typically are seen after long-term exposure (mean 35 months) in vulnerable users (Satei *et al.*, 1991). Since cocaine typically is used intermittently, even heavy users go through frequent periods of withdrawal or “crash.” The symptoms of withdrawal seen in users admitted to hospitals are listed in Table 23–8. Careful studies of cocaine users during withdrawal show gradual diminution of these symptoms over 1 to 3 weeks (Weddington *et al.*, 1990). Residual depression may be seen after cocaine withdrawal and should be treated with antidepressant agents if it persists (*see* Chapter 17).

Table 23–8
Cocaine Withdrawal Symptoms and Signs

Dysphoria, depression
Sleepiness, fatigue
Cocaine craving
Bradycardia

Pharmacological Interventions. Since cocaine withdrawal is generally mild, treatment of withdrawal symptoms usually is not required. The major problem in treatment is not detoxification but helping the patient to resist the urge to restart compulsive cocaine use. Rehabilitation programs involving individual and group psychotherapy based on the principles of Alcoholics Anonymous and behavioral treatments based on reinforcing cocaine-free urine tests result in significant improvement in the majority of cocaine users (Alterman *et al.*, 1994; Higgins *et al.*, 1994). Nonetheless, there is great interest in finding a medication that can aid in the rehabilitation of cocaine addicts.

Numerous medications have been tried in placebo-controlled clinical trials with cocaine addicts, but finding a medication that consistently improves the results of behavior therapy alone has been elusive. Animal models suggest that enhancing GABAergic inhibition can reduce reinstatement of cocaine self-administration. This finding prompted a controlled clinical trial of *topiramate* (TOPAMAX) that showed a significant improvement for this medication approved for use in epilepsy. Topiramate also was found to reduce the relapse rate in alcoholics, prompting current studies in patients dually dependent on cocaine and alcohol. *Baclofen* (LIORESAL, others), a GABA_B agonist, was found in a single-site trial to reduce relapse in cocaine addicts and currently is being studied in a multiclinic trial. A different approach was taken using *modafinil* (PROVIGIL), a medication that increases alertness and is approved for the treatment of narcolepsy. This medication was found to reduce the euphoria produced by cocaine and to relieve cocaine withdrawal symptoms. After a single-site, double-blind study found it effective in reducing relapse, modafinil is being studied in a multisite trial among cocaine-dependent patients.

Two completely different approaches are also under study: a compound that competes with cocaine at the dopamine transporter and a vaccine that produces cocaine-binding antibodies. However, these should be regarded as innovative ideas that have yet to be shown to be useful clinically. The recent spate of positive findings from placebo-controlled trials suggests that an effective medication for

cocaine addiction may be on the horizon. For now, the treatment of choice remains behavioral, with medication indicated for specific coexisting disorders such as depression.

Amphetamine and Related Agents. Subjective effects similar to those of cocaine are produced by *amphetamine*, *dextroamphetamine*, *methamphetamine*, *phenmetrazine*, *methylphenidate*, and *diethylpropion*. Amphetamines increase synaptic dopamine primarily by stimulating presynaptic release rather than by blockade of reuptake, as is the case with cocaine. Intravenous or smoked methamphetamine produces an abuse/dependence syndrome similar to that of cocaine, although clinical deterioration may progress more rapidly. In animal studies, methamphetamine in doses comparable with those used by human abusers produces neurotoxic effects in dopamine and serotonin neurons. Methamphetamine can be produced in small, clandestine laboratories starting with ephedrine, a widely available nonprescription stimulant. Oral stimulants, such as those prescribed in a weight-reduction program, have short-term efficacy because of tolerance development. Only a small proportion of patients introduced to these appetite suppressants subsequently exhibits dose escalation or drug seeking from various physicians; such patients may meet diagnostic criteria for abuse or addiction. *Fenfluramine* (no longer marketed in the United States) and *phenylpropanolamine* (no longer marketed in the United States) reduce appetite with no evidence of significant abuse potential. *Mazindol* (no longer marketed in the United States) also reduces appetite, with less stimulant properties than amphetamine.

Khat is a plant material widely chewed in East Africa and Yemen for its stimulant properties; these are due to the alkaloidal *cathinone*, a compound similar to amphetamine (Kalix, 1990). *Methcathinone*, a congener with similar effects, has been synthesized in clandestine laboratories, but widespread use in North America has not been reported. MDMA (“ecstasy”) also has stimulant properties and will be discussed in the section on hallucinogens.

Caffeine. Caffeine, a mild stimulant, is the most widely used psychoactive drug in the world. It is present in soft drinks, coffee, tea, cocoa, chocolate, and numerous prescription and over-the-counter drugs. It mildly increases norepinephrine and dopamine release and enhances neural activity in numerous brain areas. Caffeine is absorbed from the digestive tract and is distributed rapidly throughout all tissues and easily crosses the placental barrier (see Chapter 27). Many of caffeine’s effects are believed to occur by means of competitive antagonism at adenosine receptors. Adenosine is a neuromodulator that influences a number of functions in the CNS (see Chap-

ters 12 and 27). The mild sedating effects that occur when adenosine activates particular adenosine-receptor subtypes can be antagonized by caffeine.

Tolerance occurs rapidly to the stimulating effects of caffeine. Thus a mild withdrawal syndrome has been produced in controlled studies by abrupt cessation of as little as one to two cups of coffee per day. Caffeine withdrawal consists of feelings of fatigue and sedation. With higher doses, headaches and nausea have been reported during withdrawal; vomiting is rare (Silverman *et al.*, 1992). Although a withdrawal syndrome can be demonstrated, few caffeine users report loss of control of caffeine intake or significant difficulty in reducing or stopping caffeine, if desired (Dews *et al.*, 1999). Thus, caffeine is not listed in the category of addicting stimulants (American Psychiatric Association, 1994).

Cannabinoids (Marijuana)

The cannabis plant has been cultivated for centuries both for the production of hemp fiber and for its presumed medicinal and psychoactive properties. The smoke from burning cannabis contains many chemicals, including 61 different cannabinoids that have been identified. One of these, Δ -9-tetrahydrocannabinol (Δ -9-THC), produces most of the characteristic pharmacological effects of smoked marijuana.

Surveys have shown that marijuana is the most commonly used illegal drug in the United States. Usage peaked during the late 1970s, when about 60% of high school seniors reported having used marijuana, and nearly 11% reported daily use. This declined steadily among high school seniors to about 40% reporting some use during their lifetime and 2% reporting daily use in the mid-1990s, followed by a gradual increase to 48% of 12th graders in 2002 reporting some use. Surveys among high school seniors tend to underestimate drug use because school dropouts are not surveyed.

Cannabinoid receptors CB-1 (mainly CNS) and CB-2 (peripheral) have been identified and cloned. An arachidonic acid derivative has been proposed as an endogenous ligand and named *anandamide*. While the physiological function of these receptors and their endogenous ligands are incompletely understood, they are likely to have important functions because they are dispersed widely with high densities in the cerebral cortex, hippocampus, striatum, and cerebellum (Iversen, 2003). Specific CB-1 antagonists have been developed and are in controlled clinical trials. One of these, *rimonabant*, has been reported to reduce relapse in cigarette smokers and to produce weight loss in obese patients.

The pharmacological effects of Δ -9-THC vary with the dose, route of administration, experience of the user, vulnera-

bility to psychoactive effects, and setting of use. Intoxication with marijuana produces changes in mood, perception, and motivation, but the effect sought after by most users is the “high” and “mellowing out.” This effect is described as different from the stimulant high and the opiate high. The effects vary with dose, but the typical marijuana smoker experiences a high that lasts about 2 hours. During this time, there is impairment of cognitive functions, perception, reaction time, learning, and memory. Impairments of coordination and tracking behavior have been reported to persist for several hours beyond the perception of the high. These impairments have obvious implications for the operation of a motor vehicle and performance in the workplace or at school.

Marijuana also produces complex behavioral changes such as giddiness and increased hunger. There are unsubstantiated claims of increased pleasure from sex and increased insight during a marijuana high. Unpleasant reactions such as panic or hallucinations and even acute psychosis may occur; several surveys indicate that 50% to 60% of marijuana users have reported at least one anxiety experience. These reactions are seen commonly with higher doses and with oral ingestion rather than smoked marijuana because smoking permits the regulation of dose according to the effects. While there is no convincing evidence that marijuana can produce a lasting schizophrenia-like syndrome, there are numerous clinical reports that marijuana use can precipitate a recurrence in people with a history of schizophrenia.

One of the most controversial of the reputed effects of marijuana is the production of an “amotivational syndrome.” This syndrome is not an official diagnosis, but it has been used to describe young people who drop out of social activities and show little interest in school, work, or other goal-directed activity. When heavy marijuana use accompanies these symptoms, the drug often is cited as the cause, even though there are no data that demonstrate a causal relationship between marijuana smoking and these behavioral characteristics. There is no evidence that marijuana use damages brain cells or produces any permanent functional changes, although there are animal data indicating impairment of maze learning that persists for weeks after the last dose. These findings are consistent with clinical reports of gradual improvement in mental state after cessation of chronic high-dose marijuana use.

Several medicinal benefits of marijuana have been described. These include anti-nausea effects that have been applied to the relief of side effects of anticancer chemotherapy, muscle-relaxing effects, anticonvulsant effects, and reduction of intraocular pressure for the treatment of glaucoma. These medical benefits come at the cost of the psychoactive effects that often impair normal activities. Thus there is no clear advantage of marijuana over con-

Nausea, cramping

ventional treatments for any of these indications (Joy *et al.*, 1999). With the cloning of cannabinoid receptors, the discovery of endogenous ligands, and the synthesis of specific agonists and antagonists, it is likely that orally effective medications will be developed without the undesirable properties of smoked marijuana and without the deleterious effects of inhaling smoke particles and the chemical products of high-temperature combustion.

Tolerance, Dependence, and Withdrawal. Tolerance to most of the effects of marijuana can develop rapidly after only a few doses, but also disappears rapidly (Martin *et al.*, 2004). Tolerance to large doses has been found to persist in experimental animals for long periods after cessation of drug use. Withdrawal symptoms and signs typically are not seen in clinical populations. In fact, relative to the number of marijuana smokers, few patients ever seek treatment for marijuana addiction. A withdrawal syndrome in human subjects has been described following close observation of marijuana users given regular oral doses of the agent on a research ward (Table 23–9). This syndrome, however, is only seen clinically in persons who use marijuana on a daily basis and then suddenly stop. Compulsive or regular marijuana users do not appear to be motivated by fear of withdrawal symptoms, although this has not been studied systematically. A large study of psychotherapy for self-identified marijuana-dependent persons reported significant reductions in the use of marijuana after treatment, but there was no control group.

Pharmacological Interventions. Marijuana abuse and addiction have no specific treatments. Heavy users may suffer from accompanying depression and thus may respond to antidepressant medication, but this should be decided on an individual basis considering the severity of the affective symptoms after the marijuana effects have dissipated. The residual drug effects may continue for several weeks. The CB-1 receptor antagonist *rimonabant* has been reported to block the acute effects of smoked marijuana, but there have been no clinical trials of this medication in the treatment of marijuana dependence.

Psychedelic Agents

Perceptual distortions that include hallucinations, illusions, and disorders of thinking such as paranoia can be produced

by toxic doses of many drugs. These phenomena also may be seen during toxic withdrawal from sedatives such as alcohol. There are, however, certain drugs that have as their primary effect the production of disturbances of perception, thought, or mood at low doses with minimal effects on memory and orientation. These are commonly called *hallucinogenic drugs*, but their use does not always result in frank hallucinations. In the late 1990s, the use of “club drugs” at all-night dance parties became popular. Such drugs include *methylenedioxyamphetamine* (MDMA, “ecstasy”), *lysergic acid diethylamide* (LSD), *phencyclidine* (PCP), and *ketamine* (KETALAR). They often are used in association with illegal sedatives such as *flunitrazepam* (ROHYPNOL) or *γ-hydroxybutyrate* (GHB). The latter drug has the reputation of being particularly effective in preventing memory storage, so it has been implicated in “date rapes.”

While psychedelic effects can be produced by a variety of different drugs, major psychedelic compounds come from two main categories. The indoleamine hallucinogens include LSD, *N,N*-dimethyltryptamine (DMT), and *psilocybin*. The phenethylamines include *mescaline*, *dimethoxymethylamphetamine* (DOM), *methylenedioxyamphetamine* (MDA), and MDMA. Both groups have a relatively high affinity for serotonin 5-HT₂ receptors (see Chapter 11), but they differ in their affinity for other subtypes of 5-HT receptors. There is a good correlation between the relative affinity of these compounds for 5-HT₂ receptors and their potency as hallucinogens in human beings (Titeler *et al.*, 1988). The 5-HT₂ receptor is further implicated in the mechanism of hallucinations by the observation that antagonists of that receptor, such as *ritanserlin*, are effective in blocking the behavioral and electrophysiological effects of hallucinogenic drugs in animal models. However, LSD has been shown to interact with many receptor subtypes at nanomolar concentrations, and at present, it is not possible to attribute the psychedelic effects to any single 5-HT receptor subtype (Peroutka, 1994).

LSD. LSD is the most potent hallucinogenic drug and produces significant psychedelic effects with a total dose of as little as 25 to 50 μg. This drug is more than 3000 times more potent than mescaline. LSD is sold on the illicit market in a variety of forms. A popular contemporary system involves postage stamp-sized papers impregnated with varying doses of LSD (50 to 300 μg or more). Most street samples sold as LSD actually contain LSD. In contrast, the samples of mushrooms and other botanicals sold as sources of psilocybin and other psychedelics have a low probability of containing the advertised hallucinogen.

The effects of hallucinogenic drugs are variable, even in the same individual on different occasions. LSD is absorbed rapidly after oral administration, with effects beginning at 40 to 60 minutes, peaking at 2 to 4 hours, and gradually returning to baseline over 6 to 8 hours. At a dose of 100 μg, LSD produces perceptual distortions and sometimes hallucinations; mood changes, including elation, paranoia, or depression; intense arousal; and sometimes a feeling of panic. Signs of LSD ingestion include pupillary dilation, increased blood pressure and pulse, flushing, salivation, lacrimation, and hyperreflexia. Visual effects are prominent. Colors seem more intense, and shapes may appear altered. The subject may focus attention on unusual items such as the pattern of hairs on the back of the hand.

A “bad trip” usually consists of severe anxiety, although at times it is marked by intense depression and suicidal thoughts. Visual disturbances usually are prominent. The bad trip from LSD may be difficult to distinguish from reactions to anticholinergic drugs and phencyclidine. There are no documented toxic fatalities from LSD use, but fatal accidents and suicides have occurred during or shortly after intoxication. Prolonged psychotic reactions lasting 2 days or more may occur after the ingestion of a hallucinogen. Schizophrenic episodes may be precipitated in susceptible individuals, and there is some evidence that chronic use of these drugs is associated with the development of persistent psychotic disorders (McLellan *et al.*, 1979).

Claims about the potential of psychedelic drugs for enhancing psychotherapy and for treating addictions and other mental disorders have not been supported by controlled treatment outcome studies. Consequently, there is no current indication for these drugs as medications.

Tolerance, Physical Dependence, and Withdrawal. Frequent, repeated use of psychedelic drugs is unusual, and thus tolerance is not commonly seen. Tolerance does develop to the behavioral effects of LSD after three to four daily doses, but no withdrawal syndrome has been observed. Cross-tolerance among LSD, mescaline, and psilocybin has been demonstrated in animal models.

Pharmacological Intervention. Because of the unpredictability of psychedelic drug effects, any use carries some risk. Dependence and addiction do not occur, but users may require medical attention because of “bad trips.” Severe agitation may require medication, and *diazepam* (20 mg orally) has been found to be effective. “Talking down” by reassurance also has been shown to be effective and is the management of first choice. Neuroleptic medications (see Chapter 18) may intensify the experience and thus are not indicated.

A particularly troubling after-effect of the use of LSD and similar drugs is the occurrence of episodic visual disturbances in a small proportion of former users. These originally were called “flashbacks” and resembled the experiences of prior LSD trips. There now is an official diagnostic category called the *hallucinogen persisting perception disorder* (HPPD; American Psychiatric Association,

1994). The symptoms include false fleeting perceptions in the peripheral fields, flashes of color, geometric pseudohallucinations, and positive afterimages (Abraham and Aldridge, 1993). The visual disorder appears stable in half the cases and represents an apparently permanent alteration of the visual system. Precipitants include stress, fatigue, emergence into a dark environment, marijuana, neuroleptics, and anxiety states.

MDMA (“Ecstasy”) and MDA. MDMA and MDA are phenylethylamines that have stimulant as well as psychedelic effects. MDMA became popular during the 1980s on college campuses because of testimonials that it enhances insight and self-knowledge. It was recommended by some psychotherapists as an aid to the process of therapy, although no controlled data exist to support this contention. Acute effects are dose-dependent and include feelings of energy, altered sense of time, and pleasant sensory experiences with enhanced perception. Negative effects include tachycardia, dry mouth, jaw clenching, and muscle aches. At higher doses, visual hallucinations, agitation, hyperthermia, and panic attacks have been reported. A typical oral dose is one or two 100-mg tablets and lasts 3 to 6 hours, although dosage and potency of street samples are variable (approximately 100 mg per tablet).

MDA and MDMA produce degeneration of serotonergic nerve cells and axons in rats. While nerve degeneration has not been demonstrated in human beings, the cerebrospinal fluid of chronic MDMA users has been found to have low levels of serotonin metabolites (Ricaute *et al.*, 2000). Thus, there is possible neurotoxicity with no evidence that the claimed benefits of MDMA actually occur.

Phencyclidine (PCP). PCP deserves special mention because of its widespread availability and because its pharmacological effects are different from those of the psychedelics such as LSD. PCP was developed originally as an anesthetic in the 1950s and later was abandoned because of a high frequency of postoperative delirium with hallucinations. It was classed as a dissociative anesthetic because, in the anesthetized state, the patient remains conscious with staring gaze, flat facies, and rigid muscles. PCP became a drug of abuse in the 1970s, first in an oral form and then in a smoked version enabling a better regulation of the dose. The effects of PCP have been observed in normal volunteers under controlled conditions. As little as 50 $\mu\text{g}/\text{kg}$ produces emotional withdrawal, concrete thinking, and bizarre responses to projective testing. Catatonic posturing also is produced and resembles that of schizophrenia. Abusers taking higher doses may appear to be reacting to hallucinations and exhibit hostile or assaultive behavior. Anesthetic effects

increase with dosage; stupor or coma may occur with muscular rigidity, rhabdomyolysis, and hyperthermia. Intoxicated patients in the emergency room may progress from aggressive behavior to coma, with elevated blood pressure and enlarged nonreactive pupils.

PCP binds with high affinity to sites located in the cortex and limbic structures, resulting in blocking of *N*-methyl-D-aspartate (NMDA)-type glutamate receptors (*see* Chapter 12). LSD and other psychedelics do not bind to NMDA receptors. There is evidence that NMDA receptors are involved in ischemic neuronal death caused by high levels of excitatory amino acids; as a result, there is interest in PCP analogs that block NMDA receptors but with fewer psychoactive effects. Both PCP and ketamine (“Special K”), another “club drug,” produce similar effects by altering the distribution of the neurotransmitter glutamate.

Tolerance, Dependence, and Withdrawal. PCP is reinforcing in monkeys, as evidenced by self-administration patterns that produce continuous intoxication. Human beings tend to use PCP intermittently, but some surveys report daily use in 7% of users queried. There is evidence for tolerance to the behavioral effects of PCP in animals, but this has not been studied systematically in human beings. Signs of a PCP withdrawal syndrome were observed in monkeys after interruption of daily access to the drug. These include somnolence, tremor, seizures, diarrhea, piloerection, bruxism, and vocalizations.

Pharmacological Intervention. Overdose must be treated by life support because there is no antagonist of PCP effects and no proven way to enhance excretion, although acidification of the urine has been proposed. PCP coma may last 7 to 10 days. The agitated or psychotic state produced by PCP can be treated with *diazepam*. Prolonged psychotic behavior requires neuroleptic medication (*see* Chapter 18). Because of the anticholinergic activity of PCP, neuroleptics with significant anticholinergic effects such as *chlorpromazine* should be avoided.

Inhalants

Abused inhalants consist of many different categories of chemicals that are volatile at room temperature and produce abrupt changes in mental state when inhaled. Examples include toluene (from model airplane glue), kerosene, gasoline, carbon tetrachloride, amyl nitrite, and nitrous oxide (*see* Chapter 64 for a discussion of the toxicology of such agents). There are characteristic patterns of response for each substance. Solvents such as toluene typically are used by children. The material usually is placed in a plastic bag and the vapors inhaled. After several minutes of inhalation, dizziness and intoxication occur. Aerosol sprays containing fluorocarbon propellants are another source of solvent intoxication. Prolonged exposure or daily use may result in damage to several organ systems. Clinical problems include cardiac arrhythmias, bone mar-

row depression, cerebral degeneration, and damage to liver, kidney, and peripheral nerves. Death occasionally has been attributed to inhalant abuse, probably *via* the mechanism of cardiac arrhythmias, especially accompanying exercise or upper airway obstruction.

Amyl nitrite produces dilation of smooth muscle and has been used in the past for the treatment of angina. It is a yellow, volatile, flammable liquid with a fruity odor. In recent years, amyl nitrite and *butyl nitrite* have been used to relax smooth muscle and enhance orgasm, particularly by male homosexuals. These agents are obtained in the form of room deodorizers and can produce a feeling of “rush,” flushing, and dizziness. Adverse effects include palpitations, postural hypotension, and headache progressing to loss of consciousness.

Anesthetic gases such as *nitrous oxide* and *halothane* sometimes are used as intoxicants by medical personnel. Nitrous oxide also is abused by food-service employees because it is supplied for use as a propellant in disposable aluminum mini tanks for whipping cream canisters. Nitrous oxide produces euphoria and analgesia and then loss of consciousness. Compulsive use and chronic toxicity are reported rarely, but there are obvious risks of overdose associated with the abuse of this anesthetic. Chronic use has been reported to cause peripheral neuropathy.

CLINICAL SUMMARY

The management of drug abuse and addiction must be individualized according to the drugs involved and the associated psychosocial problems of the individual patient. An understanding of the pharmacology of the drug or combination of drugs ingested by the patient is essential to rational and effective treatment. This may be a matter of urgency for the treatment of overdose or for the detoxification of a patient who is experiencing withdrawal symptoms. It must be recognized, however, that the treatment of the underlying addictive disorder requires months or years of rehabilitation. The behavior patterns encoded in memory during thousands of prior drug ingestions do not disappear with detoxification from the drug, even after a typical 28-day inpatient rehabilitation program. Long periods of outpatient treatment are necessary. There probably will be periods of relapse and remission. While complete abstinence is the preferred goal, in reality, most patients are at risk to resume drug-seeking behavior and require a period of retreatment. Maintenance medication can be effective in some circumstances, such as methadone, buprenor-

phine, or naltrexone for opioid dependence and disulfiram, naltrexone, or acamprostate for alcoholism. The process can best be compared to the treatment of other chronic disorders such as diabetes, asthma, or hypertension. Long-term medication may be necessary, and cures are not likely. When viewed in the context of chronic disease, the available treatments for addiction are quite successful in that the majority of patients improve, but improvement does not necessarily persist after treatment has ceased (McLellan *et al.*, 2000; O'Brien, 1994).

Long-term treatment is accompanied by improvements in physical status as well as in mental, social, and occupational function. Unfortunately, there is general pessimism in the medical community about the benefits of treatment such that most of the therapeutic effort is directed at the complications of addiction, such as pulmonary, cardiac, and hepatic disorders. Prevention of these complications can be accomplished by addressing the underlying addictive disorder.

SECTION IV

Autacoids: Drug Therapy of Inflammation

CHAPTER 24

HISTAMINE, BRADYKININ, AND THEIR ANTAGONISTS

Randal A. Skidgel and Ervin G. Erdös

HISTAMINE

History. The history of histamine (β -aminoethylimidazole) parallels that of acetylcholine (ACh). Both compounds were synthesized as chemical curiosities before their biological significance was recognized; they were first detected as uterine stimulants in extracts of ergot, from which they were subsequently isolated, and proved to be contaminants of ergot derived from bacterial action.

When Dale and Laidlaw subjected histamine to intensive pharmacological study, they discovered that it stimulated a host of smooth muscles and had an intense vasodepressor action. Remarkably, they observed that when a sensitized animal was injected with a normally inert protein, the immediate responses closely resembled those of poisoning by histamine. These observations anticipated by many years the discovery that endogenous histamine contributed to immediate hypersensitivity reactions and to responses to cellular injury. Best and colleagues (1927) isolated histamine from fresh samples of liver and lung, thereby establishing that this amine is a natural constituent of many mammalian tissues, hence the name *histamine* after the Greek word for tissue, *histos*.

Lewis and colleagues proposed that a substance with the properties of histamine (“H-substance”) was liberated from the cells of the skin by injurious stimuli, including the reaction of antigen with antibody. We now know that endogenous histamine plays a role in the immediate allergic response and is an important regulator of gastric acid secretion. More recently, a role for histamine as a modulator of neurotransmitter release in the central and peripheral nervous systems

has emerged. The presence of histamine in tissue extracts delayed the acceptance of the discovery of some peptide and protein hormones (e.g., gastrin) until the technology for separating the naturally occurring substances was sufficiently advanced (Grossman, 1966).

Early suspicions that histamine acts through more than one receptor have been borne out by the elucidation of four distinct classes of receptors for histamine, designated H_1 (Ash and Schild, 1966), H_2 (Black *et al.*, 1972), H_3 (Arrang *et al.*, 1987), and H_4 (Hough, 2001). H_1 receptors are blocked selectively by the classical “antihistamines” such as pyrilamine. Interest in the clinical use of H_1 -receptor antagonists has been renewed owing to the development of second-generation antagonists collectively referred to as *nonsedating antihistamines*. The term *third generation* has been applied to some recently developed antihistamines, such as active metabolites of first- or second-generation antihistamines that are not further metabolized (e.g., cetirizine derived from hydroxyzine or fexofenadine from terfenadine) or to antihistamines that have additional therapeutic effects. However, a review by the Consensus Group on New Generation Antihistamines concluded that none of the currently available antihistamines can be classified as true third-generation drugs, which they define as lacking in cardiotoxicity, drug–drug interactions, and central nervous system (CNS) effects with possible beneficial effects (e.g., antiinflammatory) (Holgate *et al.*, 2003). The discovery of H_2 antagonists and their ability to inhibit gastric secretion has contributed greatly to the resurgence of interest in histamine in biology and clinical medicine (see Chapter 36). H_3 receptors were discovered as presynaptic autoreceptors on histamine-containing neurons that mediated feedback inhibition of the release and synthesis of histamine. The development of selective H_3 -receptor agonists and antagonists has led to an increased understanding of the importance of H_3 receptors in histaminergic neurons *in vivo*. None of these H_3 -receptor agonists or antagonists has yet emerged as a therapeutic agent. The H_4 receptor is more similar to the H_3 receptor

Figure 24–1. Structure of histamine and some H₁, H₂, H₃, and H₄ agonists. The H₃ agonists are weaker H₄ receptor agonists.

than to the other histamine receptors and is expressed in cells of hematopoietic lineage; the availability of an H₄-specific antagonist with antiinflammatory properties should help to define the biological roles of the H₄ receptor (Thurmond *et al.*, 2004).

Chemistry. Histamine is a hydrophilic molecule consisting of an imidazole ring and an amino group connected by two methylene groups. The pharmacologically active form at all histamine receptors is the monocationic N γ -H tautomer, *i.e.*, the charged form of the species depicted in Figure 24–1, although different chemical

properties of this monocation may be involved in interactions with the H₁ and H₂ receptors (Ganellin and Parsons, 1982). The four classes of histamine receptors can be activated differently by analogs of histamine (Figure 24–1 and Table 24–1). Thus 2-methylhistamine preferentially elicits responses mediated by H₁ receptors, whereas 4(5)-methylhistamine has a preferential effect on H₂ receptors (Black *et al.*, 1972). A chiral analog of histamine with restricted conformational freedom, (*R*)- α -methylhistamine, is the preferred agonist at H₃-receptor sites, although it is a weak agonist of the H₄

Table 24–1

Characteristics of Histamine Receptors

	H ₁	H ₂	H ₃	H ₄
Size (amino acids)	487	359	373, 445, 365	390
G protein coupling (second messengers)	G _{q/11} (\uparrow Ca ²⁺ ; \uparrow cAMP)	G _s (\uparrow cAMP)	G _{i/o} (\downarrow cAMP)	G _{i/o} (\downarrow cAMP; \uparrow Ca ²⁺)
Distribution	Smooth muscle, endothelial cells, CNS	Gastric parietal cells, cardiac muscle, mast cells, CNS	CNS: presynaptic, myenteric plexus	Cells of hematopoietic origin
Representative agonist	2-CH ₃ -histamine	Dimaprit	(<i>R</i>)- α -CH ₃ -histamine	Clobenpropit (partial?)
Representative antagonist	Chlorpheniramine	Ranitidine	Thioperamide Clobenpropit	JNJ7777120 Thioperamide

Compounds affecting the H₃ and H₄ receptors exhibit some lack of specificity, although JNJ7777120 seems to be a relatively specific H₄ antagonist. JNJ7777120 is 1-[5-chloro-1H-indol-2-yl] carbonyl]-4-methylpiperazine (*see* Thurmond *et al.*, 2004).

Figure 24–2. Pathways of histamine metabolism in humans. See text for details.

receptor as well (Hough, 2001). Indeed, a number of compounds have activity at both the H₃ and H₄ receptors.

Distribution and Biosynthesis of Histamine

Distribution. Histamine is widely, if unevenly, distributed throughout the animal kingdom and is present in many venoms, bacteria, and plants. Almost all mammalian tissues contain histamine in amounts ranging from less than 1 to more than 100 μg/g. Concentrations in plasma and other body fluids generally are very low, but human cerebrospinal fluid (CSF) contains significant amounts. The mast cell is the predominant storage site for histamine in most tissues (see below); the concentration of histamine is particularly high in tissues that contain large numbers of mast cells, such as skin, bronchial tree mucosa, and intestinal mucosa.

Synthesis, Storage, and Metabolism. Histamine is formed by the decarboxylation of the amino acid histidine by the enzyme L-histidine decarboxylase (Figure 24–2). Every mammalian tissue that contains histamine is capable of synthesizing it from histidine by virtue of its content of L-histidine decarboxylase. The chief site of histamine storage in most tissues is the mast cell; in the blood, it is the basophil. These cells synthesize histamine and store it in secretory granules. At the secretory granule pH of approximately 5.5, histamine is positively charged and ionically complexed with negatively charged acidic groups on other constituents of the secretory granule, primarily proteases and heparin or chondroitin sulfate proteoglycans (Serafin and Austen, 1987). The turnover rate of histamine in secretory granules is slow, and when tissues rich in mast cells are depleted of their histamine stores, it may take weeks before concentrations return to normal levels. Non–mast cell sites of histamine formation or storage include the epidermis, the gastric mucosa, neurons within the CNS, and cells in regenerating or rapidly growing tissues. Turnover is rapid at these non–mast cell sites because the histamine is released continuously

rather than stored. Non–mast cell sites of histamine production contribute significantly to the daily excretion of histamine metabolites in the urine. Since L-histidine decarboxylase is an inducible enzyme, the histamine-forming capacity at such sites is subject to regulation. Ingested histamine does not contribute to the body's store: Histamine, in the amounts normally ingested or formed by bacteria in the gastrointestinal tract, is metabolized rapidly and eliminated in the urine.

There are two major paths of histamine metabolism in humans (Figure 24–2). The more important of these involves ring methylation to form *N*-methylhistamine, catalyzed by histamine-*N*-methyltransferase, which is distributed widely. Most of the *N*-methylhistamine formed is then converted *N*-methylimidazoleacetic acid by monoamine oxidase (MAO), and this reaction can be blocked by monoamine oxidase (MAO) inhibitors (see Chapters 17 and 20). Alternatively, histamine may undergo oxidative deamination catalyzed mainly by the nonspecific enzyme diamine oxidase (DAO), yielding imidazoleacetic acid, which is then converted to imidazoleacetic acid riboside. These metabolites have little or no activity and are excreted in the urine. Measurement of *N*-methylhistamine in urine affords a more reliable index of histamine production than assessment of histamine itself. Artificially elevated levels of histamine in urine arise from genitourinary tract bacteria that can decarboxylate histidine. In addition, the metabolism of histamine appears to be altered in patients with mastocytosis such that determination of histamine metabolites is a more sensitive diagnostic indicator of the disease than histamine.

Release and Functions of Endogenous Histamine

Histamine has important physiological roles. After its release from storage granules as a result of the interaction of antigen with immunoglobulin E (IgE) antibodies on the mast cell surface, histamine plays a central role in immediate hypersensitivity and allergic responses. The actions of histamine on bronchial smooth muscle and blood vessels account for many of the symptoms of the allergic response. In addition, certain clinically useful drugs can act directly on mast cells to release histamine, thereby explaining some of their untoward effects. Histamine has a major role in the regulation of gastric acid secretion and also modulates neurotransmitter release.

Role in Allergic Responses. The principal target cells of immediate hypersensitivity reactions are mast cells and basophils (Schwartz, 1994). As part of the allergic response to an antigen, reaginic (IgE) antibodies are generated and bind to the surfaces of mast cells and basophils via high-affinity F_c receptors that are specific for IgE. This receptor, FcεRI, consists of α, β, and two γ chains. The IgE molecules function as receptors for antigens and, via FcεRI, interact with signal-transduction systems in the membranes of sensitized cells (see Chapter 27). Atopic individuals develop IgE antibodies to commonly inhaled antigens. This is a heritable trait, and a candidate gene product has been identified as the β-chain of FcεRI. Antigen bridges the IgE molecules and activates signaling pathways in mast cells or basophils involving tyrosine kinases and subsequent phosphorylation of multiple protein substrates within 5 to 15 seconds of contact with antigen. Kinases implicated include the *Src*-related kinases Lyn and Syk. Prominent among the phosphorylated proteins are the β and γ subunits of FcεRI itself and phospholipases Cγ1 and

C γ 2 (with consequent production of IP $_3$ and mobilization of intracellular Ca $^{2+}$) (see Chapter 1). These events trigger the exocytosis of the contents of secretory granules (see Figure 6–2).

Release of Other Autacoids. The release of histamine only partially explains the biological effects that ensue from immediate hypersensitivity reactions. This is so because a broad spectrum of other inflammatory mediators is released on mast cell activation.

Stimulation of IgE receptors also activates phospholipase A $_2$ (PLA $_2$), leading to the production of a host of mediators, including platelet-activating factor (PAF) and metabolites of arachidonic acid. Leukotriene D $_4$, which is generated in this way, is a potent contractor of the smooth muscle of the bronchial tree (see Chapters 25 and 27). Kinins also are generated during some allergic responses. Thus the mast cell secretes a variety of inflammatory mediators in addition to histamine, each contributing to the major symptoms of the allergic response (see below).

Regulation of Mediator Release. The wide variety of mediators released during the allergic response explains the ineffectiveness of drug therapy focused on a single mediator. Considerable emphasis has been placed on the regulation of mediator release from mast cells and basophils, and these cells do contain receptors linked to signaling systems that can enhance or block the IgE-induced release of mediators.

Agents that act at muscarinic or α adrenergic receptors increase the release of mediators, although this effect is of little clinical significance. Epinephrine and related drugs that act through β_2 adrenergic receptors increase cellular cyclic AMP and thereby inhibit the secretory activities of mast cells. However, the beneficial effects of β adrenergic agonists in allergic states such as asthma are due mainly to their relaxant effect on bronchial smooth muscle (see Chapters 10 and 27). Cromolyn sodium is used clinically because it inhibits the release of mediators from mast and other cells in the lung (see Chapter 27).

Histamine Release by Drugs, Peptides, Venoms, and Other Agents.

Many compounds, including a large number of therapeutic agents, stimulate the release of histamine from mast cells directly and without prior sensitization. Responses of this sort are most likely to occur following intravenous injections of certain categories of substances, particularly organic bases such as amides, amidines, quaternary ammonium compounds, pyridinium compounds, piperidines, and alkaloids (Rothschild, 1966). Tubocurarine, succinylcholine, morphine, some antibiotics, radiocontrast media, and certain carbohydrate plasma expanders also may elicit the response. The phenomenon is one of clinical concern, for it may account for unexpected anaphylactoid reactions. Vancomycin-induced “red-man syndrome” involving upper body and facial flushing and hypotension may be mediated through histamine release.

In addition to therapeutic agents, certain experimental compounds stimulate the release of histamine as their dominant pharmacological characteristic. The archetype is the polybasic substance known as *compound 48/80*. This is a mixture of low-molecular-weight polymers of *p*-methoxy-*N*-methylphenethylamine, of which the hexamer is most active.

Basic polypeptides often are effective histamine releasers, and over a limited range, their potency generally increases with the number of basic groups. For example, bradykinin is a poor histamine releaser, whereas kallidin (Lys-bradykinin) and substance P, with more positively charged amino acids, are more active. Some venoms, such as that of the wasp, contain potent histamine-releasing peptides (Johnson and Erdős, 1973). Polymyxin B is also very active. Since basic polypeptides are released on tissue injury, they constitute patho-

physiological stimuli to secretion for mast cells and basophils. Anaphylatoxins (C3a and C5a), which are low-molecular-weight peptides released during activation of complement, may act similarly.

Within seconds of the intravenous injection of a histamine liberator, human subjects experience a burning, itching sensation. This effect, most marked in the palms of the hand and in the face, scalp, and ears, is soon followed by a feeling of intense warmth. The skin reddens, and the color rapidly spreads over the trunk. Blood pressure falls, the heart rate accelerates, and the subject usually complains of headache. After a few minutes, blood pressure recovers, and crops of hives usually appear on the skin. Colic, nausea, hypersecretion of acid, and moderate bronchospasm also occur frequently. The effect becomes less intense with successive injections as the mast cell stores of histamine are depleted. Histamine liberators do not deplete tissues of non-mast cell histamine.

Mechanism of Histamine-Releasing Agents. Histamine-releasing substances activate the secretory responses of mast cells and basophils by causing a rise in intracellular Ca $^{2+}$. Some are ionophores and facilitate the entry of Ca $^{2+}$ into the cell; others, such as neurotensin, act on specific G protein-coupled receptor. In contrast, basic secretagogues (e.g., substance P, mastoparan, kallidin, compound 48/80, and polymyxin B) do not act *via* specific high-affinity receptors on mast cells. Their precise mechanism of action is still unclear but likely results from either interaction with a common cell surface binding site, such as a nonspecific G protein-coupled receptor, or by direct activation of G $_i$ proteins after being taken up by the cell (Ferry *et al.*, 2002). The downstream effectors appear to be $\beta\gamma$ subunits released from G α , which activate the PLC β -IP $_3$ -Ca $^{2+}$ pathway. Antigen-IgE complexes lead to mobilization of stored Ca $^{2+}$ in phosphorylative activation of isoforms of PLC γ , as described earlier.

Histamine Release by Other Means. Clinical conditions in which release of histamine occurs in response to other stimuli include cold urticaria, cholinergic urticaria, and solar urticaria. Some of these involve specific secretory responses of the mast cells and cell-fixed IgE. However, histamine release also occurs whenever there is nonspecific cell damage from any cause. The redness and urticaria that follow scratching of the skin is a familiar example.

Increased Proliferation of Mast Cells and Basophils and Gastric Carcinoid Tumors.

In urticaria pigmentosa (cutaneous mastocytosis), mast cells aggregate in the upper corium and give rise to pigmented cutaneous lesions that urticate (*i.e.*, sting) when stroked. In systemic mastocytosis, overproliferation of mast cells also is found in other organs. Patients with these syndromes suffer a constellation of signs and symptoms attributable to excessive histamine release, including urticaria, dermographism, pruritus, headache, weakness, hypotension, flushing of the face, and a variety of gastrointestinal effects such as peptic ulceration. Episodes of mast cell activation with attendant systemic histamine release are precipitated by a variety of stimuli, including exertion, emotional upset, exposure to heat, and exposure to drugs that release histamine directly or to which patients are allergic. In myelogenous leukemia, excessive numbers of basophils are present in the blood, raising its histamine content to high levels that may contribute to chronic pruritus. Gastric carcinoid tumors secrete histamine, which is responsible for episodes of vasodilation as part of the patchy “geographical” flush (Roberts *et al.*, 1979).

Gastric Acid Secretion. Acting at H $_2$ receptors, histamine is a powerful gastric secretagogue and evokes a copious secretion of acid from parietal cells (see Figure 36–1); it also increases the output of pepsin

and intrinsic factor. Although the secretion of gastric acid also is evoked by stimulation of the vagus nerve and by the enteric hormone gastrin, presumably by activation of M_3 and CCK_2 receptors on the parietal cell, acetylcholine and gastrin also stimulate histamine release from the enterochromaffinlike cell. There is no doubt that histamine is the dominant physiological mediator of acid secretion: Blockade of H_2 receptors not only eliminates acid secretion in response to histamine but also causes nearly complete inhibition of responses to gastrin and vagal stimulation. The regulation of gastric acid secretion and the clinical utility of H_2 antagonists are discussed in Chapter 36.

Central Nervous System. There is substantial evidence that histamine functions as a neurotransmitter in the CNS. Histamine, histidine decarboxylase, and enzymes that catalyze the degradation of histamine are distributed nonuniformly in the CNS and are concentrated in synaptosomal fractions of brain homogenates. H_1 receptors are found throughout the CNS and are densely concentrated in the hypothalamus. Histamine increases wakefulness *via* H_1 receptors, explaining the potential for sedation by classical antihistamines. Histamine acting through H_1 receptors inhibits appetite (Ookuma *et al.*, 1993). Histamine-containing neurons may participate in the regulation of drinking, body temperature, and the secretion of antidiuretic hormone, as well as in the control of blood pressure and the perception of pain. Both H_1 and H_2 receptors seem to be involved in these responses (*see* Hough, 1988). Knockout of the H_1 receptor in mice by genetic engineering was associated with increased aggression, locomotion problems, and other neurological symptoms (Simons, 2003a). Central effects of histamine also may be mediated by presynaptic H_3 autoreceptors, which are found almost exclusively in the brain. This is consistent with changes in anxiety and cognition in animals treated with H_3 -receptor antagonists or in mice in which the H_3 receptor was genetically deleted.

Pharmacological Effects

Receptor–Effector Coupling and Mechanisms of Action. Histamine receptors are GPCRs (Leurs *et al.*, 2001; Hough, 2001) (Table 24–1). The H_1 histamine receptors couple to $G_{q/11}$ and activate the PLC–IP₃–Ca²⁺ pathway and its many possible sequelae, including activation of protein kinase C (PKC), Ca²⁺–calmodulin–dependent enzymes (eNOS and various protein kinases), and PLA₂. H_2 receptors link to G_s to activate the adenylyl cyclase–cyclic AMP–protein kinase A (PKA) pathway, whereas H_3 and H_4 receptors couple to $G_{i/o}$ to inhibit adenylyl cyclase (Leurs *et al.*, 2001; Hough, 2001); activation of H_4 receptors also mobilizes stored Ca²⁺ in some cells. Armed with this information, with knowledge of the cellular expression of H-receptor subtypes, and with an understanding of the differentiated functions of a particular cell type, one can predict a cell's response to histamine. Of course, a cell in a physiological setting is exposed to a myriad of hormones simultaneously, and significant interactions may occur between signaling pathways, such as the $G_q \rightarrow G_s$ cross-talk described in a number of systems (Meszaros *et al.*, 2000). Furthermore, the differential expression of H-receptor subtypes on neigh-

boring cells and the unequal sensitivities of H-receptor–effector response pathways can cause parallel and opposing cellular responses to occur together, complicating interpretation of the overall response of a tissue. For example, activation of H_1 receptors on vascular endothelium stimulates the Ca²⁺-mobilizing pathways (G_q –PLC–IP₃) and activates nitric oxide (NO) production by eNOS, relaxing nearby smooth muscle cells. Stimulation of H_1 receptors on smooth muscle similarly will mobilize Ca²⁺ but cause contraction, whereas activation of H_2 receptors on the same smooth muscle cell will link *via* G_s to enhanced cyclic AMP accumulation, activation of PKA, and then to relaxation (Leurs *et al.*, 2001; Toda, 1987).

The existence of multiple histamine receptors was predicted based on the studies of Ash and Schild and Black and colleagues a generation before the cloning of histamine receptors. Similarly, heterogeneity of H_3 receptors, predicted by kinetic and radioligand-binding studies, has been confirmed by cloning. This identified H_3 isoforms differing in the third intracellular loop TM6, TM7, and C-terminal tail and in their capacity to couple G_i , to inhibit adenylyl cyclase, and to activate mitogen-activated protein (MAP) kinase. Molecular cloning studies also have identified the H_4 receptor. H_1 and H_2 receptors are distributed widely in the periphery and in the CNS, but H_3 receptors are confined largely to the CNS. H_4 receptors, which also have been cloned, are mainly in cells of hematopoietic origin. In a species-dependent manner, adenosine receptors may interact with H_1 receptors. In the CNS of human beings, activation of adenosine A₁ receptors inhibits second-messenger generation *via* H_1 receptors. A possible mechanism for this is an interaction (cross-talk) between the G proteins to which the A₁ and H_1 receptors are functionally coupled, although multiple cell types and paracrine mediators also may be involved.

As Figures 24–1, 24–3, and 36–3 indicate, the pharmacologic definition of H_1 , H_2 , and H_3 receptors generally is clear: Relatively specific agonists and antagonists are available (Table 24–1). However, the H_4 receptor exhibits 35% to 40% homology to the H_3 receptor, and the two are harder to distinguish pharmacologically. High-affinity H_3 agonists interact with H_4 receptors as well, albeit with reduced potency, as do the H_3 antagonists *burimamide* and *clobenpropit*. Several nonimidazole compounds are selective H_3 antagonists. The atypical antipsychotic agent *clozapine* is an effective H_1 -receptor antagonist, a weak H_3 -receptor antagonist, but an H_4 -receptor agonist in the rat. Many neuroleptics are H_1 - and H_2 -receptor antagonists, but it is unclear whether interactions with H receptors play a role in the effects of antipsychotic agents. The finding of high constitutive activity of the rat and human H_3 receptor has sparked a reexamination of the potential role of inverse agonists of H_3 recep-

Figure 24–3. Representative H₁ antagonists. *Dimenhydrinate is a combination of diphenhydramine and 8-chlorotheophylline in equal molecular proportions. †Pheniramine is the same less Cl. ‡Tripeleminamine is the same less H₃CO. §Cyclizine is the same less Cl.

tors as therapeutic modulators of H₃-receptor-mediated inhibition of histamine release from histaminergic neurons. H₁ receptors also are reported to express intrinsic or constitutive activity; thus many H₁ antagonists may function as inverse agonists (Leurs *et al.*, 2002). The synthesis of a selective H₄ antagonist (an indole-methylpiperazine derivative) with antiinflammatory properties was reported recently (*see* Thurmond *et al.*, 2004).

H₁ and H₂ Receptors. Once released, histamine can exert local or widespread effects on smooth muscles and glands. It contracts many smooth muscles, such as those of the bronchi and gut, but markedly relaxes others, including those in small blood vessels. Histamine also is a potent stimulus of gastric acid secretion (*see above*). Other, less prominent effects include formation of edema and stimulation of sensory nerve endings. Bronchoconstriction and contraction of the gut are mediated by H₁ receptors (Ash and Schild, 1966). Gastric secretion results from the activation of H₂ receptors and, accordingly, can be inhibited by H₂-receptor antagonists (*see* Chapter 36). Some responses, such as vascular dilation, are mediated by both H₁- and H₂-receptor stimulation.

H₃ and H₄ Receptors. H₃ receptors are expressed mainly in the CNS, especially in the basal ganglia, hippocampus, and cortex. H₃ receptors function as autoreceptors on histaminergic neurons, much like presynaptic α_2 receptors, inhibiting histamine release and modulating the release of other neurotransmitters. H₃ antagonists promote wakefulness; conversely, H₃ agonists promote sleep. H₃ receptors appear to have high constitutive activity; thus histamine release may be tonically inhibited, and inverse agonists may reduce receptor activation and increase histamine release from histaminergic neurons. H₄ receptors are on immune active cells such as eosinophils and neutrophils, as well as in the gastrointestinal (GI) tract and CNS. Activation of H₄ receptors on eosinophils induces a cellular shape change, chemotaxis, and up-regulation of adhesion molecules such as CD11b/CD18 and intercellular adhesion molecule (ICAM)-1 (*see* Ling *et al.*, 2004), suggesting that the histamine released from mast cells acts at H₄ receptors to recruit eosinophils. H₄ antagonists may be useful inhibitors of allergic and inflammatory responses.

Effects on Histamine Release. H₂-receptor stimulation increases cyclic AMP and leads to feedback inhibition of histamine release from mast cells and basophils. Activa-

tion of H₃ and H₄ receptors decreases cellular cyclic AMP (Oda *et al.*, 2000; Hough, 2001; Macglashan, 2003); H₃ receptors also may function as presynaptic autoinhibitory receptors on histaminergic neurons.

Histamine Toxicity from Ingestion. Histamine is the toxin in food poisoning from spoiled scombroid fish such as tuna (Morrow *et al.*, 1991), in which high histidine content combines with a large bacterial capacity to decarboxylate histidine to form large quantities of histamine. Ingestion of the fish causes severe nausea, vomiting, headache, flushing, and sweating. Histamine toxicity, manifested by headache and other symptoms, also can follow red wine consumption in persons who possibly have a diminished ability to degrade histamine. The symptoms of histamine poisoning can be suppressed by H₁-receptor antagonists.

Cardiovascular System. Histamine characteristically causes dilation of resistance vessels, an increase in capillary permeability, and an overall fall in systemic blood pressure. In some vascular beds, histamine will constrict veins, contributing to the extravasation of fluid and edema formation upstream of the capillaries and postcapillary venules.

Vasodilation. This is by far the most important vascular effect of histamine in human beings. Vasodilation involves both H₁ and H₂ receptors distributed throughout the resistance vessels in most vascular beds; however, quantitative differences are apparent in the degree of dilation that occurs in various beds. Activation of either the H₁ or H₂ receptor can elicit maximal vasodilation, but the responses differ. H₁ receptors have a higher affinity for histamine and mediate an endothelium–NO–dependent dilation that is relatively rapid in onset and short-lived. By contrast, activation of H₂ receptors (stimulating the cyclic AMP–PKA pathway in smooth muscle) causes dilation that develops more slowly and is more sustained. As a result, H₁ antagonists effectively counter small dilator responses to low concentrations of histamine but only blunt the initial phase of larger responses to higher concentrations of the amine. There seems to be a variable distribution of H₁ receptors on vascular smooth muscle as well, such that direct constrictor responses can be observed in vein, in skin and skeletal muscle, and in larger coronary arteries. Histamine causes hepatic venoconstriction in dogs (Chien and Krakoff, 1963).

Increased “Capillary” Permeability. This effect of histamine on small vessels results in outward passage of plasma protein and fluid into the extracellular spaces, an increase in the flow of lymph and its protein content, and edema formation. H₁ receptors on endothelial cells are the major mediators of this response; the role of H₂ receptors is uncertain.

Increased permeability results mainly from actions of histamine on postcapillary venules, where histamine causes the endothelial cells to contract and separate at their boundaries and thus to expose the basement membrane,

which is freely permeable to plasma protein and fluid. The gaps between endothelial cells also may permit passage of circulating cells that are recruited to the tissues during the mast cell response. Recruitment of circulating leukocytes is promoted by H₁-receptor-mediated up-regulation of leukocyte adhesion. This process involves histamine-induced expression of the adhesion molecule P-selectin on the endothelial cells (Gaboury *et al.*, 1995).

Triple Response of Lewis. If histamine is injected intradermally, it elicits a characteristic phenomenon known as the *triple response* (Lewis, 1927). This consists of (1) a localized red spot extending for a few millimeters around the site of injection that appears within a few seconds and reaches a maximum in about a minute; (2) a brighter red flush, or “flare,” extending about 1 cm or so beyond the original red spot and developing more slowly; and (3) a wheal that is discernible in 1 to 2 minutes and occupies the same area as the original small red spot at the injection site. The initial red spot results from the direct vasodilating effect of histamine (H₁-receptor-mediated NO production), the flare is due to histamine-induced stimulation of axon reflexes that cause vasodilation indirectly, and the wheal reflects histamine’s capacity to increase capillary permeability (edema formation).

Constriction of Larger Vessels. Histamine tends to constrict larger blood vessels, in some species more than in others. In rodents, the effect extends to the level of the arterioles and may overshadow dilation of the finer blood vessels. A net increase in total peripheral resistance and an elevation in blood pressure can be observed. As noted earlier, H₁-receptor-mediated constriction may occur in some veins and in conduit coronary arteries (Toda, 1987).

Heart. Histamine affects both cardiac contractility and electrical events directly. It increases the force of contraction of both atrial and ventricular muscle by promoting the influx of Ca²⁺, and it speeds heart rate by hastening diastolic depolarization in the sinoatrial (SA) node. It also acts directly to slow atrioventricular (AV) conduction, to increase automaticity, and in high doses especially, to elicit arrhythmias. With the exception of slowed AV conduction, which involves mainly H₁ receptors, all these effects are largely attributable to H₂ receptors and cyclic AMP accumulation. If histamine is given intravenously, direct cardiac effects of histamine are overshadowed by baroreceptor reflexes elicited by the reduced blood pressure.

Histamine Shock. Histamine given in large doses or released during systemic anaphylaxis causes a profound and progressive fall in blood pressure. As the small blood vessels dilate, they trap large amounts of blood, and as their permeability increases, plasma escapes from the circulation. Resembling surgical or traumatic shock, these effects diminish effective blood volume, reduce venous return, and greatly lower cardiac output.

Extravascular Smooth Muscle. Histamine stimulates or, more rarely, relaxes various smooth muscles. Contraction is due to activation of H₁ receptors, and relaxation (for the most part) is due to activation of H₂ receptors. Responses vary widely among species and even among humans (*see* Parsons, in Ganellin and Parsons, 1982). Bronchial muscle of guinea pigs is exquisitely sensitive. Minute doses of histamine also will evoke intense bronchoconstriction in patients with bronchial asthma and certain other pulmo-

nary diseases; in normal human beings, the effect is much less pronounced. Although the spasmogenic influence of H₁ receptors is dominant in human bronchial muscle, H₂ receptors with dilator function also are present. Thus histamine-induced bronchospasm *in vitro* is potentiated slightly by H₂ blockade. In asthmatic subjects in particular, histamine-induced bronchospasm may involve an additional reflex component that arises from irritation of afferent vagal nerve endings (*see* Eyre and Chand, in Ganellin and Parsons, 1982; Nadel and Barnes, 1984).

The uterus of some species is contracted by histamine; in the human uterus, gravid or not, the response is negligible. Responses of intestinal muscle also vary with species and region, but the classical effect is contraction. Bladder, ureter, gallbladder, iris, and many other smooth muscle preparations are affected little or inconsistently by histamine.

Exocrine Glands. As mentioned earlier, histamine is an important physiological regulator of gastric acid secretion. This effect is mediated by H₂ receptors (*see* Chapter 36).

Peripheral Nerve Endings: Pain, Itch, and Indirect Effects. Histamine stimulates various nerve endings and sensory effects. Thus, when released in the epidermis, it causes itch; in the dermis, it evokes pain, sometimes accompanied by itching. Stimulant actions on one or another type of nerve ending, including autonomic afferents and efferents, were mentioned earlier as factors that contribute to the “flare” component of the triple response and to indirect effects of histamine on the bronchi and other organs. In the periphery, neuronal receptors for histamine are generally of the H₁ type (*see* Rocha e Silva, 1978; Ganellin and Parsons, 1982).

Clinical Uses

The practical applications of histamine are limited to uses as a diagnostic agent. Histamine (*histamine phosphate*) is used to assess nonspecific bronchial hyperreactivity in asthmatics and as a positive control injection during allergy skin testing.

H₁-RECEPTOR ANTAGONISTS

History. Antihistamine activity was first demonstrated by Bovet and Staub in 1937 with one of a series of amines with a phenolic ether moiety. The substance 2-isopropyl-5-methylphenoxy-ethyl-diethylamine protected guinea pigs against several lethal doses of histamine but was too toxic for clinical use. By 1944, Bovet and his colleagues had described *pyrilamine maleate*, an effective histamine antagonist of this category (*see* Bovet, 1950). The discovery of the highly effective diphenhydramine and *tripelennamine* soon followed (Ganellin and Parsons, 1982). In the 1980s, nonseasonal H₁-histamine-receptor antagonists were developed for treatment of allergic diseases. Despite success in blocking allergic

responses to histamine, the antihistamines available in the early 1950s failed to inhibit a number of other responses to histamine, notably gastric acid secretion. The discovery of H₂ antagonists by Black and colleagues provided a new class of agents that antagonized histamine-induced acid secretion (Black *et al.*, 1972). The pharmacology of these drugs (*cimetidine*, *famotidine*, etc.) is described in Chapter 36.

Structure–Activity Relationship. All the available H₁-receptor antagonists are reversible competitive inhibitors of the interaction of histamine with H₁ receptors. Like histamine, many H₁ antagonists contain a substituted ethylamine moiety.

Unlike histamine, which has a primary amino group and a single aromatic ring, most H₁ antagonists have a tertiary amino group linked by a two- or three-atom chain to two aromatic substituents and conform to the general formula

where Ar is aryl and X is a nitrogen or carbon atom or a —C—O— ether linkage to the β-aminoethyl side chain. Sometimes the two aromatic rings are bridged, as in the tricyclic derivatives, or the ethylamine may be part of a ring structure (Figure 24–3) (Ganellin and Parsons, 1982).

Pharmacological Properties

Most H₁ antagonists have similar pharmacological actions and therapeutic applications. Their effects are largely predictable from knowledge of the consequences of the activation of H₁ receptors by histamines.

Smooth Muscle. H₁ antagonists inhibit most of the effects of histamine on smooth muscles, especially the constriction of respiratory smooth muscle. In guinea pigs, for example, death by asphyxia follows quite small doses of histamine, yet the animal may survive a hundred lethal doses of histamine if given an H₁ antagonist. In the same species, striking protection also is afforded against anaphylactic bronchospasm. This is not so in human beings, where allergic bronchoconstriction appears to be caused by a variety of mediators such as leukotrienes and PAF (*see* Chapter 25).

Within the vascular tree, the H₁ antagonists inhibit both the vasoconstrictor effects of histamine and, to a degree,

the more rapid vasodilator effects that are mediated by activation of H₁ receptors on endothelial cells (synthesis/release of NO and other mediators). Residual vasodilation is due to H₂ receptors on smooth muscle and can be suppressed by administration of an H₂ antagonist. The efficacy of histamine antagonists on histamine-induced changes in systemic blood pressure parallels these vascular effects.

Capillary Permeability. H₁ antagonists strongly block the increased capillary permeability and formation of edema and wheal brought about by histamine.

Flare and Itch. The flare component of the triple response and the itching caused by intradermal injection of histamine are two different manifestations of the action of histamine on nerve endings. H₁ antagonists suppress both.

Exocrine Glands. H₁ antagonists do not suppress gastric secretion, but they do suppress histamine-evoked salivary, lacrimal, and other exocrine secretions with variable success. The antimuscarinic properties of many of these agents, however, may contribute to lessened secretion in cholinergically innervated glands and reduce ongoing secretion in, for example, the respiratory tree.

Immediate Hypersensitivity Reactions: Anaphylaxis and Allergy. During hypersensitivity reactions, histamine is one of the many potent autacoids released (see above), and its relative contribution to the ensuing symptoms varies widely with species and tissue. The protection afforded by histamine antagonists thus also varies accordingly. In humans, edema formation and itch are effectively suppressed. Other effects, such as hypotension, are less well antagonized. This may be explained by the participation of other types of H receptors and by effects of other mast cell mediators. These include those derived from arachidonic acid (released from membranes by PLA₂), which is converted by cyclooxygenases and lipoxygenases to prostaglandins, eicosatetraenoic acid derivatives, leukotrienes, and other mediators (Gelfand, *et al.*, 2004; Campbell and Harder, 1999) (see Chapter 25). Bronchoconstriction is reduced little, if at all.

Central Nervous System. The first-generation H₁ antagonists can both stimulate and depress the CNS. Stimulation occasionally is encountered in patients given conventional doses, who become restless, nervous, and unable to sleep. Central excitation also is a striking feature of overdose, which commonly results in convulsions, particularly in infants. Central depression, on the other hand, usually accompanies therapeutic doses of the older H₁ antagonists. Diminished alertness, slowed reaction times, and somnolence are common manifestations. Some of the H₁ antagonists are more likely to depress the CNS than others, and

patients vary in their susceptibility and responses to individual drugs. The ethanolamines (*e.g.*, diphenhydramine; Figure 24–3) are particularly prone to cause sedation.

The second-generation (“nonsedating”) H₁ antagonists (*e.g.*, *loratadine*, *cetirizine*, and *fexofenadine*) are largely excluded from the brain when given in therapeutic doses because they do not cross the blood–brain barrier appreciably. Their sedative effects are similar to those of placebo (Simons and Simons, 1994). Because of the sedation that occurs with first-generation antihistamines, these drugs cannot be tolerated or used safely by many patients unless given only at bedtime. Even then, patients may experience an antihistamine “hangover” in the morning, resulting in sedation with or without psychomotor impairment (Simons, 2003b). Thus the development of nonsedating antihistamines was an important advance that allowed the general use of these agents.

An interesting and useful property of certain H₁ antagonists is the capacity to counter motion sickness (see Chapters 7 and 37). This effect was first observed with *dimenhydrinate* and subsequently with diphenhydramine (the active moiety of dimenhydrinate), various piperazine derivatives, and *promethazine*.

Anticholinergic Effects. Many of the first-generation H₁ antagonists tend to inhibit responses to acetylcholine that are mediated by muscarinic receptors. These atropinelike actions are sufficiently prominent in some of the drugs to be manifest during clinical usage (see below). Promethazine has perhaps the strongest muscarinic-blocking activity among these agents and is among the most effective of the H₁ antagonists in combating motion sickness. Since *scopolamine* is a potent preventer of motion sickness (see Chapter 7), it is possible that the anticholinergic properties of H₁ antagonists are largely responsible for this effect. The second-generation H₁ antagonists have no effect on muscarinic receptors.

Local Anesthetic Effect. Some H₁ antagonists have local anesthetic activity, and a few are more potent than procaine. Promethazine (PHENERGAN) is especially active. However, the concentrations required for this effect are several orders of magnitude higher than those which antagonize histamine’s interactions with its receptors.

Absorption, Fate, and Excretion. The H₁ antagonists are well absorbed from the GI tract. Following oral administration, peak plasma concentrations are achieved in 2 to 3 hours, and effects usually last 4 to 6 hours; however, some of the drugs are much longer acting (Table 24–2).

Extensive studies of the metabolic fate of the older H₁ antagonists are limited. Diphenhydramine, given orally, reaches a maximal concentration in the blood in about 2 hours, remains at about this level for another 2 hours, and then falls exponentially with a plasma elimination half-

Table 24-2

*Preparations and Dosage of Representative H₁-Receptor Antagonists**

CLASS AND NONPROPRIETARY NAME	TRADE NAME	DURATION OF ACTION, HOURS	PREPARATIONS†	SINGLE DOSE (ADULT)
First-Generation Agents				
<i>Tricyclic Dibenzoxepins</i>				
Doxepin hydrochloride	SINEQUAN	6–24	O, L, T	10–150 mg
<i>Ethanolamines</i>				
Carbinoxamine maleate	RONDEC,¶ others	3–6	O, L	4–8 mg
Clemastine fumarate	TAVIST, others	12	O, L	1.34–2.68 mg
Diphenhydramine HCl	BENADRYL; others	12	O, L, I, T	25–50 mg
Dimenhydrinate	DRAMAMINE; others	4–6	O, L, I	50–100 mg
<i>Ethylenediamines</i>				
Pyrilamine maleate	POLY–HISTINE-D¶	4–6	O, L, T	25–50 mg
Tripelennamine HCl	PBZ	4–6	O	25–50 mg, 100 mg (sustained release)
Tripelennamine citrate	PBZ	4–6	L	37.5–75 mg
<i>Alkylamines</i>				
Chlorpheniramine maleate	CHLOR-TRIMETON; others	24	O, L, I	4 mg 8–12 mg (sustained release) 5–20 mg (injection)
Brompheniramine maleate	BROMPHEN; others	4–6	O, L, I	4 mg 8–12 mg (sustained release) 5–20 mg (injection)
<i>Piperazines</i>				
Hydroxyzine HCl	ATARAX; others	6–24	O, L, I	25–100 mg
Hydroxyzine pamoate	VISTARIL	6–24	O, L	25–100 mg
Cyclizine HCl	MAREZINE	4–6	O	50 mg
Cyclizine lactate	MAREZINE	4–6	I	50 mg
Meclizine HCl	ANTIVERT; others	12–24	O	12.5–50 mg
<i>Phenothiazines</i>				
Promethazine HCl	PHENERGAN; others	4–6	O, L, I, S	12.5–50 mg
<i>Piperidines</i>				
Cyproheptadine HCl§	PERIACTIN	4–6	O, L	4 mg
Phenindamine tartrate	NOLAHIST	4–6	O	25 mg
Second-Generation Agents				
<i>Alkylamines</i>				
Acrivastine‡	SEMPREX-D¶	6–8	O	8 mg
<i>Piperazines</i>				
Cetirizine hydrochloride‡	ZYRTEC	12–24	O	5–10 mg
<i>Phthalazinones</i>				
Azelastine hydrochloride‡	ASTELIN	12–24	T	2 sprays per nostril
<i>Piperidines</i>				
Levocabastine hydrochloride	LIVOSTIN	6–12	T	One drop
Loratadine	CLARITIN	24	O, L	10 mg
Desloratadine	CLARINEX, AERIUS	24	O	5 mg
Ebastine	EBASTEL	24	O	10–20 mg
Mizolastine	MIZOLLEN	24	O	10 mg
Fexofenadine	ALLEGRA, TELFAST	12–24	O	60 mg

HCl, hydrochloride. *For a discussion of phenothiazines, see Chapter 18. †Preparations are designated as follows: O, oral solids; L, oral liquids; I, Injection; S, suppository; T, topical. Many H₁-receptor antagonists also are available in preparations that contain multiple drugs. ‡Has mild sedating effects. ¶Trade name drug also contains other medications. §Also has antiserotonin properties.

time of about 4 to 8 hours. The drug is distributed widely throughout the body, including the CNS. Little, if any, is excreted unchanged in the urine; most appears there as metabolites. Other first-generation H₁ antagonists appear to be eliminated in much the same way (see Paton and Webster, 1985).

Peak concentrations of these drugs are achieved rapidly in the skin and persist after plasma levels have declined (Simons, 2003a). This is consistent with inhibition of “wheal and flare” responses to the intradermal injection of histamine or allergen, which last for 36 hours or more after treatment, even when concentrations in plasma are very low. Such results emphasize the need for flexibility in the interpretation of the recommended dosage schedules (Table 24–2); less frequent dosage may suffice. *Doxepin*, a tricyclic antidepressant (see Chapter 17), is one of the most potent antihistamines available; it is about 800 times more potent than diphenhydramine. This may account for the observation that doxepin can be effective in the treatment of chronic urticaria when other antihistamines have failed; it also is available as a topical preparation.

Like many other drugs that are metabolized extensively, H₁ antagonists are eliminated more rapidly by children than by adults and more slowly in those with severe liver disease. H₁-receptor antagonists also induce hepatic cytochrome P450 enzymes (CYPs) and thus may facilitate their own metabolism (see Paton and Webster, 1985).

The second-generation H₁ antagonist loratadine is absorbed rapidly from the GI tract and metabolized in the liver to an active metabolite by the hepatic CYPs (Simons and Simons, 1994) (see Chapter 3). Consequently, metabolism of loratadine can be affected by other drugs that compete for the P450 enzymes. Two other second-generation H₁ antagonists that were marketed previously, *astemizole* and *terfenadine*, also underwent metabolism by CYPs to active metabolites. Both these drugs were found in rare cases to induce a potentially fatal arrhythmia, *torsades de pointes*, when their metabolism was impaired, such as by liver disease or drugs that inhibit the CYP3A family (see Chapter 34). This led to the withdrawal of terfenadine and astemizole from the market in 1998 and 1999. The withdrawal of terfenadine prompted the development of its active metabolite, fexofenadine, as a replacement. This compound lacks the toxic side effects of terfenadine, is not sedating, and retains the antiallergic properties of the parent compound (Meeves and Appajoyyula, 2003). Another antihistamine developed using this strategy is *desloratidine*, an active metabolite of loratadine. Cetirizine, loratadine, and fexofenadine are all well absorbed and are excreted mainly in the unmetabolized form. Cetirizine and loratadine are excreted primarily into

the urine, whereas fexofenadine is excreted primarily in the feces.

Side Effects. Common Adverse Effects. The most frequent side effect in the first-generation H₁ antagonists is sedation. Although sedation may be a desirable adjunct in the treatment of some patients, it may interfere with the patient’s daytime activities. Concurrent ingestion of alcohol or other CNS depressants produces an additive effect that impairs motor skills. Other untoward central actions include dizziness, tinnitus, lassitude, incoordination, fatigue, blurred vision, diplopia, euphoria, nervousness, insomnia, and tremors.

The next most frequent side effects involve the digestive tract and include loss of appetite, nausea, vomiting, epigastric distress, and constipation or diarrhea. Taking the drug with meals may reduce their incidence. H₁ antagonists appear to increase appetite and cause weight gain in rare patients. Other side effects apparently owing to the antimuscarinic actions of some of the first-generation H₁-receptor antagonists include dryness of the mouth and respiratory passages (sometimes inducing cough), urinary retention or frequency, and dysuria. These effects are not observed with second-generation H₁ antagonists.

Other Adverse Effects. Drug allergy may develop when H₁ antagonists are given orally but results more commonly from topical application. Allergic dermatitis is not uncommon; other hypersensitivity reactions include drug fever and photosensitization. Hematological complications such as leukopenia, agranulocytosis, and hemolytic anemia are very rare. Because H₁ antihistamines cross the placenta, caution must be used when they are taken by women who are or may become pregnant. Several antihistamines (e.g., *azelastine*, *hydroxyzine*, and *fexofenadine*) showed teratogenic effects in animal studies, whereas others (e.g., *chlorpheniramine*, *diphenhydramine*, *cetirizine*, and *loratadine*) did not (see Simons, 2003b). Antihistamines can be excreted in small amounts in breast milk, and first-generation antihistamines taken by lactating mothers may cause symptoms in the nursing infant such as irritability, drowsiness, or respiratory depression (see Simons, 2003b). Since H₁ antagonists interfere with skin tests for allergy, they must be withdrawn well before such tests are performed.

In acute poisoning with H₁ antagonists, their central excitatory effects constitute the greatest danger. The syndrome includes hallucinations, excitement, ataxia, incoordination, athetosis, and convulsions. Fixed, dilated pupils with a flushed face, together with sinus tachycardia, urinary retention, dry mouth, and fever, lend the syndrome a remarkable similarity to that of *atropine* poisoning. Terminally, there is deepening coma with cardiorespiratory collapse and death usually within 2 to 18 hours. Treatment is along general symptomatic and supportive lines.

Available H₁ Antagonists. Summarized below are the therapeutic and side effects of a number of H₁ antagonists based on their chemical structures. Representative preparations are listed in Table 24-2.

Dibenzoxepin Tricyclics (Doxepin). Doxepin, the only drug in this class, is marketed as a tricyclic antidepressant (see Chapter 17). However, it also is a remarkably potent H₁ antagonist. It can cause drowsiness and is associated with anticholinergic effects. Doxepin is much better tolerated by patients who have depression than by those who do not. In nondepressed patients, sometimes even very small doses, *e.g.*, 20 mg, may be poorly tolerated because of disorientation and confusion.

Ethanolamines (Prototype: Diphenhydramine). These drugs possess significant antimuscarinic activity and have a pronounced tendency to induce sedation. About half of those treated with conventional doses experience somnolence. The incidence of GI side effects, however, is low with this group.

Ethylenediamines (Prototype: Pyrilamine). These include some of the most specific H₁ antagonists. Although their central effects are relatively feeble, somnolence occurs in a fair proportion of patients. GI side effects are quite common.

Alkylamines (Prototype: Chlorpheniramine). These are among the most potent H₁ antagonists. The drugs are less prone than some H₁ antagonists to produce drowsiness and are more suitable agents for daytime use, but again, a significant proportion of patients do experience sedation. Side effects involving CNS stimulation are more common than with other groups.

First-Generation Piperazines. The oldest member of this group, *chlorcyclizine*, has a more prolonged action and produces a comparatively low incidence of drowsiness. Hydroxyzine is a long-acting compound that is used widely for skin allergies; its considerable CNS-depressant activity may contribute to its prominent antipruritic action. *Cyclizine* and *meclizine* have been used primarily to counter motion sickness, although promethazine and diphenhydramine (dimenhydrinate) are more effective (as is scopolamine; see below).

Second-Generation Piperazines (Cetirizine). Cetirizine is the only drug in this class. It has minimal anticholinergic effects. It also has negligible penetration into the brain but is associated with a somewhat higher incidence of drowsiness than the other second-generation H₁ antagonists.

Phenothiazines (Prototype: Promethazine). Most drugs of this class are H₁ antagonists and also possess considerable anticholinergic activity. Promethazine, which has prominent sedative effects, and its many congeners are used primarily for their antiemetic effects (see Chapter 37).

First-Generation Piperidines (Cyproheptadine, Phenindamine). *Cyproheptadine* uniquely has both antihistamine and antiserotonin activity. *Cyproheptadine* and *phenindamine* cause drowsiness and also have significant anticholinergic effects.

Second-Generation Piperidines (Prototype: Terfenadine). Terfenadine and astemizole were withdrawn from the market. Current drugs in this class include loratadine, desloratadine, and fexofenadine. These agents are highly selective for H₁ receptors, lack significant anticholinergic actions, and penetrate poorly into the CNS. Taken together, these properties appear to account for the low incidence of side effects of piperidine antihistamines.

Therapeutic Uses

H₁ antagonists have an established and valued place in the symptomatic treatment of various immediate hypersensitivity reactions. In addition, the central properties of some of the series are of therapeutic value for suppressing motion sickness or for sedation.

Allergic Diseases. H₁ antagonists are most useful in acute types of allergy that present with symptoms of rhinitis, urticaria, and conjunctivitis. Their effect is confined to the suppression of symptoms attributable to the histamine released by the antigen-antibody reaction. In bronchial asthma, histamine antagonists have limited efficacy and are not used as sole therapy (see Chapter 27). In the treatment of systemic anaphylaxis, in which autacoids other than histamine play major roles, the mainstay of therapy is *epinephrine*; histamine antagonists have only a subordinate and adjuvant role. The same is true for severe angioedema, in which laryngeal swelling constitutes a threat to life.

Other allergies of the respiratory tract are more amenable to therapy with H₁ antagonists. The best results are obtained in seasonal rhinitis and conjunctivitis (hay fever, pollinosis), in which these drugs relieve the sneezing, rhinorrhea, and itching of eyes, nose, and throat. A gratifying response is obtained in most patients, especially at the beginning of the season when pollen counts are low; however, the drugs are less effective when the allergens are most abundant, when exposure to them is prolonged, and when nasal congestion is prominent. Topical preparations of antihistamines such as *levocabastine* (LIVOSTIN), *azelastine* (ASTELIN), *ketotifen* (ZADITOR), and *olopatadine* (PATANOL) have been shown to be effective in allergic conjunctivitis and rhinitis. Nasal sprays or topical ophthalmic preparations of these agents are available in the United States. Histamine causes the release of inflammatory cytokines and eicosanoids and increases expression of endothelial adhesion molecules (Holgate *et al.*, 2003; Gelfand *et al.*, 2004). In addition, H₁ receptors, either *via* constitutive activity or after stimulation by agonists, can activate the proinflammatory transcription factor NF- κ B (Leurs *et al.*, 2002). Thus H₁ antihistamines have been investigated for potential anti-inflammatory properties. Although H₁ antihistamines do exhibit a variety of anti-inflammatory effects *in vitro* and in animal models, in many cases the doses required are higher than those normally achieved therapeutically, and clinical effectiveness has not yet been proven (Holgate *et al.*, 2003; Gelfand *et al.*, 2004).

Certain allergic dermatoses respond favorably to H₁ antagonists. Benefit is most striking in acute urticaria, although the itching in this

condition is perhaps better controlled than are the edema and the erythema. Chronic urticaria is less responsive, but some benefit may occur in a fair proportion of patients. Furthermore, the combined use of H₁ and H₂ antagonists sometimes is effective when therapy with an H₁ antagonist alone has failed. As mentioned earlier, doxepin may be effective in the treatment of chronic urticaria that is refractory to other antihistamines. Angioedema also responds to treatment with H₁ antagonists, but the paramount importance of epinephrine in the severe attack must be re-emphasized, especially in life-threatening laryngeal edema (see Chapter 10). In this setting, it may be appropriate to also administer an H₁ antagonist by the intravenous route.

H₁ antagonists have a place in the treatment of pruritus. Some relief may be obtained in many patients suffering atopic dermatitis and contact dermatitis (although topical corticosteroids are more effective) and in such diverse conditions as insect bites and poison ivy. Various other pruritides without an allergic basis sometimes respond to antihistamine therapy, usually when the drugs are applied topically but occasionally when they are given orally. However, the possibility of producing allergic dermatitis with local application of H₁ antagonists must be recognized. Again, doxepin may be more effective in suppressing pruritus than are other antihistamines. Since these drugs inhibit allergic dermatoses, they should be withdrawn well before skin testing for allergies. The urticarial and edematous lesions of serum sickness respond to H₁ antagonists, but fever and arthralgia often do not.

Many drug reactions attributable to allergic phenomena respond to therapy with H₁ antagonists, particularly those characterized by itch, urticaria, and angioedema; serum-sickness reactions also respond to intensive treatment. However, explosive release of histamine generally calls for treatment with epinephrine, with H₁ antagonists being accorded a subsidiary role. Nevertheless, prophylactic treatment with an H₁ antagonist may reduce symptoms to a tolerable level when a drug known to be a histamine liberator is to be given.

Common Cold. Despite persistent popular belief, H₁ antagonists are without value in combating the common cold. The weak anticholinergic effects of the older agents may tend to lessen rhinorrhea, but this drying effect may do more harm than good, as may their tendency to induce somnolence.

Motion Sickness, Vertigo, and Sedation. Although scopolamine, given orally, parenterally, or transdermally, is the most effective of all drugs for the prophylaxis and treatment of motion sickness, some H₁ antagonists are useful in a broad range of milder conditions and offer the advantage of fewer adverse effects. These drugs include dimenhydrinate and the piperazines (*e.g.*, cyclizine and meclizine). Promethazine, a phenothiazine, is more potent and more effective; its additional antiemetic properties may be of value in reducing vomiting, but its pronounced sedative action usually is disadvantageous. Whenever possible, the various drugs should be administered an hour or so before the anticipated motion. Treatment after the onset of nausea and vomiting rarely is beneficial.

Some H₁ antagonists, notably dimenhydrinate and meclizine, often are of benefit in vestibular disturbances such as Meniere's disease and in other types of true vertigo. Only promethazine has usefulness in treating the nausea and vomiting subsequent to chemotherapy or radiation therapy for malignancies; however, other effective antiemetic drugs are available (see Chapter 37).

Diphenhydramine can reverse the extrapyramidal side effects caused by phenothiazines (see Chapter 18). The anticholinergic actions of this agent also can be used in the early stages of Parkinson's disease (see Chapter 20), but it is less effective than other agents.

The tendency of some H₁-receptor antagonists to produce somnolence has led to their use as hypnotics. H₁ antagonists, principally

diphenhydramine, often are present in various proprietary remedies for insomnia that are sold over the counter. While these remedies generally are ineffective in the recommended doses, some sensitive individuals may derive benefit. The sedative and mild antianxiety activities of hydroxyzine and diphenhydramine have contributed to their use as weak anxiolytics.

H₂-Receptor Antagonists. The pharmacology and clinical utility of H₂ antagonists to inhibit gastric acid secretion are described in Chapter 36.

THE HISTAMINE H₃ RECEPTOR AND ITS LIGANDS

The H₃ receptor was characterized and localized in a variety of cells, including the cerebral histaminergic neurons using (*R*)- α -methylhistamine, a selective H₃ agonist, and thioperamide, an antagonist (Arrang *et al.*, 1987). The H₃ receptor was shown to couple to a pertussis toxin-sensitive G protein, and its cDNA was identified as an orphan heptahelical receptor (Lovenberg *et al.*, 1999). Further studies on the H₃ receptor uncovered a variety of isoforms resulting from alternative splicing, as well as interspecies differences, that can result in receptors with unique binding and signaling properties (Hancock *et al.*, 2003).

The H₃ receptors are localized on terminals as well as on cell bodies/dendrites in the hypothalamic tuberomammillary nucleus on histaminergic neurons. By inhibiting Ca²⁺ conductance, the activated H₃ receptor depresses neuronal firing at the level of cell bodies/dendrites and decreases histamine release from depolarized terminals. Thus H₃-receptor ligands are unique agents to modify histaminergic neurotransmission in brain; the agonists decrease it, and the antagonists increase it. H₃ receptors are also presynaptic heteroreceptors on a variety of neurons in brain and peripheral tissues, including noradrenergic, serotonergic, GABAergic, and glutamatergic neurons, as well as on sensitive C-fibers. H₃ receptors in brain have significant constitutive activity in the absence of agonist both *in vitro* and *in vivo*; consequently, inverse agonists of high intrinsic activity (rather than neutral antagonists) will activate these neurons. H₃-receptor ligands currently are research tools to delineate the functional role of cerebral histamine and are drug candidates in neuropsychiatry (Schwartz and Arrang, 2002).

In the enterochromaffinlike cells of the stomach, H₃ receptors inhibit gastrin-induced release of histamine and, therefore, decrease HCl secretion mediated by H₂ receptors, but the effect is not large enough to warrant development of therapeutic agents. In contrast to histaminergic neurons, the H₃ receptors on other cell types may neither be tonically stimulated by endogenous histamine nor exhibit constitutive activity because inverse agonists/antagonists do not exert clear-cut effects. However, the receptors respond to agonists; *e.g.*, H₃ agonists decrease tachykinin release from capsaicin-sensitive C-fiber terminals and thereby reduce capsaicin-induced plasma extravasation and are antinociceptive. H₃ agonists also depress exaggerated catecholamine release in the heart, *e.g.*, during ischemia.

The H₃-receptor antagonists/inverse agonists that cross the blood-brain barrier have a range of central effects by activating histaminergic neurons, a consideration for therapeutic indications. In animal experiments, they induce a marked arousal at the expense of slow-wave sleep owing to the critical role of the posterior hypothalamic area in wakefulness. They also improve attention and learning, effects that are attributable to overstimulation of cortical H₁ receptors by endogenous histamine, which points to their possible application in pathological diurnal somnolence or minimal cognitive impairment.

The beneficial effects of these drugs in animal models of convulsions also suggest antiepileptic activity devoid of sedative side effects.

H₃ antagonists suppress food intake, increase locomotion, and increase anxiety (Leurs *et al.*, 1998), but recent H₃-receptor knockout mice unexpectedly exhibited obesity, reduced locomotion, and decreased anxiety (*see*, for example, Rizk *et al.*, 2004). This may reflect nonspecific actions of H₃-receptor antagonists or, more likely, the presence of compensatory mechanisms in the knockout mice.

Many early H₃ antagonists such as *impromidine* and *burimamide* had mixed effects because they also were agonists for the H₂ receptor. *Thioperamide* was the first specific H₃ antagonist available experimentally. A number of other imidazole derivatives have been developed as H₃ antagonists, including *clobenpropit*, *ciproxifan*, and *proxifyfan*. Some H₃ antagonists can bind to α adrenergic receptors, H₄ receptors (*see* below), and CYPs, prompting an effort to develop more selective H₃-receptor antagonists using non-imidazole-based structures. For example, two piperazine amide antagonists (A-304121 and A-317920) were shown recently to have high affinity for the H₃ receptor without detectable binding to α_2 adrenergic, 5-HT₃, H₁, H₂, or H₄ receptors (Esbenshade *et al.*, 2003). Although none has yet been approved for clinical use, some H₃-receptor ligands are currently in phase II clinical trials. Their potential therapeutic indications derive from effects observed in animal models.

THE HISTAMINE H₄ RECEPTOR AND ITS LIGANDS

The discovery of a fourth histamine receptor with a unique pharmacology and distribution has opened new avenues of investigation (Hough, 2001). The H₄ receptor has the highest sequence similarity with the H₃ receptor and binds many H₃ agonists, although with lower affinity [*e.g.*, *imetit* and *immepip* have approximately 10 to 60 times lower and (*R*)- α -methylhistamine has approximately 200 to 500 times lower affinity for H₄] (Hough, 2001). The H₃ antagonist *thioperamide* also has significant H₄ antagonistic activity, whereas H₃ antagonists *clobenpropit* and *burimamide* are partial agonists of the H₄ receptor. The H₄ receptor couples through G_{i/o} to decrease cyclic AMP accumulation and, presumably *via* the $\beta\gamma$ subunits, activates phospholipase C β and increases intracellular Ca²⁺ (Hough, 2001; Hofstra *et al.*, 2003).

Because the H₄ receptor is expressed primarily on cells of hematopoietic origin (notably mast cells, basophils, and eosinophils) and to a lesser extent in the intestine (Hough, 2001; Oda *et al.*, 2000; Hofstra *et al.*, 2003), there is great interest in the possible role of H₄ receptors in inflammatory processes. Indeed, the H₄ receptor can mediate histamine-induced chemotaxis of mast cells (Hofstra *et al.*, 2003), leukotriene B₄ production, and mast cell–dependent neutrophil recruitment induced by zymosan (Takeshita *et al.*, 2003). A potent and highly selective H₄-receptor antagonist (JNJ777120) has been developed that can block all these H₄-mediated responses (Thurmond *et al.*, 2004). H₄ antagonists are promising drug candidates to treat inflammatory conditions involving mast cells and eosinophils, such as allergic rhinitis, asthma, and rheumatoid arthritis (Thurmond *et al.*, 2004).

CLINICAL SUMMARY OF THE HISTAMINE H₄ RECEPTOR AND ITS LIGANDS

H₁ Antihistamines. These medications are used widely in the treatment of allergic disorders. H₁ antihistamines

are most effective in relieving the symptoms of seasonal rhinitis and conjunctivitis (*e.g.*, sneezing, rhinorrhea, and itching of the eyes, nose, and throat). In bronchial asthma, they have limited beneficial effects and are not useful as sole therapy. H₁-histamine antagonists are useful adjuncts to epinephrine in the treatment of systemic anaphylaxis or severe angioedema. Certain allergic dermatoses, such as acute urticaria, respond favorably to H₁ antagonists, which help to relieve the itch in atopic dermatitis or contact dermatitis but have no effect on the rash. Chronic urticaria is less responsive, but some benefit may occur, especially when combined with H₂ antagonists.

Side effects are most prominent with first-generation H₁ antihistamines (*e.g.*, diphenhydramine, chlorpheniramine, doxepin, and hydroxyzine), which cross the blood–brain barrier and cause sedation. Some of the first-generation H₁-receptor antagonists also have anticholinergic properties that can be responsible for symptoms such as dryness of the mouth and respiratory passages, urinary retention or frequency, and dysuria. The second-generation drugs (*e.g.*, cetirizine, loratadine, desloratadine, and fexofenadine) are largely devoid of these side effects because they do not penetrate the CNS and do not have antimuscarinic properties. Thus they are usually the drugs of choice for the treatment of allergic disorders.

The significant sedative effects of some first-generation antihistamines have led to their use in treating insomnia, although there are better drugs for this purpose. Hydroxyzine and diphenhydramine are used in some cases as weak anxiolytics. Some first-generation H₁ antagonists (*e.g.*, dimenhydrinate, cyclizine, meclizine, and promethazine) can prevent motion sickness, although scopolamine is more effective. Antiemetic effects of these H₁ antihistamines can be beneficial in treating vertigo or postoperative emesis.

Many H₁ antihistamines are metabolized by CYPs. Thus, inhibitors of CYP activity such as macrolide antibiotics (*e.g.*, *erythromycin*) or imidazole antifungals (*e.g.*, *ketoconazole*) can increase H₁ antihistamine levels, leading to toxicity. Some newer antihistamines, such as cetirizine, fexofenadine, levocabastine, and acrivastine, are not subject to these drug interactions.

Caution should be used in treating pregnant or lactating women with certain H₁ antihistamines, especially first-generation drugs, because of their possible teratogenic effects or symptomatic effects on infants owing to secretion into breast milk; cetirizine and loratadine are probably the best choices if H₁ antihistamines are required, but if they are not effective, diphenhydramine can be used safely in pregnant (but not breast-feeding) women.

H₂ Antihistamines. These drugs (*e.g.*, cimetidine and ranitidine) are used primarily to inhibit gastric acid secretion in the treatment of GI disorders and are discussed in detail in Chapter 36.

H₃ and H₄ Antihistamines. Although specific H₃- and H₄-receptor antagonists have been developed, no drugs have been approved for clinical use. Based on the functions of H₃ receptors in the CNS, H₃ antagonists have potential use in improving attention and learning, in stimulating arousal, and as antiepileptic agents. Because of the unique localization and function of H₄ receptors on cells of hematopoietic origin, H₄ antagonists are promising candidates to treat inflammatory conditions such as allergic rhinitis, asthma, and rheumatoid arthritis.

BRADYKININ, KALLIDIN, AND THEIR ANTAGONISTS

A number of factors, including tissue damage, allergic reactions, viral infections, and other inflammatory events, activate a series of proteolytic reactions that generate bradykinin and kallidin in the tissues. These peptides contribute to inflammatory responses as autacoids that act locally to produce pain, vasodilation, and increased vascular permeability. Much of their activity is due to stimulation of the release of potent mediators such as prostaglandins, NO, or endothelium-derived hyperpolarizing factor (EDHF).

A number of interesting discoveries have contributed to the elucidation of the functions of kinins. Kinin metabolites released by basic carboxypeptidases that were formally considered inactive degradation products are agonists of a receptor (B₁) that differs from that of intact kinins (B₂), whose expression is induced by tissue injury. Kinins and their des-Arg metabolites also release vasoactive agents and may be mediators of inflammation and pain. These findings may open novel avenues for therapeutic intervention in chronic inflammatory conditions.

History. In the 1920s and 1930s, Frey, Kraut, and Werle characterized a hypotensive substance in urine and found a similar material in saliva, plasma, and a variety of tissues (*see* Werle, 1970). The pancreas also was a rich source, so they named this material *kallikrein* after a Greek synonym for that organ, *kallikréas*. By 1937, Werle, Götze, and Keppler had established that kallikreins generate a pharmacologically active substance from an inactive precursor present in plasma. In 1948, Werle and Berek named the active substance *kallidin* and showed it to be a polypeptide cleaved from a plasma globulin that they termed *kallidinogen* (*see* Werle, 1970).

Interest in the field intensified when Rocha e Silva and associates reported that trypsin and certain snake venoms acted on plasma

globulin to produce a substance that lowered blood pressure and caused a slowly developing contraction of the gut (Rocha e Silva *et al.*, 1949; Beraldo and Andrade, 1997). Because of this slow response, they named the substance *bradykinin*, a term derived from the Greek words *bradys*, meaning “slow,” and *kinein*, meaning “to move.” In 1960, the nonapeptide bradykinin was isolated by Elliott and coworkers and synthesized by Boissonnas and associates. Shortly thereafter, kallidin was found to be a decapeptide—bradykinin with an additional lysine residue at the amino terminus (Beraldo and Andrade, 1997). These peptides have related chemical structures and pharmacological properties and are distributed widely in nature. For the whole group, the generic term *kinins* has been adopted, and kallidin and bradykinin are referred to as plasma kinins. The kinins had short half-lives because they were destroyed by plasma and tissue enzymes originally called *kininase I* and *kininase II*. The former released a single C-terminal amino acid; the latter, a dipeptide. Angiotensin converting enzyme (ACE) and kininase II later were shown to be the same enzyme (Yang *et al.*, 1970).

In 1970, Ferreira and colleagues reported the isolation of a bradykinin-potentiating factor from the venom of the Brazilian snake *Bothrops jararaca*. Ondetti and colleagues (1971) subsequently determined the structures of peptides from the venom that inhibited ACE. ACE inhibitors (*see* Chapter 30) are used widely in the treatment of hypertension, diabetic nephropathy, congestive heart failure, and post-myocardial infarction (Gavras *et al.*, 1974).

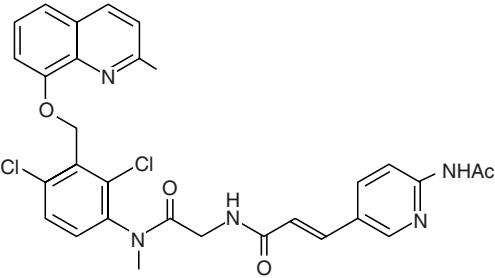

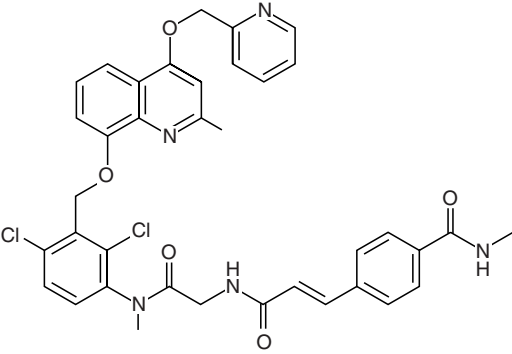

In 1980, Regoli and Barabé divided the kinin receptors into B₁ and B₂ classes based on the rank order of potency of kinin analogs, and this was validated at the molecular level by cloning of the B₁ and B₂ receptors (Bhoola *et al.*, 1992; Hess, 1997). A primary feature that distinguishes peptide ligands of the B₁ and B₂ receptors is the presence of a C-terminal Arg residue; intact kinins (bradykinin and kallidin) are agonists of the B₂ receptor, whereas their des-Arg forms ([des-Arg⁹]bradykinin and [des-Arg¹⁰]kallidin) are agonists for the B₁ receptor. First-generation kinin-receptor antagonists were developed in the mid-1980s (Vavrek and Stewart, 1985), and second-generation receptor-specific kinin antagonists were developed in the early 1990s. These antagonists have led to increasing acceptance of the importance of kinins. Studies involving B₁- and B₂-receptor knockout mice (Hess, 1997; Pesquero *et al.*, 2000) have furthered our understanding of the role of bradykinin in the regulation of cardiovascular homeostasis and inflammatory processes.

The Endogenous Kallikrein–Kininogen–Kinin System

Synthesis and Metabolism of Kinins. Bradykinin is a nonapeptide (Table 24–3). Kallidin has an additional lysine residue at the N-terminal position and is sometimes referred to as *lysyl-bradykinin*. The two peptides are cleaved from α_2 globulins termed *kininogens* (Figure 24–4). There are two kininogens, high-molecular-weight (HMW) and low-molecular-weight (LMW) kininogen. A number of serine proteases will generate kinins, but the highly specific proteases that release bradykinin and kallidin from the kininogens are termed *kallikreins* (*see* below).

Kallikreins. Bradykinin and kallidin are cleaved from HMW or LMW kininogens by plasma or tissue kallikrein, respectively (Figure 24–4). Plasma kallikrein and tissue kallikrein are distinct enzymes that are activated by different mechanisms (Bhoola *et al.*, 1992). Plasma prekallikrein is an inactive protein of about 88,000 daltons that complexes in a 1:1 ratio with its substrate, HMW kininogen. The ensuing proteolytic cascade is restrained by the protease inhibitors

Table 24-3
Structure of Kinin Agonists and Antagonists

NAME	STRUCTURE	FUNCTION
Bradykinin	Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg	Agonist, B ₂
Kallidin	Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg	Agonist, B ₂
[des-Arg ⁹]-bradykinin	Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe	Agonist, B ₁
[des-Arg ¹⁰]-kallidin	Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe	Agonist, B ₁
des-Arg ⁹ -[Leu ⁸]-bradykinin	Arg-Pro-Pro-Gly-Phe-Ser-Pro-Leu	Antagonist, B ₁
HOE 140	[D-Arg]-Arg-Pro-Hyp-Gly-Thi-Ser-Tic-Oic-Arg	Antagonist, B ₂
CP 0127	B(D-Arg-Arg-Pro-Hyp-Gly-Phe-Cys-D-Phe-Leu-Arg) ₂	Antagonist, B ₂
FR 173657		Antagonist, B ₂
FR 190997		Agonist, B ₂

ABBREVIATIONS: Hyp, *trans*-4-hydroxy-Pro; Thi, β -(2-thienyl)-Ala; Tic, [D]-1,2,3,4-tetrahydroisoquinolin-3-yl-carbonyl; Oic, (3*as*,7*as*)-octahydroindol-2-yl-carbonyl. B, bisuccinimidehexane.

present in plasma. Among the most important of these are the inhibitor of the activated first component of complement (C1-INH) and α_2 -macroglobulin. Under experimental conditions, the kallikrein-kinin system is activated by the binding of factor XII, also known as *Hageman factor*, to negatively charged surfaces. Factor XII, a protease that is common to both the kinin and the intrinsic coagulation cascades (see Chapter 54), undergoes autoactivation and, in turn, activates kallikrein. Importantly, kallikrein further activates factor XII, thereby exerting a positive feedback on the system. *In vivo*, factor XII does not undergo autoactivation on binding to endothelial cells. Instead, the binding of a HMW kininogen–prekallikrein complex to a multiprotein receptor complex on endothelial cells leads to activation of prekallikrein by a lysosomal enzyme designated *prolylcarboxypeptidase*, which is also present on endothelial cell membranes (Schmaier, 2004). Kallikrein activates factor XII, cleaves HMW kininogen, and

activates prourokinase (Schmaier, 2004; Colman, 1999). Human tissue kallikrein is a member of a large multigene family of 15 members with high sequence identity that are clustered at chromosome 19q13.4 (Yousef and Diamandis, 2002). Only the classical (or “true”) tissue kallikrein, hK1, generates kinins from kininogen. Another member, hK3, better known as the prostate-specific antigen (PSA), is an important marker in diagnosing prostate cancer.

Compared with plasma kallikrein, tissue kallikrein is a smaller protein (29,000 daltons). It is synthesized as a preproprotein in the epithelial cells or secretory cells of a number of tissues, including salivary glands, pancreas, prostate, and distal nephron. Tissue kallikrein is also expressed in human neutrophils. It acts locally near its sites of origin. The synthesis of tissue prokallikrein is controlled by a number of factors, including aldosterone in the kidney and salivary gland and androgens in certain other glands. The secretion of

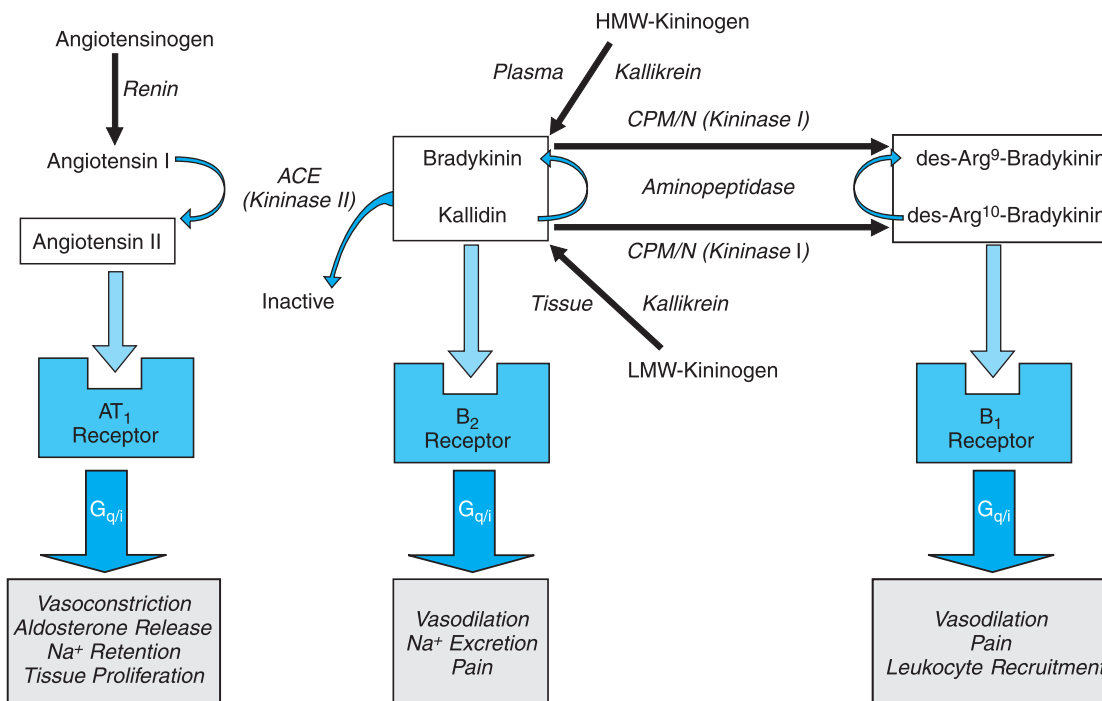

Figure 24–4. Synthesis and receptor interactions of active peptides generated by the kallikrein–kinin and renin–angiotensin systems. Bradykinin (BK) is generated by the action of *plasma* kallikrein on high-molecular-weight (HMW) kininogen, whereas kallidin (Lys-bradykinin) is synthesized by the hydrolysis of low-molecular-weight (LMW) kininogen by *tissue* kallikrein. Kallidin and BK are natural ligands of the B₂ receptor but can be converted to corresponding agonists of the B₁ receptor by removal of the C-terminal Arg by the action of kininase I–type enzymes: the plasma membrane–bound carboxypeptidase M (CPM) or soluble plasma carboxypeptidase N (CPN). Kallidin or [des-Arg¹⁰]kallidin can be converted to the active peptides BK or [des-Arg⁹]BK by aminopeptidase removal of the N-terminal Lys residue. In a parallel fashion, the inactive decapeptide angiotensin I (Ang I) is generated by the action of renin on the plasma substrate angiotensinogen. By removal of the C-terminal His–Leu dipeptide, angiotensin converting enzyme (ACE) generates the active peptide Ang II. These two systems have opposing effects. Whereas Ang II is a potent vasoconstrictor that also causes aldosterone release and Na⁺ retention via activation of the AT₁ receptor, BK is a vasodilator that stimulates Na⁺ excretion by activating the B₂ receptor. ACE generates active Ang II and at the same time inactivates BK and kallidin; thus its effects are prohypertensive, and ACE inhibitors are effective antihypertensive agents. The B₂ receptor mediates most of BK’s effects under normal circumstances, whereas synthesis of the B₁ receptor is induced by inflammatory mediators and plays a major role in chronic inflammatory conditions. Both the B₁ and B₂ receptors couple through G_{q/i} to activate PLC and increase intracellular Ca²⁺; the physiological response depends on receptor distribution on particular cell types and occupancy by agonist peptides. For instance, on endothelial cells, activation of B₂ receptors results in Ca²⁺–calmodulin–dependent activation of eNOS and generation of NO, which causes cGMP accumulation and relaxation in neighboring smooth muscle cells. On smooth muscle cells, activation of kinin receptor coupling through the same pathway results in an increased [Ca²⁺]_i and contraction. B₁ and B₂ receptors also can couple through G_i to activate PLA₂, causing the release of arachidonic acid and the local generation of prostanoids and other metabolites. For further details, *see* text.

the tissue prokallikrein also may be regulated; *e.g.*, its secretion from the pancreas is enhanced by stimulation of the vagus nerve (*see* Margolius, 1989). The activation of tissue prokallikrein to kallikrein requires proteolytic cleavage to remove a 7–amino acid propeptide (Bhoola *et al.*, 1992).

Kininogens. The two substrates for the kallikreins, HMW kininogen and LMW kininogen, are derived from a single gene by alternative splicing. HMW kininogen and LMW kininogen have been divided into functional domains. The HMW kininogen contains 626 amino acid residues; the internal bradykinin sequence of 9 amino acid resi-

dues, domain 4, connects an N-terminal “heavy chain” sequence (362 amino acids). This consists of domains 1 through 3 and a C-terminal “light chain” sequence (255 amino acids) containing domains D5H and D6. LMW kininogen is identical to the larger form of the protein from the amino terminus through the bradykinin sequence; its short light chain differs (Takagaki *et al.*, 1985). HMW kininogen is cleaved by plasma and tissue kallikrein to yield bradykinin or kallidin, respectively. LMW kininogen is a substrate only of tissue kallikrein, and the product is kallidin. The kininogens also inhibit cysteine proteinases, inhibit thrombin binding, and exhibit antiadhesive and profibrinolytic properties.

Functions and Pharmacology of Kallikreins and Kinins

The availability of more specific bradykinin antagonists and the generation of bradykinin-receptor Knockout mice have advanced our understanding of the roles of the kinins significantly. These compounds currently are being investigated in diverse areas such as pain, inflammation and chronic inflammatory diseases, the cardiovascular system, and reproduction.

Pain. The kinins are powerful algescic agents that cause an intense burning pain when applied to the exposed base of a blister. Bradykinin excites primary sensory neurons and provokes the release of neuropeptides such as substance P, neurokinin A, and calcitonin gene-related peptide (Geppetti, 1993). Although there is overlap, B₂ receptors generally mediate acute bradykinin algesia, whereas the pain of chronic inflammation appears to involve increased numbers of B₁ receptors.

Inflammation. Kinins participate in a variety of inflammatory diseases. Plasma kinins increase permeability in the microcirculation. The effect, like that of histamine and serotonin in some species, is exerted on the small venules and involves separation of the junctions between endothelial cells. This, together with an increased hydrostatic pressure gradient, causes edema. Such edema, coupled with stimulation of nerve endings (*see below*), results in a “wheal and flare” response to intradermal injections in human beings.

In hereditary angioedema, bradykinin is formed, and there is depletion of the components of the kinin cascade during episodes of swelling, laryngeal edema, and abdominal pain. B₁ receptors on inflammatory cells such as macrophages can elicit production of the inflammatory mediators interleukin 1 (IL-1) and tumor necrosis factor α (TNF- α) (Dray and Perkins, 1993). Kinin levels are increased in a number of chronic inflammatory diseases, including rhinitis caused by inhalation of antigens and that associated with rhinoviral infection. Kinins may be significant in conditions such as gout, disseminated intravascular coagulation, inflammatory bowel disease, rheumatoid arthritis, and asthma. Kinins also may contribute to the skeletal changes seen in chronic inflammatory states. Kinins stimulate bone resorption through B₁ and possibly B₂ receptors, perhaps by osteoblast-mediated osteoclast activation (*see Chapter 61*).

Respiratory Disease. The kinins have been implicated in the pathophysiology of allergic airway disorders such as

asthma and rhinitis. Inhalation or intravenous injection of kinins causes bronchospasm in asthmatic patients but not in normal individuals. This bradykinin-induced bronchoconstriction is blocked by anticholinergic agents but not by antihistamines or cyclooxygenase inhibitors. Similarly, nasal challenge with bradykinin is followed by sneezing and serious glandular secretions in patients with allergic rhinitis. A bradykinin B₂-receptor antagonist improved pulmonary function in patients with severe asthma.

Cardiovascular System. Urinary kallikrein concentrations are decreased in individuals with high blood pressure. In experimental animals and humans, infusion of bradykinin causes vasodilation and lowers blood pressure. Hypertensives also excrete less urinary kallikrein (Margolius, 1989, 1995). Bradykinin causes vasodilation by activating its B₂ receptor on endothelial cells. The endothelium-dependent dilation is mediated by NO, prostacyclin, and a hyperpolarizing epoxyeicosatrienoic acid that is a CYP-derived metabolite of arachidonic acid (Vanhoutte, 1989; Campbell *et al.*, 1996).

The availability of specific bradykinin antagonists and genetically altered animals has enhanced our understanding of the role of endogenous bradykinin in the regulation of blood pressure (Madeddu *et al.*, 1997). Basal blood pressure is normal in B₂-receptor antagonist-treated animals or B₂-receptor knockout mice. However, these animals exhibit an exaggerated blood pressure response to salt loading or activation of the renin-angiotensin system. These data suggest that the endogenous kallikrein-kinin system plays a minor role in the regulation of blood pressure under normal circumstances, but it may be important in hypertensive states.

The kallikrein-kinin system appears to be cardioprotective. Because part of the activity of the widely used ACE inhibitors is attributed to enhancement of bradykinin effects, much was learned about the function of kinins, such as their antiproliferative effects. Bradykinin contributes to the beneficial effect of preconditioning the heart against ischemia and reperfusion injury. In the presence of endothelial cells, bradykinin prevents vascular smooth muscle cell growth and proliferation. Bradykinin stimulates tissue plasminogen activator (tPA) release from the vascular endothelium (Brown *et al.*, 1999). In this way, bradykinin may contribute to the endogenous defense against cardiovascular events such as myocardial infarction and stroke.

Kinins also may increase sympathetic outflow *via* central and peripheral nervous mechanisms.

Kidney. Renal kinins act in a paracrine manner to regulate urine volume and composition (Saitoh *et al.*, 1995).

Kallikrein is synthesized and secreted by the connecting cells of the distal nephron. Tissue kininogen and kinin receptors are present in the cells of the collecting duct. Like other vasodilators, kinins increase renal blood flow. Bradykinin also causes natriuresis by inhibiting sodium reabsorption at the cortical collecting duct. Renal kallikreins are increased by treatment with mineralocorticoids, ACE inhibitors, and neutral endopeptidase (neprilysin) inhibitors.

Other Effects. The rat uterus in estrus is especially sensitive to contraction by kinins through the B₂ receptor. Kinins promote dilation of the fetal pulmonary artery, closure of the ductus arteriosus, and constriction of the umbilical vessels, all of which occur in the transition from fetal to neonatal circulation.

The kallikrein-kinin system also functions in many other areas in the body, serving to mediate edema formation and smooth muscle contraction. The slowly developing contraction of the isolated guinea pig ileum that the peptide induces first prompted the name *bradykinin*. The kinins also affect the CNS, in addition to their ability to disrupt the blood-brain barrier and allow increased CNS penetration. A bradykinin analog (RMP7) that is resistant to degradation by carboxypeptidase N and M and ACE has been tested in the laboratory and clinically to enhance the penetration of drugs to brain tumors through the blood-brain barrier (*see Inamura et al., 1994*).

Potential Therapeutic Uses. Bradykinin contributes to many of the effects of the ACE inhibitors (Figure 24-4). *Aprotinin*, a kallikrein inhibitor, is administered to patients undergoing coronary bypass to minimize bleeding and blood requirements (*see below*). Kinin agonists potentially may increase the delivery of chemotherapeutic agents past the blood-brain barrier. Based on some of the actions outlined earlier, kinin antagonists are being tested in inflammatory conditions.

Kallikrein Inhibitors. Aprotinin (TRASYLOL) is a natural proteinase inhibitor obtained for commercial purposes from bovine lung, but it is identical with Kunitz's pancreatic trypsin inhibitor (Waxler and Rabito, 2003). Aprotinin inhibits mediators of the inflammatory response, fibrinolysis, and thrombin generation following cardiopulmonary bypass surgery, including kallikrein and plasmin. In several placebo-controlled, double-blind studies, administration of aprotinin reduced requirements for blood products in patients undergoing coronary artery bypass grafting. Depending on patient risk factors, aprotinin is given as a loading dose of either 1 or 2 million kallikrein inhibitor units (KIU), followed by continuous infusion of 250,000 or 500,000 KIU/h during surgery. Hypersensitivity reactions may occur with aprotinin, including anaphylactic or anaphylactoid reactions. The rate of such reactions is less than 1% in patients who have not been exposed previously to aprotinin and higher (1% to 9%) in patients who have been

exposed to aprotinin. A test dose of aprotinin (10,000 KIU) should be given prior to full dosing; however, this test is not risk-free. Aprotinin can interfere with an activated clotting time used to determine the effectiveness of heparin anticoagulation (*see Chapter 54*). For this reason, alternate methods must be used in patients treated with aprotinin. In one multicenter study, there was an increased closure rate of saphenous vein grafts in patients treated with aprotinin compared with placebo; there were no differences in rates of myocardial infarction or death (Waxler and Rabito, 2003).

Bradykinin and the Effects of ACE Inhibitors. ACE inhibitors are used widely in the treatment of hypertension, and they reduce mortality in patients with diabetic nephropathy, left ventricular dysfunction, previous myocardial infarction, or coronary artery disease. ACE inhibitors block the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor and growth promoter (Figure 24-4) (*see Chapter 30*). Studies using the specific bradykinin B₂ antagonist HOE-140 demonstrate that bradykinin also contributes to many of the protective effects of ACE inhibitors. For example, administration of HOE-140 in animal models attenuates the favorable effects of ACE inhibitors on blood pressure, myocardial infarct size, and ischemic preconditioning (Linz *et al.*, 1995). Bradykinin-receptor antagonism also attenuates blood pressure lowering by acute ACE inhibition in human beings (Gainer *et al.*, 1998). The contribution of bradykinin to the effects of ACE inhibitors may result not only from decreased degradation of bradykinin but also from induction of enhanced receptor sensitivity (Marcic *et al.*, 1999).

Occasional patients receiving ACE inhibitors have experienced angioedema, which occurs most often shortly after initiating therapy. This is a class effect of ACE inhibitors and is thought to be connected to the inhibition of kinin metabolism by ACE (Slater *et al.*, 1988). ACE inhibitor-associated angioedema is more common in blacks than in Caucasians. A common side effect of ACE inhibitors (especially in women) is a chronic nonproductive cough that dissipates when the drug is stopped. The finding that angiotensin AT₁-receptor-subtype antagonists do not cause cough provides presumptive evidence for the role of bradykinin in this effect, but the mechanism and receptor subtype involved have not been clearly defined.

Preliminary data suggest that bradykinin also may contribute to the effects of the AT₁-receptor antagonists. During AT₁-receptor blockade, angiotensin II concentrations increase. Renal bradykinin concentrations also increase through the effects of angiotensin II on the unopposed AT₂-subtype receptor (Widdop *et al.*, 2003). Whether or not bradykinin contributes to the clinical effects of the

AT₁-receptor antagonists remains to be determined. In addition, a new class of antihypertensive agents, the combined ACE–neutral endopeptidase inhibitors, has been tested. These drugs inhibit two kinin-degrading enzymes; consequently, bradykinin may be expected to contribute more significantly to their clinical and side effects. In clinical trials, administration of the combination drug *omapatrilat* was associated with a threefold higher incidence of angioedema than was an ACE inhibitor alone, causing withdrawal of the combination and reduced enthusiasm for their further development.

Bradykinin Antagonists. The substitution of a D-aromatic amino acid for the proline residue at position seven conferred antagonist activity to bradykinin and blocked the action of ACE. The addition of an N-terminal D-arginine residue also increased the half-life of these antagonists. However, the early kinin antagonists were partial agonists and had short half-lives owing to enzymatic degradation by carboxypeptidase N *in vivo*. The longer-acting, more selective kinin antagonist HOE-140 was developed by substituting synthetic amino acids at positions seven [D-tetrahydroisoquinoline-3-carboxylic acid (Tic)] and eight [octahydroindole-2-carboxylic acid (Oic)] (Table 24–3). This compound has contributed to our understanding of the functions of bradykinin *in vitro* and *in vivo*.

The development of orally active nonpeptide-receptor antagonists promises to make bradykinin antagonism therapeutically feasible in the treatment of inflammatory disease. The first of these, WIN64338, suffered from having muscarinic cholinergic activity. More recently, the nonpeptide antagonist FR173657 (Table 24–3) has been shown to decrease bradykinin-induced edema and hypotension in animal models. On the other hand, synthetic B₂-receptor agonists (such as FR190997; Table 24–3) may be cardioprotective. Synthetic small-molecule bradykinin agonists or antagonists will not necessarily bind to the same extracellular domains of the B₂ receptor as the peptide but may interact with the hydrophobic transmembrane portion (Heitsch, 2003).

CLINICAL SUMMARY

Aprotinin (TRASYLOL), the potent inhibitor of kallikrein and other serine proteases, is employed clinically to reduce blood loss in patients undergoing coronary artery bypass surgery.

Because kinins and [des-Arg]kinins enhance pain and inflammation *via* activation of the two kinin receptors, B₂- and B₁-receptor antagonists may be useful in the future to treat inflammation. Although initial trials of peptide-based antagonists have not yet yielded convincingly positive effects, small synthetic nonpeptidic antagonists that absorb better and have more favorable pharmacokinetic profiles could be more promising therapeutic agents.

ACE inhibitors are widely used drugs in the treatment of hypertension, congestive heart failure, and diabetic

nephropathy, and they reduce mortality in patients with a variety of cardiovascular risk factors (*see* Chapter 30). One effect of ACE inhibitors is to prevent the degradation of bradykinin. Because bradykinin, by activating its B₂ receptor, is responsible for many of the beneficial cardioprotective effects of ACE inhibitors, the search is on to find a suitable stable B₂ agonist for clinical evaluation. A major problem for such applications is to establish a safe therapeutic window between potentially protecting the heart and avoiding proinflammatory stimulation (Heitsch, 2003).

ACKNOWLEDGMENT

We are grateful for the helpful contributions of Dr. Jean-Charles Schwartz of INSERM U.109, Paris; Dr. Allen P. Kaplan of the Medical University of South Carolina, Charleston; Dr. Sara F. Rabinowitz of Cook County Hospital, Chicago; and Dr. William B. Campbell of the Medical College of Wisconsin, Milwaukee.

LIPID-DERIVED AUTACOIDS: EICOSANOIDS AND PLATELET-ACTIVATING FACTOR

Emer M. Smyth, Anne Burke, and Garret A. FitzGerald

Membrane lipids supply the substrate for the synthesis of eicosanoids and platelet-activating factor. Eicosanoids—arachidonate metabolites, including prostaglandins, prostacyclin, thromboxane A₂, leukotrienes, lipoxins and hepoxylins—are not stored but are produced by most cells when a variety of physical, chemical, and hormonal stimuli activate acyl hydrolases that make arachidonate available. Membrane glycerophosphocholine derivatives can be modified enzymatically to produce platelet-activating factor (PAF). PAF is formed by a smaller number of cell types, principally leukocytes, platelets, and endothelial cells. Eicosanoids and PAF lipids contribute to inflammation, smooth muscle tone, hemostasis, thrombosis, parturition, and gastrointestinal secretion. Several classes of drugs, most notably *aspirin*, the *traditional nonsteroidal antiinflammatory agents* (tNSAIDs), and the specific inhibitors of cyclooxygenase-2 (COX-2), such as the *coxibs*, owe their principal therapeutic effects to blockade of eicosanoid formation. In order to understand the therapeutic potential of selective inhibitors of eicosanoid synthesis and action, it is enlightening to first review the synthesis, metabolism, and mechanism of action of eicosanoids and PAF.

EICOSANOIDS

History. In 1930, Kurzrok and Lieb, two American gynecologists, observed that strips of uterine myometrium relax or contract when exposed to semen. Subsequently, Goldblatt in England and von Euler in Sweden reported independently on smooth muscle-contracting and vasodepressor activities in seminal fluid and accessory reproductive glands. Von Euler identified the active material as a lipid-soluble acid, which he named *prostaglandin*, inferring its ori-

gin in the prostatic gland. Samuelsson, Bergström, and their colleagues elucidated the structures of prostaglandin E₁ (PGE₁) and prostaglandin F₁α (PGF₁α) in 1962. In 1964, Bergström and coworkers and van Dorp and associates independently achieved the biosynthesis of PGE₂ from arachidonic acid using homogenates of sheep seminal vesicle. The discoveries of thromboxane A₂ (TxA₂), prostacyclin (PGI₂), and the leukotrienes followed in short order. Vane, Smith, and Willis reported that aspirin and NSAIDs act by inhibiting prostaglandin biosynthesis (Vane, 1971). This remarkable period of discovery culminated with the award of the Nobel Prize to Bergström, Samuelsson, and Vane in 1982. For his discovery of norepinephrine as the neurotransmitter in the sympathetic branch of the autonomic nervous system, von Euler shared the Nobel Prize in 1970 with Julius Axelrod and Bernard Katz.

Prostaglandins (PGs), leukotrienes (LTs), and related compounds are called *eicosanoids*, from the Greek *eikosi* (“twenty”). Precursor essential fatty acids contain 20 carbons and three, four, or five double bonds: 8,11,14-eicosatrienoic acid (dihomo- γ -linolenic acid), 5,8,11,14-eicosatetraenoic acid [arachidonic acid (AA); Figure 25–1], and 5,8,11,14,17-eicosapentaenoic acid (EPA). In humans, AA, the most abundant precursor, is either derived from dietary linoleic acid (9,12-octadecadienoic acid) or ingested directly as a dietary constituent. EPA is a major constituent of oils from fatty fish such as salmon.

Biosynthesis. Biosynthesis of eicosanoids is limited by the availability of substrate and depends primarily on the release of AA, esterified in the *sn*-2 domain of cell membrane phospholipids or other complex lipids, to the eicosanoid-synthesizing enzymes by acyl hydrolases, most notably phospholipase A₂. Chemical and physical stimuli activate the Ca²⁺-dependent translocation of group IV cytosolic PLA₂ (cPLA₂), which has high affinity for AA, to the membrane, where it hydrolyzes the *sn*-2 ester bond of membrane phospholipids (particularly phosphatidylcholine and phosphatidylethanolamine), releasing arachidonate. Multiple additional PLA₂ isoforms [group IIA secretory (sPLA₂), group V (sPLA₂), group VI Ca²⁺ independent (iPLA₂), and group X (sPLA₂)] have been characterized. Under nonstimulated conditions, AA liberated by iPLA₂ is reincorporated into cell membranes, so there is negligible eicosanoid biosynthesis. While cPLA₂ dominates in the acute release of AA, the inducible sPLA₂ contributes under conditions

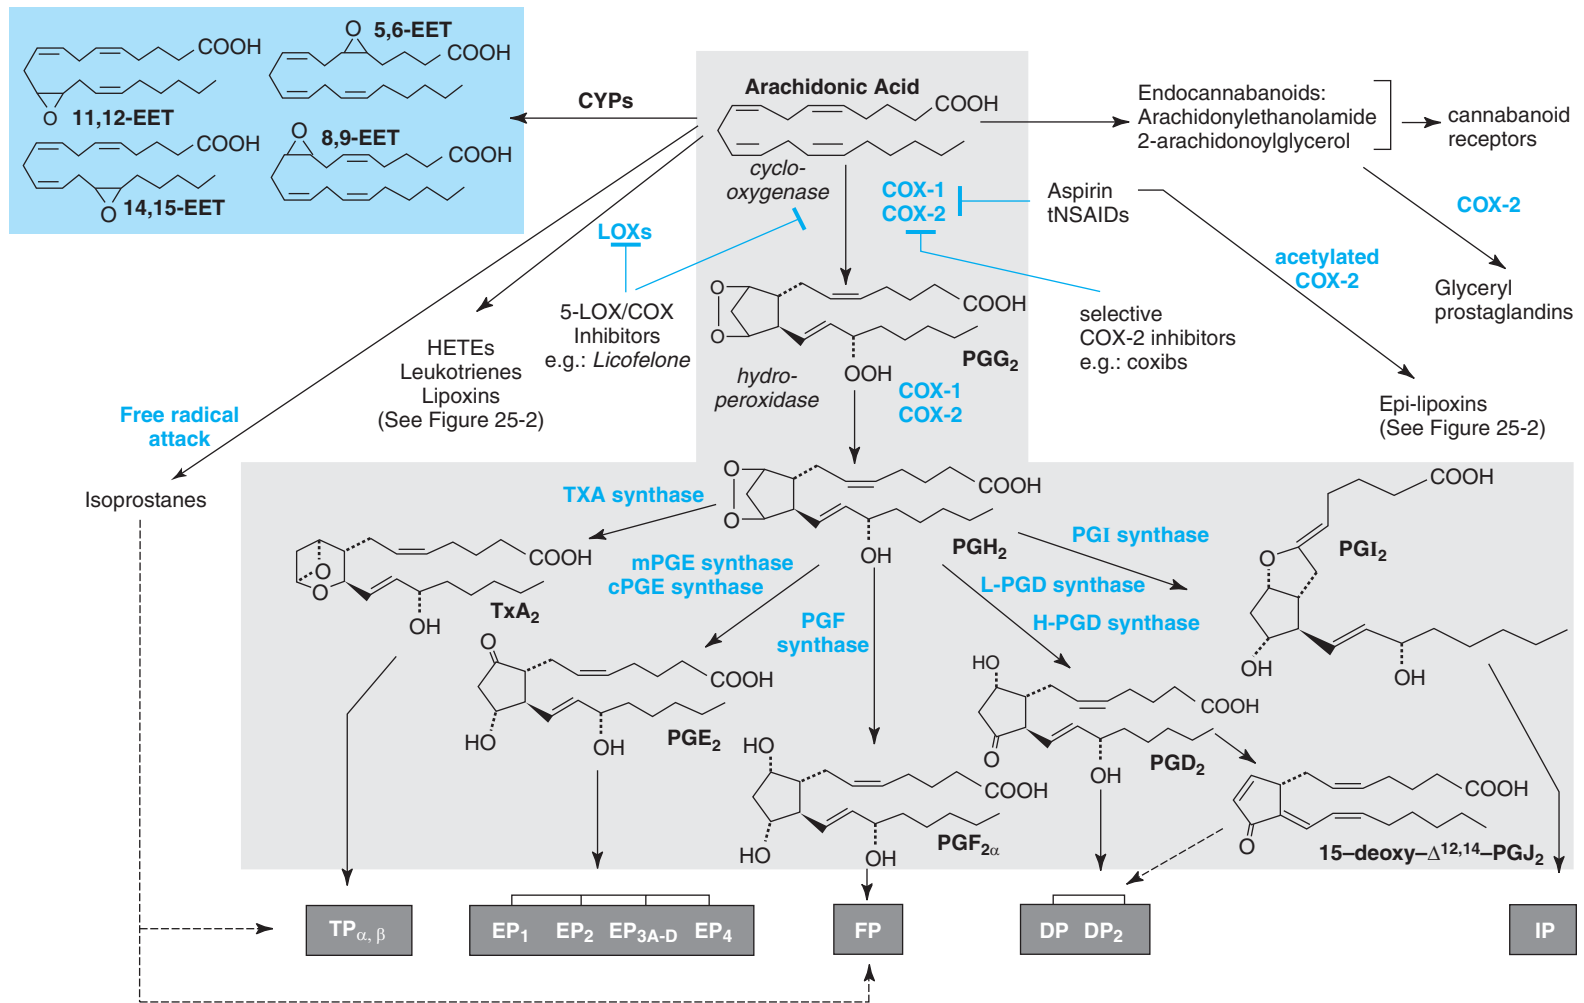

Figure 25–1. Metabolism of arachidonic acid. The cyclooxygenase (COX) pathway is highlighted in gray. The lipoxygenase (LOX) pathways are expanded in Figure 25–2. Major degradation pathways are shown in Figure 25–3. Cyclic endoperoxides (PGG₂ and PGH₂) arise from the sequential cyclooxygenase and hydroperoxidase actions of COX-1 or COX-2 on arachidonic acid released from membrane phospholipids. Subsequent products are generated by tissue-specific synthases and transduce their effects *via* membrane-bound receptors (*gray boxes*). Dashed lines indicate putative ligand–receptor interactions. EETs (*shaded in blue*) and isoprostanes are generated *via* CYP activity and nonenzymatic free radical attack, respectively. COX-2 can use modified arachidonoylglycerol, an endocannabinoid, to generate the glyceryl prostaglandins. Aspirin and tNSAIDs are nonselective inhibitors of COX-1 and COX-2 but do not affect LOX activity. Epilipoxins are generated by COX-2 following its acetylation by aspirin (Figure 25–2). Dual 5-LOX–COX inhibitors interfere with both pathways. *See text for other abbreviations.*

of sustained or intense stimulation of AA production. Once liberated, a portion of the AA is metabolized rapidly to oxygenated products by several distinct enzyme systems, including *cyclooxygenases*, *lipoxygenases*, and CYPs.

Products of Prostaglandin G/H Synthases. The prostaglandins prostacyclin and thromboxane, collectively termed *prostanoids*, can be considered analogs of unnatural compounds with the trivial names *prostanic acid* and *thrombanic acid*, with the structures shown below:

AA is metabolized successively to the cyclic endoperoxide prostaglandins G (PGG) and H (PGH) (Figure 25–1) by the cyclooxygenase (COX) and hydroperoxidase (HOX) activities of the prostaglandin G/H synthases. Isomerases and synthases effect the transformation of PGH₂ into terminal prostanoids distinguished by substitutions on their cyclopentane rings.

Prostaglandins of the E and D series are hydroxyketones, whereas the F_α prostaglandins are 1,3-diols (Figure 25–1). A, B, and C prostaglandins are unsaturated ketones that arise nonenzymatically from PGE during extraction procedures; it is unlikely that they occur biologically. PGJ₂ and related compounds result from the dehydration of PGD₂. Prostacyclin (PGI₂) has a double-ring structure; in addition to a cyclopentane ring, a second ring is formed by an oxygen bridge between carbons 6 and 9. Thromboxanes (Tx) contain a six-member oxirane ring instead of the cyclopentane ring of the prostaglandins. The main classes are further subdivided in accord with the number of double bonds in their side chains, as indicated by numerical subscripts. Dihomo- γ -linolenic acid is the precursor of the one series, AA for the two series, and EPA for the three series. Prostanoids derived from AA carry the subscript 2 and are the major series in mammals. There is little evidence that one- or three-series prostanoids are made in adequate amounts to be important under normal circumstances. However, the health benefits of dietary supplementation with ω -3 fatty acids remain a focus of investigation.

Synthesis of prostanoids is accomplished in a stepwise manner by a complex of microsomal enzymes. The first enzyme in this synthetic pathway is prostaglandin endoperoxide G/H synthase, which is colloquially called *cyclooxygenase*, or COX. There are two distinct COX isoforms, COX-1 and COX-2 (Smith *et al.*, 1996). COX-1 is expressed constitutively in most cells, whereas COX-2 is up-regulated by cytokines, shear stress, and growth factors. Thus COX-1 is considered to subservise housekeeping functions such as cytoprotection of the gastric epithelium (*see* Chapter 36). COX-2 is the major source of prostanoids formed in inflammation and cancer. This distinction is overly simplistic: There are physiological and pathophysiological processes in which each enzyme is uniquely involved and others in which they function coordinately (*see* Smith and Langenbach, 2001).

In addition to 61% amino acid identity, the crystal structures of COX-1 and COX-2 are remarkably similar (FitzGerald and Loll, 2001). Both isoforms are expressed as dimers homotypically inserted into the endoplasmic reticular membrane; their COX activity oxygenates and cyclizes unesterified AA to form PGG₂, whereas their HOX activity converts PGG₂ to PGH₂ (Smith and Langenbach, 2001). These chemically unstable intermediates are transformed enzymatically into the prostaglandins thromboxane and prostacyclin by isomerases and synthases that are expressed in a relatively cell-specific fashion such that most cells make one or two dominant prostanoids. For example, COX-1-derived TxA₂ is the dominant product in platelets, whereas COX-2-derived PGE₂ and TxA₂ dominate in activated macrophages. Two classes of PGE synthases have been cloned. Microsomal PGE synthases 1 and 2 colocalize with COX-2 in some, but not all, tissues and may be induced by cytokines and tumor promoters. Similarly, cytosolic PGE synthase colocalizes with COX-1 and may be important in constitutive formation of PGE₂. Two forms of PGD synthase and PGF synthase have been identified. In heterologous expression systems, COX-1 couples preferentially with TxA₂ and PGF synthase, whereas COX-2 prefers PGI₂ synthase (Smyth and FitzGerald, 2003).

Prostanoids are released from cells predominantly by facilitated transport through the prostaglandin transporter and possibly other transporters (*see* Schuster, 2002).

Products of Lipoxygenases. Lipoxygenases (LOXs) are a family of non-heme iron-containing enzymes that catalyze the oxygenation of polyenic fatty acids to corresponding lipid hydroperoxides (*see* Brash, 1999). The enzymes require a fatty acid substrate with two *cis* double bonds separated by a methylene group. AA, which contains several double bonds in this configuration, is metabolized to hydroperoxy eicosatetraenoic acids (HPETEs), which vary in the site of insertion of the hydroperoxy group. Analogous to PGG₂ and PGH₂, these unstable intermediates, normally with *S* chirality, are further metabolized by a variety of enzymes. HPETEs are converted to their corresponding hydroxy fatty acid (HETE) either nonenzymatically or by a peroxidase.

There are five active human lipoxygenases—5-LOX, 12(*S*)-LOX, 12(*R*)-LOX, 15-LOX-1, and 15-LOX-2—classified according to the site of hydroperoxy group insertion and, when necessary, the stereoconfiguration (*S* or *R*) of their products. Their expression is frequently cell-specific (Brash, 1999); platelets have only 12(*S*)-LOX, whereas leukocytes contain both 5(*S*)- and 12(*S*)-LOX (Figure 25–2). The epidermis contains a distinct subgroup of LOXs including epidermal 12(*S*)-, 12(*R*)- and 15-LOXs. A novel epidermal enzyme, lipoxygenase-3, has been reported to metabolize further the product of 12(*R*)-LOX in the skin (Yu *et al.*, 2003).

The 5-LOX pathway leads to the synthesis of the *leukotrienes* (LTs), which play a major role in the development and persistence of the inflammatory response (Brink *et al.*, 2003) (Figure 25–2). A nomenclature (LTB₄, LTB₅, etc.) similar to that of prostanoids applies to the subclassification of the LTs. When eosinophils, mast cells, polymorphonuclear leukocytes, or monocytes are activated, 5-LOX translocates to the nuclear membrane and associates with 5-LOX-activating protein (FLAP), an integral membrane protein essential for LT biosynthesis. FLAP may act as an AA transfer protein that presents the substrate to the 5-LOX (Brash, 1999). An experimental drug, MK-886, binds to FLAP and blocks LT production. A two-step reaction is catalyzed by 5-LOX: oxygenation of AA at C-5 to form 5-HPETE, followed by dehydration of 5-HPETE to an unstable 5,6-epoxide known as LTA₄. LTA₄ is transformed into bioactive eicosanoids by multiple pathways depending on the cellular

Figure 25–2. Lipoxigenase pathways of arachidonic acid metabolism. FLAP presents arachidonic acid to 5-LOX, leading to the generation of the LTs. Cysteinyl LTs are shaded in gray. Lipoxins (shaded in blue) are products of cellular interaction via a 5-LOX–12-LOX pathway or via a 15-LOX–5-LOX pathway. Biological effects are transduced via membrane-bound receptors (dark gray boxes). Dashed line indicates putative ligand–receptor interactions. Zileuton inhibits 5-LOX but not the COX pathways (expanded in Figure 25–1). Dual 5-LOX–COX inhibitors interfere with both pathways. CysLT antagonists prevent activation of the CysLT₁ receptor. See text for abbreviations.

context: transformation by LTA_4 hydrolase to a 5,12-dihydroxyeicosatetraenoic acid known as LTB_4 ; conjugation with reduced glutathione by LTC_4 synthase, in eosinophils, monocytes, and mast cells, to form LTC_4 ; and extracellular metabolism of the peptide moiety of LTC_4 , leading to the removal of glutamic acid and subsequent cleavage of glycine, to generate LTD_4 and LTE_4 , respectively (see Brash, 1999). LTC_4 , LTD_4 , and LTE_4 , the *cysteinyl leukotrienes*, were known originally as the *slow-reacting substance of anaphylaxis* (SRS-A), first described more than 60 years ago (see Chapter 27). LTB_4 and LTC_4 are actively transported out of the cell.

15-LOX exists in at least two isoforms, 15-LOX-1 and 15-LOX-2. The former prefers linoleic acid as a substrate and forms 15(S)-hydroxyoctadecadienoic acid, whereas the latter uses AA to generate 15(S)-HETE. Platelet-type 12-LOX generates 12(S)-HETE from AA, whereas the leukocyte isozyme can synthesize both 12- and 15-HETE and often is referred to as *12/15-LOX*. 12-LOX can further metabolize LTA_4 , the primary product of the 5-LOX pathway, to form the *lipoxins* LXA_4 and LXB_4 . These mediators also can arise through 5-LOX metabolism of 15-HETE. 15(R)-HETE, derived from aspirin-acetylated COX-2, can be further transformed in leukocytes by 5-LOX to the *epilipoxins* 15-epi- LXA_4 or 15-epi- LXB_4 , the so-called aspirin-triggered lipoxins (Brink *et al.*, 2003). 12-HETE also can undergo a catalyzed molecular rearrangement to epoxyhydroxyeicosatrienoic acids called *hexopilins*.

The epidermal LOXs are distinct from “conventional” enzymes in their substrate preferences and products, and their roles in normal skin function are not clear. AA and linoleic acid apparently are not the natural substrates for the epidermal LOXs. Epidermal accumulation of 12(R)-HETE is a feature of psoriasis and ichthyosis. Inhibitors of 12(R)-LOX are under investigation for the treatment of these proliferative skin disorders.

Products of Cytochrome P450. Multiple CYPs metabolize arachidonic acid (Capdevila and Falck, 2002). For instance, epoxyeicosatrienoic acids (EETs) can be formed by CYP epoxygenases, primarily CYP2C and CYP2J in humans. Four regioisomers (14,15-, 11,12-, 8,9-, and 5,6-EETs), each containing a mixture of the (R,S) and (S,R) enantiomers, are formed in a CYP isoform-specific manner. Their biosynthesis can be altered by pharmacological, nutritional, and genetic factors that affect CYP expression (see Chapter 3).

EETs are metabolized by numerous pathways. The corresponding dihydroxyeicosatrienoic acids (DHETs) are formed by epoxide hydrolases (EHs), whereas lysolipid acylation results in incorporation of EETs into cellular phospholipids. Glutathione conjugation and oxidation by COX and CYPs generate a series of glutathione conjugates, epoxyprostaglandins, diepoxides, tetrahydrofuran (THF) diols, and epoxyalcohols whose biological relevance is not known. Intracellular fatty acid-binding proteins (FABPs) may bind EETs and DHETs differentially, thus modulating their metabolism, activities, and targeting.

EETs are important modulators of cardiovascular and renal function. They are synthesized in endothelial cells and cause vasodilation in a number of vascular beds by activating the large conductance Ca^{2+} -activated K^+ channels of smooth muscle cells. This results in hyperpolarization of smooth muscle and thus relaxation, leading to reduced blood pressure. Substantial evidence indicates that EETs may function as endothelium-derived hyperpolarizing factors (EDHFs), particularly in the coronary circulation (Quilley and McGiff, 2000). Endogenous biosynthesis of EETs is increased in human syndromes of hypertension (Catella *et al.*, 1990). An analog of 11,12-EET abrogated the enhanced renal microvascular reactivity to angiotensin II (Ang II) associated with hypertension (Imig *et al.*, 2001), and blood pressure is lower in mice deficient in soluble EH (Sinal *et al.*, 2000);

these findings suggest that EH enzyme may be a potential pharmacological target for hypertension. Much evidence suggests the existence of EET receptors, although none has been cloned.

Other Pathways. The isoicosanoids, a family of eicosanoid isomers, are formed nonenzymatically by direct free radical-based attack on AA and related lipid substrates (Lawson *et al.*, 1999; Fam and Morrow, 2003). Unlike eicosanoids, these compounds are generated initially on the esterified lipid in cell membranes, from which they are cleaved, presumably by phospholipases; the free isoicosanoids circulate and are excreted in urine. Consequently, their production is not blocked *in vivo* by agents that suppress metabolism of free arachidonate, such as inhibitors of COX-1 or COX-2. The $PGF_{2\alpha}$ isomer F_2-I isoprostane 8-iso- $PGF_{2\alpha}$ also known as *iPF_{2\alpha}III*, was the first such compound to be identified. Unlike other isoprostanes studied to date, it may originate *via* a COX pathway or by a free radical-dependent mechanism. The former pathway does not contribute detectably to its levels in urine, although more abundant compounds, such as 8,12-iso- $PGF_{2\alpha}VI$, which are not formed *via* COXs, represent more attractive markers of lipid peroxidation *in vivo*. Since several isoprostanes can activate prostanoid receptors, it has been speculated that they may contribute to the pathophysiology of inflammatory responses in a manner insensitive to COX inhibitors.

In the brain, the endocannabinoids arachidonylethanolamide (anandamide) and 2-arachidonoylglycerol are endogenous ligands of cannabinoid receptors (Maccarrone and Finazzi-Agro, 2002). They mimic several pharmacological effects of Δ^9 -tetrahydrocannabinol, the active principle of *Cannabis sativa* preparations such as hashish and marijuana, including inhibition of adenylyl cyclase, inhibition of L-type Ca^{2+} channels, analgesia, and hypothermia. Glyceryl prostaglandins (PG-Gs) are generated by the oxygenation of 2-arachidonoylglycerol by COX-2; their biological significance remains to be clarified.

Inhibitors of Eicosanoid Biosynthesis. A number of the biosynthetic steps just described can be inhibited by drugs. Inhibition of phospholipase A_2 decreases the release of the precursor fatty acid and thus the synthesis of all its metabolites. Since phospholipase A_2 is activated by Ca^{2+} and calmodulin, it may be inhibited by drugs that reduce the availability of Ca^{2+} . *Glucocorticoids* also inhibit phospholipase A_2 , but they appear to do so indirectly by inducing the synthesis of a group of proteins termed *annexins* (formerly *lipocortins*) that modulate phospholipase A_2 activity (see Chapter 59). Glucocorticoids also down-regulate induced expression of COX-2 but not of COX-1 (Smith *et al.*, 1996). Aspirin and tNSAIDs were found originally to prevent the synthesis of prostaglandins from AA in tissue homogenates (Vane, 1971). It now is known that these drugs inhibit the COX but not the HOX moieties of the prostaglandin G/H synthases and thus the formation of their downstream prostanoid products. *These drugs do not inhibit LOXs and may result in increased formation of LTs by shunting of substrate to the lipoxigenase pathway.* Dual inhibitors of the COX and 5-LOX pathways are under investigation (Martel-Pelletier *et al.*, 2003). However, the interplay between these enzyme families remains to be defined by genetic and pharmaco-

logical approaches. Acetylated COX-2 generates 12(R)-HETE coincident with suppression of PG formation. The importance of this pathway remains to be established *in vivo*.

COX-1 and COX-2 differ in their sensitivity to inhibition by certain antiinflammatory drugs (Marnett *et al.*, 1999). This observation has led to the recent development of agents that selectively inhibit COX-2, including the coxibs (*see* Chapter 26). These drugs could have therapeutic advantages over NSAIDs because COX-2 is the predominant cyclooxygenase at sites of inflammation, whereas COX-1 is the major source of cytoprotective prostaglandins in the gastrointestinal tract. The matter is not settled, but the antiinflammatory actions of the coxibs were associated with improved gastrointestinal safety compared with their nonselective counterparts in at least one trial of clinical outcomes (Bombardier *et al.*, 2000; FitzGerald and Patrono, 2001). However, the theoretical disadvantage of unopposed COX-1 activity associated with these agents raises safety issues for renal function and thromboresistance of the vessel wall (FitzGerald, 2003). Indeed, a polymorphism of the COX-2 gene has been associated with a decreased risk of myocardial infarction and stroke (Cipollone *et al.*, 2004).

Since the metabolites of PGH₂ can produce a variety of biological effects (*see* below), there are theoretical advantages in compounds that preferentially and selectively inhibit the downstream enzymes that metabolize PGH₂. For example, agents that inhibit TxA₂ synthase might block platelet aggregation and induce vasodilation. Indeed, such drugs block TxA₂ production *in vitro* and *in vivo*; however, they have been disappointing in clinical development perhaps owing to activation of the TxA₂ receptor, the TP, by accumulated PGH₂ precursor. Their use in TP antagonists may circumvent this problem. Although some compounds with combined activities were evaluated, these agents did not have concordant potencies as enzyme inhibitors and receptor antagonists across the dosing range. Activation of the TP receptor by oxidized lipids could broaden the clinical indications for these compounds beyond their conventional targets in cardiovascular disease. More recently, mice lacking mPGE synthase-1 exhibited resistance to inflammatory stimuli similar to that observed after treatment with tNSAIDs. Inhibitors of PGE synthase-1 may retain the clinical efficacy of selective COX-2 inhibitors while avoiding cardiovascular complications attributable to suppression of COX-2-derived PGI₂.

Since leukotrienes mediate inflammation, efforts have focused on development of leukotriene-receptor antagonists and selective inhibitors of the LOXs. *Zileuton*, an inhibitor of 5-lipoxygenase, was marketed in the United States for the treatment of asthma but has been withdrawn. In addition, cysteinyl leukotriene-receptor antagonists, including *zafirlukast*, *pranlukast*, and *montelukast*, have established efficacy in the treatment of asthma (*see* Chapter 27). A common polymorphism in the gene for LTC₄ synthase that correlates with increased LTC₄ generation is associated with aspirin-intolerant asthma and with the efficacy of antileukotriene therapy (*see* Kanaoka and Boyce, 2004). Interestingly, while polymor-

phisms in the genes encoding 5-LOX or FLAP do not appear to be linked to asthma (Sayers *et al.*, 2003), studies have demonstrated an association of these genes with myocardial infarction, stroke (Helgadottir *et al.*, 2004), and atherosclerosis (Dwyer *et al.*, 2004); thus, inhibition of LT biosynthesis may be useful in the prevention of cardiovascular disease.

Eicosanoid Catabolism. Most eicosanoids are efficiently and rapidly inactivated. About 95% of infused PGE₂ (but not PGI₂) is inactivated during one passage through the pulmonary circulation. Broadly speaking, the enzymatic catabolic reactions are of two types: a relatively rapid initial step, catalyzed by widely distributed prostaglandin-specific enzymes, wherein prostaglandins lose most of their biological activity; and a second step in which these metabolites are oxidized, probably by enzymes identical to those responsible for the β and ω oxidation of fatty acids (Figure 25–3). The initial step is the oxidation of the 15-OH group to the corresponding ketone by prostaglandin 15-OH dehydrogenase (PGDH) (*see* Tai *et al.*, 2002). Two types of 15-PGDHs have been identified. Type I, an NAD⁺-dependent enzyme, is the predominant form involved in eicosanoid catabolism. There is little circulating PGDH activity; thus, it is likely that metabolism first requires active transport to the intracellular space (*see* Schuster, 2002). The 15-keto compound then is reduced to the 13,14-dihydro derivative, a reaction catalyzed by prostaglandin Δ^{13} -reductase. This enzyme is identical to the LTB₄ 12-hydroxydehydrogenase (*see* below). Subsequent steps consist of β and ω oxidation of the prostaglandin side chains, giving rise to polar dicarboxylic acids in the case of PGEs, which then are excreted in the urine as major metabolites (Figure 25–1); these reactions occur primarily in the liver.

Unlike PGE₂, PGD₂ initially is reduced *in vivo* to the F-ring prostaglandin 9 α 11 β -PGF₂, which possesses significant biological activity. Subsequently, this compound undergoes metabolism similar to that of other eicosanoids (Figure 25–3). TxA₂ breaks down nonenzymatically ($t_{1/2}$ = 30 seconds) into the chemically stable but biologically inactive TxB₂, which then is further metabolized by 11-hydroxy TxB₂ dehydrogenase to generate 11-dehydro-TxB₂ or by β -oxidation to form 2,3-dinor-TxB₂ (Figure 25–3).

The degradation of PGI₂ ($t_{1/2}$ = 3 min) apparently begins with its spontaneous hydrolysis in blood to 6-keto-PGF_{1 α} . The metabolism of this compound in humans involves the same steps as those for PGE₂ and PGF_{2 α} .

The degradation of LTC₄ occurs in the lungs, kidney, and liver. The initial steps involve its conversion to LTE₄. LTC₄ also may be inactivated by oxidation of its cysteinyl sulfur to a sulfoxide. In leukocytes, LTB₄ is inactivated principally by oxidation by members of the CYP4F subfamily. Conversion to 12-oxo-LTB₄ by LTB 12-hydroxydehydrogenase (*see* above) is a key pathway in tissues other than leukocytes.

Pharmacological Properties of Eicosanoids

The eicosanoids show numerous and diverse effects in biological systems. This discussion highlights those that are thought to be the most important.

Cardiovascular System. In most vascular beds, PGE₂ elicits vasodilation and a drop in blood pressure (Narumiya *et al.*, 1999; Smyth and FitzGerald, 2003), although vasocon-

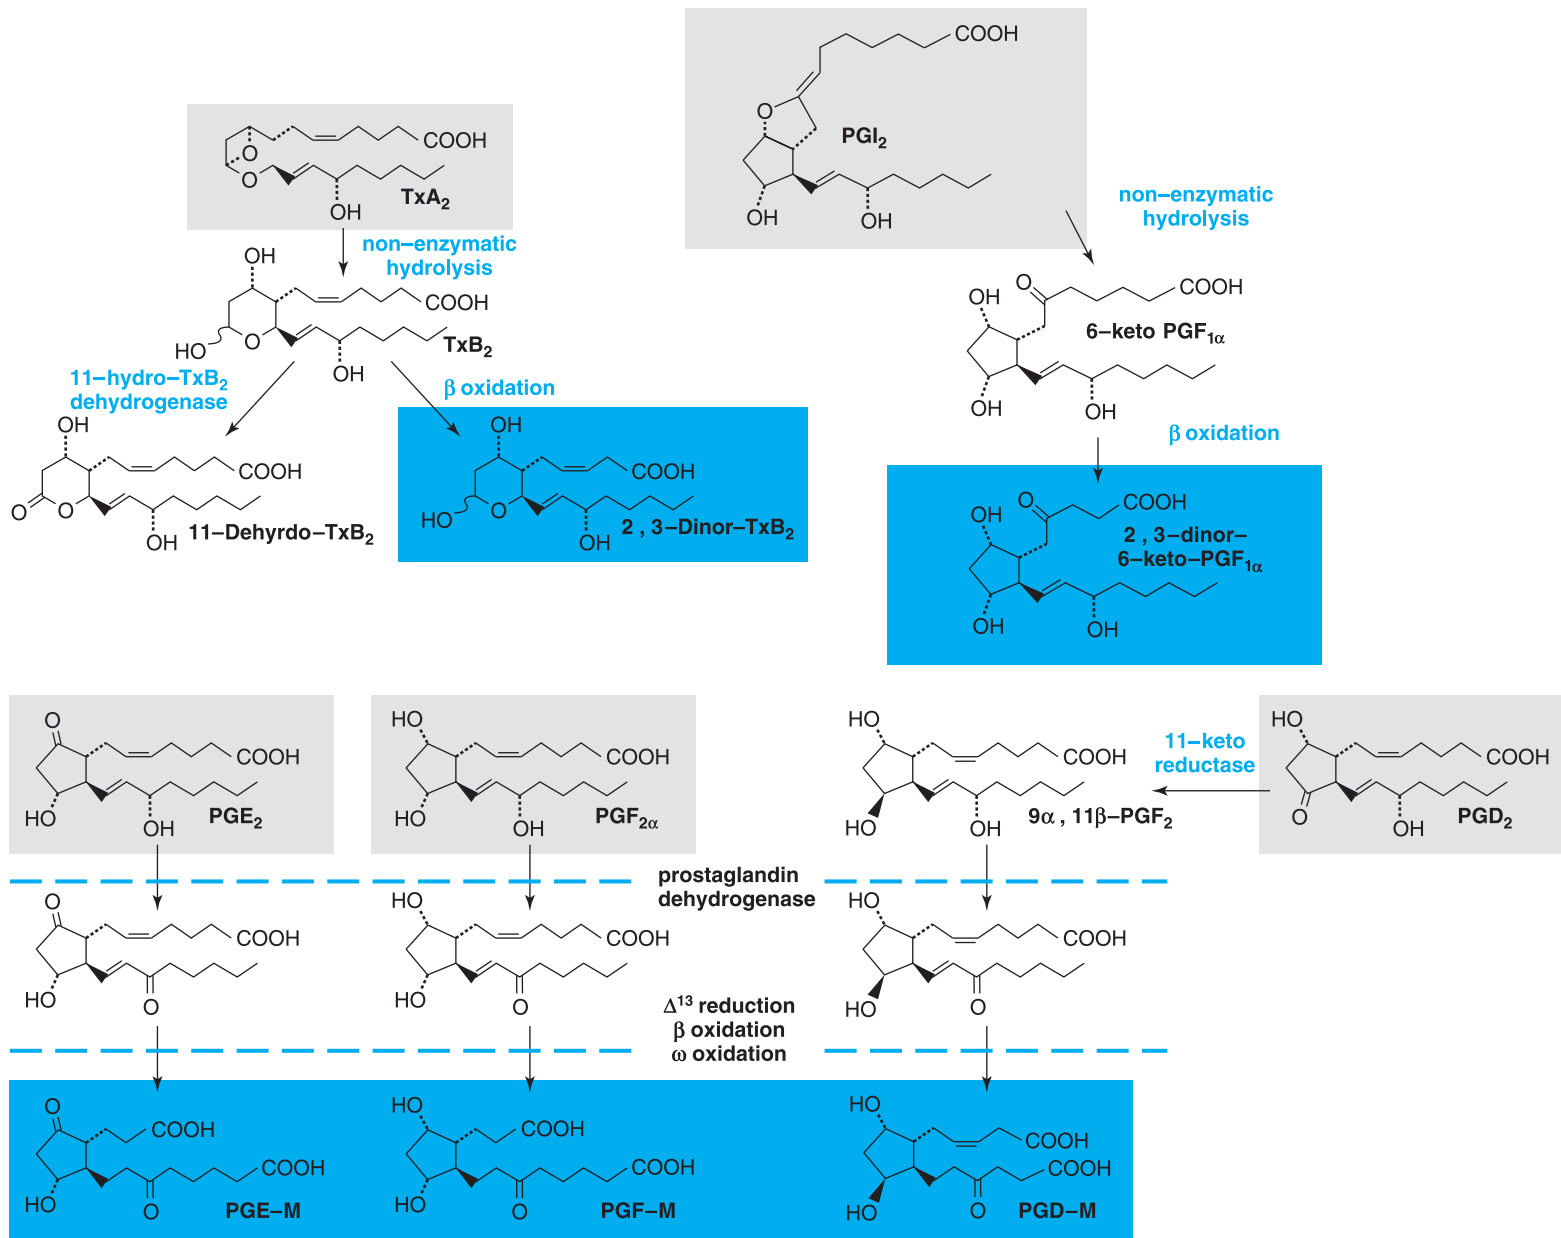

Figure 25-3. Major pathways of prostanoic acid degradation. Active metabolites are shaded in gray. Major urinary metabolites are shaded in blue. The blue dashed lines indicate reactions that use common enzymatic processes. M, metabolite. See text for other abbreviations.

strictor effects have been reported, depending on which PGE₂ receptor is activated (*see* below). Infusion of PGD₂ in humans results in flushing, nasal stuffiness, and hypotension; subsequent formation of F-ring metabolites may result in hypertension. Responses to PGF_{2α} vary with species and vascular bed; it is a potent constrictor of both pulmonary arteries and veins in humans. Blood pressure is increased by PGF_{2α} in some experimental animals owing to venoconstriction; however, in humans, PGF_{2α} does not alter blood pressure.

PGI₂ relaxes vascular smooth muscle, causing prominent hypotension and reflex tachycardia on intravenous administration. It is about five times more potent than PGE₂ in producing this effect. TxA₂ is a potent vasoconstrictor. It contracts vascular smooth muscle *in vitro* and is a vasoconstrictor in the whole animal and in isolated vascular beds.

Cardiac output generally is increased by prostaglandins of the E and F series. Weak, direct inotropic effects have been noted in various isolated preparations. In the intact animal, however, increased force of contraction and increased heart rate are in large measure a reflex consequence of a fall in total peripheral resistance.

LTC₄ and LTD₄ cause hypotension in humans (Brink *et al.*, 2003). This may result partly from a decrease in intravascular volume and also from decreased cardiac contractility secondary to a marked LT-induced reduction in coronary blood flow. Although LTC₄ and LTD₄ have little effect on most large arteries or veins, coronary arteries and distal segments of the pulmonary artery are contracted by nanomolar concentrations of these agents. The renal vasculature is resistant to this constrictor action, but the mesenteric vasculature is not.

The CysLTs have prominent effects on the microvasculature. LTC₄ and LTD₄ appear to act on the endothelial lining of postcapillary venules to cause exudation of plasma; they are more than a thousandfold more potent than histamine in this regard. At higher concentrations, LTC₄ and LTD₄ constrict arterioles and reduce exudation of plasma.

Isoprostanes usually are vasoconstrictors, although there are examples of vasodilation in precontracted vessels.

Platelets. Low concentrations of PGE₂ enhance and higher concentrations inhibit platelet aggregation (Fabre *et al.*, 2001). Both PGI₂ and PGD₂ inhibit the aggregation of human platelets *in vitro*.

TxA₂, the major product of COX-1 in platelets, induces platelet aggregation. Perhaps more importantly, TxA₂ acts as an amplification signal for other, more potent platelet agonists such as thrombin and adenosine diphosphate (ADP) (FitzGerald, 1991). The actions of TxA₂ on platelets are restrained by PGI₂, which inhibits platelet aggregation by all recognized agonists. The biological

importance of 12-HETE formation is poorly understood, although deletion of the platelet 12-LOX augments ADP-induced platelet aggregation and AA-induced sudden death in mice. Some isoprostanes increase the response of platelets to pro-aggregatory agonists *in vitro*.

Inflammation and Immunity. Eicosanoids play a major role in the inflammatory and immune responses, as reflected by the clinical usefulness of the NSAIDs. While LTs generally are proinflammatory and lipoxins anti-inflammatory, prostanoids can exert both kinds of activity.

LTB₄ is a potent chemotactic agent for polymorphonuclear leukocytes, eosinophils, and monocytes (Martel-Pelletier *et al.*, 2003). In higher concentrations, LTB₄ stimulates the aggregation of polymorphonuclear leukocytes and promotes degranulation and the generation of superoxide. LTB₄ promotes adhesion of neutrophils to vascular endothelial cells and their transendothelial migration and stimulates synthesis of proinflammatory cytokines from macrophages and lymphocytes. Prostaglandins generally inhibit lymphocyte function and proliferation, suppressing the immune response (Rocca and FitzGerald, 2002). PGE₂ depresses the humoral antibody response by inhibiting the differentiation of B-lymphocytes into antibody-secreting plasma cells. PGE₂ acts on T-lymphocytes to inhibit mitogen-stimulated proliferation and lymphokine release by sensitized cells. PGE₂ and TxA₂ also may play a role in T-lymphocyte development by regulating apoptosis of immature thymocytes (Tilley *et al.*, 2001). PGD₂, a major product of mast cells, is a potent chemoattractant for eosinophils and induces chemotaxis and migration of Th2 lymphocytes (Smyth and FitzGerald, 2003). The degradation product, 15d-PGJ₂, also may activate eosinophils *via* the DP2 (CRTH2) receptor (Monneret *et al.*, 2002).

Lipoxins have diverse effects on leukocytes, including activation of monocytes and macrophages and inhibition of the activation of neutrophils, eosinophils, and lymphocytes (McMahon and Godson, 2004).

Smooth Muscle. Prostaglandins contract or relax many smooth muscles besides those of the vasculature. The LTs contract most smooth muscles.

Bronchial and Tracheal Muscle. In general, PGF_{2α} and PGD₂ contract and PGE₂ and PGI₂ relax bronchial and tracheal muscle. Prostaglandin endoperoxides and TxA₂ constrict human bronchial smooth muscle. Although important in allergen-evoked bronchospasm in guinea pigs, these mediators, unlike PGD₂, do not appear relevant to this response in humans. Roughly 10% of people given aspirin or tNSAIDs develop bronchospasm (Szczechlik *et al.*, 2004). This appears attributable to a shift in AA metabolism to LT formation, as reflected by an increase in urinary LTE₄ in response to aspirin challenge in such individuals. This substrate diversion appears to involve COX-1; such patients do not

develop bronchospasm when treated with selective inhibitors of COX-2. LTC₄ and its metabolites LTD₄ and LTE₄ are bronchoconstrictors in many species, including humans (Brink *et al.*, 2003). These LTs act principally on smooth muscle in the airways and are a thousand times more potent than histamine both *in vitro* and *in vivo*. They also stimulate bronchial mucus secretion and cause mucosal edema.

PGI₂ causes bronchodilation in most species; human bronchial tissue is particularly sensitive, and PGI₂ antagonizes bronchoconstriction induced by other agents.

Uterus. Strips of nonpregnant human uterus are contracted by PGF_{2α} and TxA₂ but are relaxed by E prostaglandins. Sensitivity to the contractile response is most prominent before menstruation, whereas relaxation is greatest at midcycle. Uterine strips obtained at hysterectomy from pregnant women are contracted by PGF_{2α} and by low concentrations of PGE₂. PGE₂, together with oxytocin, is essential for the onset of parturition. PGI₂ and high concentrations of PGE₂ produce relaxation. The intravenous infusion of PGE₂ or PGF_{2α} to pregnant women produces a dose-dependent increase in uterine tone and in the frequency and intensity of rhythmic uterine contractions. Uterine responsiveness to prostaglandins increases as pregnancy progresses but remains smaller than the response to oxytocin.

Gastrointestinal Muscle. The E and F prostaglandins stimulate contraction of the main longitudinal muscle from stomach to colon. Prostaglandin endoperoxides, TxA₂, and PGI₂ also produce contraction but are less active. Circular muscle generally relaxes in response to PGE₂ and contracts in response to PGF_{2α}. The LTs have potent contractile effects. PGs reduce transit time in the small intestine and colon. Diarrhea, cramps, and reflux of bile have been noted in response to oral PGE₂; these are common side effects (along with nausea and vomiting) in patients given PGs for abortion. The E and F prostaglandins stimulate the movement of water and electrolytes into the intestinal lumen. Such effects may underlie the watery diarrhea that follows their oral or parenteral administration. By contrast, PGI₂ does not induce diarrhea; indeed, it prevents that provoked by other PGs.

PGE₂ appears to contribute to the water and electrolyte loss in cholera, a disease that is somewhat responsive to therapy with tNSAIDs.

Gastric and Intestinal Secretions. In the stomach, PGE₂ and PGI₂ contribute to increased mucus secretion (*cytoprotection*), reduced acid secretion, and reduced pepsin content. These effects result from their vasodilatory properties and probable direct effects on secretory cells. PGE₂ and its analogs also inhibit gastric damage caused by a variety of ulcerogenic agents and promote healing of duodenal and gastric ulcers (*see* Chapter 36). While COX-1 may be the dominant source of such cytoprotective PGs under physiological conditions, COX-2 predominates during ulcer healing. Selective inhibitors of COX-2 and deletion of the enzyme delay ulcer healing in rodents, but the impact of such drugs in humans is unclear. CysLTs, by constricting gastric blood vessels and enhancing production of proinflammatory cytokines, may contribute to the gastric damage.

Kidney and Urine Formation. PGs influence renal salt and water excretion by alterations in renal blood flow and by direct effects on renal tubules (Cheng and Harris, 2004). PGE₂ and PGI₂ infused directly into the renal arteries of dogs increase renal blood flow and provoke diuresis, natriuresis, and kaliuresis, with little change in glomerular filtration rate. TxA₂ decreases renal blood flow, decreases the rate of glomerular filtration, and participates in tubuloglo-

merular feedback. PGEs inhibit water reabsorption induced by antidiuretic hormone (ADH). PGE₂ also inhibits chloride reabsorption in the thick ascending limb of the loop of Henle in the rabbit. PGI₂, PGE₂, and PGD₂ stimulate renin secretion from the renal cortex apparently through a direct effect on the granular juxtaglomerular cells.

Eye. Although PGF_{2α} induces constriction of the iris sphincter muscle, its overall effect in the eye is to decrease intraocular pressure (IOP) by increasing the aqueous humor outflow of the eye *via* the uveoscleral and trabecular meshwork pathway. A variety of F prostaglandin-receptor agonists have proven effective in the treatment of open-angle glaucoma, a condition associated with the loss of COX-2 expression in the pigmented epithelium of the ciliary body (*see* Chapter 63).

Central Nervous System. While effects have been reported following injection of several PGs into discrete brain areas, the best established biologically active mediators are PGE₂ and PGD₂. The induction of fever by a range of endogenous and exogenous pyrogens appears to be mediated by PGE₂ (Smyth and FitzGerald, 2003). Exogenous PGF_{2α} and PGI₂ induce fever but do not contribute to the pyretic response. PGD₂ and TxA₂ do not induce fever. PGD₂ also appears to act on arachnoid trabecular cells in the basal forebrain to mediate an increase in extracellular adenosine that, in turn, facilitates induction of sleep.

PGs contribute to pain both peripherally and centrally. PLA₂ and COX-2 synthesis are increased at sites of local inflammation that are, in turn, associated with increased central PGE₂ biosynthesis (Samad *et al.*, 2002). PGE₂ and PGI₂ sensitize the peripheral nerve endings to painful stimuli by lowering the threshold of nociceptors. Centrally, PGE₂ can increase excitability in pain transmission neuronal pathways in the spinal cord. Hyperalgesia also is produced by LTB₄. The release of these eicosanoids during the inflammatory process thus serves as an amplification system for the pain mechanism (*see* below). The role of PGE₂ and PGI₂ in inflammation is discussed in Chapter 26. COX-2 has been implicated in several neurological diseases, and clinical trials of selective inhibitors of COX-2 are ongoing in the chemoprevention of Alzheimer's disease, Parkinson's disease, and epilepsy.

Endocrine System. A number of endocrine tissues respond to PGs. In a number of species, the systemic administration of PGE₂ increases circulating concentrations of adrenocorticotrophic hormone (ACTH), growth hormone, prolactin, and gonadotropins. Other effects include stimulation of steroid production by the adrenals, stimulation of insulin release, and

thyrotropin-like effects on the thyroid. The critical role of $\text{PGF}_{2\alpha}$ in parturition relies on its ability to induce an oxytocin-dependent decline in progesterone levels. PGE_2 works as part of a positive-feedback loop to induce oocyte maturation required for fertilization during and after ovulation.

LOX metabolites also have endocrine effects. 12-HETE stimulates the release of aldosterone from the adrenal cortex and mediates a portion of the aldosterone release stimulated by angiotensin II, but not that which occurs in response to ACTH.

Bone. PGs are strong modulators of bone metabolism. PGE_2 stimulates bone formation and resorption through osteoblastic and osteoclastic activities affecting bone strength and composition (Narumiya *et al.*, 1999; Smyth and FitzGerald, 2003).

Mechanism of Action of Eicosanoids. Many of the responses just described can be understood in light of the distribution of eicosanoid receptors and their coupling to second-messenger systems that modulate cellular activity.

Prostaglandin Receptors. PGs activate membrane receptors locally near their sites of formation. The diversity of their effects is explained to a large extent by their interaction with a diverse family of distinct receptors (Table 25–1). All eicosanoid receptors are G protein-coupled receptors that interact with G_s , G_i , and G_q to modulate the activities of adenylyl cyclase and phospholipase C (*see* Chapter 1). Single gene products have been identified for the receptors for prostacyclin (the IP receptor), $\text{PGF}_{2\alpha}$ (the FP receptor), and TxA_2 (the TP receptor). Four distinct

Table 25–1
Eicosanoid Receptors

RECEPTOR	PRIMARY LIGAND	SECONDARY LIGAND	PRIMARY COUPLING	MAJOR PHENOTYPE IN KNOCKOUT MICE
DP_1	PGD_2		\uparrow cAMP (G_s)	\downarrow Allergic asthma
$\text{DP}_2/\text{CHRT}_2$	PGD_2	15d-PGJ ₂ ?	\uparrow Ca^{2+}_i (G_i)	?
EP_1	PGE_2		G_q	Decreased response of colon to carcinogens
EP_2	PGE_2		\uparrow cAMP	Impaired ovulation and fertilization; salt sensitive hypertension
EP_{3A-D}	PGE_2		\downarrow cAMP (G_i) \uparrow cAMP (G_s) \uparrow PLC (G_q)	Resistance to pyrogens
EP_4	PGE_2		\uparrow cAMP (G_s)	Patent ductus arteriosus
$\text{FP}_{A,B}$	$\text{PGF}_{2\alpha}$	IsoP?	G_q	Failure of parturition
IP	PGI_2	PGE_2	\uparrow cAMP (G_s)	\uparrow Thrombotic response, \downarrow response to vascular injury
$\text{TP}_{\alpha,\beta}$	TxA_2	IsoPs	\uparrow PLC (G_q , G_i , $G_{12/13}$, G_{16})	\uparrow Bleeding time, \uparrow response to vascular injury
BLT_1	LTB_4		G_{16} , G_i	Some suppression of inflammatory response
BLT_2	LTB_4	12(S)-HETE 12(R)-HETE	G_q -like, G_i -like, G_z -like	?
CysLT_1	LTD_4	$\text{LTC}_4/\text{LTE}_4$	\uparrow PLC (G_q)	\downarrow Innate and adaptive immune vascular permeability response, \uparrow pulmonary inflammatory and fibrotic response
CysLT_2	$\text{LTC}_4/\text{LTD}_4$	LTE_4	\uparrow PLC (G_q)	\downarrow Pulmonary inflammatory and fibrotic response

This table lists the major classes of eicosanoid receptors and their signaling characteristics. Splice variants are indicated where appropriate. Major phenotypes in knockout mouse models are listed. ABBREVIATIONS: Ca^{2+}_i , cytosolic Ca^{2+} ; cAMP, cyclic AMP; PLC, phospholipase C (activation leads to increased cellular inositol phosphate and diacyl glycerol generation and increased Ca^{2+}_i); IsoPs, isoprostanes; DP_2 is a member of the fMLP receptor superfamily; fMLP, formyl-methionyl-leucyl-phenylalanine. *See* text for other abbreviations.

PGE₂ receptors (EP 1–4) and two PGD₂ receptors (DP₁ and DP₂) have been cloned. Additional isoforms of the TP (α and β), FP (A and B), and EP₃ (A–D) receptors can arise through differential mRNA splicing (Narumiya *et al.*, 1999; Smyth and FitzGerald, 2003).

Cell Signaling Pathways and Expression. The prostanoid receptors appear to derive from an ancestral EP receptor and share high homology. Phylogenetic comparison of this family reveals three subclusters: The first consists of the relaxant receptors EP₂, EP₄, IP, and DP₁, which increase cellular cyclic AMP generation; the second consists of the contractile receptors EP₁, FP, and TP, which increase cytosolic levels of Ca²⁺; and a third, presently consisting only of EP₃, can couple to both elevation of intracellular calcium and a decrease in cyclic AMP. The DP₂ receptor is an exception and is unrelated to the other prostanoid receptors; rather, it is a member of the fMLP receptor superfamily (Table 25–1).

TP α and TP β receptor isoforms couple *via* G_q and several other G proteins to activate the PLC–IP₃–Ca²⁺ pathway. Activation of TP receptors also may activate or inhibit adenylyl cyclase *via* G_s (TP α) or G_i (TP β), respectively, and signal *via* G_q and related proteins to MAP kinase signaling pathways. TP is expressed in platelets, vasculature, lung, kidney, heart, thymus, and spleen.

The IP receptor couples with G_s to stimulate adenylyl cyclase activity. It is expressed in many tissues and cells, including human kidney, lung, spine, liver, vasculature, and heart.

The DP₁ receptor also couples with adenylyl cyclase through G_s. It is the least abundant of the prostanoid receptors, with low levels of mRNA reported in mouse ileum, lung, stomach, and uterus. The DP₁ receptor is also expressed in the central nervous system (CNS), where it appears to be limited specifically to the leptomeninges. The DP₂ receptor couples with the G_q–PLC–IP₃ pathway to increase intracellular Ca²⁺. It is found on T cells and eosinophils and at the fetal–maternal interface in human decidua.

The EP₂ and EP₄ receptors activate adenylyl cyclase *via* G_s. The EP₂ receptor is expressed at much lower levels in most tissues and can be induced in response to inflammatory stimuli, suggesting distinct roles for these two G_s-coupled EP receptors. The EP₁ receptor, *via* an unclassified G protein, and the EP_{3D} receptor, *via* G_q, activate the PLC–IP₃–Ca²⁺ pathway. EP_{3B}/EP_{3C} receptors couple with G_s-mediated activation of adenylyl cyclase; the EP_{3D}/EP_{3A} isoforms inhibit adenylyl cyclase *via* G_i. EP₁ and EP₂ receptors have limited distribution compared with the distribution of EP₃ and EP₄ receptors.

The FP_A and FP_B receptors couple *via* G_q–PLC–IP₃ to mobilize cellular Ca²⁺ and activate protein kinase C (PKC). In addition, stimulation of FP activates Rho kinase, leading to the formation of actin stress fibers, phosphorylation of p125 focal adhesion kinase, and cell rounding. The FP receptor is expressed in kidney, heart, lung, stomach, and eye; it is most abundant in the corpus luteum, where its expression pattern varies during the estrus cycle.

Leukotriene and Lipoxin Receptors. Several receptors for the LTs and lipoxins have been identified (Brink *et al.*, 2003) (Table 25–1). Two receptors exist for both LTB₄ (BLT₁ and BLT₂) and the cysteinyl leukotrienes (CysLT₁ and CysLT₂). A single lipoxin receptor, ALX, is identical to the formyl peptide-1 (fMLP-1) receptor; the nomenclature now reflects LXA₄ as its natural and most potent ligand. A putative LXB₄ receptor has not yet been cloned. Receptors for the HETEs have been proposed but not yet isolated.

Cell Signaling Pathways and Expression. Phylogenetic comparison reveals two clusters of leukotriene/lipoxin receptors: the

chemoattractant receptors (BLT₁, BLT₂, and ALX), which also contain the DP₂ receptor for PGD₂, and the cysteinyl leukotriene receptors (CysLT₁ and CysLT₂). All are GPCRs and couple with G_q and other G proteins (Table 25–1), depending on the cellular context. The BLT₁ receptor is expressed predominantly in leukocytes, thymus, and spleen, whereas BLT₂, the low-affinity receptor for LTB₄, is found in spleen, leukocytes, ovary, liver, and intestine. BLT₂ binds 12(*S*)- and 12(*R*)-HETE with reasonable affinity, although the biological relevance of this observation is not clear.

CysLT₁ receptors have been studied in greater detail than CysLT₂ receptors and mostly with LTD₄ as an agonist. Activation of G_q, leading to increased intracellular Ca²⁺, is the primary signaling pathway reported. CysLT₁ is expressed in lung and intestinal smooth muscle, spleen, and peripheral blood leukocytes, whereas CysLT₂ is found in heart, spleen, peripheral blood leukocytes, adrenal medulla, and brain.

Responses to ALX receptor activation vary with cell type. In human neutrophils, AA release is stimulated, whereas Ca²⁺ mobilization is blocked; in monocytes, LXA₄ stimulates Ca²⁺ mobilization. The ALX receptor is expressed in lung, peripheral blood leukocytes, and spleen.

Other Agents. Other AA metabolites (*e.g.*, isoprostanes, epoxy-eicosatrienoic acids, and hepxilins) have potent biological activities, and there is evidence for distinct receptors for some of these substances. The isoprostanes appear to act as incidental ligands at the TP receptor (Audoly *et al.*, 2000), which may be important in the pathology of cardiovascular disease. Certain eicosanoids, most notably 15-deoxy- $\Delta^{12,14}$ -PGJ₂ (15d-PGJ₂), a dehydration product of PGD₂, have been reported as endogenous ligands for a family of nuclear receptors called *peroxisome proliferator-activated receptors* (PPARs) that regulate lipid metabolism and cellular proliferation and differentiation. However, their affinities for PPARs are significantly lower than for cell surface receptors, raising doubt about the physiological relevance of the ligand–receptor interaction. 15d-PGJ₂ can bind PPAR γ *in vitro*, but the quantities formed *in vivo* are orders of magnitude lower than those necessary for PPAR activation (Bell-Parikh *et al.*, 2003).

Endogenous Prostaglandins, Thromboxanes, and Leukotrienes: Functions in Physiological and Pathological Processes

The widespread biosynthesis and myriad of pharmacological actions of eicosanoids are reflected in their complex physiology and pathophysiology. The development of mice with targeted disruptions of genes regulating eicosanoid biosynthesis and eicosanoid receptors has revealed unexpected roles for these autacoids and has clarified hypotheses about their function (Austin and Funk, 1999; Narumiya and FitzGerald, 2001; Smyth and FitzGerald, 2003).

Platelets. Platelet aggregation leads to activation of membrane phospholipases, with the release of AA and consequent eicosanoid biosynthesis. In human platelets, TxA₂ and 12-HETE are the two major eicosanoids formed, although eicosanoids from other sources (*e.g.*, PGI₂ derived from vascular endothelium) also affect platelet function. A naturally occurring mutation in the first intracellular loop of the TP receptor is associated with a mild bleeding diathesis

and resistance of platelet aggregability to TP agonists (Hirata *et al.*, 1994). The importance of the TxA_2 pathway is evident from the efficacy of low-dose aspirin in the secondary prevention of myocardial infarction and ischemic stroke. In addition, platelet thromboxane formation is augmented markedly in acute coronary artery syndromes (Fitzgerald *et al.*, 1986). Deletion of the TP receptor in the mouse prolongs bleeding time, renders platelets unresponsive to TP agonists, modifies their response to collagen but not to ADP, and blunts the response to vasopressors and the proliferative response to vascular injury.

PGI_2 inhibits platelet aggregation and disaggregates preformed clumps. Deficiency of the IP receptor in mice does not alter platelet aggregation significantly *ex vivo* (Yang *et al.*, 2002). However, PGI_2 does limit platelet activation by TxA_2 *in vivo*, reducing the thrombotic response to vascular injury (Cheng *et al.*, 2002). Deletion of the IP receptor augments the response to ischemia-reperfusion injury. High concentrations of PGE_2 , released in response to major inflammatory mediators, also activate the IP receptor, inhibiting platelet aggregation. Low concentrations of PGE_2 activate the EP_3 receptor, leading to platelet aggregation (Fabre *et al.*, 2001).

Reproduction and Parturition. Studies with knockout mice confirm a role for PGs in reproduction and parturition (Austin and Funk, 1999; Narumiya and FitzGerald, 2001; Smyth and FitzGerald, 2003). COX-1-derived $\text{PGF}_{2\alpha}$ appears important for luteolysis, consistent with delayed parturition in mice deficient in COX-1. Subsequent up-regulation of COX-2 generates prostanoids, including $\text{PGF}_{2\alpha}$ and TxA_2 , that are important in the final stages of parturition. Mice lacking both COX-1 and oxytocin undergo normal parturition, demonstrating the critical interplay between $\text{PGF}_{2\alpha}$ and oxytocin in onset of labor. EP_2 -receptor-deficient mice demonstrate a preimplantation defect, which likely underlies some of the breeding difficulties seen in COX-2 knockouts.

Vasculature. Locally generated PGE_2 and PGI_2 modulate vascular tone. PGI_2 , the major arachidonate metabolite released from the vascular endothelium, is derived primarily from COX-2 in humans (Catella-Lawson *et al.*, 1999; McAdam *et al.*, 1999) and is regulated by shear stress and by both vasoconstrictor and vasodilator autacoids. Knockout studies argue against a role for PGI_2 in the homeostatic maintenance of vascular tone; PGI synthase polymorphisms have been associated with essential hypertension and myocardial infarction (Smyth and FitzGerald, 2003). PGI_2 limits pulmonary hypertension induced by hypoxia and systemic hypertension induced by angiotensin II. Deficiency of EP_1 or EP_4 receptors reduces resting blood pressure in male mice; EP_1 -receptor deficiency is associated with elevated renin-angiotensin activity. Both EP_2 - and EP_4 -receptor-deficient animals develop hypertension in response to a high-salt diet, reflecting the importance of PGE_2 in maintenance of renal blood flow and salt excretion (*see below*). PGI_2 and PGE_2 are implicated in the hypotension associated with septic shock. PGs also may play a role in the maintenance of placental blood flow.

COX-2-derived PGE_2 , via the EP_4 receptor, maintains the ductus arteriosus patent until birth, when reduced PGE_2 levels (a consequence of increased PGE_2 metabolism) permit closure of the ductus arteriosus (Coggins *et al.*, 2002). The tNSAIDs induce closure of a patent ductus in neonates (*see Chapter 26*). Contrary to expectation, animals lacking the EP_4 receptor die with a patent ductus during the perinatal period (Table 25-1) because the mechanism for control of the ductus *in utero*, and its remodeling at birth, is absent. PGI_2 specifically limits TxA_2 -induced smooth muscle proliferation in vascu-

lar injury, suggesting a role for these prostanoids in vascular remodeling (Cheng *et al.*, 2002).

Lung. A complex mixture of autacoids is released when sensitized lung tissue is challenged by the appropriate antigen. COX-derived bronchodilator (PGE_2) and bronchoconstrictor (*e.g.*, $\text{PGF}_{2\alpha}$, TxA_2 , and PGD_2) substances are released. Polymorphisms in the genes for PGD_2 synthase and the TP receptor have been associated with asthma in humans, and deletion of DP_1 receptor in mice sharply reduces allergen-induced infiltration of lymphocytes and eosinophils and airway hyper-reactivity (Smyth and FitzGerald, 2003).

The CysLTs probably dominate during allergic constriction of the airway (Drazen, 1999). Deficiency of 5-LOX leads to reduced influx of eosinophils in airways and attenuates bronchoconstriction. Furthermore, unlike COX inhibitors and histaminergic antagonists, CysLT receptor antagonists and 5-LOX inhibitors are effective in the treatment of human asthma (*see above*). The relatively slow LT metabolism in lung contributes to the long-lasting bronchoconstriction that follows challenge with antigen and may be a factor in the high bronchial tone that is observed in asthmatics in periods between acute attacks (*see Chapter 27*).

Kidney. Long-term use of all COX inhibitors is limited by the development of hypertension, edema, and congestive heart failure in a significant number of patients. PGE_2 , along with PGI_2 , apparently derived from COX-2, plays a critical role in maintaining renal blood flow and salt excretion, whereas there is some evidence that the COX-1-derived vasoconstrictor TxA_2 may play a counterbalancing role. Biosynthesis of PGE_2 and PGI_2 is increased by factors that reduce renal blood flow (*e.g.*, stimulation of sympathetic nerves; angiotensin II).

Barter's syndrome is an autosomal recessive trait that is manifested as hypokalemic metabolic alkalosis. The syndrome results from inappropriate renal salt absorption caused primarily by dysfunctional mutations in the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ cotransporter NKCC2, a target of loop diuretics in the ascending thick limb of the loop of Henle (Simon *et al.*, 1996) (*see Chapter 28*). The syndrome also can result from dysfunctional alterations in proteins whose activities can limit NKCC2 function: the K^+ channel ROMK2 (Kir1.1) that recycles K^+ into the tubular fluid; the basolateral membrane Cl^- channel, ClC-Kb ; and Barttin, the integral membrane protein that forms the β -subunit of the ClC-Kb heteromer (O'Shaughnessy and Karet, 2004). The antenatal variant of Barter's syndrome, owing to dysfunctional ROMK2, also is known as *hyperprostaglandin E syndrome*. The elevated PGE_2 may exacerbate the symptoms of salt and water loss. The relationship between dysfunctional ROMK2 and elevated PGE_2 synthesis is not clear. However, in patients with antenatal Barter's syndrome, inhibition of COX-2 ameliorates many of the clinical symptoms (Nusing *et al.*, 2001).

Inflammatory and Immune Responses. PGs and LTs are synthesized in response to a host of stimuli that elicit inflammatory and immune responses, and eicosanoids contribute importantly to inflammation and immunity (Tilley *et al.*, 2001; Brink *et al.*, 2003). Prostanoid biosynthesis is increased significantly in inflamed tissue. Recruitment of leukocytes and the induction of COX-2 expression by inflammatory stimuli provided a rational basis for the development of COX-2-specific inhibitors for treatment of chronic inflammatory diseases (*see Chapter 26*). However, COX-1 also has a role in inflammation: It appears that COX-1 is responsible for acute and COX-2 for sustained prostanoid production following an inflammatory stimulus.

Prostanoids generally promote acute inflammation, although there are some exceptions, such as the inhibitory actions of PGE₂ on mast cell activation (Tilley *et al.*, 2001). Furthermore, deletion of COX-2 and, to a lesser extent, deletion of COX-1 are associated with greater severity of inflammatory colitis, consistent with the exacerbation of inflammatory bowel disease seen in patients receiving tNSAIDs. Both PGE₂ and PGI₂ markedly enhance edema formation and leukocyte infiltration by promoting blood flow in the inflamed region. Both have been associated with inflammatory pain, and both potentiate the pain-producing activity of bradykinin and other autacoids.

LTs are potent mediators of inflammation. Deletion of 5-LOX or FLAP reduces inflammatory responses (Austin and Funk, 1999). Generation of BLT₁-deficient mice confirms the role of LTB₄ in chemotaxis, adhesion, and recruitment of leukocytes to inflamed tissues (Toda *et al.*, 2002). Increased vascular permeability resulting from innate and adaptive immune challenges is offset in mice deficient in CysLT₁ or LTC₄ synthase (*see* Kanaoka and Boyce, 2004) (Table 25-1). Deletion either of LTC₄ synthase (and thus loss of CysLT biosynthesis) or CysLT₂ reduced chronic pulmonary inflammation and fibrosis in response to bleomycin. In contrast, absence of CysLT₁ led to an exaggerated response. These findings demonstrate a role for CysLT₂ in promoting, and an unexpected role for CysLT₁ in counteracting, chronic inflammation.

Cancer. There has been significant interest in the role of PGs and COX-2 in the development of malignancies. Angiogenesis, which is required for multistage carcinogenesis, is promoted by COX-2-derived TxA₂, PGE₂, and PGI₂. The role of COX-2 in colon cancer and breast cancer is an area of particular current interest. Various PGs induce proliferation of colon cancer cells, and COX inhibitors reduce colon tumor formation in experimental animals. Indeed, in large epidemiological studies, the incidental use of tNSAIDs is associated with a 40% to 50% reduction in relative risk of developing colon cancer. Furthermore, in patients with familial polyposis coli, cyclooxygenase inhibitors significantly decrease polyp formation (Williams *et al.*, 1999). A polymorphism in COX-2 has been associated with increased risk of colon cancer (Cox *et al.*, 2004). Several studies suggest that COX-2 expression is associated with markers of tumor progression in breast cancer. In mouse mammary tissue, COX-2 is pro-oncogenic (Liu *et al.*, 2001), whereas aspirin use is associated with a reduced risk of breast cancer in women, especially for hormone-receptor-positive tumors (Terry *et al.*, 2004).

Therapeutic Uses

Inhibitors and Antagonists. As a consequence of the important and diverse physiological roles of eicosanoids, mimicking their effects with stable agonists, inhibiting eicosanoid formation, and antagonizing eicosanoid receptors produce noticeable and therapeutically useful responses. As outlined earlier and in Chapter 26, the tNSAIDs and their subclass of selective COX-2 inhibitors are used widely as antiinflammatory drugs, whereas low-dose aspirin is employed frequently for cardioprotection. LT antagonists are useful clinically in the treatment of asthma, and FP agonists are used in the treatment of open-angle glau-

coma. EP agonists are used to induce labor and to ameliorate gastric irritation owing to tNSAIDs.

There are as yet no potent selective antagonists of prostanoid receptors in clinical use. TP antagonists are under evaluation in cardiovascular disease, whereas EP agonists and antagonists are under evaluation in the treatment of bone fracture and osteoporosis. Orally active antagonists of LTC₄ and D₄ have been approved for the treatment of asthma (*see* Chapter 27). These agents act by binding to the CysLT₁ receptor and include montelukast and zafirlukast. In patients with mild to moderately severe asthma, they cause bronchodilation, reduce the bronchoconstriction caused by exercise and exposure to antigen, and decrease the patient's requirement for the use of β₂ adrenergic agonists (Drazen, 1997). Their effectiveness in patients with aspirin-induced asthma also has been shown.

The use of eicosanoids or eicosanoid derivatives themselves as therapeutic agents is limited in part because systemic administration of prostanoids frequently is associated with significant adverse effects and because of their short half-lives in the circulation. Despite these limitations, however, several prostanoids are of clinical utility in the situations discussed below.

Therapeutic Abortion. There has been intense interest in the effects of the PGs on the female reproductive system. When given early in pregnancy, their action as *abortifacients* may be variable and often incomplete and accompanied by adverse effects. PGs appear, however, to be of value in missed abortion and molar gestation, and they have been used widely for the induction of midtrimester abortion. Several studies have shown that systemic or intravaginal administration of the PGE₁ analog *misoprostol* in combination with *mifepristone* (RU486) or *methotrexate* (Christin-Maitre *et al.*, 2000) is highly effective in the termination of early pregnancy.

PGE₂ or PGF_{2α} can induce labor at term. However, they may have more value when used to facilitate labor by promoting ripening and dilation of the cervix.

Gastric Cytoprotection. The capacity of several PG analogs to suppress gastric ulceration is a property of therapeutic importance. Of these, misoprostol (CYTOTEK), a PGE₁ analog, is approved by the Food and Drug Administration (FDA). Misoprostol appears to heal gastric ulcers about as effectively as the H₂-receptor antagonists (*see* Chapter 36); however, relief of ulcerogenic pain and healing of duodenal ulcers have not been achieved consistently with misoprostol. This drug currently is used primarily for the prevention of ulcers that often occur during long-term treatment with NSAIDs. In this setting, misoprostol appears to be as effective as the proton pump inhibitor *omeprazole*.

Impotence. PGE₁ (*alprostadil*) may be used in the treatment of impotence. Intracavernous injection of PGE₁ causes complete or partial erection in impotent patients who do not have disorders of the vascular system or cavernous body damage. The erection lasts for 1 to 3 hours and is sufficient for sexual intercourse. PGE₁ is more effective than papaverine. The agent is available as a sterile powder that is reconstituted with water for injections (CAVERJECT),

although it has been superseded largely by the use of PDE5 inhibitors, such as *sildenafil*, *tadalafil*, and *vardenafil* (see Chapter 31).

Maintenance of Patent Ductus Arteriosus. The ductus arteriosus in neonates is highly sensitive to vasodilation by PGE₁. Maintenance of a patent ductus may be important hemodynamically in some neonates with congenital heart disease. PGE₁ (alprostadil, PROSTIN VR PEDIATRIC) is highly effective for palliative, but not definitive, therapy to maintain temporary patency until surgery can be performed. Apnea is observed in about 10% of neonates so treated, particularly those who weigh less than 2 kg at birth.

Pulmonary Hypertension. Primary pulmonary hypertension is a rare idiopathic disease that mainly affects young adults. It leads to right-sided heart failure and frequently is fatal. Long-term therapy with PGI₂ (*epoprostenol*, FLOLAN) has either delayed or precluded the need for lung or heart–lung transplantation in a number of patients. In addition, many affected individuals have had a marked improvement in symptoms after receiving treatment with PGI₂ (McLaughlin *et al.*, 1998). Epoprostenol also has been used successfully to treat portopulmonary hypertension that arises secondary to liver disease, again with a goal to facilitating ultimate transplantation (Krowka *et al.*, 1999).

PLATELET-ACTIVATING FACTOR

History. In 1971, Henson demonstrated that a soluble factor released from leukocytes caused platelets to aggregate. Benveniste and his coworkers characterized the factor as a polar lipid and named it *platelet-activating factor*. During this period, Muirhead described an antihypertensive polar renal lipid (APRL) produced by interstitial cells of the renal medulla that proved to be identical to PAF. Hanahan and coworkers then synthesized acetylglyceryletherphosphorylcholine (AGEPC) and determined that this phospholipid had chemical and biological properties identical with those of PAF. Independent determination of the structures of PAF and APRL showed them to be structurally identical to AGEPC. The commonly accepted name for this substance is platelet-activating factor (PAF); however, its actions extend far beyond platelets.

Chemistry and Biosynthesis. PAF is 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine. Its structure is

PAF contains a long-chain alkyl group joined to the glycerol backbone in an ether linkage at position 1 and an acetyl group at position 2. PAF actually represents a family of phospholipids because the alkyl group at position 1 can vary in length from 12 to 18 carbon atoms. In human neutrophils, PAF consists predominantly of a mixture of the 16- and 18-carbon ethers, but its composition may change when cells are stimulated.

Like the eicosanoids, PAF is not stored in cells but is synthesized in response to stimulation. The major pathway by which PAF is generated involves the precursor 1-*O*-alkyl-2-acyl-glycerophosphocholine, a lipid found in high concentrations in the membranes of many

Figure 25–4. Synthesis and degradation of platelet-activating factor. RCOO⁻ is a mixture of fatty acids but is enriched in arachidonic acid that may be metabolized to eicosanoids. CoA, coenzyme A.

types of cells. The 2-acyl substituents include AA. PAF is synthesized from this substrate in two steps (Figure 25–4). The first involves the action of phospholipase A₂, the initiating enzyme for eicosanoid biosynthesis, with the formation of 1-*O*-alkyl-2-lyso-glycerophosphocholine (lyso-PAF) and a free fatty acid (usually AA) (Prescott *et al.*, 2000). Eicosanoid and PAF biosynthesis thus is closely coupled, and deletion of cPLA₂ in mice leads to an almost complete loss of both prostanoid and PAF generation. The second, rate-limiting step is performed by the acetylcoenzyme-A-lyso-PAF acetyltransferase. PAF synthesis also can occur *de novo*; a phosphocholine substituent is transferred to alkyl acetyl glycerol by a distinct lysoglycerophosphate acetylcoenzyme-A transferase. This pathway may contribute to physiological levels of PAF for normal cellular functions. The synthesis of PAF may be stimulated during antigen–antibody reactions or by a variety of agents, including chemotactic peptides, thrombin, collagen, and other autacoids; PAF also can stimulate its own formation. Both the phospholipase and acetyltransferase are Ca²⁺-dependent enzymes; thus, PAF synthesis is regulated by the availability of Ca²⁺.

The inactivation of PAF also occurs in two steps (Stafforini *et al.*, 1997) (Figure 25–4). Initially, the acetyl group of PAF is removed by PAF acetylhydrolase to form lyso-PAF; this enzyme, a group VI phospholipase A₂, exists as secreted and intracellular isoforms and has marked specificity for phospholipids with short acyl chains at the *sn*-2 position. Lyso-PAF is then converted to a 1-*O*-alkyl-2-acyl-glycerophosphocholine by an acyltransferase.

PAF is synthesized by platelets, neutrophils, monocytes, mast cells, eosinophils, renal mesangial cells, renal medullary cells, and vascular endothelial cells. PAF is released from monocytes

but retained by leukocytes and endothelial cells. In endothelial cells, it is displayed on the surface for juxtacrine signaling (Prescott *et al.*, 2000).

In addition to these enzymatic routes, PAF-like molecules can be formed from the oxidative fragmentation of membrane phospholipids (oxPLs) (Prescott *et al.*, 2002). These compounds are increased in settings of oxidant stress such as cigarette smoking and differ structurally from PAF in that they contain a fatty acid at the *sn*-1 position of glycerol joined through an ester bond and various short-chain acyl groups at the *sn*-2 position. OxPLs mimic the structure of PAF closely enough to bind to its receptor (*see below*) and elicit the same responses. Unlike the synthesis of PAF, which is highly controlled, oxPL production is unregulated; degradation by PAF acetylhydrolase, therefore, is necessary to suppress the toxicity of oxPLs. Levels of PAF acetylhydrolase (also known as *lipoprotein-associated phospholipase A₂*) are increased in colon cancer, cardiovascular disease, and stroke (Prescott *et al.*, 2002), and polymorphisms have been associated with altered risk of cardiovascular events (Ninio *et al.*, 2004). A common missense mutation in Japanese people is associated disproportionately with more severe asthma (Stafforini *et al.*, 1999).

Pharmacological Properties. Cardiovascular System. PAF is a potent dilator in most vascular beds; when administered intravenously, it causes hypotension in all species studied. PAF-induced vasodilation is independent of effects on sympathetic innervation, the renin-angiotensin system, or arachidonate metabolism and likely results from a combination of direct and indirect actions. PAF induces vasoconstriction or vasodilation depending on the concentration, vascular bed, and involvement of platelets or leukocytes. For example, the intracoronary administration of very low concentrations of PAF increases coronary blood flow by a mechanism that involves the release of a platelet-derived vasodilator. Coronary blood flow is decreased at higher doses by the formation of intravascular aggregates of platelets and/or the formation of TxA₂. The pulmonary vasculature also is constricted by PAF, and a similar mechanism is thought to be involved.

Intradermal injection of PAF causes an initial vasoconstriction followed by a typical wheal and flare. PAF increases vascular permeability and edema in the same manner as histamine and bradykinin. The increase in permeability is due to contraction of venular endothelial cells, but PAF is more potent than histamine or bradykinin by three orders of magnitude.

Platelets. PAF potently stimulates platelet aggregation *in vitro*. While this is accompanied by the release of TxA₂ and the granular contents of the platelet, PAF does not require the presence of TxA₂ or other aggregating agents to produce this effect. The intravenous injection of PAF causes formation of intravascular platelet aggregates and thrombocytopenia.

Leukocytes. PAF stimulates polymorphonuclear leukocytes to aggregate, to release LTs and lysosomal enzymes, and to generate superoxide. Since LTB₄ is more potent in inducing leukocyte aggregation, it may mediate the aggregatory effects of PAF. PAF also promotes aggregation of monocytes and degranulation of eosinophils. It is chemotactic for eosinophils, neutrophils, and monocytes and promotes endothelial adherence and diapedesis of neutrophils. When given systemically, PAF causes leukocytopenia, with neutrophils showing the greatest decline. Intradermal injection causes the accumulation of neutrophils and mononuclear cells at the site of injection. Inhaled PAF increases the infiltration of eosinophils into the airways.

Smooth Muscle. PAF generally contracts gastrointestinal, uterine, and pulmonary smooth muscle. PAF enhances the amplitude of spontaneous uterine contractions; quiescent muscle contracts rapidly in a phasic fashion. These contractions are inhibited by inhibitors of PG synthesis. PAF does not affect tracheal smooth muscle but contracts airway smooth muscle. Most evidence suggests that another autacoid (*e.g.*, LTC₄ or TxA₂) mediates this effect of PAF. When given by aerosol, PAF increases airway resistance as well as the responsiveness to other bronchoconstrictors. PAF also increases mucus secretion and the permeability of pulmonary microvessels; this results in fluid accumulation in the mucosal and submucosal regions of the bronchi and trachea.

Stomach. In addition to contracting the fundus of the stomach, PAF is the most potent known ulcerogen. When given intravenously, it causes hemorrhagic erosions of the gastric mucosa that extend into the submucosa.

Kidney. When infused intrarenally in animals, PAF decreases renal blood flow, glomerular filtration rate, urine volume, and excretion of Na⁺ without changes in systemic hemodynamics (Lopez-Novoa, 1999). These effects are the result of a direct action on the renal circulation. PAF exerts a receptor-mediated biphasic effect on afferent arterioles, dilating them at low concentrations and constricting them at higher concentrations. The vasoconstrictor effect appears to be mediated, at least in part, by COX products, whereas vasodilation is a consequence of the stimulation of NO production by endothelium.

Mechanism of Action of PAF. Extracellular PAF exerts its actions by stimulating a specific GPCR that is expressed in numerous cell types (Ishii *et al.*, 2002). The PAF receptor's strict recognition requirements, including a specific head group and specific atypical *sn*-2 residue, also are met by oxPLs. The PAF receptor couples with G_q to activate the PLC-IP₃-Ca²⁺ pathway and phospholipases A₂ and D such that AA is mobilized from diacylglycerol, resulting in the synthesis of PGs, TxA₂, or LTs, which may function as extracellular mediators of the effects of PAF. PAF also may exert actions without leaving its cell of origin. For example, PAF is synthesized in a regulated fashion by endothelial cells stimulated by inflammatory mediators. This PAF is presented on the surface of the endothelium, where it activates the PAF receptor on juxtaposed cells, including platelets, polymorphonuclear leukocytes, and monocytes, and acts cooperatively with P-selectin to promote adhesion (Prescott *et al.*, 2000). Endothelial cells under oxidant stress release oxPLs, which activate leukocytes and platelets and can spread tissue damage.

Receptor Antagonists. Many compounds have been described that are PAF-receptor antagonists that selectively inhibit the actions of PAF *in vivo* and *in vitro*. One would expect a PAF receptor antagonist to be a potent antiinflammatory agent that might be useful in the therapy of disorders such as asthma, sepsis, and other diseases in which PAF is postulated to play a role. However, trials in humans have been disappointing, and the clinical efficacy of PAF antagonists has yet to be realized.

Physiological and Pathological Functions of PAF. PAF generally is viewed as a mediator of pathological events. Dysregulation of PAF signaling or degradation has been associated with some human diseases, aided by data from genetically modified animals.

Platelets. Since PAF is synthesized by platelets and promotes aggregation, it was proposed as the mediator of cyclooxygenase inhibitor-resistant, thrombin-induced aggregation. However, PAF

antagonists fail to block thrombin-induced aggregation, even though they prolong bleeding time and prevent thrombus formation in some experimental models. Thus, PAF does not function as an independent mediator of platelet aggregation but contributes to thrombus formation in a manner analogous to Tx_A₂ and ADP.

Reproduction and Parturition. A role for PAF in ovulation, implantation, and parturition has been suggested by numerous studies. However, PAF receptor-deficient mice are normal reproductively, indicating that PAF may not be essential for reproduction.

Inflammatory and Allergic Responses. The proinflammatory actions of PAF and its elaboration by endothelial cells, leukocytes, and mast cells under inflammatory conditions are well characterized. PAF and PAF-like molecules are thought to contribute to the pathophysiology of inflammatory disorders, including anaphylaxis, bronchial asthma, endotoxic shock, and skin diseases. The plasma concentration of PAF is increased in experimental anaphylactic shock, and the administration of PAF reproduces many of its signs and symptoms, suggesting a role for the autacoid in anaphylactic shock. In addition, mice overexpressing the PAF receptor exhibit bronchial hyperreactivity and increased lethality when treated with endotoxin (Ishii *et al.*, 2002). PAF receptor knockout mice display milder anaphylactic responses to exogenous antigen challenge, including less cardiac instability, airway constriction, and alveolar edema; they are, however, still susceptible to endotoxic shock. Deletion of the PAF receptor augments the lethality of infection with gram-negative bacteria while improving host defense against gram-positive pneumococcal pneumonia (Soares *et al.*, 2002; Rijneveld *et al.*, 2004).

Despite the broad implications of these observations, the effects of PAF antagonists in the treatment of inflammatory and allergic disorders have been disappointing. Although PAF antagonists reverse the bronchoconstriction of anaphylactic shock and improve survival in animal models, the impact of these agents on animal models of asthma and inflammation is marginal. Similarly, in patients with asthma, PAF antagonists partially inhibit the bronchoconstriction induced by antigen challenge but not by challenges by methacholine, exercise, or inhalation of cold air. These results may reflect the complexity of these pathological conditions and the likelihood that other mediators contribute to the inflammation associated with these disorders.

ANALGESIC-ANTIPYRETIC AGENTS; PHARMACOTHERAPY OF GOUT

Anne Burke, Emer Smyth, and Garret A. FitzGerald

This chapter describes *aspirin*, *acetaminophen*, the other non-narcotic nonsteroidal antiinflammatory drugs (NSAIDs) used to treat pain and inflammation, and the drugs used for hyperuricemia and gout.

Most currently available traditional NSAIDs (tNSAIDs) act by inhibiting the prostaglandin G/H synthase enzymes, colloquially known as the cyclooxygenases. The inhibition of cyclooxygenase-2 (COX-2) is thought to mediate, in large part, the antipyretic, analgesic, and antiinflammatory actions of tNSAIDs, while the simultaneous inhibition of cyclooxygenase-1 (COX-1) largely but not exclusively accounts for unwanted adverse effects in the gastrointestinal tract. Selective inhibitors of COX-2 are a subclass of NSAIDs that are also discussed. Aspirin, which irreversibly acetylates cyclooxygenase, is discussed, along with several structural subclasses of tNSAIDs, including propionic acid derivatives (*ibuprofen*, *naproxen*), acetic acid derivatives (*indomethacin*), and enolic acids (*piroxicam*), all of which compete in a reversible manner with the arachidonic acid (AA) substrate at the active site of COX-1 and COX-2. Acetaminophen is a very weak antiinflammatory drug; it is effective as an antipyretic and analgesic agent at typical doses that partly inhibit COXs, but appears to have fewer gastrointestinal side effects than the tNSAIDs.

Inflammation. The inflammatory process is the response to an injurious stimulus. It can be evoked by a wide variety of noxious agents (*e.g.*, infections, antibodies, or physical injuries). The ability to mount an inflammatory response is essential for survival in the face of environmental pathogens and injury; in some situations and diseases, the inflammatory response may be exaggerated and sustained without apparent benefit and even with severe adverse con-

sequences. No matter what the initiating stimulus, the classic inflammatory response includes calor (warmth), dolor (pain), rubor (redness), and tumor (swelling).

Inflammatory responses occur in three distinct temporal phases, each apparently mediated by different mechanisms: (1) an acute phase, characterized by transient local vasodilation and increased capillary permeability; (2) a delayed, subacute phase characterized by infiltration of leukocytes and phagocytic cells; and (3) a chronic proliferative phase, in which tissue degeneration and fibrosis occur.

Many mechanisms are involved in the promotion and resolution of the inflammatory process (Serhan and Chiang, 2004; Kyriakis and Avruch, 2001). Although earlier studies emphasized the promotion of migration of cells out of the microvasculature, recent work has focused on adhesive interactions, including the E-, P-, and L-selectins, intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and leukocyte integrins, in the adhesion of leukocytes and platelets to endothelium at sites of inflammation (Meager, 1999).

Activated endothelial cells play a key role in “targeting” circulating cells to inflammatory sites. Expression of the adhesion molecules varies among cell types involved in the inflammatory response. Cell adhesion occurs by recognition of cell-surface glycoproteins and carbohydrates on circulating cells due to the augmented expression of adhesion molecules on resident cells. Thus, endothelial activation results in leukocyte adhesion as the leukocytes recognize newly expressed L-selectin and P-selectin; other important interactions include those of endothelial-expressed E-selectin with sialylated Lewis X and other glycoproteins on the leukocyte surface and

endothelial ICAM-1 with leukocyte integrins. It has been proposed that some, but not all, tNSAIDs may interfere with adhesion by inhibiting expression or activity of certain of these cell-adhesion molecules (Diaz-Gonzalez and Sanchez-Madrid, 1998). Novel classes of antiinflammatory drugs directed against cell-adhesion molecules are under active development but have not yet entered the clinical arena.

In addition to the cell-adhesion molecules outlined above, the recruitment of inflammatory cells to sites of injury involves the concerted interactions of several types of soluble mediators. These include the complement factor C5a, platelet-activating factor, and the eicosanoid LTB₄ (see Chapter 25). All can act as chemotactic agonists. Several cytokines also play essential roles in orchestrating the inflammatory process, especially interleukin-1 (IL-1) and tumor necrosis factor (TNF) (Dempsey *et al.*, 2003). IL-1 and TNF are considered principal mediators of the biological responses to bacterial lipopolysaccharide (LPS, also called endotoxin). They are secreted by monocytes and macrophages, adipocytes, and other cells. Working in concert with each other and various cytokines and growth factors (including IL-8 and granulocyte-macrophage colony-stimulating factor; see Chapter 53), they induce gene expression and protein synthesis in a variety of cells to mediate and promote inflammation.

IL-1 comprises two distinct polypeptides (IL-1 α and IL-1 β) that bind to the same cell-surface receptors and produce similar biological responses. Plasma IL-1 levels are increased in patients with active inflammation. IL-1 can bind to two types of receptors, an 80-kd IL-1 receptor type 1 and a 68-kd IL-1 receptor type 2, which are present on different cell types.

TNF, originally termed "cachectin" because of its ability to produce a wasting syndrome, is composed of two closely related proteins: mature TNF (TNF- α) and lymphotoxin (TNF- β), both of which are recognized by the same cell-surface receptors. There are two types of TNF receptors, a 75-kd type 1 receptor and a 55-kd type 2 receptor. IL-1 and TNF produce many of the same proinflammatory responses.

A naturally occurring IL-1 receptor antagonist (IL-1ra), competes with IL-1 for receptor binding, blocks IL-1 activity *in vitro* and *in vivo*, and in experimental animals can prevent death induced by administration of bacteria or LPS. IL-1ra often is found in high levels in patients with various infections or inflammatory conditions. Thus, the balance between IL-1 and IL-1ra may contribute to the extent of an inflammatory response. Preliminary studies suggest that the administration of IL-1ra (designated anakinra)—by blocking IL-1 action on its receptor—may be beneficial in rheumatoid arthritis and other inflammatory conditions (Louie *et al.*, 2003; Olson and Stein, 2004).

Other cytokines and growth factors [*e.g.*, IL-2, IL-6, IL-8, and granulocyte/macrophage colony stimulating fac-

tor (GM-CSF)] contribute to manifestations of the inflammatory response. The concentrations of many of these factors are increased in the synovia of patients with inflammatory arthritis. Certain relevant peptides, such as substance P, which promotes firing of pain fibers, also are elevated and act in concert with cytokines at the site of inflammation. Other cytokines and growth factors counter the effects and initiate resolution of inflammation. These include transforming growth factor- β_1 (TGF- β_1), which increases extracellular matrix formation and acts as an immunosuppressant, IL-10, which decreases cytokine and prostaglandin E₂ formation by inhibiting monocytes, and interferon gamma, IFN- γ , which possesses myelosuppressive activity and inhibits collagen synthesis and collagenase production by macrophages.

Histamine was one of the first identified mediators of the inflammatory process. Although several H₁ histamine-receptor antagonists are available, they are useful only for the treatment of vascular events in the early transient phase of inflammation (see Chapter 24). Bradykinin and 5-hydroxytryptamine (serotonin, 5-HT) also may play a role in mediating inflammation, but their antagonists ameliorate only certain types of inflammatory response (see Chapter 24). Leukotriene (LT)-receptor antagonists (*montelukast* and *zafirlukast*) exert antiinflammatory actions and have been approved for the treatment of asthma (see Chapter 27). Another lipid autacoid, platelet-activating factor (PAF), has been implicated as an important mediator of inflammation; however, inhibitors of PAF synthesis and PAF-receptor antagonists have proven disappointing in the treatment of inflammation (see Chapter 25).

Intradermal, intravenous, or intra-arterial injections of small amounts of prostaglandins mimic many components of inflammation. Administration of prostaglandin E₂ (PGE₂) or prostacyclin (PGI₂) causes erythema and an increase in local blood flow. Such effects may persist for up to 10 hours with PGE₂ and include the capacity to counteract the vasoconstrictor effects of substances such as norepinephrine and angiotensin II, properties not generally shared by other inflammatory mediators. In contrast to their long-lasting effects on cutaneous vessels and superficial veins, prostaglandin-induced vasodilation in other vascular beds vanishes within a few minutes.

Although PGE₁ and PGE₂ (but not PGF_{2 α}) cause edema when injected into the hind paw of rats, it is not clear if they can increase vascular permeability in the postcapillary and collecting venules without the participation of other inflammatory mediators (*e.g.*, bradykinin, histamine, and leukotriene C₄ [LTC₄]). Furthermore, PGE₁ is not produced in significant quantities in humans

in vivo, except under rare circumstances such as essential fatty acid deficiency. Unlike LTs, prostaglandins are unlikely to be involved in chemotactic responses, even though they may promote the migration of leukocytes into an inflamed area by increasing blood flow.

Rheumatoid Arthritis. Although the detailed pathogenesis of rheumatoid arthritis is largely unknown, it appears to be an autoimmune disease driven primarily by activated T cells, giving rise to T cell–derived cytokines, such as IL-1 and TNF- α . Activation of B cells and the humoral response also are evident, although most of the antibodies generated are IgGs of unknown specificity, apparently elicited by polyclonal activation of B cells rather than from a response to a specific antigen.

Many cytokines, including IL-1 and TNF- α , have been found in the rheumatoid synovium. Glucocorticoids interfere with the synthesis and actions of cytokines, such as IL-1 or TNF- α (see Chapter 59). Although some of the actions of these cytokines are accompanied by the release of prostaglandins and thromboxane A₂ (TXA₂), COX inhibitors appear to block only their pyrogenic effects. In addition, many of the actions of the prostaglandins are inhibitory to the immune response, including suppression of the function of helper T cells and B cells and inhibition of the production of IL-1 (see Chapter 25). Thus, it has been suggested that COX-independent effects may contribute to the efficacy of NSAIDs in this setting. Besides an impact on adhesive interactions, salicylate and certain tNSAIDs can directly inhibit the activation and function of neutrophils, perhaps by blockade of integrin-mediated neutrophil responses by inhibiting downstream Erk signaling (Pillinger *et al.*, 1998).

NSAIDS: NONSTEROIDAL ANTIINFLAMMATORY DRUGS

All NSAIDs, including the subclass of selective COX-2 inhibitors, are antiinflammatory, analgesic, and antipyretic. NSAIDs are a chemically heterogeneous group of compounds, often chemically unrelated (although most of them are organic acids), which nevertheless share certain therapeutic actions and adverse effects. Aspirin also inhibits the COX enzymes but in a manner molecularly distinct from the competitive, reversible, active site inhibitors and is often distinguished from the NSAIDs. Similarly, acetaminophen, which is antipyretic and analgesic but largely devoid of antiinflammatory activity, also is conventionally segregated from the group despite its sharing NSAID activity with other actions relevant to its clinical action *in vivo*. General properties shared by aspirin, the NSAIDs, and acetaminophen as a class of COX inhibitors are considered first, followed by a discussion of important differences among representative drugs.

History. The history of aspirin provides an interesting example of the translation of a compound from the realm of herbal folklore to contemporary therapeutics. The use of willow bark and leaves to relieve

fever has been attributed to Hippocrates, but was most clearly documented by the Rev. Edmund Stone in a 1763 letter to the president of the Royal Society. Similar properties were attributed to potions from Meadowsweet (*Spiraea ulmaria*), from which the name aspirin is derived. Salicin was crystallized in 1829 by Leroux, and Pina isolated salicylic acid in 1836. In 1859, Kolbe synthesized salicylic acid, and by 1874 it was being produced industrially. It soon was being used for rheumatic fever, gout, and as a general antipyretic. Its unpleasant taste and adverse gastrointestinal effects made it difficult to tolerate for more than short periods. In 1899, Hoffmann, a chemist at Bayer Laboratories, sought to improve the adverse-effect profile of salicylic acid (which his father was taking with difficulty for arthritis). He came across the earlier work of the French chemist, Gerhardt, who had acetylated salicylic acid in 1853, apparently ameliorating its adverse-effect profile but without improving its efficacy, and therefore abandoned the project. Hoffman resumed the quest, and Bayer began testing acetylsalicylic acid in animals by 1899—the first time that a drug was tested on animals in an industrial setting—and proceeded soon thereafter to human studies and the marketing of aspirin.

Mechanism of Action and Therapeutic Effects of NSAIDs

Although it had been used for almost a century, the mechanism of action of aspirin (and the tNSAIDs) was elucidated only in 1971, when John Vane and his associates demonstrated that low concentrations of aspirin and indomethacin inhibited the enzymatic production of prostaglandins (see Chapter 25). There was some evidence that prostaglandins participated in the pathogenesis of inflammation and fever at that time. Subsequent observations demonstrated that prostaglandins are released whenever cells are damaged and that aspirin and tNSAIDs inhibit their biosynthesis in all cell types. However, aspirin and tNSAIDs generally do not inhibit the formation of other inflammatory mediators, including other eicosanoids such as the LTs (see Chapter 25). While the clinical effects of these drugs are explicable in terms of inhibition of prostaglandin synthesis, substantial inter- and intraindividual differences in clinical response have been noted. At higher concentrations, NSAIDs also are known to reduce production of superoxide radicals, induce apoptosis, inhibit the expression of adhesion molecules, decrease nitric oxide synthase, decrease proinflammatory cytokines (e.g., TNF- α , interleukin-1), modify lymphocyte activity, and alter cellular membrane functions. However, there are differing opinions as to whether these actions might contribute to the antiinflammatory activity of NSAIDs (Vane and Botting, 1998) at the concentrations attained during clinical dosing in people. The hypothesis that their antiinflammatory actions in humans derive from COX inhibition alone has not been rejected, based on current evidence.

Inhibition of Prostaglandin Biosynthesis by NSAIDs.

The principal therapeutic effects of NSAIDs derive from their ability to inhibit prostaglandin production. The first enzyme in the prostaglandin synthetic pathway is prostaglandin G/H synthase, also known as cyclooxygenase or COX. This enzyme converts arachidonic acid (AA) to the unstable intermediates PGG₂ and PGH₂ and leads to the production of thromboxane A₂ (TXA₂) and a variety of prostaglandins (see Chapter 25) (Figures 25–1 and 25–2).

Therapeutic doses of aspirin and other NSAIDs reduce prostaglandin biosynthesis in humans, and there is a rea-

sonably good correlation between the potency of these drugs as cyclooxygenase inhibitors and their antiinflammatory activity. Apparent discrepancies may be partially attributed to the experimental conditions, which do not always mimic the *in vivo* situation (e.g., the effect of binding of the drugs to plasma proteins, or the effects of the drug on purified COX compared to intracellular COX). Further support linking cyclooxygenase inhibition to antiinflammatory activity is the high degree of stereoselectivity among several pairs of enantiomers of α -methyl arylacetic acids for inhibition of cyclooxygenase and suppression of inflammation; in each instance the *d* or (+) isomer is more potent in inhibiting cyclooxygenase and suppressing inflammation.

There are two forms of cyclooxygenase, cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). Splice variants of COX-1 that retain enzymatic activity have been described, one of which has been called "COX-3." It is not clear at present how relevant these splice variants are to prostaglandin synthesis and NSAID action in humans. COX-1 is a primarily constitutive isoform found in most normal cells and tissues, while cytokines and inflammatory mediators that accompany inflammation induce COX-2 production (Seibert *et al.*, 1997). However, COX-2 also is constitutively expressed in certain areas of kidney and brain (Breder *et al.*, 1995) and is induced in endothelial cells by laminar shear forces (Topper *et al.*, 1996). Importantly, COX-1, but not COX-2, is expressed as the dominant, constitutive isoform in gastric epithelial cells and is the major source of cytoprotective prostaglandin formation. Inhibition of COX-1 at this site is thought to account largely for the gastric adverse events that complicate therapy with tNSAIDs, thus providing the rationale for the development of NSAIDs specific for inhibition of COX-2 (FitzGerald and Patrono, 2001).

Aspirin and NSAIDs inhibit the COX enzymes and prostaglandin production; they do not inhibit the lipoxygenase pathways of AA metabolism and hence do not suppress LT formation (*see* Chapter 25). Glucocorticoids suppress the induced expression of COX-2, and thus COX-2-mediated prostaglandin production. They also inhibit the action of phospholipase A₂, which releases AA from the cell membrane. These effects contribute to the antiinflammatory actions of glucocorticoids, which are discussed in greater detail in Chapter 59. Table 26–1 provides a classification of NSAIDs and other analgesic and antipyretic agents based on their chemical structures.

Aspirin covalently modifies COX-1 and COX-2, irreversibly inhibiting cyclooxygenase activity. This is an

important distinction from all the NSAIDs because the duration of aspirin's effects is related to the turnover rate of cyclooxygenases in different target tissues. The duration of effect of nonaspirin NSAIDs, which competitively inhibit the active sites of the COX enzymes, relates more directly to the time course of drug disposition. The importance of enzyme turnover in relief from aspirin action is most notable in platelets, which, being anucleate, have a markedly limited capacity for protein synthesis. Thus, the consequences of inhibition of platelet COX-1 (COX-2 is expressed only in megakaryocytes) last for the lifetime of the platelet. Inhibition of platelet COX-1-dependent TXA₂ formation therefore is cumulative with repeated doses of aspirin (at least as low as 30 mg/day) and takes roughly 8 to 12 days—the platelet turnover time—to recover once therapy has been stopped.

COXs are configured such that the active site is accessed by the AA substrate *via* a hydrophobic channel. Aspirin acetylates serine 530 of COX-1, located high up in the hydrophobic channel. Interposition of the bulky acetyl residue prevents the binding of AA to the active site of the enzyme and thus impedes the ability of the enzyme to make prostaglandins. Aspirin acetylates a homologous serine at position 516 in COX-2. Although covalent modification of COX-2 by aspirin also blocks the cyclooxygenase activity of this isoform, an interesting property not shared by COX-1 is that acetylated COX-2 synthesizes 15(*R*)-hydroxyicosatetraenoic acid [15(*R*)-HETE]. This may be metabolized, at least *in vitro*, by 5-lipoxygenase to yield 15-epilipoxin A₄, which has potent antiinflammatory properties (Serhan and Oliw, 2001). Due to these features, repeated doses of aspirin that acutely do not completely inhibit platelet COX-1-derived TXA₂ can exert a cumulative effect with complete blockade. This has been shown in randomized trials for doses as low as 30 mg per day. However, most of the clinical trials demonstrating cardioprotection from low-dose aspirin have used doses in the range of 75 to 81 mg/day.

The unique sensitivity of platelets to inhibition by such low doses of aspirin is related to their presystemic inhibition in the portal circulation before aspirin is deacetylated to salicylate on first pass through the liver (Pederson and FitzGerald, 1984). In contrast to aspirin, salicylic acid has no acetylating capacity. It is a weak, reversible competitive inhibitor of cyclooxygenase. High doses of salicylate inhibit the activation of NF κ B *in vitro*, but the relevance of this property to the concentrations attained *in vivo* is not clear (Yin *et al.*, 1998).

The vast majority of NSAIDs listed in Table 26–1 are organic acids, and in contrast to aspirin, act as reversible, competitive inhibitors of cyclooxygenase activity. Even the nonacidic parent drug *nabumetone* is converted to an active acetic acid derivative *in vivo*. As organic acids, the compounds generally are well absorbed orally, highly bound to plasma proteins, and excreted either by glomerular filtration or by tubular secretion. They also accumulate in sites of inflammation, potentially confounding the relationship between plasma concentrations and duration of drug effect. The tNSAIDs include those with shorter (less than 6 hours) or longer (greater than 10 hours) half-lives.

Table 26-1

Classification and Comparison of Nonsteroidal Analgesics

CLASS/DRUG (substitution)	PHARMACOKINETICS		DOSING [§]		COMMENTS	COMPARED TO ASPIRIN
<i>Salicylates</i>						
Aspirin (acetyl ester)	Peak C _p *	1 hour	Antiplatelet	40–80 mg/d	Permanent platelet COX-1 inhibition (due to acetyl group)	
	Protein binding	80%–90%	Pain/fever	325–650 mg every 4–6 hours		
	Metabolites [†]	Salicylic acid	Rheumatic fever	1 g every 4–6 hours	Main side effects: GI, increased bleeding time, hypersensitivity reaction	
	Half-life [‡]		Children	10 mg/kg every 4–6 hours		
	Therapeutic	2–3 hours			Avoid in children with acute febrile illness	
	High/toxic	15–30 hours				
Diflunisal (defluoro-phenyl)	Peak C _p	2–3 hours	250–500 mg every 8–12 hours		Not metabolized to salicylic acid	Analgesic and anti-inflammatory effects 4–5 times more potent
	Protein binding	99%				
	Metabolites	Glucuronide			Competitive COX inhibitor	Antipyretic effect weaker
	Half-life	8–12 hours			Excreted into breast milk	Fewer platelet and GI side effects
	Therapeutic					
<i>Para-aminophenol derivative</i>						
Acetaminophen	Peak C _p	30–60 min	10–15 mg/kg every 4 hours (maximum of 5 doses/24 hours)		Weak nonspecific inhibitor at common doses	Analgesic and antipyretic effects equivalent to aspirin
	Protein binding	20–50%				
	Metabolites	Glucuronide conjugates (60%); sulfuric acid conjugates (35%)				
	Half-life	2 hours			Overdose leads to production of toxic metabolite and liver necrosis	
<i>Acetic acid derivatives</i>						
Indomethacin (methylated indole)	Peak C _p	1–2 hours	25 mg 2–3 times/day; 75–100 mg at night		Side effects (3%–50% of patients): frontal headache, neutropenia, thrombocytopenia; 20% discontinue therapy	10–40 times more potent; intolerance limits dose
	Protein binding	90%				
	Metabolites	O-demethylation (50%); unchanged (20%)				
	Half-life	2½ hours				

(Continued)

Table 26–1

Classification and Comparison of Nonsteroidal Analgesics (Continued)

CLASS/DRUG (substitution)	PHARMACOKINETICS		DOSING [§]	COMMENTS	COMPARED TO ASPIRIN
Sulindac (sulfoxide pro- drug)	Peak C _p	1–2 hours; 8 hours for sulfide metabolite; extensive enterohepatic circulation	150–200 mg twice/day	20% suffer GI side effects, 10% get CNS side effects	Efficacy comparable to aspirin
	Metabolites	Sulfone and conjugates (30%); sulindac and conjugates (25%)			
	Half-life	7 hours; 18 hours for metabolite			
Etodolac (pyranocar- boxylic acid)	Peak C _p	1 hour	200–400 mg 3–4 times/day	Some COX-2 selectivity <i>in vitro</i>	100 mg etodolac, similar efficacy to aspirin 650 mg, but may be better tolerated
	Protein binding	99%			
	Metabolites	Hepatic metabolites			
	Half-life	7 hours			
Femanates (<i>N</i> -phenyl- anthranilates)				Isolated cases of hemolytic anemia reported	Efficacy similar to aspirin; GI side effects (25%)
Mefenamic acid	Peak C _p	2–4 hours	500-mg load, then 250 mg every 6 hours	May have some central action	
	Protein binding	High			
	Metabolites	Conjugates of 3-hydroxy and 3-carboxyl metabolites (20% recovered in feces)			
Meclofenamate	Half-life	3–4 hours	50–100 mg 4–6/day (maximum of 400 mg/day)		Efficacy similar to aspirin; 25% experience GI side effects
	Peak C _p	0.5–2 hours			
	Protein binding	99%			
	Metabolites	Hepatic metabolism; fecal and renal excretion			
Flufenamic acid	Half-life	2–3 hours			
	<i>Not available in United States</i>				

Tolmetin (heteroaryl acetate deriv- ative)	Peak C _p	20–60 minutes	400–600 mg 3 times/day	Food delays and decreases peak absorption May persist longer in synovial fluid to give a biological efficacy longer than its plasma t _{1/2}	Efficacy similar 25%–40% develop side effects; 5%–10% discontinue drug
	Protein binding	99%	Children (anti-inflammatory)		
Ketorolac (pyrrolizine carboxylate)	Metabolites	Oxidized to carboxylic acid/other derivatives, then conjugated		Commonly given parenterally (60 mg IM followed by 30 mg every 6 hours, or 30 mg IV every 6 hours) Also available as ocular preparation 0.25%, 1 drop every 6 hours	Potent analgesic, poor antiinflammatory
	Half-life	5 hours			
	Peak C _p	30–60 mins after IM route	<65 years: 20 mg (orally), then 10 mg every 4–6 hours (not to exceed 40 mg/24 hours); >65 years: 10 mg every 4–6 hours (not to exceed 40 mg/24 hours)		
Diclofenac (phenylacetate derivatives)	Protein binding	99%	50 mg 3 times/day or 75 mg 2 times/day	Also available as topical gel, ophthalmic solution, and oral tablets combined with misoprostol First-pass effect; oral bioavailability, 50%	More potent; 20% develop side effects, 2% discontinue use, 15% develop elevated liver enzymes
	Metabolites	Glucuronide and sulfide metabolites (renal 65%, bile 35%)			
	Half-life	1–2 hours			
<i>Propionic acid derivatives</i>					
Ibuprofen	Peak C _p	15–30 minutes	Analgesia	200–400 mg every 4–6 hours	10%–15% discontinue due to adverse effects Children's dosing Antipyretic: 5–10 mg/kg every 6 hours (maximum 40 mg/kg per day) Antiinflammatory: 20–40 mg/kg per day in 3–4 divided doses
	Protein binding	99%	Antiinflammatory	300 mg every 6–8 hours or 400–800 mg 3–4 times/day	
	Metabolites	Conjugates of hydroxyl and carboxyl metabolites			Equipotent
	Half-life	2–4 hours			

(Continued)

Table 26-1

Classification and Comparison of Nonsteroidal Analgesics (Continued)

CLASS/DRUG (substitution)	PHARMACOKINETICS		DOSING [§]		COMMENTS	COMPARED TO ASPIRIN
Naproxen	Peak C _p	1 hour	250 mg 4 times/day or 500 mg 2 times/day		Peak antiinflammatory effects may not be seen until 2–4 weeks of use Decreased protein binding and delayed excretion increase risk of toxicity in elderly	More potent <i>in vitro</i> ; usually better tolerated; variably prolonged $t_{1/2}$ may afford cardioprotection in some individuals
	Protein binding	99% (less in elderly)	Children			
	Metabolites	6-demethyl and other metabolites	Antiinflammatory	5 mg/kg twice a day		
	Half-life	14 hours				
Fenoprofen	Peak C _p	2 hours	200 mg 4–6 times/day; 300–600 mg 3–4 times/day			15% experience side effects; few discontinue use
	Protein binding	99%				
	Metabolites	Glucuronide, 4-OH metabolite				
Ketoprofen	Peak C _p	1–2 hours	Analgnesia	25 mg 3–4 times/day;		30% develop side effects (usually GI, usually mild)
	Protein binding	98%				
	Metabolites	Glucuronide conjugates	Antiinflammatory	50–75 mg 3–4 times/day		
	Half-life	2 hours				
Flurbiprofen	Peak C _p	1–2 hours	200–300 mg/day in 2–4 divided doses		Available as a 0.03% ophthalmic solution	
	Protein binding	99%				
	Metabolites	Hydroxylates and conjugates				
Oxaprozin	Peak C _p	3–4 hours	600–1800 mg/day		Long $t_{1/2}$ allows for daily administration; slow onset of action; inappropriate for fever/acute analgesia	
	Protein binding	99%				
	Major metabolites	Oxidates and glucuronide conjugates				
	Half-life	40–60 hours				

Enolic acid derivatives

Piroxicam	Peak [drug] Protein binding Metabolites Half-life	3–5 hours 99% Hydroxylates and then conjugated 45–50 hours	20 mg/day		May inhibit activation of neutrophils, activity of proteoglycanase, collagenases	Equipotent; perhaps better tolerated 20% develop side effects; 5% discontinue drug
Meloxicam	Peak [drug] Protein binding Metabolites Half-life	5–10 hours 99% Hydroxylation 15–20 hours	7.5–15 mg/day			Some COX-2 selectivity, especially at lower doses
Nabumetone (naphthyl alkanone)	Peak [drug] Protein binding Major metabolites Half-life	3–6 hours 99% <i>O</i> -demethylation, then conjugation 24 hours	500–1000 mg 1–2 times/day		A prodrug, rapidly metabolized to 6-methoxy-2-naphthyl-acetic acid; pharmacokinetics reflect active compound	Shows some COX-2 selectivity (active metabolite does not) Fewer GI side effects than many NSAIDs

COX-2 selective inhibitors

Celecoxib [diaryl substituted pyrazone; (sulfonamide derivative)]	Peak [drug] Protein binding Metabolites Half-life	2–4 hours 97% Carboxylic acid and glucuronide conjugates 6–12 hours	100 mg 1–2 times/day		Substrate for CYP2C9; inhibitor of CYP2D6 Co-administration with inhibitors of CYP2C9 or substrates of CYP2D6 should be done with caution	See text for overview of COX-2 inhibitors
Valdecoxib (BEXTRA)	Peak [drug] Protein binding Metabolites	2–4 hours, delayed by food 98% Hepatic metabolism to hydroxyl derivatives, then renal excretion	Analgesia Primary dysmenorrhea 20 mg twice daily 10 mg once daily		Substrate for CYP2C9 and CYP3A4; weak inhibitor of CYP2C9 and CYP2C19	Increased incidence of heart attack and stroke in patients undergoing bypass grafting

Evidence for cardiovascular adverse events

Marked decrease in gastrointestinal side effects and in platelet effects

(Continued)

Table 26-1*Classification and Comparison of Nonsteroidal Analgesics (Continued)*

CLASS/DRUG (substitution)	PHARMACOKINETICS	DOSING [§]	COMMENTS	COMPARED TO ASPIRIN
Valdecoxib (<i>cont.</i>)	Half-life	7–8 hours	$t_{1/2}$ longer in elderly or with hepatic impairment	
Parecoxib Etoricoxib Lumaricoxib	} <i>Not approved for use in the United States</i>			

*Time to peak plasma drug concentration (C_p) after a single dose. In general, food delays absorption but does not decrease peak concentration †The majority of NSAIDs undergo hepatic metabolism, and the metabolites are excreted in the urine. Major metabolites or disposal pathways are listed. ‡Typical half-life is listed for therapeutic doses; if much different with toxic dose, this is given also. §Limited dosing information given. For additional information, refer to text and product information literature. Additional references can be found in earlier editions of this textbook.

Most tNSAIDs inhibit both COX-1 and COX-2 with little selectivity, although some, conventionally thought of as tNSAIDs—*diclofenac*, *meloxicam*, and *nimesulide*—exhibit selectivity for COX-2 that is close to that of *celecoxib* *in vitro*. Indeed, meloxicam achieved approval in some countries as a selective inhibitor of COX-2. The hypothesis that the antiinflammatory effects of NSAIDs would be accompanied by a lower ulcerogenic potential propelled efforts to design drugs with greater selectivity for COX-2 versus COX-1 (FitzGerald and Patrono, 2001). These efforts led to the approval and marketing of *rofecoxib*, *celecoxib*, and *valdecoxib* as selective COX-2 inhibitors, known as the coxibs, and the development of others (e.g., *etoricoxib* and *lumiracoxib*). Based on whole blood assays, several previously marketed tNSAIDs also have selectivity ratios comparable to those of the least-selective of the novel COX-2 inhibitors, celecoxib. These include meloxicam, nimesulide, and diclofenac (Warner *et al.*, 1999; FitzGerald and Patrono, 2001).

Observational studies suggest that acetaminophen, which is a very weak antiinflammatory agent at the typical daily dose of 1000 mg, is associated with a reduced incidence of gastrointestinal adverse effects compared to tNSAIDs. At this dose, acetaminophen inhibits both cyclooxygenases by about 50%. The ability of acetaminophen to inhibit the enzyme is conditioned by the peroxide tone of the immediate environment (Boutaud *et al.*, 2002). This may partly explain the poor antiinflammatory activity of acetaminophen, since sites of inflammation usually contain increased concentrations of leukocyte-generated peroxides.

Pain. NSAIDs usually are classified as mild analgesics. However, consideration of the type of pain, as well as its intensity, is important in the assessment of analgesic efficacy. NSAIDs are particularly effective when inflammation has caused sensitization of pain receptors to normally painless mechanical or chemical stimuli. Pain that accompanies inflammation and tissue injury probably results from local stimulation of pain fibers and enhanced pain sensitivity (hyperalgesia), in part a consequence of increased excitability of central neurons in the spinal cord.

Bradykinin, released from plasma kininogen, and cytokines, such as TNF- α , IL-1, and IL-8, appear to be particularly important in eliciting the pain of inflammation. These agents liberate prostaglandins and probably other mediators that promote hyperalgesia. Neuropeptides, such as substance P and calcitonin gene-related peptide (CGRP), also may be involved in eliciting pain.

Large doses of PGE₂ or PGF_{2 α} previously given to women by intramuscular or subcutaneous injection to induce abortion, cause intense local pain. Prostaglandins also can cause headache and vascular pain when infused intravenously. The capacity of prostaglandins to sensitize pain receptors to mechanical and chemical stimulation apparently results from a lowering of the threshold of the polymodal nociceptors of C fibers. In general, NSAIDs do not affect either hyperalgesia or pain caused by the direct action of prostaglandins, consistent with the notion that the analgesic effects of these agents are due to inhibition of prostaglandin synthesis. However, some data have suggested that relief of pain by these compounds may occur *via* mechanisms other than inhibition

of prostaglandin synthesis, including antinociceptive effects at peripheral or central neurons. Indeed, for all the use of NSAIDs in the relief of pain, we have a poor understanding of how the two COX enzymes interact in the mediation of the perception of pain, irrespective of any COX-independent actions of individual NSAIDs.

Fever. Regulation of body temperature requires a delicate balance between the production and loss of heat; the hypothalamus regulates the set point at which body temperature is maintained. This set point is elevated in fever, and NSAIDs promote its return to normal. These drugs do not influence body temperature when it is elevated by factors such as exercise or in response to ambient temperature.

Fever may reflect infection or result from tissue damage, inflammation, graft rejection, or malignancy. These conditions all enhance formation of cytokines such as IL-1 β , IL-6, interferons, and TNF- α . The cytokines increase synthesis of PGE₂ in circumventricular organs in and adjacent to the preoptic hypothalamic area; PGE₂, in turn, increases cyclic AMP and triggers the hypothalamus to elevate body temperature by promoting an increase in heat generation and a decrease in heat loss. Aspirin and NSAIDs suppress this response by inhibiting PGE₂ synthesis. Prostaglandins, especially PGE₂, acting *via* its EP3 receptor, can produce fever when infused into the cerebral ventricles or when injected into the hypothalamus. As with pain, NSAIDs do not inhibit the fever caused by directly administered prostaglandins; rather they inhibit fever caused by agents that enhance the synthesis of IL-1 and other cytokines, which presumably cause fever, at least in part, by inducing the endogenous synthesis of prostaglandins.

Therapeutic Effects. All NSAIDs, including selective COX-2 inhibitors, are antipyretic, analgesic, and antiinflammatory, with the exception of acetaminophen, which is antipyretic and analgesic but is largely devoid of antiinflammatory activity.

When employed as analgesics, these drugs usually are effective only against pain of low-to-moderate intensity, such as dental pain. Although their maximal efficacy is generally much less than the opioids, NSAIDs lack the unwanted adverse effects of opiates in the CNS, including respiratory depression and the development of physical dependence. NSAIDs do not change the perception of sensory modalities other than pain. Chronic postoperative pain or pain arising from inflammation is controlled particularly well by NSAIDs, whereas pain arising from the hollow viscera usually is not relieved. An exception to this is menstrual pain. The release of prostaglandins by the endometrium during menstruation may cause severe cramps and other symptoms of primary dysmenorrhea; treatment of this condition with NSAIDs has met with considerable success (Marjoribanks *et al.*,

2003). Not surprisingly, the selective COX-2 inhibitors such as rofecoxib and etoricoxib are also efficacious in this condition.

NSAIDs reduce fever in most situations, but not the circadian variation in temperature or the rise in response to exercise or increased ambient temperature. Comparative analysis of the impact of tNSAIDs and selective COX-2 inhibitors suggests that COX-2 is the dominant source of prostaglandins that mediate the rise in temperature evoked by bacterial LPS administration (McAdam *et al.*, 1999). This is consistent with the antipyretic clinical efficacy of both subclasses of NSAIDs.

It seems logical to select an NSAID with rapid onset for the management of fever associated with minor illness in adults. Due to the association with Reye's syndrome, aspirin and other salicylates are contraindicated in children and young adults less than 20 years old with fever associated with viral illness. Reye's syndrome is characterized by the acute onset of encephalopathy, liver dysfunction, and fatty infiltration of the liver and other viscera (Glasgow and Middleton, 2001). The etiology and pathophysiology are not clear. However, the epidemiologic evidence for an association between aspirin use in children and Reye's syndrome was sufficiently compelling that labeling of aspirin and aspirin-containing medications to indicate Reye's syndrome as a risk in children was mandated in 1986. Since then, the use of aspirin in children has declined dramatically, and Reye's syndrome has almost disappeared. Acetaminophen has not been implicated in Reye's syndrome and is the drug of choice for antipyresis in children and teens.

NSAIDs find their chief clinical application as anti-inflammatory agents in the treatment of musculoskeletal disorders, such as rheumatoid arthritis and osteoarthritis. In general, NSAIDs provide only symptomatic relief from pain and inflammation associated with the disease, do not arrest the progression of pathological injury to tissue, and are not considered to be "disease-modifying" anti-rheumatic drugs (*see below*). A number of NSAIDs are FDA approved for the treatment of ankylosing spondylitis and gout. The use of NSAIDs for mild arthropathies, together with rest and physical therapy, generally is effective. When the symptoms are limited either to trouble sleeping because of pain or significant morning stiffness, a single NSAID dose given at night may suffice. Patients with more debilitating disease may not respond adequately to full therapeutic doses of NSAIDs and may require aggressive therapy with second-line agents. The choice of drugs for children with juvenile rheumatoid arthritis commonly is restricted to those that have been specifically tested in children, such as aspirin (*see discussion of Reye's syn-*

drome, above, under "Fever"), naproxen, or *tolmetin*. Etoricoxib—not yet approved in the United States—also has been shown to be effective in the treatment of ankylosing spondylitis and gout.

Prostaglandins also have been implicated in the maintenance of patency of the ductus arteriosus, and indomethacin and other tNSAIDs have been used in neonates to close the inappropriately patent ductus. Both COX-1 and COX-2 appear to participate in maintaining patency of the ductus arteriosus in fetal lambs (Clyman *et al.*, 1999), while in mice COX-2 appears to play the dominant role (Loftin *et al.*, 2002). It is not known which isoform(s) is involved in maintaining patency of the fetal ductus *in utero* in humans.

Other Clinical Uses. Systemic Mastocytosis. Systemic mastocytosis is a condition in which there are excessive mast cells in the bone marrow, reticuloendothelial system, gastrointestinal system, bones, and skin. In patients with systemic mastocytosis, prostaglandin D₂, released from mast cells in large amounts, has been found to be the major mediator of severe episodes of vasodilation and hypotension; this PGD₂ effect is resistant to antihistamines. The addition of aspirin or *ketoprofen* has provided relief (Worobec, 2000). However, aspirin and tNSAIDs can cause degranulation of mast cells, so blockade with H₁ and H₂ histamine receptor antagonists should be established before NSAIDs are initiated.

Bartter's Syndrome. Bartter's syndrome includes a series of rare disorders (1-0.1/100,000) characterized by hypokalemic, hypochloremic metabolic alkalosis with normal blood pressure and hyperplasia of the juxtaglomerular apparatus. Fatigue, muscle weakness, diarrhea, and dehydration are the main symptoms. Distinct variants are caused by mutations in a Na⁺:K⁺:2Cl⁻ cotransporter, an apical ATP-regulated K⁺ channel, a basolateral Cl⁻ channel, a protein (barttin) involved in cotransporter trafficking, and the extracellular calcium-sensing receptor. Renal COX-2 is induced and biosynthesis of PGE₂ is increased. Treatment with indomethacin, combined with potassium repletion and *spironolactone*, is associated with improvement in the biochemical derangements and symptoms. Selective COX-2 inhibitors also have been used (Guay-Woodford, 1998).

Cancer Chemoprevention. Chemoprevention of cancer is an area where the potential use of aspirin and/or NSAIDs is under active investigation. Epidemiological studies suggested that frequent use of aspirin is associated with as much as a 50% decrease in the risk of colon cancer (Kune *et al.*, 1998) and similar observations have been made with other cancers (Jacobs *et al.*, 2004). NSAIDs

have been used in patients with familial adenomatous polyposis (FAP), an inherited disorder characterized by multiple adenomatous colon polyps developing during adolescence and the inevitable occurrence of colon cancer by the sixth decade.

Studies in small numbers of patients over short periods of follow-up have shown a decrease in the polyp burden with the use of *sulindac*, celecoxib, or rofecoxib (Cruz-Correa *et al.*, 2002; Hallak *et al.*, 2003; Steinbach *et al.*, 2000). Celecoxib is approved as an adjunct to endoscopic surveillance and surgery in FAP based on superiority in a short-term placebo-controlled trial for polyp prevention/regression. However, more recent or longer-term studies have been somewhat disappointing with regard to the primary prevention of polyps (Giardiello *et al.*, 2002), and the prematurely terminated Adenoma Prevention with Celecoxib (APC) trial showed a 2.5 times increase in cardiovascular risk for patients taking 200 mg twice a day of celecoxib, and a 3.4 times increase in risk for patients taking 400 mg twice a day (Solomon *et al.*, 2005). Controlled evidence is not available to determine if selective COX-2 inhibitors differ from non-COX-2 selective tNSAIDs or aspirin in the extent of adenomatous colorectal polyp reduction in patients with FAP. Likewise, it is unknown whether there is even a clinical benefit from the reduction. Increased expression of COX-2 has been reported in multiple epithelial tumors, and in some cases the degree of expression has been related to prognosis. Deletion or inhibition of COX-2 dramatically inhibits polyp formation in mouse genetic models of polyposis coli. Although the phenotypes in these models do not completely recapitulate the human disease, deletion of COX-1 had a similar effect. Speculation as to how the two COXs might interact in tumorigenesis includes the possibility that products of COX-1 might induce expression of COX-2. However, the nature of this interaction is poorly understood, as are its therapeutic consequences. Meanwhile, large scale chemoprevention studies focused on aspirin, tNSAIDs, or specific inhibitors of COX-2 are underway (Rigas and Shiff, 2000).

Niacin Tolerability. Large doses of niacin (nicotinic acid) effectively lower serum cholesterol levels, reduce LDL, and raise HDL (*see* Chapter 35). However, niacin is tolerated poorly because it induces intense flushing. This flushing is mediated by a release of prostaglandin D₂ from the skin, which can be inhibited by treatment with aspirin (Jungnickel *et al.*, 1997) and would be susceptible to inhibition of PGD synthesis or antagonism of its DP receptors.

Adverse Effects of NSAID Therapy. Common adverse events that complicate therapy with aspirin and NSAIDs are outlined in Table 26–2. Age generally is correlated with an increased probability of developing serious adverse reactions to NSAIDs, and caution is warranted in choosing a lower starting dose for elderly patients.

Gastrointestinal. The most common symptoms associated with these drugs are gastrointestinal, including anorexia, nausea, dys-

Table 26–2
Common and Shared Side Effects of NSAIDs

SYSTEM	MANIFESTATIONS
GI (side effects decreased with COX-2–selective drugs)	Abdominal pain Nausea Anorexia Gastric erosions/ulcers Anemia GI hemorrhage Perforation Diarrhea
Renal	Salt and water retention Edema, worsening of renal function in renal/cardiac and cirrhotic patients Decreased effectiveness of anti-hypertensive medications Decreased effectiveness of diuretic medications Decreased urate excretion (especially with aspirin) Hyperkalemia
CNS	Headache Vertigo Dizziness Confusion Depression Lowering of seizure threshold Hyperventilation (salicylates)
Platelets (side effects decreased with COX-2–selective drugs)	Inhibited platelet activation Propensity for bruising Increased risk of hemorrhage
Uterus	Prolongation of gestation Inhibit labor
Hypersensitivity	Vasomotor rhinitis Angioneurotic edema Asthma Urticaria Flushing Hypotension Shock
Vascular	Closure of ductus arteriosus

pepsia, abdominal pain, and diarrhea. These symptoms may be related to the induction of gastric or intestinal ulcers, which is estimated to occur in 15% to 30% of regular users. Ulceration may range from small superficial erosions to full-thickness perfor-

ration of the muscularis mucosa. There may be single or multiple ulcers, and ulceration can be accompanied by gradual blood loss leading to anemia or by life-threatening hemorrhage. The risk is further increased in those with *Helicobacter pylori* infection, heavy alcohol consumption, or other risk factors for mucosal injury, including the concurrent use of glucocorticoids. Although there is a perception that tNSAIDs vary considerably in their tendency to cause such erosions and ulcers, this is based on overview analyses of small and heterogeneous studies, often at single doses of individual tNSAIDs. Large-scale comparative studies of tNSAIDs have not been performed, and there is no reliable information on which to assess the comparative likelihood of GI ulceration on antiinflammatory doses of aspirin *versus* tNSAIDs. Thus, most information is derived from the use of surrogate markers or from epidemiological datasets and suggests that the relative risk for serious adverse gastrointestinal events is elevated about threefold in tNSAID users compared to nonusers. Epidemiological studies suggest that combining low-dose aspirin (for cardioprotection) with other NSAIDs synergistically increases the likelihood of gastrointestinal adverse events (*see* section on drug interactions, below).

All of the selective COX-2 inhibitors have been shown to be less prone than equally efficacious doses of tNSAIDs to induce endoscopically visualized gastric ulcers (Deeks *et al.*, 2002), and this has provided the basis of FDA approval of valdecoxib and celecoxib. To date, three comparative studies of clinical outcome have been published, two of which reported a significant difference in serious gastrointestinal events. The VIGOR study showed that important gastrointestinal events—mainly bleeds—were reduced from 4% to 2% in subjects treated with rofecoxib (now withdrawn from the market worldwide), and the TARGET trial (which actually was two distinct comparative studies with naproxen and ibuprofen, respectively) showed a reduction in ulcer complications in patients taking lumiracoxib (Schnitzer *et al.*, 2004). In contrast, adverse events with celecoxib were not significantly decreased in the CLASS study (Silverstein *et al.*, 2000). While the outcome of the VIGOR study was consistent with the hypothesis that COX-2-selective inhibitors are associated with a decreased incidence of gastrointestinal adverse events, the results were tempered by a fivefold increase in the incidence of myocardial infarction, probably reflecting a cardiovascular hazard in predisposed individuals treated with selective COX-2 inhibitors together with a modest cardioprotective effect of naproxen (*see* cardiovascular section, below).

Gastric damage by NSAIDs can be brought about by at least two distinct mechanisms (*see* Chapter 36). Inhibition of COX-1 in gastric epithelial cells depresses mucosal cytoprotective prostaglandins, especially PGI₂ and PGE₂. These eicosanoids inhibit acid secretion by the stomach, enhance mucosal blood flow, and promote the secretion of cytoprotective mucus in the intestine. Inhibition of PGI₂ and PGE₂ synthesis may render the stomach more susceptible to damage and can occur with oral, parenteral, or transdermal administration of aspirin or NSAIDs. There is some evidence that COX-2 also contributes to constitutive formation of these prostaglandins by human gastric epithelium; products of COX-2 certainly contribute to ulcer healing in rodents (Mizuno *et al.*, 1997). This may partly reflect an impairment of angiogenesis by the inhibitors (Jones *et al.*, 1999). Indeed, coincidental deletion or inhibition of both COX-1 and COX-2 seems necessary to replicate NSAID-induced gastropathy in mice, and there is some evidence for gastric pathology in the face of prolonged inhibition

or deletion of COX-2 alone (Sigthorsson *et al.*, 2002). Another mechanism by which NSAIDs or aspirin may cause ulceration is by local irritation from contact of orally administered drug with the gastric mucosa. Local irritation allows backdiffusion of acid into the gastric mucosa and induces tissue damage. It also is possible that enhanced generation of lipoxygenase products (*e.g.*, LTs) contributes to ulcerogenicity in patients treated with NSAIDs.

Coadministration of the PGE₁ analog *misoprostol* or proton pump inhibitors (PPIs), which now are available over the counter in the United States, in conjunction with NSAIDs can be beneficial in the prevention of duodenal and gastric ulceration (Rostom *et al.*, 2002). While a combination of aspirin with a selective COX-2 inhibitor will undermine its distinction from a tNSAID with respect to serious GI complications, we do not know if the combination retains an advantage over aspirin plus a tNSAID.

Cardiovascular. Given their relatively short half-lives, tNSAIDs, unlike aspirin, are not thought to afford cardioprotection, and most epidemiological overviews are consistent with this likelihood (Garcia Rodriguez *et al.*, 2004). An exception in some individuals may be naproxen. Although there is considerable variation, a small study suggests that platelet inhibition might be anticipated throughout the dosing interval in some but not all individuals on naproxen (Capone *et al.*, 2004). Epidemiological evidence of cardioprotection is less impressive; it suggests about a 10% reduction in myocardial infarction, compared to 20% to 25% with low-dose aspirin. This would fit with heterogeneity of response to naproxen. Reliance on prescription databases may have constrained the ability of this approach to address the question with precision. Controlled evaluation of naproxen in cardioprotection has not been performed, and naproxen should not be used as a substitute for aspirin for this purpose. Several groups have attached nitric oxide-donating moieties to NSAIDs and to aspirin in the hope of reducing the incidence of adverse events. It seems likely that benefit may be attained by abrogation of the inhibition of angiogenesis by tNSAIDs during ulcer healing in rodents (Ma *et al.*, 2002). However, the clinical benefit of this strategy remains to be established. Similarly, LTs may accumulate in the presence of COX inhibition, and there is some evidence in rodents that combined lipoxygenase (LOX)-COX inhibition may be a useful strategy. Combined inhibitors are under clinical evaluation (Charlier and Michaux, 2003).

Selective inhibitors of COX-2 depress PGI₂ formation by endothelial cells without concomitant inhibition of platelet thromboxane. Experiments in mice suggest that PGI₂ restrains the cardiovascular effects of TXA₂, affording a mechanism by which selective inhibitors might increase the risk of thrombosis (McAdam *et al.*, 1999; Catella-Lawson *et al.*, 1999). This mechanism should pertain to individuals otherwise at risk of thrombosis, such as those with rheumatoid arthritis, as the relative risk of myocardial infarction is increased in these patients compared to patients with osteoarthritis or no arthritis. The incidence of myocardial infarction and stroke has diverged in such at-risk patients when COX-2 inhibitors are compared with tNSAIDs (FitzGerald, 2003). Placebo-controlled trials have now revealed an increased incidence of myocardial infarction and stroke in patients treated with rofecoxib (Bresalier *et al.*, 2005), valdecoxib (Nussmeier *et al.*, 2005), and celecoxib (Solomon *et al.*, 2005) consistent with a mechanism-based cardiovascular hazard for the class (FitzGerald, 2003). Regulatory agencies in the United States, Europe, and Australia have reviewed these studies and other available evidence and have concluded that all three drugs

increase the risk of heart attack and stroke and will be labeled accordingly and restricted with respect to marketing directly to consumers. Patients at increased risk of cardiovascular disease or thrombosis are particularly prone to cardiovascular adverse events on these agents.

Blood Pressure, Renal, and Renovascular Adverse Events. tNSAIDs and COX-2 inhibitors have been associated with renal and renovascular adverse events (Cheng and Harris, 2004). NSAIDs have little effect on renal function or blood pressure in normal human subjects. However, in patients with congestive heart failure, hepatic cirrhosis, chronic kidney disease, hypovolemia, and other states of activation of the sympathoadrenal or renin-angiotensin systems, prostaglandin formation becomes crucial in model systems and in humans (Patrono and Dunn, 1987). NSAIDs are associated with loss of the prostaglandin-induced inhibition of both the reabsorption of Cl^- and the action of antidiuretic hormone, leading to the retention of salt and water. Experiments in mice that attribute the generation of vasodilator prostaglandins (PGE_2 and PGI_2) to COX-2 raise the likelihood that the incidence of hypertensive complications (either new onset or worsened control) induced by NSAIDs in patients may correlate with the degree of inhibition of COX-2 in the kidney and the selectivity with which it is attained (Qi *et al.*, 2002). Deletion of receptors for both PGI_2 and PGE_2 elevate blood pressure in mice, mechanistically integrating hypertension with a predisposition to thrombosis. Although this hypothesis has never been addressed directly, epidemiological studies suggest hypertensive complications occur more commonly in patients treated with coxibs than with tNSAIDs.

NSAIDs promote reabsorption of K^+ as a result of decreased availability of Na^+ at distal tubular sites and suppression of the prostaglandin-induced secretion of renin. The latter effect may account in part for the usefulness of NSAIDs in the treatment of Bartter's syndrome (*see above*).

Analgesic Nephropathy. Analgesic nephropathy is a condition of slowly progressive renal failure, decreased concentrating capacity of the renal tubule, and sterile pyuria. Risk factors are the chronic use of high doses of combinations of NSAIDs and frequent urinary tract infections. If recognized early, discontinuation of NSAIDs permits recovery of renal function.

Pregnancy and Lactation. In the hours before parturition, there is induction of myometrial COX-2 expression, and levels of prostaglandin E_2 and $\text{F}_{2\alpha}$ increase markedly in the myometrium during labor (Slater *et al.*, 2002). Prolongation of gestation by NSAIDs has been demonstrated in model systems and in humans. Some NSAIDs, particularly indomethacin, have been used off-label to terminate preterm labor. However, this use is associated with closure of the ductus arteriosus and impaired fetal circulation *in utero*, particularly in fetuses older than 32 weeks' gestation. COX-2-selective inhibitors have been used as tocolytic agents; this use has been associated with stenosis of the ductus arteriosus and oligohydramnios. Finally, the use of NSAIDs and aspirin late in pregnancy may increase the risk of postpartum hemorrhage. Therefore pregnancy, especially close to term, is a relative contraindication to the use of all NSAIDs, and their use must be weighed against potential fetal risk, even in cases of premature labor, and especially in cases of pregnancy-induced hypertension, where they have been used with questionable effect (Duley *et al.*, 2004).

Hypersensitivity. Certain individuals display hypersensitivity to aspirin and NSAIDs, as manifested by symptoms that range from vasomotor rhinitis with profuse watery secretions, angioede-

ma, generalized urticaria, and bronchial asthma to laryngeal edema, bronchoconstriction, flushing, hypotension, and shock. Aspirin intolerance is a contraindication to therapy with any other NSAID because cross-sensitivity can provoke a life-threatening reaction reminiscent of anaphylactic shock. Despite the resemblance to anaphylaxis, this reaction does not appear to be immunological in nature.

Although less common in children, this syndrome may occur in 10% to 25% of patients with asthma, nasal polyps, or chronic urticaria, and in 1% of apparently healthy individuals. It is provoked by even low doses (<80 mg) of aspirin and apparently involves COX inhibition. Cross-sensitivity extends to other salicylates, structurally dissimilar NSAIDs, and rarely acetaminophen (*see below*). Treatment of aspirin hypersensitivity is similar to that of other severe hypersensitivity reactions, with support of vital organ function and administration of epinephrine. Aspirin hypersensitivity is associated with an increase in biosynthesis of LTs, perhaps reflecting diversion of AA to lipoxygenase metabolism. Indeed, results in a small number of patients suggest that blockade of 5-lipoxygenase with the drug *zileuton* (no longer marketed in the United States) or use of the leukotriene receptor antagonists may ameliorate the symptoms and signs of aspirin intolerance, albeit incompletely.

Aspirin Resistance. All forms of treatment failure with aspirin have been collectively called "aspirin resistance." Although this has attracted much attention, there is little information concerning the prevalence of a stable, aspirin-specific resistance or the precise mechanisms that might convey this "resistance." Genetic variants of COX-1 that cosegregate with resistance have been described, but the relation to clinical outcome is not clear.

Drug Interactions

Concomitant NSAIDs and Low-Dose Aspirin. Many patients combine either tNSAIDs or COX-2 inhibitors with "cardioprotective" low-dose aspirin. Epidemiological studies suggest that this combination therapy increases significantly the likelihood of gastrointestinal adverse events over either class of NSAID alone.

Prior occupancy of the active site of platelet COX-1 by the commonly consumed tNSAID ibuprofen impedes access of aspirin to its target Ser 529 and prevents irreversible inhibition of platelet inhibition (Catella-Lawson *et al.*, 2001). Epidemiological studies have provided conflicting data as to whether this adversely impacts clinical outcomes, but they generally are constrained by the use of prescription databases to examine an interaction between two drug groups commonly obtained without prescription. Evidence in support of this interaction has been observed in comparing ibuprofen-treated patients with and without aspirin in two coxib outcome studies (CLASS and TARGET), but the trials were not powered to address this question definitively. In theory, this interaction should not occur with selective COX-2 inhibitors, because mature human platelets lack COX-2.

Other Drug Interactions. Angiotensin-converting enzyme (ACE) inhibitors act, at least partly, by preventing the breakdown of kinins that stimulate prostaglandin pro-

duction. Thus, it is logical that NSAIDs might attenuate the effectiveness of ACE inhibitors by blocking the production of vasodilator and natriuretic prostaglandins. Due to hyperkalemia, the combination of NSAIDs and ACE inhibitors also can produce marked bradycardia leading to syncope, especially in the elderly and in patients with hypertension, diabetes mellitus, or ischemic heart disease. NSAIDs may increase the frequency or severity of gastrointestinal ulceration when combined with corticosteroids and augment the risk of bleeding in patients receiving *warfarin*. Many NSAIDs are highly bound to plasma proteins and thus may displace other drugs from their binding sites. Such interactions can occur in patients given salicylates or other NSAIDs together with *warfarin*, sulfonylurea hypoglycemic agents, or *methotrexate*; the dosage of such agents may require adjustment to prevent toxicity. The problem with *warfarin* is accentuated, both because almost all NSAIDs suppress normal platelet function and because some NSAIDs also increase *warfarin* levels by interfering with its metabolism; thus, concurrent administration should be avoided.

Pharmacokinetics and Pharmacodynamics. Most of the NSAIDs are rapidly and completely absorbed from the gastrointestinal tract, with peak concentrations occurring within 1 to 4 hours. Aspirin begins to acetylate platelets within minutes of reaching the presystemic circulation. The presence of food tends to delay absorption without affecting peak concentration. Most NSAIDs are extensively protein-bound (95% to 99%) and undergo hepatic metabolism and renal excretion. In general, NSAIDs are not recommended in the setting of advanced hepatic or renal disease due to their adverse pharmacodynamic effects (*see below*). Many NSAIDs metabolized by hepatic CYPs are subject to circadian variation in their metabolic disposition; however, the implications of this observation are not clear.

Other Clinical Considerations in the Rational Selection of Therapy. The choice of an agent for use as an antipyretic or analgesic is seldom a problem. Drugs with more rapid onset of action and shorter duration of action probably are preferable for simple fevers accompanying minor viral illnesses or pain after minor musculoskeletal injuries, whereas a longer duration of action may be preferable for postoperative pain management. Sometimes a loading dose of such NSAIDs may be required.

The choice among tNSAIDs for the treatment of chronic arthritic conditions such as rheumatoid arthritis largely is empirical. Substantial differences in response have been noted among individuals treated with the same tNSAID and within an individual treated with different tNSAIDs, even when the drugs are structurally related. It

is reasonable to give a drug for a week or two as a therapeutic trial and to continue it if the response is satisfactory. Initially, all patients should be asked about previous hypersensitivity to aspirin or any member of the NSAID class. Thereafter, low doses of the chosen agent should be prescribed to determine initial patient tolerance. Doses then may be adjusted to maximize efficacy or minimize adverse effects.

Adverse effects usually become manifest in the first weeks of therapy, although gastric ulceration and bleeding may present much later. If the patient does not achieve therapeutic benefit from one NSAID, another should be tried. It is best to avoid combination therapy with more than one NSAID. There is little evidence of extra benefit for the patient, and the risk of side effects is at least additive.

Placebo-controlled trials have now established that at least three selective inhibitors of COX-2—rofecoxib, valdecoxib, and celecoxib—confer an increased risk of heart attack and stroke. This would be expected to complicate treatment with newer, highly selective agents, such as lumiracoxib and etoricoxib, although definitive information is not yet available. However, of more immediate concern are some tNSAIDs, such as meloxicam and diclofenac, which resemble celecoxib in terms of their selectivity. Evidence for hazard with both drugs has been suggested from observational studies, but controlled trials to address this hypothesis have not been performed. The cardiovascular hazard from both celecoxib and rofecoxib—the two inhibitors for which data are available from placebo-controlled trials lasting more than 1 year—increased with chronicity of dosing. This is consistent with a mechanism-based acceleration of atherogenesis directly *via* inhibition of PGI₂ and indirectly due to the rise in blood pressure consequent to inhibition of COX-2 derived PGE₂ and PGI₂.

If COX-2 inhibitors are selected, they should be used at the lowest possible dose for the shortest period of time, and patients at risk of cardiovascular disease or prone to thrombosis should not be treated with these drugs. Small absolute risks of thrombosis attributable to these drugs may interact geometrically with small absolute risks from genetic variants like factor V Leiden or concomitant therapies, such as the anovulant pill.

A final important consideration in the selection of an NSAID is the cost of therapy, particularly since these agents frequently are used chronically.

Other forms of antiarthritic therapy should be considered for the seriously debilitated arthritis patient who cannot tolerate these drugs or in whom they are not adequately effective. Gold is dis-

cussed briefly in a separate section of this chapter. Other relevant drugs are discussed in separate chapters and include immunosuppressive agents, glucocorticoids, biologic agents including cytokine receptor inhibitors, antimalarials, and penicillamine.

For mild arthropathies, the scheme outlined above, together with rest and physical therapy, probably will be effective. When the patient has problems sleeping because of pain or morning stiffness, a larger single dose of the drug may be given at night. However, patients with more debilitating disease may not respond adequately, prompting the initiation of more aggressive therapy.

The choice of drugs for children is considerably restricted, and only drugs that have been extensively tested in children should be used. This commonly points towards naproxen and ibuprofen. The COX-2-selective inhibitor rofecoxib was approved by the FDA for juvenile rheumatoid arthritis but since has been withdrawn from the market worldwide.

Before 1986, aspirin was used extensively in children and found to be well tolerated, but concerns were raised about its role in Reye's syndrome. Aspirin still can be used in children as an analgesic or antirheumatism agent in the absence of a viral syndrome; however, its use for these purposes also has declined markedly.

THE SALICYLATES

Despite the introduction of many new drugs, aspirin is still the most widely consumed analgesic, antipyretic, and antiinflammatory agent and is the standard for the comparison and evaluation of the others. Prodigious amounts of the drug are consumed in the United States; some estimates place the quantity as high as 10,000 to 20,000 tons annually. Aspirin is the most common household analgesic; yet, because the drug is so generally available, the possibility of misuse and serious toxicity probably is underappreciated, and it remains a cause of fatal poisoning in children. The clinical pharmacology of the salicylates has been reviewed (Amann and Peskar, 2002).

Chemistry. Salicylic acid (ortho-hydroxybenzoic acid) is so irritating that it can only be used externally; therefore various derivatives of this acid have been synthesized for systemic use. These comprise two large classes, namely esters of salicylic acid obtained from substitutions within the carboxyl group and salicylate esters of organic acids, in which the carboxyl group is retained and substitution is made in the hydroxyl group. For example, aspirin is an ester of acetic acid. In addition, there are salts of salicylic acid. The chemical relationships can be seen from the structural formulas shown in Figure 26-1.

Structure-Activity Relationships. Salicylates generally act by virtue of their content of salicylic acid, although some of the unique effects of aspirin are caused by its capacity to acetylate proteins, as described above. Substitutions on the carboxyl or hydroxyl

Figure 26-1. Structural formulas of the salicylates.

groups change the potency or toxicity of salicylates. The ortho position of the hydroxyl group is an important feature for the action of the salicylates. The effects of simple substitutions on the benzene ring have been studied extensively, and new salicylates are being synthesized. A difluorophenyl derivative, *diflunisal*, also is available for clinical use.

Pharmacological Properties of Therapeutic Doses

Analgesia. The types of pain usually relieved by salicylates are those of low intensity that arise from integumental structures rather than from viscera, especially headache, myalgia, and arthralgia. The salicylates are used more widely for pain relief than are any other classes of drugs. The salicylates alleviate pain by virtue of a peripheral action; direct effects on the CNS also may be involved.

Antipyresis. Salicylates usually lower elevated body temperatures rapidly and effectively. However, moderate doses that produce this effect also increase oxygen consumption and metabolic rate. These compounds have a pyretic effect at toxic doses, and sweating exacerbates the dehydration that occurs in salicylate intoxication (*see below*).

Respiration. Salicylates increase oxygen consumption and CO₂ production (especially in skeletal muscle) at full therapeutic doses; these effects are a result of uncoupling oxidative phosphorylation. The increased production of CO₂ stimulates respiration (mainly by an increase in depth of respiration with only a slight increase in

rate). The increased alveolar ventilation balances the increased CO₂ production, and thus plasma CO₂ tension (PCO₂) does not change or may decrease slightly.

Acid–Base and Electrolyte Balance and Renal Effects. Therapeutic doses of salicylate produce definite changes in the acid–base balance and electrolyte pattern. Compensation for the initial event, respiratory alkalosis (*see* above), is achieved by increased renal excretion of bicarbonate, which is accompanied by increased Na⁺ and K⁺ excretion; plasma bicarbonate is thus lowered, and blood pH returns toward normal. This is the stage of compensatory renal acidosis. This stage is seen most often in adults given intensive salicylate therapy and seldom proceeds further unless toxicity ensues (*see* below). Salicylates can cause retention of salt and water, as well as acute reduction of renal function in patients with congestive heart failure, renal disease, or hypovolemia. Although long-term use of salicylates alone rarely is associated with nephrotoxicity, the prolonged and excessive ingestion of analgesic mixtures containing salicylates in combination with other compounds can produce papillary necrosis and interstitial nephritis (*see* section on analgesic nephropathy, above).

Cardiovascular Effects. Low doses of aspirin (<100 mg daily) are used widely for their cardioprotective effects. At high therapeutic doses (>3 g daily), as might be given for acute rheumatic fever, salt and water retention can lead to an increase (up to 20%) in circulating plasma volume and decreased hematocrit (*via* a dilutional effect). There is a tendency for the peripheral vessels to dilate because of a direct effect on vascular smooth muscle. Cardiac output and work are increased. Those with carditis or compromised cardiac function may not have sufficient cardiac reserve to meet the increased demands, and congestive cardiac failure and pulmonary edema can occur. High doses of salicylates can produce noncardiogenic pulmonary edema, particularly in older patients who ingest salicylates regularly over a prolonged period.

Gastrointestinal Effects. The ingestion of salicylates may result in epigastric distress, nausea, and vomiting. Salicylates also may cause gastric ulceration, exacerbation of peptic ulcer symptoms (heartburn, dyspepsia), gastrointestinal hemorrhage, and erosive gastritis. These effects occur primarily with acetylated salicylates (*i.e.*, aspirin). Because nonacetylated salicylates lack the ability to acetylate cyclooxygenase and thereby irreversibly inhibit its activity, they are weaker inhibitors than aspirin.

Aspirin-induced gastric bleeding sometimes is painless, and if unrecognized may lead to iron-deficiency anemia (*see* Chapter 53). The daily ingestion of antiinflammatory doses of aspirin (4 or 5 g) results in an average fecal blood loss of between 3 and 8 ml per day, as compared with approximately 0.6 ml per day in untreated subjects. Gastroscopic examination of aspirin-treated subjects often reveals discrete ulcerative and hemorrhagic lesions of the gastric mucosa; in many cases, multiple hemorrhagic lesions with sharply demarcated areas of focal necrosis are observed. The incidence of bleeding may be higher with salicylates that dissolve slowly and deposit as particles in the gastric mucosal folds.

Hepatic Effects. Salicylates can cause hepatic injury, usually in patients treated with high doses of salicylates that result in plasma

concentrations of more than 150 µg/ml. The injury is not an acute effect; rather, the onset characteristically occurs after several months of treatment. The majority of cases occur in patients with connective tissue disorders. There usually are no symptoms, simply an increase in serum levels of hepatic transaminases, but some patients note right upper quadrant abdominal discomfort and tenderness. Overt jaundice is uncommon. The injury usually is reversible upon discontinuation of salicylates. However, the use of salicylates is contraindicated in patients with chronic liver disease. Considerable evidence, as discussed above, implicates the use of salicylates as an important factor in the severe hepatic injury and encephalopathy observed in Reye's syndrome.

Uricosuric Effects. The effects of salicylates on uric acid excretion are markedly dependent on dose. Low doses (1 or 2 g per day) may decrease urate excretion and elevate plasma urate concentrations; intermediate doses (2 or 3 g per day) usually do not alter urate excretion; large doses (more than 5 g per day) induce uricosuria and lower plasma urate levels. However, such large doses are tolerated poorly. Even small doses of salicylate can block the effects of *probenecid* and other uricosuric agents that decrease tubular reabsorption of uric acid.

Effects on the Blood. Ingestion of aspirin by healthy individuals prolongs the bleeding time. For example, a single 325-mg dose of aspirin approximately doubles the mean bleeding time of normal persons for a period of 4 to 7 days. This effect is due to irreversible acetylation of platelet cyclooxygenase and the consequent reduced formation of TXA₂ until sufficient numbers of new, unmodified platelets are produced from megakaryocyte precursors.

Patients with severe hepatic damage, hypoprothrombinemia, vitamin K deficiency, or hemophilia should avoid aspirin because the inhibition of platelet hemostasis can result in hemorrhage. If possible, aspirin therapy should be stopped at least 1 week before surgery; care also should be exercised in the use of aspirin during long-term treatment with oral anticoagulant agents because of the combined danger of prolongation of bleeding time coupled with blood loss from the gastric mucosa. On the other hand, aspirin is used widely for the prophylaxis of thromboembolic disease, especially in the coronary and cerebral circulation, and is coupled frequently with oral anticoagulants in patients with bioprosthetic or mechanical heart valves (*see* Chapter 54).

Salicylates do not ordinarily alter the leukocyte or platelet count, the hematocrit, or the hemoglobin content. However, doses of 3 to 4 g per day markedly decrease plasma iron concentration and shorten erythrocyte survival time. Aspirin can cause a mild degree of hemolysis in individuals with a deficiency of glucose-6-phosphate dehydrogenase. As noted above (*Cardiovascular Effects*), high doses (>3 g daily) can expand plasma volume and decrease hematocrit by dilution.

Effects on Rheumatic, Inflammatory, and Immunological Processes and on Connective Tissue Metabolism. Although salicylates suppress clinical signs and even improve the histological picture in acute rheumatic fever, subsequent tissue damage, such as cardiac lesions and other visceral involvement, is unaffected by salicylate therapy. In addition to their effect on prostaglandin biosynthesis, the mechanism of action of the salicylates in rheumatic disease also may involve effects on other cellular and immunological processes in mesenchymal and connective tissues.

Because of the known relationship between rheumatic fever and immunological processes, attention has been directed to the capacity of salicylates to suppress a variety of antigen-antibody reactions. These include the inhibition of antibody production, of antigen-antibody aggregation, and of antigen-induced release of histamine. Salicylates also induce a nonspecific stabilization of capillary permeability during immunological insults. The concentrations of salicylates needed to produce these effects are high, and the relationship of these effects to the antirheumatic efficacy of salicylates is not clear.

Salicylates also can influence the metabolism of connective tissue, and these effects may be involved in their antiinflammatory action. For example, salicylates can affect the composition, biosynthesis, or metabolism of connective tissue mucopolysaccharides in the ground substance that provides barriers to the spread of infection and inflammation.

Metabolic Effects. Oxidative Phosphorylation. The uncoupling of oxidative phosphorylation by salicylates is similar to that induced by 2,4-dinitrophenol. The effect may occur with doses of salicylate used in the treatment of rheumatoid arthritis and can result in the inhibition of a number of ATP-dependent reactions. Other consequences include the salicylate-induced increase in O_2 uptake and CO_2 production (described above), the depletion of hepatic glycogen, and the pyretic effect of toxic doses of salicylate (*see below*). Salicylates in toxic doses may decrease aerobic metabolism and increase the production of strong organic acids.

Carbohydrate Metabolism. Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen.

Endocrine Effects. Long-term administration of salicylates decreases thyroidal uptake and clearance of iodine, but increases O_2 consumption and the rate of disappearance of thyroxine and triiodothyronine from the circulation. These effects probably are caused by the competitive displacement by salicylate of thyroxine and triiodothyronine from transthyretin and the thyroxine-binding globulin in plasma (*see Chapter 56*).

Salicylates and Pregnancy. There is no evidence that moderate therapeutic doses of salicylates are teratogenic in human beings; however, babies born to women who ingest salicylates for long periods may have significantly reduced birth weights. When administered during the third trimester there also is an increase in perinatal mortality, anemia, antepartum and postpartum hemorrhage, prolonged gestation, and complicated deliveries; thus, its use during this period should be avoided. As mentioned previously, administration of NSAIDs during the third trimester of pregnancy also can cause premature closure of the ductus arteriosus. The use of aspirin has been advocated for the treatment of women at high risk of preeclampsia, but it is estimated that treatment of 90 women is required to prevent one case of preeclampsia (Villar *et al.*, 2004).

Local Irritant Effects. Salicylic acid is irritating to skin and mucosa and destroys epithelial cells. The keratolytic action of the free acid is employed for the local treatment of warts, corns, fungal infections, and certain types of eczematous dermatitis. After treatment with salicylic acid, tissue cells swell, soften, and desquamate. *Methyl salicylate (oil of wintergreen)* is irritating to skin and gastric mucosa and is used as a counter-irritant for the relief of mild musculoskeletal pain.

Pharmacokinetics. Absorption. Orally ingested salicylates are absorbed rapidly, partly from the stomach but mostly from the upper small intestine. Appreciable concentrations are found in plasma in less than 30 minutes; after a single dose, a peak value is reached in about 1 hour and then declines gradually. The rate of absorption is determined by many factors, particularly the disintegration and dissolution rates of the tablets administered, the pH at the mucosal surface, and gastric emptying time.

Salicylate absorption occurs by passive diffusion primarily of nondissociated salicylic acid or acetylsalicylic acid across gastrointestinal membranes and hence is influenced by gastric pH. Even though salicylate is more ionized as the pH is increased, a rise in pH also increases the solubility of salicylate and thus dissolution of the tablets. The overall effect is to enhance absorption. As a result, there is little meaningful difference between the rates of absorption of sodium salicylate, aspirin, and the numerous buffered preparations of salicylates. The presence of food delays absorption of salicylates. Rectal absorption of salicylate usually is slower than oral absorption and is incomplete and inconsistent.

Salicylic acid is absorbed rapidly from the intact skin, especially when applied in oily liniments or ointments, and systemic poisoning has occurred from its application to large areas of skin. Methyl salicylate likewise is speedily absorbed when applied cutaneously; however, its gastrointestinal absorption may be delayed many hours, making gastric lavage effective for removal even in poisonings that present late after oral ingestion.

Distribution. After absorption, salicylates are distributed throughout most body tissues and transcellular fluids, primarily by pH-dependent passive processes. Salicylates are transported actively by a low-capacity, saturable system out of the CSF across the choroid plexus. The drugs readily cross the placental barrier.

The volume of distribution of usual doses of aspirin and sodium salicylate in normal subjects averages about 170 ml/kg of body weight; at high therapeutic doses, this volume increases to about 500 ml/kg because of saturation of binding sites on plasma proteins. Ingested aspirin mainly is absorbed as such, but some enters the systemic circulation as salicylic acid after hydrolysis by esterases in the gastrointestinal mucosa and liver. Aspirin can be detected in the plasma only for a short time as a result of hydrolysis in plasma, liver, and erythrocytes; for example, 30 minutes after a dose of 0.65 g, only 27% of the total plasma salicylate is in the acetylated form. Methyl salicylate also is hydrolyzed rapidly to salicylic acid, mainly in the liver.

Roughly 80% to 90% of the salicylate in plasma is bound to proteins, especially albumin, at concentrations encountered clinically; the proportion of the total that is bound declines as plasma concentrations increase. Hypoalbuminemia, as may occur in rheumatoid arthritis, is associated with a proportionately higher level of free salicylate in the plasma. Salicylate competes with a variety of compounds for plasma protein binding sites; these include *thyroxine, triiodothyronine, penicillin, phenytoin, sulfapyrazone, bilirubin, uric acid, and other NSAIDs such as naproxen*. Aspirin is bound to a more limited extent; however, it acetylates human plasma albumin *in vivo* by reaction with the ϵ -amino group of lysine and may change the binding of other drugs to albumin. Aspirin also acetylates hormones, DNA, and hemoglobin and other proteins.

Biotransformation and Excretion. The biotransformation of salicylates takes place in many tissues, but particularly in the hepatic endoplasmic reticulum and mitochondria. The three chief metabol-

ic products are salicylic acid (the glycine conjugate), the ether or phenolic glucuronide, and the ester or acyl glucuronide. In addition, a small fraction is oxidized to gentisic acid (2,5-dihydroxybenzoic acid) and to 2,3-dihydroxybenzoic and 2,3,5-trihydroxybenzoic acids; gentisuric acid, the glycine conjugate of gentisic acid, also is formed.

Salicylates are excreted in the urine as free salicylic acid (10%), salicylic acid (75%), salicylic phenolic (10%) and acyl glucuronides (5%), and gentisic acid (less than 1%). However, excretion of free salicylates is extremely variable and depends upon the dose and the urinary pH. In alkaline urine, more than 30% of the ingested drug may be eliminated as free salicylate, whereas in acidic urine this may be as low as 2%.

The plasma half-life for aspirin is about 20 minutes, and for salicylate 2 to 3 hours at antiplatelet doses, rising to 12 hours at usual antiinflammatory doses. The half-life of salicylate may be as long as 15 to 30 hours at high therapeutic doses or when there is intoxication. This dose-dependent elimination is the result of the limited capacity of the liver to form salicylic acid and the phenolic glucuronide, resulting in a larger proportion of unchanged drug being excreted in the urine at higher doses.

Relationship of Plasma Salicylate Concentration to Therapeutic and Common Adverse Effects and Toxicity. Aspirin is one of the NSAIDs for which plasma salicylate can provide a means to monitor therapy and toxicity. Intermittent analgesic-antipyretic doses of aspirin typically produce plasma aspirin levels of less than 20 $\mu\text{g/ml}$ and plasma salicylate levels of below 60 $\mu\text{g/ml}$. The daily ingestion of antiinflammatory doses of 4 to 5 g of aspirin produces plasma salicylate levels in the range of 120 to 350 $\mu\text{g/ml}$ (Table 26-1). Optimal antiinflammatory effects for patients with rheumatic diseases require plasma salicylate concentrations of 150 to 300 $\mu\text{g/ml}$. Significant adverse effects can be seen at levels of more than 300 $\mu\text{g/ml}$. Hyperventilation generally occurs at concentrations greater than 350 $\mu\text{g/ml}$ and other signs of intoxication, such as acidosis, at concentrations greater than 460 $\mu\text{g/ml}$. In the lower part of the range, the drug clearance is nearly constant (despite the fact that saturation of metabolic capacity is approached) because the fraction of drug that is free, and thus available for metabolism or excretion, increases as binding sites on plasma proteins are saturated. The total concentration of salicylate in plasma is thus a relatively linear function of dose at lower concentrations. At higher concentrations, however, as metabolic pathways of disposition become saturated, small increments in dose can disproportionately increase plasma salicylate concentration. Failure to anticipate this phenomenon can lead to toxicity. Since the range of plasma salicylate concentrations needed for optimal efficacy may overlap with those at which tinnitus (ringing of the ears) is noted, it is especially important to individualize antiinflammatory doses of aspirin. Tinnitus may be a reliable index of exceeding the acceptable plasma concentration in patients with normal hearing, but is not a reliable indicator in patients with preexisting hearing loss; thus, surveillance for this symptom is no substitute for periodic monitoring of serum salicylate levels.

The plasma concentration of salicylate is increased by conditions that decrease glomerular filtration rate or reduce proximal tubule secretion of salicylates, such as renal disease or the presence of inhibitors that compete for the transport system (*e.g.*, probenecid). Changes in urinary pH also have significant effects on salicylate excretion. For example, the clearance of salicylate is

about four times as great at pH 8 as at pH 6, and it is well above the glomerular filtration rate at pH 8. High rates of urine flow decrease tubular reabsorption, whereas the opposite is true in oliguria. The conjugates of salicylic acid with glycine and glucuronic acid do not readily back-diffuse across the renal tubular cells. Their excretion, therefore, is by glomerular filtration and proximal tubular secretion but is not pH dependent.

Therapeutic Uses

Systemic Uses. The two most commonly used preparations of salicylate for systemic effects are aspirin (acetylsalicylic acid) and sodium salicylate. The dose of salicylate depends on the condition being treated.

Other salicylates available for systemic use include *salsalate* (*salicylsalicylic acid*; DISALCID, others), which is hydrolyzed to salicylic acid during and after absorption, *sodium thiosalicylate* (injection; REXOLATE), *choline salicylate* (oral liquid; ARTHROPAN), and *magnesium salicylate* (tablets; MAGAN, MOMENTUM, others). A combination of choline and magnesium salicylates (*choline magnesium, trisalicylate*, TRILISATE, others) also is available. Diflunisal (DOLOBID) is discussed below.

Antipyresis. Antipyretic therapy is reserved for patients in whom fever in itself may be deleterious and for those who experience considerable relief when fever is lowered. Little is known about the relationship between fever and the acceleration of inflammatory or immune processes; it may at times be a protective physiological mechanism. The course of the patient's illness may be obscured by the relief of symptoms and the reduction of fever by the use of antipyretic drugs. The antipyretic dose of salicylate for adults is 325 mg to 650 mg orally every 4 hours. Salicylates are contraindicated for fever associated with viral infection in children; for nonviral etiologies, 50 to 75 mg/kg per day has been given in four to six divided doses, not to exceed a total daily dose of 3.6 g. The route of administration nearly always is oral; parenteral administration (with sodium thiosalicylate) is rarely necessary. The rectal administration of aspirin suppositories may be necessary in infants or when the oral route is unavailable.

Analgesia. Salicylates are valuable for the nonspecific relief of minor aches and pain (*e.g.*, headache, arthritis, dysmenorrhea, neuralgia, and myalgia). For this purpose, they are prescribed in the same doses and manner as for antipyresis.

Rheumatoid Arthritis. Although aspirin is regarded as the standard against which other drugs should be compared for the treatment of rheumatoid arthritis, many clinicians favor the use of other NSAIDs perceived to have better gastrointestinal tolerability, even though this perception remains unproven by convincing clinical trials. As for NSAIDs, therapy with salicylates produces analgesia adequate to allow more effective movement and physical therapy in osteoarthritis and rheumatoid arthritis. In addition, aspirin therapy is associated with improvement in appetite, a feeling of well-being, and a reduction in the inflammation in joint tissues and surrounding structures. Patients with progressive or resistant disease require therapy with more toxic, second-line drugs, such as antimalarials, penicillamine, glucocorticoids, methotrexate, or immunosuppressive agents. In the United States, methotrexate is the second-line drug used most frequently, while in Europe, *sulfasalazine* is generally preferred.

Drug Interactions. The plasma concentration of salicylates generally is little affected by other drugs, but concurrent administration of

aspirin lowers the concentrations of indomethacin, naproxen, ketoprofen, and *fenoprofen*, at least in part by displacement from plasma proteins. Important adverse interactions of aspirin with warfarin, sulfonyleureas, and methotrexate are mentioned above. Other interactions of aspirin include the antagonism of spironolactone-induced natriuresis and the blockade of the active transport of penicillin from CSF to blood.

Local Uses. Inflammatory Bowel Disease. *Mesalamine* (5-aminosalicylic acid; ASACOL, others) is a salicylate that is used for its local effects in the treatment of inflammatory bowel disease (see Chapter 38). The drug is not effective orally because it is poorly absorbed and is inactivated before reaching the lower intestine. It currently is available as a suppository and rectal suspension enema (ROWASA) for treatment of mild to moderate proctosigmoiditis; a rectal suppository (CANASA, others) for the treatment of distal ulcerative colitis, proctosigmoiditis, or proctitis. Two oral formulations that deliver drug to the lower intestine, *olsalazine* (sodium azodisalicylate, a dimer of 5-aminosalicylate linked by an azo bond; DIPENTUM) and *mesalamine* formulated in a pH-sensitive polymer-coated oral preparation (ASACOL) and controlled-release capsule (PENTASA), are efficacious in treatment of inflammatory bowel disease, in particular ulcerative colitis. Sulfasalazine (sali-cylazosulfapyridine; AZULFIDINE) contains *mesalamine* linked covalently to sulfapyridine (see Chapter 38); it is absorbed poorly after oral administration, but it is cleaved to its active components by bacteria in the colon. The drug is of benefit in the treatment of inflammatory bowel disease, principally because of the local actions of *mesalamine*. Sulfasalazine and *olsalazine* also have been used in the treatment of rheumatoid arthritis and ankylosing spondylitis.

Salicylate Intoxication. Salicylate poisoning or serious intoxication often occurs in children and sometimes is fatal. The drugs should not be viewed as harmless household remedies, and salicylate intoxication should be seriously considered in any young child with coma, convulsions, or cardiovascular collapse. The fatal dose varies with the preparation of salicylate. Death has followed use of 10 to 30 g of sodium salicylate or aspirin in adults, but much larger amounts (130 g of aspirin in one case) have been ingested without a fatal outcome. The lethal dose of methyl salicylate (oil of wintergreen, sweet birch oil, gaultheria oil, betula oil) is considerably less than that of sodium salicylate. As little as 4 ml (4.7 g) of methyl salicylate may be fatal in children. Symptoms of poisoning by methyl salicylate differ little from those described below for aspirin. Central excitation, intense hyperpnea, and hyperpyrexia are prominent features. The odor of the drug can be detected easily on the breath and in the urine and vomitus. Poisoning by salicylic acid differs only in the increased prominence of GI symptoms due to the marked local irritation.

Salicylism. Mild chronic salicylate intoxication is called *salicylism*. When fully developed, the syndrome includes headache, dizziness, tinnitus, difficulty hearing, dimness of vision, mental confusion, lassitude, drowsiness, sweating, thirst, hyperventilation, nausea, vomiting, and occasionally diarrhea.

Neurological Effects. In high doses, salicylates have toxic effects on the CNS, consisting of stimulation (including convulsions) followed by depression. Confusion, dizziness, tinnitus, high-tone deafness,

delirium, psychosis, stupor, and coma may occur. The tinnitus and hearing loss of salicylate poisoning are caused by increased labyrinthine pressure or an effect on the hair cells of the cochlea, perhaps secondary to vasoconstriction in the auditory microvasculature. Tinnitus typically is observed at plasma salicylate concentrations of 200 to 450 $\mu\text{g/ml}$, and there is a close relationship between the extent of hearing loss and plasma salicylate concentration. An occasional patient may note tinnitus at lower plasma concentrations of salicylate. Tinnitus generally resolves within 2 or 3 days after withdrawal of the drug.

Salicylates induce nausea and vomiting, which result from stimulation of sites that are accessible from the CSF, probably in the medullary chemoreceptor trigger zone. In humans, centrally induced nausea and vomiting generally appear at plasma salicylate concentrations of about 270 $\mu\text{g/ml}$, but these same effects may occur at much lower plasma levels as a result of local gastric irritation.

Respiration. The respiratory effects of salicylates contribute to the serious acid-base balance disturbances that characterize poisoning by this class of compounds. Salicylates stimulate respiration directly and indirectly. Uncoupling of oxidative phosphorylation leads to increased peripheral CO_2 production and a compensatory increase in minute ventilation, usually with no overall change in PCO_2 . Uncoupling of oxidative phosphorylation also leads to excessive heat production, and salicylate toxicity is associated with hyperthermia, particularly in children.

Salicylates directly stimulate the respiratory center in the medulla. This is characterized by an increase in depth and a pronounced increase in respiration rate. Patients with salicylate poisoning may have prominent increases in respiratory minute volume, and respiratory alkalosis ensues. This can be seen with plasma salicylate concentrations of 350 $\mu\text{g/ml}$, and marked hyperventilation occurs when the level approaches 500 $\mu\text{g/ml}$. However, should salicylate toxicity be associated with the coadministration of a barbiturate or opioid (e.g., FIORINAL or DARVON COMPOUND 32), then central respiratory depression will prevent hyperventilation, and the salicylate-induced uncoupling of oxidative phosphorylation will be associated with a marked increase in plasma PCO_2 and respiratory acidosis.

Prolonged exposure to high doses of salicylates leads to depression of the medulla, with central respiratory depression and circulatory collapse, secondary to vasomotor depression. Because enhanced CO_2 production continues, respiratory acidosis ensues. Respiratory failure is the usual cause of death in fatal cases of salicylate poisoning.

Acid-Base Balance and Electrolytes. As described above, high therapeutic doses of salicylate are associated with a primary respiratory alkalosis and compensatory renal acidosis. Subsequent changes in acid-base status generally occur only when toxic doses of salicylates are ingested by infants and children or occasionally after large doses in adults.

The phase of primary respiratory alkalosis rarely is recognized in children with salicylate toxicity. They usually present in a state of mixed respiratory and renal acidosis, characterized by a decrease in blood pH, a low plasma bicarbonate concentration, and normal or nearly normal plasma PCO_2 . Direct salicylate-induced depression of respiration prevents adequate respiratory hyperventilation to match the increased peripheral production of CO_2 . Consequently, plasma PCO_2 increases and blood pH decreases. Because

the concentration of bicarbonate in plasma already is low due to increased renal bicarbonate excretion, the acid–base status at this stage essentially is an uncompensated respiratory acidosis. Superimposed, however, is a true metabolic acidosis caused by accumulation of acids as a result of three processes. First, toxic concentrations of salicylates displace about 2 to 3 mEq per liter of plasma bicarbonate. Second, vasomotor depression caused by toxic doses of salicylates impairs renal function, with consequent accumulation of sulfuric and phosphoric acids. Third, salicylates in toxic doses may decrease aerobic metabolism as a result of inhibition of various enzymes. This derangement of carbohydrate metabolism leads to the accumulation of organic acids, especially pyruvic, lactic, and acetoacetic acids.

The same series of events also causes alterations of water and electrolyte balance. The low plasma PCO_2 leads to decreased renal tubular reabsorption of bicarbonate and increased renal excretion of Na^+ , K^+ , and water. Water also is lost by salicylate-induced sweating (especially in the presence of hyperthermia) and hyperventilation; dehydration, which can be profound, particularly in children, rapidly occurs. Because more water than electrolyte is lost through the lungs and by sweating, the dehydration is associated with hypernatremia. Prolonged exposure to high doses of salicylate also causes depletion of K^+ due to both renal and extrarenal factors.

Cardiovascular Effects. Toxic doses of salicylates lead to an exaggeration of the unfavorable cardiovascular responses seen at high therapeutic doses (*see above*), and central vasomotor paralysis occurs. Petechiae may be seen due to defective platelet function.

Metabolic Effects

Carbohydrate Metabolism. Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen; these effects are explained partly by the release of epinephrine. Such doses also reduce aerobic metabolism of glucose, increase glucose-6-phosphatase activity, and promote the secretion of glucocorticoids. There is a greater risk of hypoglycemia and subsequent permanent brain injury in children.

Nitrogen Metabolism. Salicylates in toxic doses cause a significant negative nitrogen balance, characterized by an aminoaciduria. Adrenocortical activation may contribute to the negative nitrogen balance by enhancing protein catabolism.

Fat Metabolism. Salicylates reduce lipogenesis by partially blocking incorporation of acetate into fatty acids; they also inhibit epinephrine-stimulated lipolysis in fat cells and displace long-chain fatty acids from binding sites on human plasma proteins. The combination of these effects leads to increased entry and enhanced oxidation of fatty acids in muscle, liver, and other tissues, and to decreased plasma concentrations of free fatty acids, phospholipid, and cholesterol; the oxidation of ketone bodies also is increased.

Endocrine Effects. Very large doses of salicylate stimulate steroid secretion by the adrenal cortex through an effect on the hypothalamus and transiently increase plasma concentrations of free corticosteroids by their displacement from plasma proteins. The therapeutic antiinflammatory effects of salicylate are independent of these effects.

Treatment. Salicylate poisoning represents an acute medical emergency, and death may result despite heroic efforts (Dargan *et al.*,

2002). Monitoring of salicylate levels is a useful guide to therapy but must be used in conjunction with an assessment of the patient's overall clinical condition, acid–base balance, formulation of salicylate ingested, timing, and dose.

There is no specific antidote for salicylate poisoning. Management begins with a rapid assessment (*see Chapter 64*) followed by the “A (airway), B (breathing), C (circulation), D (decontamination)” approach to medical emergencies.

Airway. Because of the need for respiratory alkalosis to compensate for the metabolic acidosis of salicylate toxicity, intubation should be avoided unless the patient demonstrates hypoventilation or obtundation.

Breathing. The use of paralytic agents and difficulty in achieving the very high minute volumes needed tend to induce respiratory acidosis in the patient. Aspirin ($\text{pK}_a = 3.5$) becomes non-ionized at an acidic pH and crosses the blood–brain barrier more readily, increasing its toxic central effects. It is the tissue rather than plasma levels that are dangerous to the patient. Noncardiogenic pulmonary edema interferes with oxygenation of the patient and high concentrations of inspired oxygen may be required.

Circulation. Aspirin poisoning leads to inappropriate vasodilation compounded by volume depletion and acidosis, which worsens vasodilation. Aggressive volume repletion with intravenous fluids should be instituted. The aim is to achieve large-volume diuresis to optimize salicylate elimination. If necessary, vasopressors (*e.g.*, norepinephrine, phenylephrine) are added.

Decontamination. Activated charcoal is used to prevent further absorption of aspirin from the GI tract. This is particularly important when enteric-coated aspirin, which has delayed absorption, has been ingested. Sodium bicarbonate should be administered to maintain the pH between 7.5 and 7.55, and if possible, the pH of the urine greater than 8. Forced alkaline diuresis maximizes salicylate elimination. Hemodialysis may be required if the above measures are inadequate, there is clinical deterioration despite therapy, or if plasma salicylate levels are greater than 1000 $\mu\text{g}/\text{ml}$. Plasma salicylate, glucose, pH, and potassium should be monitored frequently and therapy modified accordingly. Decreased CNS glucose levels may occur despite normal plasma glucose levels, and supplemental glucose should be given in cases of altered mental status, regardless of the plasma glucose levels.

Diflunisal

Diflunisal (DOLOBID) is a difluorophenyl derivative of salicylic acid (Figure 26–1).

It is almost completely absorbed after oral administration, and peak plasma concentrations occur within 2 to 3 hours. It is extensively bound to plasma albumin (99%). It is not converted to salicylic acid *in vivo*. About 90% of the drug is excreted as glucuronide conjugates, and its rate of elimination is dose-dependent. At the usual analgesic dose (500 to 750 mg per day), the plasma half-life averages between 8 and 12 hours (Davies, 1983). Diflunisal appears in the milk of lactating women.

Diflunisal is more potent than aspirin in antiinflammatory tests in animals and appears to be a competitive inhibitor of cyclooxy-

genase. However, it is largely devoid of antipyretic effects, perhaps because of poor penetration into the CNS. The drug has been used primarily as an analgesic in the treatment of osteoarthritis and musculoskeletal strains or sprains; in these circumstances it is about three to four times more potent than aspirin. The usual initial dose is 500 to 1000 mg, followed by 250 to 500 mg every 8 to 12 hours. For rheumatoid arthritis or osteoarthritis, 250 to 500 mg is administered twice daily; maintenance dosage should not exceed 1.5 g per day. Diflunisal does not produce auditory side effects and appears to cause fewer and less intense gastrointestinal and antiplatelet effects than does aspirin.

PARA-AMINOPHENOL DERIVATIVES: ACETAMINOPHEN

Acetaminophen (paracetamol; *N*-acetyl-*p*-aminophenol; **TYLENOL**, others) is the active metabolite of *phenacetin*, a so-called coal tar analgesic. (Due to its association with analgesic nephropathy, hemolytic anemia, and perhaps bladder cancer, phenacetin is no longer available for medicinal purposes.) Acetaminophen is an effective alternative to aspirin as an analgesic-antipyretic agent; however, its antiinflammatory effects are much weaker. While it is indicated for pain relief in patients with noninflammatory osteoarthritis, it is not a suitable substitute for aspirin or other NSAIDs in chronic inflammatory conditions such as rheumatoid arthritis. Acetaminophen is well tolerated and has a low incidence of gastrointestinal side effects. It is available without a prescription and is used as a common household analgesic. However, acute overdosage can cause severe hepatic damage, and the number of accidental or deliberate poisonings with acetaminophen continues to grow. Chronic use of less than 2 g/day is not typically associated with hepatic dysfunction.

History. *Acetanilide* is the parent member of this group of drugs. It was introduced into medicine in 1886 under the name *antifebrin* by Cahn and Hepp, who had discovered its antipyretic action accidentally. However, acetanilide proved to be excessively toxic. A number of chemical derivatives were developed and tested. One of the more satisfactory of these was phenacetin. It was introduced into therapy in 1887 and was extensively employed in analgesic mixtures until it was implicated in analgesic-abuse nephropathy and withdrawn in the 1980s. Discussion of its pharmacology can be found in earlier editions of this textbook.

Acetaminophen was first used in medicine by von Mering in 1893. However, it gained popularity only after 1949, when it was recognized as the major active metabolite of both acetanilide and phenacetin.

Pharmacological Properties. Acetaminophen has analgesic and antipyretic effects similar to those of aspirin. However, as mentioned above, it has only weak antiinflammatory effects and has

been thought to have a generally poor ability to inhibit COX in the presence of high concentrations of peroxides, as are found at sites of inflammation. However, this aspect of its action has not been addressed rigorously. Certainly, the most commonly consumed daily dose, 1000 mg, results in roughly 50% inhibition of both COX-1 and COX-2 in whole blood assays *ex vivo* in healthy volunteers. It has been suggested that COX inhibition might be disproportionately pronounced in the brain, explaining its antipyretic efficacy (Boutaud *et al.*, 2002; Ouellet and Percival, 2001; Catella-Lawson *et al.*, 2001). A COX-1 splice variant identified in canine brain, termed COX-3, shows some susceptibility for inhibition by acetaminophen *in vitro* (Chandrasekharan *et al.*, 2002). However, it is presently unknown if this splice variant exists in human brain or if its inhibition relates to the efficacy of acetaminophen in humans. Minor metabolites contribute significantly to the toxic effects of acetaminophen (*see below*). The pharmacological properties of acetaminophen have been reviewed by Brune (1988).

Single or repeated therapeutic doses of acetaminophen have no effect on the cardiovascular and respiratory systems, on platelets, or on coagulation. Acid-base changes and uricosuric effects do not occur, nor does the drug produce the gastric irritation, erosion, or bleeding that may occur after salicylate administration.

Pharmacokinetics and Metabolism. Oral acetaminophen has excellent bioavailability. Peak plasma concentrations occur within 30 to 60 minutes and the half-life in plasma is about 2 hours after therapeutic doses. Acetaminophen is relatively uniformly distributed throughout most body fluids. Binding of the drug to plasma proteins is variable but less than with other NSAIDs; only 20% to 50% is bound at the concentrations encountered during acute intoxication. Some 90% to 100% of the drug may be recovered in the urine within the first day at therapeutic dosing, primarily after hepatic conjugation with glucuronic acid (about 60%), sulfuric acid (about 35%), or cysteine (about 3%); small amounts of hydroxylated and deacetylated metabolites also have been detected (Table 26-1). Children have less capacity for glucuronidation of the drug than do adults. A small proportion of acetaminophen undergoes CYP-mediated *N*-hydroxylation to form *N*-acetyl-*p*-benzoquinoneimine (NAPQI), a highly reactive intermediate. This metabolite normally reacts with sulfhydryl groups in glutathione (GSH) and thereby is rendered harmless. However, after ingestion of large doses of acetaminophen, the metabolite is formed in amounts sufficient to deplete hepatic GSH and contributes significantly to the toxic effects of overdose (*see below*).

Therapeutic Uses. Acetaminophen is a suitable substitute for aspirin for analgesic or antipyretic uses; it is particularly valuable for patients in whom aspirin is contraindicated (*e.g.*, those with peptic ulcer, aspirin hypersensitivity, children with a febrile illness). The conventional oral dose of acetaminophen is 325 to 1000 mg (650 mg rectally); total daily doses should not exceed 4000 mg (2000 mg/day for chronic alcoholics). The most common daily dose is 1000 mg, the dose at which epidemiological studies suggest that gastrointestinal adverse effects are less common than with therapeutic doses of tNSAIDs (Garcia Rodriguez *et al.*, 2004). Higher doses, which may accomplish complete inhibition of COXs, may approach the adverse effect profile of tNSAIDs. Single doses for children range from 40 mg to 480 mg, depending upon age and weight; no more than five doses should be administered in 24 hours. A dose of 10 mg/kg also may be used.

Toxicity and Common Adverse Effects. Acetaminophen usually is well tolerated at recommended therapeutic doses. Rash and other allergic reactions occur occasionally. The rash usually is erythematous or urticarial, but sometimes it is more serious and may be accompanied by drug fever and mucosal lesions. Patients who show hypersensitivity reactions to the salicylates only rarely exhibit sensitivity to acetaminophen. The use of acetaminophen has been associated anecdotally with neutropenia, thrombocytopenia, and pancytopenia.

The most serious acute adverse effect of overdosage of acetaminophen is a potentially fatal hepatic necrosis. Renal tubular necrosis and hypoglycemic coma also may occur. The mechanism by which overdosage with acetaminophen leads to hepatocellular injury and death involves its conversion to the toxic NAPQI metabolite (see Chapter 64). The glucuronide and sulfate conjugation pathways become saturated, and increasing amounts undergo CYP-mediated *N*-hydroxylation to form NAPQI. This is eliminated rapidly by conjugation with GSH and then further metabolized to a mercapturic acid and excreted into the urine. In the setting of acetaminophen overdose, hepatocellular levels of GSH become depleted. The highly reactive NAPQI metabolite binds covalently to cell macromolecules, leading to dysfunction of enzymatic systems and structural and metabolic disarray. Furthermore, depletion of intracellular GSH renders the hepatocytes highly susceptible to oxidative stress and apoptosis.

Hepatotoxicity. In adults, hepatotoxicity may occur after ingestion of a single dose of 10 to 15 g (150 to 250 mg/kg) of acetaminophen; doses of 20 to 25 g or more are potentially fatal. Conditions of CYP induction (e.g., heavy alcohol consumption) or GSH depletion (e.g., fasting or malnutrition) increase the susceptibility to hepatic injury, which has been documented, albeit uncommonly, with doses in the therapeutic range. Symptoms that occur during the first 2 days of acute poisoning by acetaminophen reflect gastric distress (nausea, abdominal pain, and anorexia) and belie the potential seriousness of the intoxication. Plasma transaminases become elevated, sometimes markedly so, beginning approximately 12 to 36 hours after ingestion. Clinical indications of hepatic damage are manifest within 2 to 4 days of ingestion of toxic doses, with right subcostal pain, tender hepatomegaly, jaundice, and coagulopathy. Renal impairment or frank renal failure may occur. Liver enzyme abnormalities typically peak 72 to 96 hours after ingestion. The onset of hepatic encephalopathy or worsening coagulopathy beyond this time indicates a poor prognosis. Biopsy of the liver reveals centrilobular necrosis with sparing of the periportal area. In nonfatal cases, the hepatic lesions are reversible over a period of weeks or months.

Management of Acetaminophen Overdose

Acetaminophen overdose constitutes a medical emergency. Severe liver damage occurs in 90% of patients with plasma concentrations of acetaminophen greater than 300 $\mu\text{g}/\text{ml}$ at 4 hours or 45 $\mu\text{g}/\text{ml}$ at 15 hours after the ingestion of the drug. Minimal hepatic damage can be anticipated when the drug concentration is less than 120 $\mu\text{g}/\text{ml}$ at 4 hours or 30 $\mu\text{g}/\text{ml}$ at 12 hours after ingestion. The nomogram provided in Figure 26-2 relates the plasma levels of acetaminophen and time after ingestion to the predicted severity of liver injury.

Early diagnosis and treatment of acetaminophen overdose is essential to optimize outcome. Perhaps 10% of poisoned patients

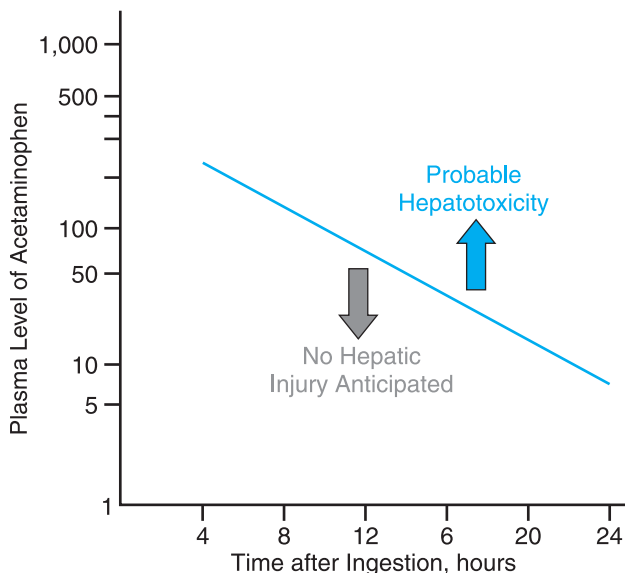

Figure 26-2. Relationship of plasma levels of acetaminophen and time after acute ingestion to hepatic injury. (Adapted with permission from Rumack *et al.*, 1981.)

who do not receive specific treatment develop severe liver damage; 10% to 20% of these eventually die of hepatic failure despite intensive supportive care. Activated charcoal, if given within 4 hours of ingestion, decreases acetaminophen absorption by 50% to 90% and is the preferred method of gastric decontamination. Gastric lavage generally is not recommended.

N-acetylcysteine (NAC) (MUCOMYST, MUCOSIL, PARVOLEX) is indicated for those at risk of hepatic injury. NAC therapy should be instituted in suspected cases of acetaminophen poisoning before blood levels become available, with treatment terminated if assay results subsequently indicate that the risk of hepatotoxicity is low.

NAC functions by detoxifying NAPQI. It both repletes GSH stores and may conjugate directly with NAPQI by serving as a GSH substitute. There is some evidence that in cases of established acetaminophen toxicity, NAC may protect against extrahepatic injury by its antioxidant and antiinflammatory properties (Keays *et al.*, 1991; Jones, 1998). Even in the presence of activated charcoal, there is ample absorption of NAC, and neither should activated charcoal be avoided nor NAC administration be delayed because of concerns of a charcoal-NAC interaction. Adverse reactions to NAC include rash (including urticaria, which does not require drug discontinuation), nausea, vomiting, diarrhea, and rare anaphylactoid reactions.

An oral loading dose of 140 mg/kg is given, followed by the administration of 70 mg/kg every 4 hours for 17 doses. Where available, the intravenous loading dose is 150 mg/kg by intravenous infusion in 100 ml of 5% dextrose over 15 minutes (for those weighing less than 20 kg), followed by 50 mg/kg by intravenous infusion in 250 ml of 5% dextrose over 4 hours, then 100 mg/kg by intravenous infusion in 500 ml of 5% dextrose over 16 hours.

Assistance in treatment of patients with acetaminophen overdose can be obtained from national poison centers: 1-800-222-1222 in the United States and 0870-600-6266 in the United Kingdom.

In addition to NAC therapy, aggressive supportive care is warranted. This includes management of hepatic and renal failure should they occur and intubation should the patient become obtunded. Hypoglycemia can result from liver failure, and plasma glucose should be monitored closely. Fulminant hepatic failure is an indication for liver transplantation, and a liver transplant center should be contacted early in the course of treatment of patients who develop severe liver injury despite NAC therapy.

ACETIC ACID DERIVATIVES: INDOMETHACIN, SULINDAC, AND ETODOLAC

Indomethacin was the product of a laboratory search for drugs with antiinflammatory properties. It was introduced in 1963 for the treatment of rheumatoid arthritis and related disorders. It is a nonselective COX inhibitor. Although indomethacin still is used clinically and is effective, toxicity and the availability of safer alternatives have limited its use. Sulindac was developed in an attempt to find a less toxic, but effective, congener of indomethacin and also is a nonselective COX inhibitor. The pharmacology of both drugs has been reviewed (Rainsford, 2003; Haanen, 2001). *Etodolac* is a structurally related tNSAID; it has been found to be a somewhat selective inhibitor of COX-2.

Indomethacin

Chemistry. The structural formula of indomethacin, a methylated indole derivative, is:

Pharmacological Properties. Indomethacin has prominent anti-inflammatory and analgesic-antipyretic properties similar to those of the salicylates. Indomethacin is a more potent inhibitor of the cyclooxygenases than is aspirin, but patient intolerance generally limits its use to short-term dosing. Indomethacin has analgesic properties distinct from its antiinflammatory effects, and there is evidence for central and peripheral actions.

Indomethacin also inhibits the motility of polymorphonuclear leukocytes and depresses the biosynthesis of mucopolysaccharides. It also may have a direct, cyclooxygenase-independent vasoconstrictor effect (Edlund *et al.*, 1985). Observational studies have raised the possibility that indomethacin may increase the risk of myocardial infarction and stroke, but controlled clinical trials to address this hypothesis have not been performed.

Pharmacokinetics and Metabolism. Oral indomethacin has excellent bioavailability. Peak concentrations occur 1 to 2 hours after dosing (Table 26–1). Indomethacin is 90% bound to plasma proteins and tissues. The concentration of the drug in the CSF is low, but its concentration in synovial fluid is equal to that in plasma within 5 hours of administration.

Between 10% and 20% of indomethacin is excreted unchanged in the urine, partly by tubular secretion. The majority is converted to inactive metabolites, including those formed by *O*-demethylation (about 50%), conjugation with glucuronic acid (about 10%), and *N*-deacylation. Free and conjugated metabolites are eliminated in the urine, bile, and feces. There is enterohepatic cycling of the conjugates and probably of indomethacin itself. The half-life in plasma is variable, perhaps because of enterohepatic cycling, but averages about 2.5 hours.

Drug Interactions. The total plasma concentration of indomethacin plus its inactive metabolites is increased by concurrent administration of probenecid, but it is not clear if concomitant use requires dose adjustment. Indomethacin does not interfere with the uricosuric effect of probenecid.

Indomethacin does not directly modify the effect of warfarin, but platelet inhibition and gastric irritation increase the risk of bleeding; concurrent administration is not recommended. Indomethacin antagonizes the natriuretic and antihypertensive effects of *furosemide* and thiazide diuretics and blunts the antihypertensive effect of β receptor antagonists, AT₁ receptor antagonists, and ACE inhibitors.

Therapeutic Uses. A high rate of intolerance limits the long-term analgesic use of indomethacin (INDOCIN). Likewise, it is not used commonly as an analgesic or antipyretic unless the fever has been refractory to other agents (*e.g.*, Hodgkin's disease).

Indomethacin is effective for relieving joint pain, swelling, and tenderness, increasing grip strength, and decreasing the duration of morning stiffness. It is estimated to be approximately 20 times more potent than aspirin. Overall, about two-thirds of patients benefit from treatment with indomethacin, which typically is initiated at 25 mg two or three times daily. In some patients, 100 mg taken at night provides better nighttime analgesia and relief from morning stiffness. Failure to obtain adequate symptom relief with 100 mg within 7 to 10 days is an indication to try an alternative therapy.

When tolerated, indomethacin often is more effective than aspirin in the treatment of ankylosing spondylitis and osteoarthritis. It also is very effective in the treatment of acute gout, although it is not uricosuric.

Indomethacin is FDA approved for closure of persistent patent ductus arteriosus. A typical regimen involves the intravenous administration of 0.1 to 0.2 mg/kg every 12 hours for three doses. Successful closure can be expected in more than 70% of neonates treated with the drug. Such therapy is indicated primarily in premature infants who weigh between 500 and 1750 g, who have a hemodynamically significant patent ductus arteriosus, and in whom other supportive maneuvers have been attempted. Unexpectedly, treatment with indomethacin also may decrease the incidence and severity of intraventricular hemorrhage in low-birth-weight neonates (Ment *et al.*, 1994). The principal limitation of treating neonates is renal toxicity, and therapy is stopped if the output of urine falls to less than 0.6 ml/kg per hour. Renal failure, enterocolitis, thrombocytopenia, or hyperbilirubinemia are contraindications to the use of indomethacin.

Common Adverse Effects. A very high percentage (35% to 50%) of patients receiving usual therapeutic doses of indomethacin experience untoward symptoms, and about 20% must discontinue its use because of the side effects. Most adverse effects are dose-related.

Gastrointestinal complaints are common and can be serious. Diarrhea may occur and sometimes is associated with ulcerative lesions of the bowel. Underlying peptic ulcer disease is a contraindication to indomethacin use. Acute pancreatitis has been reported, as have rare, but potentially fatal, cases of hepatitis. The most frequent CNS effect (indeed, the most common side effect) is severe frontal headache, occurring in 25% to 50% of patients who take the drug for long periods. Dizziness, vertigo, light-headedness, and mental confusion may occur. Seizures have been reported, as have severe depression, psychosis, hallucinations, and suicide. Caution is advised when administering indomethacin to elderly patients or to those with underlying epilepsy, psychiatric disorders, or Parkinson's disease, because they are at greater risk for the development of serious CNS adverse effects.

Hematopoietic reactions include neutropenia, thrombocytopenia, and rarely aplastic anemia. As is common with other tNSAIDs, platelet function is impaired transiently during the dosing interval.

Sulindac

Chemistry. Sulindac is related closely to indomethacin; its structural formula is:

Sulindac is a prodrug whose antiinflammatory activity resides in its sulfide metabolite.

Pharmacological Properties. Sulindac is less than half as potent as indomethacin. Because sulindac is a prodrug, it appears to be either inactive or relatively weak *in vitro* because it is not metabolized to its active sulfide metabolite. The sulfide metabolite is more than 500 times more potent than sulindac as an inhibitor of cyclooxygenase. The notion that gastric or intestinal mucosa is not directly exposed to high concentrations of active drug after oral administration of sulindac provides a rationale for the claim that there is a lower incidence of GI toxicity with sulindac as compared with indomethacin. This claim ignores the fact that the mucosa of the GI tract is directly exposed to circulating levels of active drug. Formal proof of the hypothetical advantage of sulindac is lacking, and the clinical experience in this regard has been disappointing. Similarly, early clinical studies suggesting that sulindac, in contrast to other NSAIDs, did not alter renal prostaglandin levels and therefore might avoid the association with hypertension in susceptible individuals, have been discredited (Kulling *et al.*, 1995). In short, the same precautions that apply to other NSAIDs regarding patients at risk for gastrointestinal toxicity or renal impairment also apply to sulindac.

Pharmacokinetics and Metabolism. The metabolism and pharmacokinetics of sulindac are complex. About 90% of the drug is absorbed in humans after oral administration (Table 26–1). Peak concentrations of sulindac in plasma are attained within 1 to 2 hours, while those of the sulfide metabolite occur about 8 hours after the oral administration of sulindac.

Sulindac undergoes two major biotransformations. It is oxidized to the sulfone and then reversibly reduced to the sulfide, the active metabolite. The sulfide is formed largely by the action of bowel microflora on sulindac excreted in the bile.

All three compounds are found in comparable concentrations in human plasma. The half-life of sulindac itself is about 7 hours, but the active sulfide has a half-life as long as 18 hours. Sulindac and its metabolites undergo extensive enterohepatic circulation, and all are bound extensively to plasma protein.

Little of the sulfide (or of its conjugates) is found in urine. The principal components excreted in the urine are the sulfone and its conjugates, which account for nearly 30% of an administered dose; sulindac and its conjugates account for about 20%. Up to 25% of an oral dose may appear as metabolites in the feces.

Therapeutic Uses. Sulindac (CLINORIL) has been used mainly for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and acute gout. Its analgesic and antiinflammatory effects are comparable to those achieved with aspirin. The most common dosage for adults is 150 to 200 mg twice a day. The drug usually is given with food to reduce gastric discomfort, although this may delay absorption and reduce its concentration in plasma. A use proposed for sulindac is to prevent colon cancer in patients with familial adenomatous polyposis (*see above*).

Common Adverse Effects. Although the incidence of toxicity is lower than with indomethacin, untoward reactions to sulindac are common. The typical gastrointestinal side effects are seen in nearly 20% of patients, but are thought to be less severe at common doses than with indomethacin. CNS side effects as described above for indomethacin are seen in up to 10% of patients. Rash and pruritus occur in 5% of patients. Transient elevations of hepatic transaminases in plasma are less common.

Etodolac

Etodolac is another acetic acid derivative with some degree of COX-2 selectivity. Thus, at antiinflammatory doses, the frequency of gastric irritation may be less than with other tNSAIDs (Warner *et al.*, 1999).

Pharmacokinetics and Metabolism. Etodolac is rapidly and well absorbed orally. It is highly bound to plasma protein and undergoes hepatic metabolism and renal excretion (Table 26–1). The drug may undergo enterohepatic circulation in humans; its half-life in plasma is about 7 hours.

Therapeutic Uses. A single oral dose (200 to 400 mg) of etodolac (LODINE) provides postoperative analgesia that typically lasts for 6 to 8 hours. Etodolac also is effective in the treatment of osteoarthritis and rheumatoid arthritis and the drug appears to be uricosuric. A sustained-release preparation (LODINE XL) is available, allowing once-a-day administration.

Common Adverse Effects. Etodolac appears to be relatively well tolerated. About 5% of patients who have taken the drug for up to 1

year discontinue treatment because of side effects, which include gastrointestinal intolerance, rashes, and CNS effects.

THE FENAMATES

The fenamates are a family of NSAIDs first discovered in the 1950s that are derivatives of *N*-phenylanthranilic acid. They include *mefenamic*, *meclofenamic*, and *flufenamic acids*.

Therapeutically, they have no clear advantages over several other tNSAIDs and frequently cause GI side effects.

Mefenamic acid (PONSTEL, PONSTAN [UK], DYSMAN [UK]) and *meclofenamate sodium* (MECLOMEN) have been used mostly in the short-term treatment of pain in soft-tissue injuries, dysmenorrhea, and in rheumatoid and osteoarthritis. These drugs are not recommended for use in children or pregnant women.

Mefenamic acid and meclofenamate, but not flufenamic acid, are available in the United States. All three are available in Europe. They are used rarely for chronic therapy of the arthritides.

Chemistry. Mefenamic acid and meclofenamate are *N*-substituted phenylanthranilic acids.

Pharmacological Properties. The fenamates are typical tNSAIDs. Mefenamic acid has central and peripheral actions, and meclofenamic acid (and perhaps other fenamates) may antagonize directly certain effects of prostaglandins, although it is not clear that receptor blockade is attained at therapeutic concentrations.

Pharmacokinetic Properties. These drugs are absorbed rapidly and have short durations of action. In humans, approximately 50% of a dose of mefenamic acid is excreted in the urine, primarily as the 3-hydroxymethyl and 3-carboxyl metabolites and their conjugates. Twenty percent of the drug is recovered in the feces, mainly as the unconjugated 3-carboxyl metabolite.

Common Adverse Effects and Precautions. Approximately 25% of users develop gastrointestinal side effects at therapeutic doses. Roughly 5% of patients develop a reversible elevation of hepatic transaminases. Diarrhea, which may be severe and associated with steatorrhea and inflammation of the bowel, also is relatively common. Autoimmune hemolytic anemia is a potentially serious but rare side effect.

The fenamates are contraindicated in patients with a history of gastrointestinal disease. If diarrhea or rash occur, these drugs should be stopped at once. Vigilance is required for signs or symptoms of hemolytic anemia.

TOLMETIN, KETOROLAC, AND DICLOFENAC

Tolmetin and *ketorolac* are structurally related heteroaryl acetic acid derivatives with different pharmacological fea-

tures. Diclofenac is a phenylacetic acid derivative that was developed specifically as an antiinflammatory agent.

Tolmetin

Tolmetin is an antiinflammatory, analgesic, and antipyretic agent introduced into clinical practice in the United States in 1976. Tolmetin, in recommended doses (200 to 600 mg three times a day), appears to be approximately equivalent in efficacy to moderate doses of aspirin. Tolmetin possesses typical tNSAID properties and side effects (Morley *et al.*, 1982).

Pharmacokinetics and Metabolism. Tolmetin demonstrates rapid and complete absorption, extensive plasma protein binding, and a short half-life (Table 26–1). It undergoes extensive hepatic metabolism, mostly by oxidation of the *para*-methyl group to a carboxylic acid. Metabolites are excreted in the urine. Accumulation of the drug in synovial fluid begins within 2 hours and persists for up to 8 hours after a single oral dose.

Therapeutic Uses. Tolmetin (*tolmetin sodium*; TOLECTIN) is approved in the United States for the treatment of osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis; it also has been used in the treatment of ankylosing spondylitis. In general, tolmetin is thought to have similar therapeutic efficacy to aspirin. The maximum recommended dose is 2 g per day, typically given in divided doses with meals, milk, or antacids to lessen abdominal discomfort. However, peak plasma concentrations and bioavailability are reduced when the drug is taken with food.

Common Adverse Effects. Side effects occur in 25% to 40% of patients who take tolmetin, and 5% to 10% discontinue use of the drug. Gastrointestinal side effects are the most common (15%) and gastric ulceration has been observed. CNS side effects similar to those seen with indomethacin and aspirin occur, but they are less common and less severe.

Ketorolac

Ketorolac is a potent analgesic but only a moderately effective antiinflammatory drug. It is one of the few NSAIDs approved for parenteral administration. The structure of ketorolac is:

Pharmacological Properties. Ketorolac has greater systemic analgesic than antiinflammatory activity. Like other tNSAIDs, it inhibits platelet aggregation and promotes gastric ulceration. Ketorolac also has antiinflammatory activity when topically administered in the eye. The pharmacology of ketorolac has been reviewed (Buckley and Brogden, 1990).

Pharmacokinetics and Metabolism. Ketorolac has a rapid onset of action, extensive protein binding, and a short duration of action

(Table 26–1). Oral bioavailability is about 80%. Urinary excretion accounts for about 90% of eliminated drug, with about 10% excreted unchanged and the remainder as a glucuronidated conjugate. The rate of elimination is reduced in the elderly and in patients with renal failure.

Therapeutic Uses. Ketorolac (administered as the tromethamine salt TORADOL, ULTRAM) has been used as a short-term alternative (less than 5 days) to opioids for the treatment of moderate to severe pain and is administered intramuscularly, intravenously, or orally. Unlike opioids, tolerance, withdrawal, and respiratory depression do not occur. Like other NSAIDs, aspirin sensitivity is a contraindication to the use of ketorolac. Typical doses are 30 to 60 mg (intramuscular); 15 to 30 mg (intravenous); and 5 to 30 mg (oral). Ketorolac is used widely in postoperative patients, but it should not be used for routine obstetric analgesia. Topical (ophthalmic) ketorolac is FDA approved for the treatment of seasonal allergic conjunctivitis and postoperative ocular inflammation after cataract extraction.

Common Adverse Effects. Side effects at usual oral doses include somnolence, dizziness, headache, gastrointestinal pain, dyspepsia, nausea, and pain at the site of injection.

Diclofenac

Diclofenac is the most commonly used tNSAID in Europe (McNeely and Goa, 1999). The selective inhibitor of COX-2 lumiracoxib is an analog of diclofenac. The structure of diclofenac is:

Pharmacological Properties. Diclofenac has analgesic, antipyretic, and antiinflammatory activities. Its potency against COX-2 is substantially greater than that of indomethacin, naproxen, or several other tNSAIDs. In addition, diclofenac appears to reduce intracellular concentrations of free AA in leukocytes, perhaps by altering its release or uptake. The selectivity of diclofenac for COX-2 resembles that of celecoxib. Indeed, the incidence of serious gastrointestinal adverse effects did not differ between celecoxib and diclofenac in the CLASS trial (Juni *et al.*, 2002). Furthermore, observational studies have raised the possibility of a cardiovascular hazard from chronic therapy with diclofenac. A large-scale randomized comparison of diclofenac and the selective COX-2 inhibitor etoricoxib is currently under way.

Pharmacokinetics. Diclofenac has rapid absorption, extensive protein binding, and a short half-life (Table 26–2). There is a substantial first-pass effect, such that only about 50% of diclofenac is available systemically. Diclofenac accumulates in synovial fluid after oral administration, which may explain why its duration of therapeutic effect is considerably longer than the plasma half-life. Diclofenac is metabolized in the liver by a

member of the CYP2C subfamily to 4-hydroxydiclofenac, the principal metabolite, and other hydroxylated forms; after glucuronidation and sulfation the metabolites are excreted in the urine (65%) and bile (35%).

Therapeutic Uses. Diclofenac is approved in the United States for the long-term symptomatic treatment of rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis. Three formulations are available: an intermediate-release potassium salt (CATAFLAM), a delayed-release form (VOLTARIN, VOLTAROL [UK]), and an extended-release form (VOLTARIN-XR). The usual daily dosage for those indications is 100 to 200 mg, given in several divided doses. Diclofenac also is useful for short-term treatment of acute musculoskeletal pain, postoperative pain, and dysmenorrhea. Diclofenac is also available in combination with misoprostol, a PGE₁ analog (ARTHROTEC) (Davis *et al.*, 1995). This combination, which retains the efficacy of diclofenac while reducing the frequency of gastrointestinal ulcers and erosions, is cost-effective relative to the selective COX-2 inhibitors despite the cost of the added misoprostol (Morant *et al.*, 2002). In addition, an ophthalmic solution of diclofenac is available for treatment of postoperative inflammation following cataract extraction.

Common Adverse Effects. Diclofenac produces side effects (particularly gastrointestinal) in about 20% of patients, and approximately 2% of patients discontinue therapy as a result. Modest elevation of hepatic transaminases in plasma occurs in 5% to 15% of patients. Although usually moderate, transaminase values may increase more than threefold in a small percentage of patients. The elevations usually are reversible. Another member of this phenylacetic acid family of NSAIDs, *bromfenac*, was withdrawn from the market because of its association with severe, irreversible liver injury in some patients. Therefore, transaminases should be measured during the first 8 weeks of therapy with diclofenac, and the drug should be discontinued if abnormal values persist or if other signs or symptoms develop. Other untoward responses to diclofenac include CNS effects, rashes, allergic reactions, fluid retention, and edema, and rarely impairment of renal function. The drug is not recommended for children, nursing mothers, or pregnant women. Consistent with its preference for COX-2, and unlike ibuprofen, diclofenac does not interfere with the antiplatelet effect of aspirin (Catella-Lawson *et al.*, 2001). Given these observations, diclofenac is not a suitable alternative to a selective COX-2 inhibitor in individuals at risk of cardiovascular or cerebrovascular disease.

PROPRIONIC ACID DERIVATIVES

Propionic acid derivatives are approved for use in the symptomatic treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and acute gouty arthritis; they also are used as analgesics, for acute tendinitis and bursitis, and for primary dysmenorrhea.

Ibuprofen, the most commonly used tNSAID in the United States, was the first member of the propionic acid class of NSAIDs to come into general use, and it is available without a prescription in the United States. Naprox-

Figure 26–3. Chemical structures of the propionic acid derivatives.

en, also available without prescription, has a longer but variable half-life, making twice-daily administration feasible (and perhaps once daily in some individuals). Oxaprozin also has a long half-life and may possibly be given once daily. The structural formulas of these drugs are shown in Figure 26–3.

Small clinical studies suggest that the propionic acid derivatives are comparable in efficacy to aspirin for the control of the signs and symptoms of rheumatoid arthritis and osteoarthritis, perhaps with improved tolerability.

Ibuprofen, naproxen, *flurbiprofen*, fenopropfen, ketoprofen, and *oxaprozin*, which are available in the United States, are described individually below. Several additional agents in this class are in use or under study in other countries. These include *fenbufen*, *carprofen*, *pirprofen*, *indobufen*, and *tiaprofenic acid*.

Pharmacological Properties. The pharmacodynamic properties of the propionic acid derivatives do not differ significantly. All are nonselective cyclooxygenase inhibitors with the effects and side effects common to other tNSAIDs. Although there is considerable variation in their potency as COX inhibitors, this is not of obvious clinical consequence. Some of the propionic acid derivatives, particularly naproxen, have prominent inhibitory effects on leukocyte function, and some data suggest that naproxen may have slightly better efficacy with regard to analgesia and relief of morning stiffness (Hart and Huskisson, 1984). Epidemiological studies suggest that while the relative risk of myocardial infarction is unaltered by ibuprofen, it is reduced by around 10% by naproxen, compared to a reduction of 20% to 25% by aspirin. This suggestion of benefit accords with the clinical pharmacology of naproxen that suggests that some but not all individuals dosed with 500 mg twice daily sustain platelet inhibition throughout the dosing interval.

Drug Interactions. As do other NSAIDs, the propionic acid derivatives may interfere with the action of antihypertensive and diuretic agents, increase the risk of bleeding with warfarin, and increase the risk of bone marrow suppression with methotrexate. Ibuprofen also has been shown to interfere with the antiplatelet effects of aspirin (*see above*). There is also evidence for a similar interaction between aspirin and naproxen. In addition, propionic acid derivatives may interact with other drugs due to the high avidity for albumin. However, they have not been shown to alter the pharmacokinetics of the oral hypoglycemic drugs or warfarin.

Ibuprofen

Ibuprofen is supplied as tablets containing 200 to 800 mg; only the 200-mg tablets (ADVIL, MOTRIN, NUPRIN, BRUFEN [UK], ANADIN ULTRA [UK], others) are available without a prescription.

Doses of up to 800 mg four times daily can be used in the treatment of rheumatoid arthritis and osteoarthritis, but lower doses often are adequate. The usual dose for mild to moderate pain, such as that of primary dysmenorrhea, is 400 mg every 4 to 6 hours as needed. Ibuprofen has been reviewed (Davies, 1998a).

Pharmacokinetics. Ibuprofen is absorbed rapidly, bound avidly to protein, and undergoes hepatic metabolism (90% is metabolized to hydroxylate or carboxylate derivatives) and renal excretion of metabolites. The half-life is roughly 2 hours. Slow equilibration with the synovial space means that its antiarthritic effects may persist after plasma levels decline. In experimental animals, ibuprofen and its metabolites readily cross the placenta.

Common Adverse Effects. Ibuprofen is thought to be better tolerated than aspirin and indomethacin and has been used in patients with a history of gastrointestinal intolerance to other NSAIDs. Nevertheless, 5% to 15% of patients experience gastrointestinal side effects.

Other adverse effects of ibuprofen have been reported less frequently. They include thrombocytopenia, rashes, headache, dizzi-

ness, blurred vision, and in a few cases toxic amblyopia, fluid retention, and edema. Patients who develop ocular disturbances should discontinue the use of ibuprofen. Ibuprofen can be used occasionally by pregnant women; however, the concerns apply regarding third-trimester effects, including delay of parturition. Excretion into breast milk is thought to be minimal, so ibuprofen also can be used with caution by women who are breastfeeding.

Naproxen

The pharmacological properties and therapeutic uses of naproxen (ALEVE, NAPROSYN, others) have been reviewed (Davies and Anderson, 1997).

Pharmacokinetics. Naproxen is absorbed fully when administered orally. Food delays the rate but not the extent of absorption. Peak concentrations in plasma occur within 2 to 4 hours and are somewhat more rapid after the administration of naproxen sodium. Absorption is accelerated by the concurrent administration of sodium bicarbonate but delayed by magnesium oxide or aluminum hydroxide. Naproxen also is absorbed rectally, but more slowly than after oral administration. The half-life of naproxen in plasma is variable. About 14 hours in the young, it may increase about twofold in the elderly because of age-related decline in renal function (Table 26–1).

Metabolites of naproxen are excreted almost entirely in the urine. About 30% of the drug undergoes 6-demethylation, and most of this metabolite, as well as naproxen itself, is excreted as the glucuronide or other conjugates.

Naproxen is almost completely (99%) bound to plasma proteins after normal therapeutic doses. Naproxen crosses the placenta and appears in the milk of lactating women at approximately 1% of the maternal plasma concentration.

Common Adverse Effects. Typical gastrointestinal adverse effects with naproxen occur at approximately the same frequency as with indomethacin, but perhaps with less severity. CNS side effects range from drowsiness, headache, dizziness, and sweating, to fatigue, depression, and ototoxicity. Less common reactions include pruritus and a variety of dermatological problems. A few instances of jaundice, impairment of renal function, angioedema, thrombocytopenia, and agranulocytosis have been reported.

Fenoprofen

The pharmacological properties and therapeutic uses of fenoprofen (NALFON) have been reviewed (Brogden *et al.*, 1981).

Pharmacokinetics and Metabolism. Oral doses of fenoprofen are readily but incompletely (85%) absorbed. The presence of food in the stomach retards absorption and lowers peak concentrations in plasma, which usually are achieved within 2 hours. The concomitant administration of antacids does not seem to alter the concentrations that are achieved.

After absorption, fenoprofen binds avidly to protein, is extensively metabolized, and is excreted in the urine with a half-life of approximately 3 hours (Table 26–1).

Common Adverse Effects. The gastrointestinal side effects of fenoprofen are similar to those of ibuprofen or naproxen and occur in approximately 15% of patients.

Ketoprofen

Ketoprofen (ORUDIS, ORUVAIL) shares the pharmacological properties of other propionic acid derivatives (Veys, 1991) and is available for sale without a prescription in the United States. A more potent S-enantiomer is available in Europe (Barbanoj *et al.*, 2001). In addition to COX inhibition, ketoprofen may stabilize lysosomal membranes and antagonize the actions of bradykinin. It is unknown if these actions are relevant to its efficacy in humans.

Pharmacokinetics. Ketoprofen demonstrates a pharmacokinetic profile similar to fenoprofen (Table 26–1). It has a half-life in plasma of about 2 hours except in the elderly, in whom it is slightly prolonged. Ketoprofen is conjugated with glucuronic acid in the liver, and the conjugate is excreted in the urine. Patients with impaired renal function eliminate the drug more slowly.

Common Adverse Effects. Approximately 30% of patients experience mild gastrointestinal side effects with ketoprofen, which are decreased if the drug is taken with food or antacids. Ketoprofen can cause fluid retention and increased plasma concentrations of creatinine. These effects generally are transient and asymptomatic and are more common in patients who are receiving diuretics or in those older than 60. Thus, renal function should be monitored in such patients.

Flurbiprofen

The pharmacological properties, therapeutic indications, and adverse effects of flurbiprofen (ANSAID) are similar to those of other antiinflammatory derivatives of propionic acid (Table 26–1) and have been reviewed (Davies, 1995). Flurbiprofen also has been investigated as an antiplatelet therapy; however, evidence that it offers an advantage over aspirin in this regard has not appeared.

Oxaprozin

Oxaprozin (DAYPRO) has similar pharmacological properties, adverse effects, and therapeutic uses to those of other propionic acid derivatives (Davies, 1998b). However, its pharmacokinetic properties differ considerably. Peak plasma levels are not achieved until 3 to 6 hours after an oral dose, while its half-life of 40 to 60 hours allows for once-daily administration.

ENOLIC ACIDS (OXICAMS)

The oxicam derivatives are enolic acids that inhibit COX-1 and COX-2 and have antiinflammatory, analgesic, and antipyretic activity. In general, they are nonselective COX inhibitors, although one member (meloxicam) shows modest COX-2 selectivity comparable to celecoxib in human blood *in vitro* and was approved as a selective COX-2 inhibitor in some countries (*see below*). They are similar in efficacy to aspirin, indomethacin, or naproxen for the long-term treatment of rheumatoid

arthritis or osteoarthritis. Controlled trials comparing gastrointestinal tolerability with aspirin have not been performed. The main advantage suggested for these compounds is their long half-life, which permits once-a-day dosing.

Piroxicam

The pharmacological properties and therapeutic uses of piroxicam have been reviewed (Guttadauria, 1986).

Pharmacological Properties. Piroxicam is effective as an anti-inflammatory agent. It can inhibit activation of neutrophils, apparently independently of its ability to inhibit cyclooxygenase; hence, additional modes of antiinflammatory action have been proposed, including inhibition of proteoglycanase and collagenase in cartilage. Approximately 20% of patients experience side effects with piroxicam, and about 5% of patients discontinue use because of these effects.

Pharmacokinetics and Metabolism. Piroxicam is absorbed completely after oral administration and undergoes enterohepatic recirculation; peak concentrations in plasma occur within 2 to 4 hours (Table 26-1). Food may delay absorption. Estimates of the half-life in plasma have been variable; the average is roughly 50 hours.

After absorption, piroxicam is extensively (99%) bound to plasma proteins. Concentrations in plasma and synovial fluid are similar at steady state (*e.g.*, after 7 to 12 days). Less than 5% of the drug is excreted into the urine unchanged. The major metabolic transformation in humans is CYP-mediated hydroxylation of the pyridyl ring (predominantly by an isozyme of the CYP2C subfamily), and this inactive metabolite and its glucuronide conjugate account for about 60% of the drug excreted in the urine and feces.

Therapeutic Uses. Piroxicam (FELDENE) is approved in the United States for the treatment of rheumatoid arthritis and osteoarthritis. Due to its slow onset of action and delayed attainment of steady state, it is less suited for acute analgesia but has been used in acute gout. Caution is warranted in patients taking lithium because piroxicam can reduce the renal excretion of this drug to a clinically significant extent. The usual daily dose is 20 mg and because of the long half-life, steady-state blood levels are not reached for 7 to 12 days.

Meloxicam

Meloxicam (MOBIC) was approved recently by the FDA for use in osteoarthritis. It has been reviewed (Fleischmann *et al.*, 2002).

The recommended dose for meloxicam is 7.5 to 15 mg once daily for osteoarthritis and 15 mg once daily for rheumatoid arthritis.

Meloxicam demonstrates roughly tenfold COX-2 selectivity on average in *ex vivo* assays (Panara *et al.*, 1999). However, this is

quite variable, and a clinical advantage or hazard has yet to be established. Indeed, even with surrogate markers, the relationship to dose is nonlinear. There is significantly less gastric injury compared to piroxicam (20 mg/day) in subjects treated with 7.5 mg/day of meloxicam, but the advantage is lost with 15 mg/day (Patoia *et al.*, 1996). Like diclofenac, meloxicam would not seem like a desirable alternative to prescribing celecoxib to patients at increased risk of myocardial infarction or stroke.

Other Oxicams

A number of other oxicam derivatives are under study or in use outside of the United States. These include several prodrugs of piroxicam (*amproxicam*, *droxicam*, and *pivoxicam*), which have been designed to reduce gastrointestinal irritation. However, as with sulindac, any theoretical diminution in gastric toxicity associated with administration of a prodrug is offset by gastric COX-1 inhibition from active drug circulating systemically. Other oxicams under study or in use outside the United States include *lornoxiam* (XEFO [UK]) (Balfour *et al.*, 1996), *cinnoxiam* (SINARTROL [ITALY]), *sudoxicam*, and *tenoxicam* (Nilsen, 1994). The efficacy and toxicity of these drugs are similar to those of piroxicam. Lornoxicam is unique among the enolic acid derivatives in that it has a rapid onset of action and a relatively short half-life (3 to 5 hours) (Skjodt and Davies, 1998).

Nabumetone

Nabumetone is an antiinflammatory agent approved in 1991 for use in the United States. It has been reviewed (Davies, 1997). The structure of nabumetone is:

Clinical trials with nabumetone (RELAFEN) have indicated substantial efficacy in the treatment of rheumatoid arthritis and osteoarthritis, with a relatively low incidence of side effects. The dose typically is 1000 mg given once daily. The drug also has off-label use in the short-term treatment of soft-tissue injuries.

Pharmacological Properties. Nabumetone is a prodrug; thus it is a weak inhibitor of COX *in vitro* but a potent COX inhibitor *in vivo*.

Pharmacokinetics and Metabolism. Nabumetone is absorbed rapidly and is converted in the liver to one or more active metabolites, principally 6-methoxy-2-naphthylacetic acid, a potent non-selective inhibitor of COX (Patrignani *et al.*, 1994). This metabolite, inactivated by *O*-demethylation in the liver, is then conjugated before excretion, and is eliminated with a half-life of about 24 hours.

Side Effects. Nabumetone is associated with crampy lower abdominal pain and diarrhea, but the incidence of gastrointestinal ulceration appears to be lower than with other tNSAIDs (Scott *et al.*, 2000), although randomized, controlled studies directly comparing tolerability and clinical outcomes have not been performed. Other

side effects include rash, headache, dizziness, heartburn, tinnitus, and pruritus.

PYRAZOLON DERIVATIVES

This group of drugs includes *phenylbutazone*, *oxyphenbutazone*, *antipyrine*, *aminopyrine*, and *dipyrone*; currently, only antipyrine otic drops are available in the United States. These drugs were used clinically for many years but have essentially been abandoned because of their propensity to cause irreversible agranulocytosis. Dipyrone was reintroduced in Europe approximately 10 years ago because epidemiological studies suggested that the risk of adverse effects was similar to that of acetaminophen and lower than that of aspirin. However, its use remains limited. The pyrazolone derivatives are discussed in previous editions of this book.

CYCLCOXYGENASE-2 SELECTIVE NSAIDS

The therapeutic use of the tNSAIDs has been limited by poor tolerability. Chronic users are prone to experience gastrointestinal irritation in up to 20% of cases. However, the incidence of these adverse events had been falling sharply in the population prior to the introduction of the coxibs, perhaps reflecting a move away from use of high-dose aspirin as an antiinflammatory drug strategy. Studies of the immediate early genes induced by inflammation led to the discovery of a gene with significant homology to the original COX enzyme, now designated COX-2. Because expression of this second COX enzyme was regulated by cytokines and mitogens, it was proposed to be the dominant source of prostaglandin formation in inflammation and cancer. It further was proposed that the original, constitutively expressed COX was the predominant source of cytoprotective prostaglandins formed by the gastrointestinal epithelium. Thus, selective inhibition of COX-2 was postulated to afford efficacy similar to tNSAIDs but with better tolerability. Subsequent crystallization of COX-1 and COX-2 revealed remarkable conservation of tertiary structure. However, one difference was in the hydrophobic channel by which the AA substrate gains access to the COX active site, buried deep within the molecule. This channel is more accommodating in the COX-2 structure and consequently exhibits wider substrate specificity than in COX-1. It also contains a side pocket that in retrospect affords a structural explanation for the identification in screens of the two enzymes *in vitro* of small molecule inhibitors that are differentially specific for COX-2 (Smith *et al.*, 2000). Although there were differences in relative hierarchies, depending on whether screens were performed using recombinantly

expressed enzymes, cells, or whole blood assays, most tNSAIDs expressed similar selectivity for inhibition of the two enzymes.

This section focuses on drugs that were developed specifically to favor inhibition of COX-2, of which the initial class are the coxibs. As discussed above, several older drugs (*e.g.*, nimesulide [not available in the United States], diclofenac, and meloxicam) exhibit relative selectivity for COX-2 inhibition in whole blood assays that resembles that of the first-approved specific inhibitor of COX-2, celecoxib (Brune and Hinz, 2004; FitzGerald and Patrono, 2001).

Three members of the initial class of COX-2 inhibitors, the coxibs, were approved for use in the United States and Europe. Both rofecoxib and valdecoxib have now been withdrawn from the market in view of their adverse event profile. Two others, *parecoxib* and *etoricoxib*, are approved in Europe but still under consideration in the United States. The newest drug in the class, lumiracoxib, is under consideration for approval in Europe and the United States. The relative degree of selectivity for COX-2 inhibition is lumiracoxib = etoricoxib > valdecoxib = rofecoxib >> celecoxib. However, there is considerable difference in response to the coxibs among individuals and it is not known how the degree of selectivity may relate to either efficacy or adverse effect profile, although it seems likely to be related to both. No controlled clinical trials comparing outcomes among the coxibs have been performed. The chemical structures of the coxibs are shown in Figure 26–4.

Pharmacokinetics. Most of the coxibs are distributed widely throughout the body. Celecoxib is particularly lipophilic, so it accumulates in fat and is readily transported into the CNS. Lumiracoxib is more acidic than the others, which may favor its accumulation at sites of inflammation. Despite these subtle differences, all of the coxibs achieve sufficient brain concentrations to have a central analgesic effect and all reduce prostaglandin formation in inflamed joints. All are well absorbed, but peak concentrations are achieved with lumiracoxib and etoricoxib in approximately 1 hour compared to 2 to 4 hours with the other agents (Table 26–1). All of the coxibs are extensively protein-bound (etoricoxib and rofecoxib approximately 90%, the others approximately 97% to 99%). Published estimates of the half-lives of these drugs vary (2 to 6 hours for lumiracoxib, 6 to 12 hours for celecoxib and valdecoxib, 15 to 18 hours for rofecoxib, and 20 to 26 hours for etoricoxib). However, peak plasma concentrations of lumiracoxib exceed considerably those necessary to inhibit COX-2, suggesting an extended pharmacodynamic half-life. Few data linking pharmacokinetics to pharmacodynamics for any of the coxibs are in the public domain. Likewise, there is little information on the

Figure 26–4. Chemical structures of the coxibs.

causes of inter- and intraindividual variability in drug response, which is considerable.

Drug–Drug Interactions. The coxibs are metabolized by a variety of CYPs, including CYP3A, CYP2C9, CYP2D6, and CYP1A2. Rofecoxib differs slightly in that the first step in its metabolism is catalyzed by cytosolic reductases. Celecoxib, valdecoxib, and the prodrug parecoxib all are metabolized predominantly by CYP2D6, which metabolizes approximately 20% of all drugs (see Chapter 3). Although it is poorly inducible, it has pharmacogenetic importance because polymorphic variants with very low activity differ in frequency among populations. The prevalence of homozygosity for these variants is approximately 10% in Caucasians, 5% in Indians, 2% to 3% in Africans, and 1% in Asians. Poor metabolizers are prone to develop high concentrations of relevant NSAIDs, while extensive metabolizers are prone to drug interactions involving competitive inhibition of the enzyme. For example, celecoxib inhibits the metabolism of *metoprolol* and results in its accumulation. Similar interactions have been observed with selective serotonin reuptake inhibitors, tricyclic antidepressants, some neuroleptic agents, and antiarrhythmic drugs. Valdecoxib (and parecoxib) are prone to similar interactions, while rofecoxib interacts with *theophylline*. Unlike tNSAIDs, specific inhibitors of COX-2 would not be expected to pharmacodynamically augment the bleeding risk on warfarin. However, both rofecoxib and valdecoxib may influence the disposition of warfarin, increasing measures of drug action such as the prothrombin times and amplifying the risk of bleeding. There are anecdotal suggestions of an interaction with methotrexate resulting in bone marrow depression. Specific COX-2 inhibitors, like tNSAIDs, may limit the effectiveness of several classes of antihypertensive drugs. Presently, the comparative incidence of renovascular complications on tNSAIDs versus COX-2 selective inhibitors is unknown. As with all NSAIDs, use of these drugs must be cau-

tious in patients with secondary hyperaldosteronism due to hepatic, cardiac, or renal decompensation.

Clinical Use. The first COX-2 inhibitors (*e.g.*, celecoxib, rofecoxib, and valdecoxib) gained FDA approval based on a superior side-effect profile in gastrointestinal endoscopy studies when compared to tNSAIDs. Subsequent to approval, clinical outcome studies against tNSAIDs were performed with celecoxib (the CLASS study; Silverstein *et al.*, 2000) and rofecoxib (the VIGOR study; Bombardier *et al.*, 2000). Only one of these, the VIGOR study, reported a significant difference in clinically significant gastrointestinal outcomes; these were halved from 4% on the tNSAID comparator, naproxen, to 2% on rofecoxib. Publication of the full dataset of the CLASS study revealed no difference between celecoxib and its comparators, ibuprofen and diclofenac (Juni *et al.*, 2002). While the results of these trials are reflected in the labeling of the coxibs, the data did not justify labeling the COX-2 selective inhibitors as a drug class distinct from the NSAIDs. All three of the FDA-approved coxibs have been shown to afford relief from postextraction dental pain and to afford dose-dependent relief from inflammation in osteoarthritis and rheumatoid arthritis. Celecoxib also is approved for the chemoprevention of polyposis coli; however, a placebo-controlled trial revealed a dose-dependent increase in myocardial infarction and stroke (Bresalier *et al.*, 2005).

Celecoxib

Celecoxib (CELEBREX) was approved for marketing in the United States in 1998. Details of its pharmacology have been reviewed (Davies *et al.*, 2000).

Pharmacokinetics. The bioavailability of oral celecoxib is not known, but peak plasma levels occur at 2 to 4 hours postdose. Celecoxib is bound extensively to plasma proteins. Little drug is excreted unchanged; most is excreted as carboxylic acid and glucuronide metabolites in the urine and feces. The elimination half-life is approximately 11 hours. The drug commonly is given once or twice per day during chronic treatment. Renal insufficiency is associated with a modest, clinically insignificant decrease in plasma concentration. Celecoxib has not been studied in patients with severe renal insufficiency. Plasma concentrations are increased by approximately 40% and 180% in patients with mild and moderate hepatic impairment, respectively, and dosages should be reduced by at least 50% in patients with moderate hepatic impairment. Significant interactions occur with *fluconazole* and *lithium* but not with *ketoconazole* or *methotrexate*. Celecoxib is metabolized predominantly by CYP2C9. Although not a substrate, celecoxib also is an inhibitor of CYP2D6. Clinical vigilance is necessary during coadministration of drugs that are known to inhibit CYP2C9 and drugs that are metabolized by CYP2D6.

Pharmacological Properties, Adverse Effects, and Therapeutic Uses.

Effects attributed to inhibition of prostaglandin production in the kidney—hypertension and edema—occur with nonselective COX inhibitors and also with celecoxib. Studies in mice and some epidemiological evidence suggest that the likelihood of hypertension on NSAIDs reflects the degree of inhibition of COX-2 and the selectivity with which it is attained. Thus, the risk of thrombosis, hypertension, and accelerated atherogenesis are mechanistically integrated. The coxibs should be avoided in patients prone to cardiovascular or cerebrovascular disease. None of the coxibs has established clinical efficacy over tNSAIDs, while celecoxib has failed to establish superiority over tNSAIDs in reducing gastrointestinal adverse events. While selective COX-2 inhibitors do not interact to prevent the antiplatelet effect of aspirin, it now is thought that they lose their gastrointestinal advantage over a tNSAID alone when used in conjunction with aspirin. Experience with selective COX-2 inhibitors in patients who exhibit aspirin hypersensitivity is limited, and caution should be observed.

Celecoxib is approved in the United States for the treatment of osteoarthritis and rheumatoid arthritis. The recommended dose for treating osteoarthritis is 200 mg per day as a single dose or as two 100-mg doses. In the treatment of rheumatoid arthritis, the recommended dose is 100 to 200 mg twice per day. In the light of recent information on a potential cardiovascular hazard, physicians are advised to use the lowest possible dose for the shortest possible time. Current evidence does not support use of a coxib as a first choice among the tNSAIDs.

Valdecoxib

Pharmacokinetics. Valdecoxib (BEXTRA) is absorbed rapidly (1 to 2 hours), but peak serum concentrations are delayed by the presence of food (Table 26–1). It undergoes extensive hepatic metabolism by CYP3A4 and CYP2C9 and non-CYP-dependent gluco-

ronidation. Valdecoxib is a weak inhibitor of CYP2C9 and a weak to moderate inhibitor of CYP2C19. Concomitant administration of valdecoxib with known CYP3A4 and 2C9 inhibitors (*e.g.*, *fluconazole* and *ketoconazole*) increases plasma levels of valdecoxib. Coadministration of valdecoxib with warfarin (a CYP2C9 substrate) caused a small but significant increase in the plasma level and anticoagulation effect of warfarin. Interactions with *diazepam*, *glyburide*, *norethindrone*, *ethinyl estradiol*, *omeprazole*, and *dextromethorphan* also have been documented. The metabolites of valdecoxib are excreted in the urine. The half-life is approximately 7 to 8 hours but can be significantly prolonged in the elderly or those with hepatic impairment, with subsequent drug accumulation (Fenton *et al.*, 2004). Outside the United States, valdecoxib is available for injection.

Pharmacological Properties, Adverse Effects, and Therapeutic Uses.

At therapeutic doses, valdecoxib has demonstrated significantly fewer endoscopically demonstrable lesions than tNSAIDs. Like other NSAIDs, valdecoxib can elevate blood pressure in predisposed individuals (Fenton *et al.*, 2004). Valdecoxib has received FDA approval for use in osteoarthritis, adult rheumatoid arthritis, and primary dysmenorrhea. It is also effective in moderate to severe acute pain, particularly if given preemptively (*e.g.*, before a dental procedure) and has been shown to decrease postoperative opioid requirements substantially (Fenton *et al.*, 2004). However, valdecoxib has been associated with a threefold increase in cardiovascular risk in two studies of patients undergoing cardiovascular bypass graft surgery (Furberg *et al.*, 2005). As with celecoxib, the FDA advisory committee reviewed the totality of the evidence and concluded that valdecoxib did indeed elevate the risk of heart attack and stroke and should be avoided in patients prone to these conditions. An additional concern was the causative link to Stevens-Johnson syndrome, a disfiguring skin condition that rarely complicates sulfonamides, like valdecoxib. Based on these considerations and the absence of established benefit compared to traditional NSAIDs, the FDA prompted withdrawal of valdecoxib from the market. No gastrointestinal outcome study with valdecoxib has been performed and there is no evidence that its clinical efficacy exceeds that of tNSAIDs. Thus, current evidence of benefit:risk would not support selection of valdecoxib as an NSAID of first choice, if at all. Finally, life-threatening skin reactions (including toxic epidermal necrolysis, Stevens-Johnson syndrome, and erythema multiforme) have been reported in association with valdecoxib. The drug must be discontinued at the first sign of rash, mucosal lesion, or any other sign of hypersensitivity. This additional hazard renders valdecoxib an unlikely therapeutic choice.

Rofecoxib

Rofecoxib (VIOXX) was introduced in 1999. Details of its pharmacodynamics, pharmacokinetics, therapeutic efficacy, and toxicity have been reviewed (Davies *et al.*, 2003). Based on interim analysis of data from the Adenomatous Polyp Prevention on Vioxx (APPROVe) study, which showed a significant (twofold) increase in the incidence of serious thromboembolic events in subjects receiving 25 mg of rofecoxib relative to placebo (Bresalier *et al.*, 2005), rofecoxib was withdrawn from the market worldwide (FitzGerald, 2004). The FDA advisory panel agreed that rofecoxib increased the risk of myocardial infarction and stroke and that the evidence accu-

mulated was more substantial than for valdecoxib and appeared more convincing than for celecoxib. Only rofecoxib, however, has established superiority over tNSAIDs in terms of gastrointestinal outcomes, which adjusts the risk:benefit ratio. If reintroduced, it would only merit consideration in patients with severe gastrointestinal intolerance of tNSAIDs who were at demonstrably low risk of cardiovascular or cerebrovascular disease.

Other Coxibs

Clinical experience with other coxibs is limited. Parecoxib is a pro-drug of valdecoxib and can be administered parenterally. Etoricoxib is given once a day and has been on the market in Europe. The European regulatory agency concluded that it, along with other coxibs, increased the risk of heart attack and stroke; they restricted specifically its use in patients with hypertension. Lumiracoxib is still under review in both Europe and the United States. Pharmacokinetic considerations are outlined in Table 26–1.

Parecoxib. Pharmacokinetics. Parecoxib is available outside of the United States for intravenous and intramuscular injection. It is absorbed rapidly (approximately 15 minutes) and converted (15 to 52 minutes) by deoxymethylation to valdecoxib, the active drug (Table 26–1) (Karim *et al.*, 2001).

Pharmacological Properties, Common Adverse Effects, and Therapeutic Uses. Parecoxib (DYNASTAT) is available in Germany and Australia, but not in the United Kingdom or United States. It is the only coxib available by injection and has been shown to be an effective analgesic for the perioperative period when patients are unable to take oral medication. However, it is not yet widely available, and clinical experience is limited. In general, the advantages and disadvantages pertaining to valdecoxib (*see above*) apply to parecoxib, including the risk of hypersensitivity or skin reactions.

Lumiracoxib. Pharmacokinetics. Lumiracoxib is unique among the coxibs in being a weak acid. It is rapidly and well absorbed, with peak plasma concentrations occurring in 1 to 3 hours. Its acidic nature allows it to penetrate well into areas of inflammation. The half-life in synovial fluid is considerably longer than in plasma. The concentration of lumiracoxib in synovial fluid 24 hours after administration of a single dose would be expected to result in substantial COX-2 inhibition. This may explain why once-daily dosing may suffice for some users despite its short plasma half-life. However, peak plasma concentrations greatly exceed those necessary to maximally inhibit COX-2, consistent with a longer pharmacodynamic half-life, reflected by sustained inhibition of prostacyclin metabolite excretion comparable to that observed with other coxibs. *In vitro*, lumiracoxib demonstrates greater COX-2 selectivity than any of the currently available coxibs (Tacconelli *et al.*, 2004).

Pharmacological Properties, Common Adverse Effects, and Therapeutic Uses. Lumiracoxib demonstrates potency similar to naproxen but with much greater COX-2 selectivity. Studies in small numbers of subjects showed little or no endoscopic evidence of gastric injury at high therapeutic doses (Kivitz *et al.*, 2004; Atherton *et al.*, 2004). It has been shown to be effective in the treatment of dysmenorrhea with efficacy similar to naproxen (Bitner *et al.*, 2004). It should be noted that these were not equivalence studies.

Further information regarding the safety of lumiracoxib has been provided by findings of the Therapeutic Arthritis Research and Gastrointestinal Event Trial (TARGET; Farkouh *et al.*, 2004; Schnitzer *et al.*, 2004). The trial actually consisted of two distinct studies comparing lumiracoxib to either ibuprofen or naproxen in more than 18,000 osteoarthritis patients in aggregate. Patients were aged 50 years or older and the trials were stratified on the basis of low-dose aspirin. Patients with significant preexisting coronary artery disease were excluded. TARGET detected an excess number of myocardial infarctions among patients taking lumiracoxib compared to naproxen and this difference was attenuated by aspirin. By contrast, ibuprofen appeared to undermine the beneficial effects of aspirin. The cardiovascular event rates on lumiracoxib differed considerably between the two studies, making their combined assessment complex. TARGET was grossly underpowered to assess the relative impact of lumiracoxib *versus* the tNSAIDs on vascular events. While lumiracoxib elevated blood pressure to a marginally lesser degree than the NSAIDs, these differences of a few millimeters of mercury on average were assessed retrospectively and are difficult to interpret. Lumiracoxib was associated with a significant decrease in the frequency of ulcer complications in patients not concurrently taking low-dose aspirin; the benefit disappeared, however, in patients taking aspirin. Finally, the frequency of greater than three-fold elevation of hepatic transaminases was 2.6% for lumiracoxib *versus* 0.6% for the comparator tNSAIDs. Balanced against the tradeoffs of heightened risk for cardiovascular events and hepatotoxicity, the narrow gastrointestinal protective benefit of lumiracoxib makes its use difficult to justify, particularly in patients also taking low-dose aspirin.

Etoricoxib. Pharmacokinetics. Etoricoxib is incompletely (83%) absorbed and has a long half-life of approximately 20 to 26 hours (Table 26–1) (Rodrigues *et al.*, 2003). It is extensively metabolized before excretion. Small studies suggest that those with moderate hepatic impairment are prone to drug accumulation, and the dosing interval should be adjusted (Agrawal *et al.*, 2003). Renal insufficiency does not affect drug clearance (Agrawal *et al.*, 2004).

Pharmacological Properties, Common Adverse Effects, and Therapeutic Uses. Etoricoxib (ARCOXIA) is approved in the United Kingdom as a once-daily medicine for symptomatic relief in the treatment of osteoarthritis, rheumatoid arthritis, and acute gouty arthritis, as well as for the short-term treatment of musculoskeletal pain, postoperative pain, and primary dysmenorrhea (Patrignani *et al.*, 2003). Its COX-2 selectivity is second only to lumiracoxib, and in keeping with other coxibs, it shows decreased gastrointestinal injury as assessed endoscopically. A large randomized clinical outcome study of etoricoxib (MEDAL) is under way.

OTHER NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Apazone (Azapropazone)

Apazone is a tNSAID that has antiinflammatory, analgesic, and antipyretic activity and is a potent uricosuric agent. It is available in

Europe but not the United States. Some of its function may arise from its ability to inhibit neutrophil migration, degranulation, and superoxide production.

Apazone has been used for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and gout, but usually is restricted to cases where other NSAIDs have failed. Typical doses are 600 mg three times per day for acute gout. Once symptoms have abated, or for nongout indications, typical dosage is 300 mg three to four times per day. Clinical experience to date suggests that apazone is well tolerated. Mild gastrointestinal side effects (nausea, epigastric pain, dyspepsia) and rashes occur in about 3% of patients, while CNS effects (headache, vertigo) are reported less frequently. Precautions appropriate to other nonselective COX inhibitors also apply to apazone.

Nimesulide

Nimesulide is a sulfonanilide compound available in Europe that demonstrates COX-2 selectivity similar to celecoxib in whole blood assays. Additional effects include inhibition of neutrophil activation, decrease in cytokine production, decrease in degradative enzyme production, and possibly activation of glucocorticoid receptors (Bennet, 1999). Its structure is:

Nimesulide is antiinflammatory, analgesic, and antipyretic and reportedly is associated with a low incidence of gastrointestinal adverse effects. Given its selectivity profile, it is not a logical alternative for patients switching from the coxibs because of the risk of cardiovascular and cerebrovascular events.

OTHER DRUGS FOR RHEUMATOID ARTHRITIS

Rheumatoid arthritis is an autoimmune disease that affects approximately 1% of the population. The pharmacological management of mild rheumatoid arthritis is geared towards symptomatic relief through the use of NSAIDs. Although they have antiinflammatory effects, they do not prevent or delay joint deformity. Thus, there now is a trend to use disease-modifying antirheumatic drugs earlier in the course of the disease (Olson and Stein, 2004; O'Dell, 2004). Most of these immunosuppressive and immune-modulatory agents have been discussed in other chapters (*see* Chapters 38 and 52) and will be mentioned only briefly here. The use of these agents early in the course of the disease must be weighed against their potentially serious adverse effects. Therapy is tailored to the individual patient, but short-term glucocorticoids often are used to bring the level of inflammation quickly under control. Glucocorticoids are not suitable for long-term use because of adrenal suppression, so methotrexate, sulfasalazine, or low-dose immunosuppressants commonly are used early in the course of the disease. Should these agents be

ineffective, TNF-receptor antagonists or IL-1-receptor antagonists may be administered. The combination of NSAIDs with these agents is increasingly common.

The older agents (gold, penicillamine, sulfasalazine, and *hydroxychloroquine*) have unclear mechanisms of action and with the exception of sulfasalazine, tend to have slight efficacy and significant side effects.

GOLD

Gold, in its elemental form, has been employed for centuries to relieve the itching palm. The more recent use of gold in the treatment of rheumatoid arthritis continues to wane as more effective and better-tolerated agents become available.

Gold is associated with serious adverse effects in the skin and mucous membranes (*e.g.*, erythema, glossitis, exfoliative dermatitis), kidneys (*e.g.*, proteinuria, membranous glomerulonephritis), and blood (*e.g.*, thrombocytopenia, leukopenia, agranulocytosis, aplastic anemia). These side effects tend to increase with cumulative dose. Gold therapy is reserved for patients with progressive disease who do not obtain satisfactory relief from therapy with NSAIDs and who cannot tolerate the more commonly used immunosuppressants or cytokine receptor antagonists. Gold should not be used if the disease is mild and usually is of little benefit in advanced disease.

The pharmacology of gold compounds is described in more detail in previous editions of this book.

PHARMACOTHERAPY OF GOUT

Gout results from the precipitation of urate crystals in the tissues and the subsequent inflammatory response. Acute gout usually causes an exquisitely painful distal monoarthritis, but it also can cause joint destruction, subcutaneous deposits (tophi), and renal calculi and damage. Gout affects approximately 0.5 to 1% of the population of Western countries.

The pathophysiology of gout is understood poorly. While a prerequisite, hyperuricemia does not inevitably lead to gout. Uric acid, the end product of purine metabolism, is relatively insoluble compared to its hypoxanthine and xanthine precursors, and normal serum urate levels approach the limit of solubility. In most patients with gout, hyperuricemia arises from underexcretion rather than overproduction of urate. Urate tends to crystallize in colder or more acidic conditions. Neutrophils ingesting urate crystals secrete inflammatory mediators that lower the local pH and lead to further urate precipitation.

The aims of treatment are to decrease the symptoms of an acute attack, decrease the risk of recurrent attacks, and

lower serum urate levels. This section focuses on *colchicine*, *allopurinol*, and the uricosuric agents—*probenecid*, *sulfapyrazone*, and *benzbromarone*.

Treatment of Acute Gout

Several tNSAIDs reportedly are effective in the treatment of acute gout. The specific COX-2 inhibitor etoricoxib has been shown to be effective in gout (Rubin *et al.*, 2004). When effective, NSAIDs should be given at relatively high doses for 3 to 4 days and then tapered for a total of 7 to 10 days. Indomethacin, naproxen, sulindac, and celecoxib all have been found to be effective, although the first three are the only NSAIDs that have received FDA approval for the treatment of gout. Aspirin is not used because it can inhibit urate excretion at low doses, and through its uricosuric actions increase the risk of renal calculi at higher doses. In addition, aspirin can inhibit the actions of uricosuric agents. Likewise, apazone should not be used in acute gout because of the concern that its uricosuric effects may promote nephrolithiasis.

Glucocorticoids and *corticotropin* (rarely used today) give rapid relief within hours of therapy. High doses are used initially and then tapered rapidly (*e.g.*, prednisone 30 to 60 mg/day for 3 days then tapered over 10 to 14 days), depending on the size and number of affected joints. Intra-articular glucocorticoids are useful if only a few joints are involved and septic arthritis has been ruled out. Further information on these agents is available in Chapter 59. Colchicine also is used in the treatment of acute gout (*see below*). There are anecdotal reports of the use of *ondansetron* in acute gout (*see Chapter 11*), but it is not used commonly for this purpose (Schworer and Ramadori, 1994).

Prevention of Recurrent Attacks

Recurrent attacks of gout can be prevented with the use of colchicine (*e.g.*, 0.6 mg daily or on alternate days). Indomethacin (25 mg/day) also has been used. These agents are used early in the course of uricosuric therapy when mobilization of urate is associated with a temporary increase in the risk of acute gouty arthritis.

Antihyperuricemic Therapy. Isolated hyperuricemia is not necessarily an indication for therapy, as not all of these patients develop gout. Persistently elevated uric acid levels, complicated by recurrent gouty arthritis, nephropathy, or subcutaneous tophi, can be lowered by allopurinol, which inhibits the formation of urate, or by uricosuric agents. Some physicians recommend measuring 24-hour urinary urate levels in patients who are on a low-purine diet to distinguish underexcretors from overproducers. However, tailored and empirical therapies have similar outcomes (Terkeltaub, 2003).

Certain drugs, particularly thiazide diuretics (*see Chapter 28*) and immunosuppressant agents (especially *cyclosporine*) may impair urate excretion and thereby increase the risk of gout.

Colchicine

Colchicine is one of the oldest available therapies for acute gout. Plant extracts containing colchicine were used for joint pain in the sixth century. Colchicine now is considered second-line therapy because it has a narrow thera-

peutic window and a high rate of side effects, particularly at higher doses.

Chemistry. The structural formula of colchicine is:

Its structure–activity relationship has been discussed (Levy *et al.*, 1991).

Mechanism of Action. Colchicine exerts a variety of pharmacological effects, but how these occur or how they relate to its activity in gout is not well understood. It has antimitotic effects, arresting cell division in G1 by interfering with microtubule and spindle formation (an effect shared with vinca alkaloids). This effect is greatest on cells with rapid turnover (*e.g.*, neutrophils and GI epithelium). Although somewhat controversial, colchicine may alter neutrophil motility in *ex vivo* assays (Levy *et al.*, 1991). Colchicine also renders cell membranes more rigid and decreases the secretion of chemotactic factors by activated neutrophils.

Colchicine inhibits the release of histamine-containing granules from mast cells, the secretion of insulin from pancreatic β cells, and the movement of melanin granules in melanophores. These processes also may involve interference with the microtubular system, but whether this occurs at clinically relevant concentrations is questionable.

Colchicine also exhibits a variety of other pharmacological effects. It lowers body temperature, increases the sensitivity to central depressants, depresses the respiratory center, enhances the response to sympathomimetic agents, constricts blood vessels, and induces hypertension by central vasomotor stimulation. It enhances gastrointestinal activity by neurogenic stimulation but depresses it by a direct effect, and alters neuromuscular function.

Pharmacokinetics and Metabolism. The absorption of colchicine is rapid but variable. Peak plasma concentrations occur 0.5 to 2 hours after dosing. In plasma, 50% of colchicine is protein-bound. There is significant enterohepatic circulation. The exact metabolism of colchicine is unknown but seems to involve deacetylation by the liver. Only 10% to 20% is excreted in the urine, although this increases in patients with liver disease. The kidney, liver, and spleen also contain high concentrations of colchicine, but it apparently is largely excluded from heart, skeletal muscle, and brain. The plasma half-life of colchicine is approximately 9 hours, but it can be detected in leukocytes and in the urine for at least 9 days after a single intravenous dose.

Toxic Effects. Exposure of the GI tract to large amounts of colchicine and its metabolites *via* enterohepatic circulation and the rapid rate of turnover of the gastrointestinal mucosa may explain why the GI tract is particularly susceptible to colchicine toxicity. Nausea, vomiting, diarrhea, and abdominal pain are the most common untoward effects of colchicine and the earliest signs of impending toxicity.

ty. Drug administration should be discontinued as soon as these symptoms occur. There is a latent period, which is not altered by dose or route of administration, of several hours or more between the administration of the drug and the onset of symptoms. For this reason, adverse effects are common during initial dosing for acute gout. However, since patients often remain relatively consistent in their response to a given dose of the drug, toxicity can be reduced or avoided during subsequent courses of therapy by reducing the dose. Acute intoxication causes hemorrhagic gastropathy. Intravenous colchicine sometimes is used to treat acute gouty arthritis when other medications are not effective, when the patient is unable to take oral medications, or when rapid therapeutic intervention is necessary. The narrow margin of safety for colchicine is even further diminished by intravenous administration because this route obviates early gastrointestinal side effects that can be a harbinger of serious systemic toxicity. Indiscriminate use of intravenous colchicine has been associated with preventable fatalities. Due to the high rate of serious bone marrow and renal complications (including death from sepsis), this route, although occasionally used, is not generally recommended.

Colchicine toxicity is associated with bone marrow suppression, particularly from the third to eighth days. There is a tendency toward leukocytosis with appearance of less mature forms. Chronic colchicine use may lead to agranulocytosis. Thrombocytopenia also can occur, and disseminated intravascular coagulation has been reported in cases of severe poisoning.

Chronic use is associated with a proximal myopathy. The associated weakness may go unrecognized, and creatine kinase levels should be monitored in those receiving chronic therapy. Ascending paralysis of the CNS has been reported with acute poisoning.

Proteinuria, hematuria, and acute tubular necrosis have been reported in severely intoxicated patients. Gouty nephropathy may occur in chronically treated patients. Azoospermia has been reported with chronic use.

There is no specific therapy for acute colchicine poisoning. Supportive measures should be used, particularly fluid repletion. Activated charcoal may decrease total colchicine exposure. Hemodialysis does not remove colchicine but may be required as part of supportive care. Colchicine antibodies and the use of granulocyte colony-stimulating factor to treat the leukopenia are under investigation.

Therapeutic Uses. Acute Gout. Colchicine dramatically relieves acute attacks of gout. It is effective in roughly two-thirds of patients if given within 24 hours of the onset of the attack. Pain, swelling, and redness abate within 12 hours and are completely gone within 48 to 72 hours. The typical oral dose is 0.6 mg each hour for a total of three doses. This dose should not be exceeded. Treatment with colchicine should not be repeated within 7 days to avoid cumulative toxicity.

Great care should be exercised in prescribing colchicine for elderly patients. For those with cardiac, renal, hepatic, or gastrointestinal disease, NSAIDs or glucocorticoids may be preferred.

Prevention of Acute Gout. The main indication for colchicine is in the prevention of recurrent gout, particularly in the early stages of antihyperuricemic therapy. The typical dose is 0.6 mg twice a day, which should be decreased for patients with impaired renal function. One suggestion is 0.6 mg/day for a creatinine clearance of 35 to 50 ml/minute, or in patients younger than 70 years of age, 0.6 mg every 2 to 3 days for creatinine clearances of 10 to 35 ml/minute, and avoidance in those with creatinine clearance of less than 10 ml/minute or with combined hepatic and renal disease (Terkeltaub, 2003).

Familial Mediterranean Fever. Daily administration of colchicine is useful for the prevention of attacks of familial Mediterranean fever and prevention of amyloidosis, which may complicate this disease (Zemer *et al.*, 1991).

There no longer is a role for colchicine in the treatment of primary biliary cirrhosis, psoriasis, or Behçet's disease.

Allopurinol

Allopurinol inhibits xanthine oxidase and prevents the synthesis of urate from hypoxanthine and xanthine. It is used to treat hyperuricemia in patients with gout and to prevent it in those with hematological malignancies about to undergo chemotherapy (acute tumor lysis syndrome). Even though underexcretion rather than overproduction is the underlying defect in most gout patients, allopurinol remains effective therapy.

History. Allopurinol initially was synthesized as a candidate antineoplastic agent but was found to lack antineoplastic activity. Subsequent testing showed it to be an inhibitor of xanthine oxidase that was useful clinically for the treatment of gout.

Chemistry and Pharmacological Properties. Allopurinol, an analog of hypoxanthine, has the following structural formula:

Both allopurinol and its primary metabolite, oxypurinol (alloxanthine), inhibit xanthine oxidase. Allopurinol competitively inhibits xanthine oxidase at low concentrations and is a noncompetitive inhibitor at high concentrations. Allopurinol also is a substrate for xanthine oxidase; the product of this reaction, oxypurinol, is also a noncompetitive inhibitor of the enzyme. The formation of oxypurinol, together with its long persistence in tissues, is responsible for much of the pharmacological activity of allopurinol.

In the absence of allopurinol, the dominant urinary purine is uric acid. During allopurinol treatment, the urinary purines include hypoxanthine, xanthine, and uric acid. Since each has its independent solubility, the concentration of uric acid in plasma is reduced and purine excretion increased, without exposing the urinary tract to an excessive load of uric acid. Despite their increased concentrations during allopurinol therapy, hypoxanthine and xanthine are efficiently excreted, and tissue deposition does not occur. There is a small risk of xanthine stones in patients with a very high urate load before allopurinol therapy, which can be minimized by liberal fluid intake and alkalization of the urine.

Allopurinol facilitates the dissolution of tophi and prevents the development or progression of chronic gouty arthritis by lowering the uric acid concentration in plasma below the limit of its solubility. The formation of uric acid stones virtually disappears with therapy, which prevents the development of nephropathy. Once significant renal injury has occurred, allopurinol cannot restore renal

function but may delay disease progression. The incidence of acute attacks of gouty arthritis may increase during the early months of allopurinol therapy as a consequence of mobilization of tissue stores of uric acid.

Coadministration of colchicine helps suppress such acute attacks. After reduction of excess tissue stores of uric acid, the incidence of acute attacks decreases and colchicine can be discontinued.

In some patients, the allopurinol-induced increase in excretion of oxypurines is less than the reduction in uric acid excretion; this disparity primarily is a result of reutilization of oxypurines and feedback inhibition of *de novo* purine biosynthesis.

Pharmacokinetics. Allopurinol is absorbed relatively rapidly after oral ingestion, and peak plasma concentrations are reached within 60 to 90 minutes. About 20% is excreted in the feces in 48 to 72 hours, presumably as unabsorbed drug, and 10% to 30% is excreted unchanged in the urine. The remainder undergoes metabolism, mostly to oxypurinol. Oxypurinol is excreted slowly in the urine by glomerular filtration, counterbalanced by some tubular reabsorption. The plasma half-life of allopurinol is approximately 1 to 2 hours and of oxypurinol approximately 18 to 30 hours (longer in those with renal impairment). This allows for once-daily dosing and makes allopurinol the most commonly used antihyperuricemic agent.

Allopurinol and its active metabolite oxypurinol are distributed in total tissue water, with the exception of brain, where their concentrations are about one-third of those in other tissues. Neither compound is bound to plasma proteins. The plasma concentrations of the two compounds do not correlate well with therapeutic or toxic effects.

Drug Interactions. Allopurinol increases the half-life of probenecid and enhances its uricosuric effect, while probenecid increases the clearance of oxypurinol, thereby increasing dose requirements of allopurinol.

Allopurinol inhibits the enzymatic inactivation of *mercaptapurine* and its derivative *azathioprine* by xanthine oxidase. Thus, when allopurinol is used concomitantly with oral mercaptopurine or azathioprine, dosage of the antineoplastic agent must be reduced to one-fourth to one-third of the usual dose (see Chapters 38 and 51). This is of importance when treating gout in the transplant recipient. The risk of bone marrow suppression also is increased when allopurinol is administered with cytotoxic agents that are not metabolized by xanthine oxidase, particularly *cyclophosphamide*.

Allopurinol also may interfere with the hepatic inactivation of other drugs, including warfarin. Although the effect is variable, increased monitoring of prothrombin activity is recommended in patients receiving both medications.

It remains to be established whether the increased incidence of rash in patients receiving concurrent allopurinol and *ampicillin* should be ascribed to allopurinol or to hyperuricemia. Hypersensitivity reactions have been reported in patients with compromised renal function, especially those who are receiving a combination of allopurinol and a thiazide diuretic. The concomitant administration of allopurinol and theophylline leads to increased accumulation of an active metabolite of theophylline, 1-methylxanthine; the concentration of theophylline in plasma also may be increased (see Chapter 27).

Therapeutic Uses. Allopurinol (ZYLOPRIM, ALOPRIM, others) is available for oral use and provides effective therapy for the primary hyperuricemia of gout and the hyperuricemia secondary to polycy-

themia vera, myeloid metaplasia, other blood dyscrasias, or acute tumor lysis syndrome.

Allopurinol is contraindicated in patients who have exhibited serious adverse effects or hypersensitivity reactions to the medication, and in nursing mothers and children, except those with malignancy or certain inborn errors of purine metabolism (e.g., Lesch-Nyhan syndrome). Allopurinol generally is used in complicated hyperuricemia (see above), to prevent acute tumor lysis syndrome, or in patients with hyperuricemia posttransplantation. If necessary, it can be used in conjunction with uricosuric agents.

The goal of therapy is to reduce the plasma uric acid concentration to less than 6 mg/dl (equivalent to 360 μ mol). In the management of gout, it is customary to antecede allopurinol therapy with colchicine and to avoid starting allopurinol during an acute attack of gouty arthritis. Fluid intake should be sufficient to maintain daily urinary volume of more than 2 liters; slightly alkaline urine is preferred. An initial daily dose of 100 mg is increased by 100-mg increments at weekly intervals. Most patients can be maintained on 300 mg/day. Those with more severe gout may require 400 to 600 mg/day, and those with hematological malignancies may need up to 800 mg/day beginning 2 to 3 days before the start of chemotherapy. Daily doses in excess of 300 mg should be divided. Dosage must be reduced in patients in proportion to the reduction in glomerular filtration (e.g., 300 mg/day if creatinine clearance is >90 ml/minute, 200 mg/day if creatinine clearance is between 60 and 90 ml/minute, 100 mg/day if creatinine clearance is 30 to 60 ml/minute, and 50 to 100 mg/day if creatinine clearance is <30 ml/minute) (Terkeltaub, 2003).

The usual daily dose in children with secondary hyperuricemia associated with malignancies is 150 to 300 mg, depending on age.

Allopurinol also is useful in lowering the high plasma concentrations of uric acid in patients with Lesch-Nyhan syndrome and thereby prevents the complications resulting from hyperuricemia; there is no evidence that it alters the progressive neurological and behavioral abnormalities that are characteristic of the disease.

Common Adverse Effects. Allopurinol is tolerated well by most patients. The most common adverse effects are hypersensitivity reactions that may occur after months or years of medication. The effects usually subside within a few days after medication is discontinued. Serious reactions preclude further use of the drug.

The cutaneous reaction caused by allopurinol is predominantly a pruritic, erythematous, or maculopapular eruption, but occasionally the lesion is urticarial or purpuric. Rarely, toxic epidermal necrolysis or Stevens-Johnson syndrome occurs, which can be fatal. The risk for Stevens-Johnson syndrome is limited primarily to the first 2 months of treatment (Roujeau *et al.*, 1995). Because the rash may precede severe hypersensitivity reactions, patients who develop a rash should discontinue allopurinol. If indicated, desensitization to allopurinol can be carried out starting at 10 to 25 μ g per day, with the drug diluted in oral suspension and doubled every 3 to 14 days until the desired dose is reached. This is successful in approximately half of patients (Terkeltaub, 2003). Oxypurinol is available for compassionate use in the United States for patients intolerant of allopurinol. The safety of oxypurinol in patients with severe allopurinol hypersensitivity is unknown and not recommended.

Fever, malaise, and myalgias also may occur. Such effects are noted in about 3% of patients with normal renal function and more frequently in those with renal impairment. Transient leukopenia or leukocytosis and eosinophilia are rare reactions that may require

cessation of therapy. Hepatomegaly and elevated levels of transaminases in plasma and progressive renal insufficiency also may occur.

Rasburicase

Rasburicase (ELITEK) is a recombinant urate-oxidase that catalyzes the enzymatic oxidation of uric acid into the soluble and inactive metabolite allantoin. It has been shown to lower urate levels more effectively than allopurinol (Bosly *et al.*, 2003). It is indicated for the initial management of elevated plasma uric acid levels in pediatric patients with leukemia, lymphoma, and solid tumor malignancies who are receiving anticancer therapy expected to result in tumor lysis and significant hyperuricemia.

Produced by a genetically modified *Saccharomyces cerevisiae* strain, the therapeutic efficacy may be hampered by the production of antibodies against the drug. Hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient patients, methemoglobinemia, acute renal failure, and anaphylaxis all have been associated with the use of rasburicase. Other frequently observed adverse reactions include vomiting, fever, nausea, headache, abdominal pain, constipation, diarrhea, and mucositis. Rasburicase causes enzymatic degradation of the uric acid in blood samples, and special handling is required to prevent spuriously low values for plasma uric acid in patients receiving the drug. The recommended dose of rasburicase is 0.15 mg/kg or 0.2 mg/kg as a single daily dose for 5 days, with chemotherapy initiated 4 to 24 hours after infusion of the first rasburicase dose.

URICOSURIC AGENTS

Uricosuric agents increase the rate of excretion of uric acid. In humans, urate is filtered, secreted, and reabsorbed by the kidneys. Reabsorption predominates, and the amount excreted usually is about 10% of that filtered. This process is mediated by a specific transporter, which can be inhibited.

The first step in urate reabsorption is its uptake from tubular fluid by a transporter that exchanges urate for either an organic or an inorganic anion. Uricosuric drugs compete with urate for the brush-border transporter, thereby inhibiting its reabsorption *via* the urate-anion exchanger system. However, transport is bidirectional, and depending on dosage, a drug may either decrease or increase the excretion of uric acid. Decreased excretion usually occurs at a low dosage, while increased excretion is observed at a higher dosage. Not all agents show this phenomenon, and one uricosuric drug may either add to or inhibit the action of another. The biphasic effect may be seen within the normal dosage range with some drugs such as salicylates.

Two mechanisms for a drug-induced decrease in urate excretion of urate have been advanced; they are not mutually exclusive. The first presumes that the small secretory movement of urate is

inhibited by very low concentrations of the drug. Higher concentrations may inhibit urate reabsorption in the usual manner. The second proposal suggests that the urate-retaining anionic drug gains access to the intracellular fluid by an independent mechanism and promotes reabsorption of urate across the brush border by anion exchange.

There are two mechanisms by which one drug may nullify the uricosuric action of another. First, the drug may inhibit the secretion of the uricosuric agent, thereby denying it access to its site of action, the luminal aspect of the brush border. Second, the inhibition of urate secretion by one drug may counterbalance the inhibition of urate reabsorption by the other.

Many compounds have incidental uricosuric activity, probably by acting as exchangeable anions, but only probenecid is prescribed routinely for this purpose. Benzbromarone is an alternative uricosuric agent that is available in Europe. Conversely, a number of drugs and toxins cause retention of urate; these have been reviewed elsewhere (Maalouf *et al.*, 2004).

Probenecid

Chemistry. Probenecid is a highly lipid-soluble benzoic acid derivative (pK_a 3.4) with the following structural formula:

Pharmacological Actions. Inhibition of Inorganic Acid Transport.

The actions of probenecid are confined largely to inhibition of the transport of organic acids across epithelial barriers. When tubular secretion of a substance is inhibited, its final concentration in the urine is determined by the degree of filtration, which in turn is a function of binding to plasma protein, and by the degree of reabsorption. The significance of each of these factors varies widely with different compounds. Usually, the end result is decreased tubular secretion of the compound, leading to decreased urinary and increased plasma concentration.

Uric acid is the only important endogenous compound whose excretion is known to be increased by probenecid. This results from inhibition of its reabsorption (*see above*). The uricosuric action of probenecid is blunted by the coadministration of salicylates.

Inhibition of Transport of Miscellaneous Substances. Probenecid inhibits the tubular secretion of a number of drugs, such as methotrexate and the active metabolite of *clofibrate*. It inhibits renal secretion of the inactive glucuronide metabolites of NSAIDs such as naproxen, ketoprofen, and indomethacin, and thereby can increase their plasma concentrations.

Inhibition of Monoamine Transport to CSF. Probenecid inhibits the transport of 5-hydroxyindoleacetic acid (5-HIAA) and other acidic metabolites of cerebral monoamines from the CSF to the plasma. The transport of drugs such as *penicillin G* also may be affected.

Inhibition of Biliary Excretion. Probenecid depresses the biliary secretion of certain compounds, including the diagnostic agents indocyanine green and bromosulphthalein (BSP). It also decreases the biliary secretion of *rifampin*, leading to higher plasma concentrations.

Absorption, Fate, and Excretion. Probenecid is absorbed completely after oral administration. Peak concentrations in plasma are reached in 2 to 4 hours. The half-life of the drug in plasma is dose-dependent and varies from less than 5 hours to more than 8 hours over the therapeutic range. Between 85% and 95% of the drug is bound to plasma albumin. The 5% to 15% of unbound drug is cleared by glomerular filtration. The majority of the drug is secreted actively by the proximal tubule. The high lipid solubility of the undissociated form results in virtually complete absorption by backdiffusion unless the urine is markedly alkaline. A small amount of probenecid glucuronide appears in the urine. It also is hydroxylated to metabolites that retain their carboxyl function and have uricosuric activity.

Common Adverse Effects. Probenecid is well tolerated. Approximately 2% of patients develop mild gastrointestinal irritation. The risk is increased at higher doses, and caution should be used in those with a history of peptic ulcer. It is ineffective in patients with renal insufficiency and should be avoided in those with creatinine clearance of <50 ml/minute. Hypersensitivity reactions usually are mild and occur in 2% to 4% of patients. Serious hypersensitivity is extremely rare. The appearance of a rash during the concurrent administration of probenecid and penicillin G presents the physician with an awkward diagnostic dilemma. Substantial overdosage with probenecid results in CNS stimulation, convulsions, and death from respiratory failure.

Therapeutic Use. Gout. Probenecid (BENEBMID [US], BENURYL [UK]) is marketed for oral administration. The starting dose is 250 mg twice daily, increasing over 1 to 2 weeks to 500 to 1000 mg twice daily. Probenecid increases urinary urate levels. Liberal fluid intake therefore should be maintained throughout therapy to minimize the risk of renal stones. Probenecid should not be used in gouty patients with nephrolithiasis or with overproduction of uric acid. Concomitant colchicine or NSAIDs are indicated early in the course of therapy to avoid precipitating an attack of gout, which may occur in up to 20% of gouty patients treated with probenecid alone.

Combination with Penicillin. Probenecid was developed for the purpose of delaying the excretion of penicillin. Higher doses of probenecid are used as an adjuvant to prolong penicillin concentrations. This usually is confined to those being treated for gonorrhea or neurosyphilis infections or to cases where penicillin resistance may be an issue (see Chapter 44).

Sulfinpyrazone

History. Sulfinpyrazone was developed from phenylbutazone, an early NSAID whose toxicity precluded its continued use. Sulfinpyrazone lacks antiinflammatory and analgesic activity but has potent uricosuric effects. It rarely is used today.

Chemistry. Sulfinpyrazone is a strong organic acid ($pK_a = 2.8$) that readily forms soluble salts.

Pharmacological Actions. In sufficient doses, sulfinpyrazone potentially inhibits the renal tubular reabsorption of uric acid. As with other uricosuric agents, small doses may reduce the excretion of uric acid. Like probenecid, sulfinpyrazone reduces the renal tubular secretion of many other organic anions. In addition, it may induce hypoglycemia by inhibiting the metabolism of the sulfonyleurea oral hypoglycemic

agents. The hepatic metabolism of warfarin also is impaired. The uricosuric action of sulfinpyrazone is additive to that of probenecid, but it antagonizes that of salicylates. The inhibitory effect of sulfinpyrazone on platelet function is discussed in Chapter 54.

Absorption, Fate, and Excretion. Sulfinpyrazone is absorbed well after oral administration. It is bound strongly to plasma albumin (98% to 99%) and displaces other anionic drugs that have their highest affinity for the same binding site. Its plasma half-life is about 3 hours, but its uricosuric effect may persist for as long as 10 hours. Sulfinpyrazone is secreted by the proximal tubule and undergoes little passive backdiffusion. Approximately half of the orally administered dose appears in the urine within 24 hours, mostly (90%) as unchanged drug; the remaining 10% is eliminated as the N^1 -*p*-hydroxyphenyl metabolite, which also is a potent uricosuric substance.

Common Adverse Effects. Gastrointestinal irritation occurs in roughly 10% to 15% of patients receiving sulfinpyrazone, and occasionally may lead patients to discontinue its use. Gastric distress is lessened when the drug is taken in divided doses with meals. Sulfinpyrazone should be given to patients with a history of peptic ulcer only with extreme caution. Hypersensitivity reactions, usually a rash with fever, do occur, but less frequently than with probenecid. Depression of hematopoiesis has been demonstrated, and periodic blood cell counts therefore are advised during prolonged therapy. Sulfinpyrazone should not be used by patients with underlying blood dyscrasias.

Therapeutic Use. Sulfinpyrazone (ANTURANE) is available for oral administration. The initial dosage for the treatment of chronic gout is 100 to 200 mg given twice daily. After the first week, the dosage may be gradually increased until a satisfactory lowering of plasma uric acid is achieved and maintained. This may require from 200 to 800 mg per day, divided in two to four doses and preferably given with meals or milk; a liberal fluid intake should be maintained. Larger doses are tolerated poorly and unlikely to produce a further uricosuric effect in resistant patients. Sulfinpyrazone is ineffective in patients with renal insufficiency and should be avoided in those with creatinine clearance of <50 ml/minute. As with probenecid, concomitant colchicine is indicated early in the course to avoid precipitating an attack of gout.

Benzbromarone

This is a potent uricosuric agent that is used in Europe. The drug is absorbed readily after oral ingestion, and peak concentrations in blood are achieved in about 4 hours. It is metabolized to monobromine and dehalogenated derivatives, both of which have uricosuric activity, and is excreted primarily in the bile. The uricosuric action is blunted by aspirin or sulfinpyrazone. No paradoxical retention of urate has been observed. It is a potent and reversible inhibitor of the urate-anion exchanger in the proximal tubule. As the micronized powder it is effective in a single daily dose of 40 mg to 80 mg, which makes it significantly more potent than other uricosuric drugs. It is effective in patients with renal insufficiency and may be useful clinically in patients who are either allergic or refractory to other drugs used for the treatment of gout. Preparations that combine allopurinol and benzbromarone are more effective than either drug alone in lowering serum uric acid levels, in spite of the fact

that benzbromarone lowers plasma levels of oxypurinol, the active metabolite of allopurinol.

CONCLUSION

The emergence of clear evidence from placebo-controlled trials of a cardiovascular hazard for three coxibs has prompted a broad reappraisal of NSAID therapy. Selective inhibitors of COX-2 were developed to reduce gastrointestinal adverse effects and have never been shown to exhibit an efficacy advantage over tNSAIDs. The likelihood of hazard would be expected to be related to selectivity attained *in vivo*, dose, duration of action, and duration of dosing, as well as the underlying risk profile of an individual patient. It seems likely that some of the older drugs, specifically meloxicam and diclofenac, may closely resemble celecoxib, while naproxen may afford cardioprotection due to an extended half-life in some individuals, translating into a modest benefit when compared to aspirin.

PHARMACOTHERAPY OF ASTHMA

Bradley J. Udem

Asthma is a common disorder, accounting in the United States for 1% to 3% of all office visits, 500,000 hospital admissions per year, more pediatric hospital admissions than any other single illness, and more than 5000 deaths annually.

The pharmacological therapy of asthma employs drugs aimed at reducing airway inflammation (*i.e.*, antiinflammatory agents) and drugs aimed more directly at decreasing bronchospasm (*i.e.*, bronchodilators). To these ends, six classes of therapeutic agents are presently indicated for asthma treatment: β adrenergic receptor agonists, glucocorticoids, leukotriene inhibitors, chromones, methylxanthines, and inhibitors of immunoglobulin E (IgE). Each of these classes is discussed below.

ASTHMA AS AN INFLAMMATORY ILLNESS

Asthma is associated with inflammation of the airway wall. Increased numbers of various types of inflammatory cells, most notably eosinophils but also basophils, mast cells, macrophages, and certain types of lymphocytes, can be found in airway wall biopsies and in bronchoalveolar lavage fluid from asthmatic patients. Inflammatory mediators and various cytokines also are increased in the airways of asthmatic subjects compared with healthy control subjects. How bronchial inflammation contributes to the asthmatic condition remains poorly understood. Even asthmatics with normal baseline lung function and no recent exacerbations of their asthma have increased numbers of inflammatory cells in their airways. Conversely, many individuals allergic to inhaled allergens have evidence of lower airway inflammation but suffer only from the symptoms of allergic rhinitis. The basis for this inflammation is not entirely clear. Many individuals with

asthma are atopic and have clearly defined allergen exposures that are partially or substantially responsible for their asthmatic inflammation. Epidemiological studies show a strong correlation between increasing IgE levels and the prevalence of asthma regardless of atopic status (Burrows *et al.*, 1989). Nonallergic individuals also can suffer from asthma, as is often seen in subjects in whom the onset of disease is later in life.

Although there are subtypes of asthma (allergic *versus* nonallergic), there are features of airway inflammation common to all asthmatic airways (Figure 27–1). Airway inflammation is thought to be triggered by innate and/or adapted immune responses. Although there may be multiple “triggers” for an inflammatory response (such as mast cell secretion), there is general agreement that a lymphocyte-directed eosinophilic bronchitis is a hallmark of asthma. The lymphocytes that participate in asthma pathology are biased toward the T-helper type 2 (Th2) phenotype, leading to increases in production of interleukin 4 (IL-4), IL-5, and IL-13. The IL-4 from Th2 cells (and basophils) provides help for IgE synthesis in B cells. The IL-5 provides support for eosinophil survival. The innate or adapted immune response triggers the production of additional cytokines and chemokines, resulting in trafficking of blood-borne cells (*i.e.*, eosinophils, basophils, neutrophils, and lymphocytes) into airway tissues, and these cells further generate a variety of autacoids and cytokines. The inflammatory cascade also leads to activation of resident cells within the airways that, in turn, can produce a panoply of cytokines, growth factors, chemokines, and autacoids. The chronic inflammatory response, over time, leads to epithelial shedding and reorganization, mucous hypersecretion, and airway wall remodeling most often exemplified by subepithelial fibrosis and smooth muscle hyperplasia. How these processes lead to attacks of asthma, which most often are induced or exacerbated by respiratory viral infections, remains unclear.

Figure 27-1. Simplified view of allergic inflammation in the airways. Asthma is an episodic narrowing of the bronchi thought to be caused by an underlying chronic inflammatory disorder. In allergic asthma, inhaled allergen initiates the inflammatory response by interacting with IgE bound to mast cells and basophils. This leads to a cascade of events involving other immune cells and resulting in the release of numerous inflammatory mediators into the interstitial space, where they influence the growth and function of cell types within the airway wall. The drugs available for the treatment of asthma are targeted at inhibiting the inflammatory responses and/or relaxing the bronchial smooth muscle. Letters denote the putative sites of action for the various classes of drugs used in treating asthma. β , β_2 adrenergic agonists; cs, corticosteroids; l, leukotriene modifiers; m, muscarinic receptor antagonists; cr, cromolyn; t, theophylline; aI, anti-IgE therapy. The sunburst (☼) symbolizes an allergen.

In addition to airway inflammation, asthmatics commonly exhibit bronchial hyperreactivity. Thus the concentration of a bronchial spasmogen, such as methacholine or histamine, needed to produce a 20% increase in airway resistance in asthmatics is often only 1% to 2% of the equally effective concentration in healthy control subjects. This bronchial hyperreactivity most often is nonspecific such that the airways are also inordinately reactive to stimuli such as strong odors, cold air, and pollutants. Little is known about specific mechanisms underlying this enigmatic hyperreactivity.

The pharmacotherapy of asthma centers on controlling the disease with drugs that inhibit airway inflammation. Other drugs that relax bronchial smooth muscle are used for more immediate and direct relief of the symptoms of asthma.

TREATMENT OF ASTHMA

Aerosol Delivery of Drugs

Topical application of drugs to the lungs can be accomplished by use of aerosols. In theory, this approach should produce a high local concentration in the lungs with a low systemic delivery, thereby significantly minimizing systemic side effects. The drugs used most commonly in the treatment of asthma, β_2 adrenergic receptor agonists and glucocorticoids, have potentially serious side effects when delivered systemically. Since the pathophysiology of asthma appears to involve the respiratory tract alone, the advantages of aerosol treatments with limited systemic effects are substantial. Indeed, in clinical practice, proba-

Figure 27-2. Schematic representations of the disposition of inhaled drugs. Inhalation therapy deposits asthma medications directly, but not exclusively, in the lungs. Distribution of inhaled drug between lungs and esophagus depends on particle size and efficiency of delivery to lungs. Most material, approximately 90%, will be swallowed and absorbed, entering the systemic circulation. Some drug also will be absorbed from the lungs. Optimal particle size for deposition in small airways is 1 to 5 μm .

bly more than 90% of asthmatic patients who are capable of manipulating inhaler devices can be managed by aerosol treatments alone. Because of the specialized nature of aerosol delivery and the substantial effects that these systems have on the therapeutic index, the principles of this delivery method are important to review.

The chemistry and physics of aerosol delivery systems have been reviewed (Taburet and Schmit, 1994). A schematic diagram of the fate of therapeutic agents delivered by this route is given in Figure 27-2. The critical determinant of the delivery of any particulate matter to the lungs is the size of the particles. Particles larger than 10 μm are deposited primarily in the mouth and oropharynx, whereas particles smaller than 0.5 μm are inhaled to the alveolae and subsequently exhaled without being deposited in the lungs. Particles with a diameter of 1 to 5 μm allow deposition of drugs in the small airways and therefore are the most effective. Unfortunately, no aerosol system in clinical use can produce uniform particles limited to the appropriate size range. A number of factors in addition to particle size determine effective deposition of drugs in the

bronchial tree, including the rate of breathing and breath-holding after inhalation. It is recommended that a slow, deep breath be taken and held for 5 to 10 seconds when administering drugs to the lungs.

As depicted in Figure 27-2, even under ideal circumstances only a small fraction of the aerosolized drug is deposited in the lungs, typically 2% to 10%. Most of the remainder is swallowed. Therefore, to minimize systemic effects, an aerosolized drug should be either poorly absorbed from the gastrointestinal system or rapidly inactivated *via* first-pass hepatic metabolism. Furthermore, any maneuvers that increase deposition in the lungs or decrease the percentage of drug reaching the gastrointestinal system should enhance the desired effects and reduce undesired systematic effects. For example, with metered-dose inhalers, a large-volume “spacer” can be attached to the inhaler. A spacer is a tube or expandable bellows that fits between the inhaler and the patient’s mouth; the inhaler discharges into the spacer, and the patient inhales from it. A spacer can improve markedly the ratio of inhaled to swallowed drug by limiting the amount of larger particles (>10 μm) that reach the mouth and by reducing the need for the patient to coordinate accurately inhalation with inhaler activation (Bryant and Shimizu, 1988). This is not a trivial concern: More than 50% of patients using inhalers do not use proper technique and thus deposit too small a fraction of inhaled drug into the lungs.

The two types of devices used for aerosol therapy are *metered-dose inhalers* and *nebulizers*. Both devices provide a range of particle sizes that includes the desired 1- to 5- μm range. When used appropriately, they are equally effective in drug delivery to the lungs, even in the setting of fairly severe asthma exacerbations (Turner *et al.*, 1988; Benton *et al.*, 1989). Nevertheless, some clinicians and many patients prefer to use nebulizers for severe asthma exacerbations with poor inspiratory ability. Metered-dose inhalers offer the advantages of being cheaper and portable; nebulizers offer the advantage of not requiring hand-breathing coordination. In addition, nebulizer therapy can be delivered by face-mask to young children or older patients who are confused. A substantial disadvantage of metered-dose inhalers is that most contain chlorofluorocarbons. Temporary exemptions have been given for these devices until safe alternative propellants can be developed. An albuterol metered-dose inhaler using hydrofluoroalkane as a propellant (PROVENTIL HFA) is available for clinical use in the United States.

An alternative to aerosolized delivery is the use of *dry-powder inhalers*. These typically use lactose or glucose powders to carry the drugs. One disadvantage of these devices is that a relatively high airflow is needed to suspend the powder properly. Young children, the elderly, and those suffering from a significant asthma exacerbation may be unable to generate such airflow rates. The dry powder can be irritating when inhaled. Storage of dry-powder inhalers in areas where there are wide temperature fluctuations or high humidity can impair their performance.

β_2 Adrenergic Receptor Agonists

The history, chemistry, pharmacological properties, and mechanisms of action of the β adrenergic agonists are discussed in Chapter 10. Their discussion here is restricted to their uses in asthma.

Mechanism of Action and Use in Asthma. The β adrenergic receptor agonists available for the treatment of asthma are selective for the β_2 -receptor subtype. With few exceptions, they are delivered directly to the airways *via* inhalation. The agonists can be classified as short- or long-acting. This subclassification is useful from a pharmacological perspective: Short-acting agonists are used only for symptomatic relief of asthma, whereas long-acting agonists are used prophylactically in the treatment of the disease.

The mechanism of the antiasthmatic action of β adrenergic receptor agonists is undoubtedly linked to the direct relaxation of airway smooth muscle and consequent bronchodilation. Although human bronchial smooth muscle receives little or no sympathetic innervation, it nevertheless contains large numbers of β_2 adrenergic receptors. Stimulation of these receptors activates the G_s adenylyl cyclase-cyclic AMP pathway with a consequent reduction of in smooth muscle tone (Sylvester, 2004). β_2 Adrenergic receptor agonists also increase the conductance of large Ca^{2+} -sensitive K^+ channels in airway smooth muscle, leading to membrane hyperpolarization and relaxation. This occurs at least partly by mechanisms independent of adenylyl cyclase activity and cyclic AMP production and may involve the regulation of capacitative Ca^{2+} entry by small G proteins. (Kume *et al.*, 1994; Ostrom and Ehlert, 1998; Koike *et al.*, 2004; Sylvester, 2004).

There are β_2 adrenergic receptors on cell types in the airways other than bronchial smooth muscle. Of particular interest, stimulation of β_2 adrenergic receptors inhibits the function of numerous inflammatory cells, including mast cells, basophils, eosinophils, neutrophils, and lymphocytes. In general, stimulating β_2 adrenergic receptors in these cell types increases intracellular cyclic AMP, activating a signaling cascade that inhibits the release of inflammatory mediators and cytokines (Barnes, 1999).

As noted below, long-term exposure to β_2 -agonists may desensitize some of these receptor-response pathways; thus there is little evidence that these drugs, used chronically, reduce airway inflammation.

Short-Acting β_2 Adrenergic Receptor Agonists. Drugs in this class include *albuterol* (PROVENTIL, VENTOLIN), *levalbuterol*, the (R)-enantiomer of albuterol (XOPENEX), *metaproterenol* (ALUPENT), *terbutaline* (BRETHAIRE), and

pirbuterol (MAXAIR). These drugs are used for acute inhalation treatment of bronchospasm. Terbutaline (BRETHINE, BRICANYL), albuterol, and metaproterenol also are available in oral dosage form. Each of the inhaled drugs has an onset of action within 1 to 5 minutes and produces bronchodilation that lasts for about 2 to 6 hours. When given in oral dosage forms, the duration of action is somewhat longer (oral terbutaline, for example, has a duration of action of 4 to 8 hours). Although there are slight differences in the relative β_2/β_1 -receptor potency ratios among the drugs, all of them are selective for the β_2 subtype.

The most effective drugs in relaxing airway smooth muscle and reversing bronchoconstriction are short-acting β_2 adrenergic receptor agonists. They are the preferred treatment for rapid symptomatic relief of dyspnea associated with asthmatic bronchoconstriction (Fanta *et al.*, 1986; Nelson, 1995). Although these drugs are prescribed on an as-needed basis, it is imperative that guidelines be given to the patient so that reliance on relief of symptoms during times of deteriorating asthma does not occur. When the asthma symptoms become persistent, the patient should be reevaluated so that drugs aimed at controlling, in addition to reversing, the disease can be prescribed.

Long-Acting β Adrenergic Receptor Agonists. *Salmeterol xinafoate* (SEREVENT) and *formoterol* (FORADIL) are long-lasting adrenergic agents with very high selectivity for the β_2 -receptor subtype (Cheung *et al.*, 1992; D'Alonzo *et al.*, 1994). Inhalation of salmeterol provides persistent bronchodilation lasting over 12 hours. The mechanism underlying the extended duration of action of salmeterol is not yet fully understood. The extended side chain on salmeterol renders it 10,000 times more lipophilic than albuterol (Brittain, 1990). The lipophilicity regulates the diffusion rate away from the receptor by determining the degree of partitioning in the lipid bilayer of the membrane. Subsequent to binding the receptor, the less lipophilic, short-acting agonists are removed rapidly from the receptor environment by diffusion in the aqueous phase. Unbound salmeterol, by contrast, persists in the membrane and only slowly dissociates from the receptor environment.

Long-acting β adrenergic receptor agonists relax airway smooth muscle and cause bronchodilation by the same mechanisms as short-duration agonists. Chronic treatment with a receptor agonist often leads to receptor desensitization and a diminution of effect. The rate and degree of β_2 adrenergic receptor desensitization depend on the cell type. For example, the β_2 receptors on human bronchial smooth muscle are relatively resistant to desensitization, whereas receptors on mast cells and lymphocytes are desensitized rapidly following agonist exposure (Chong and Peachell, 1999; Johnson and Coleman, 1995). This

may help to explain why there is little evidence that these drugs are effective in inhibiting airway inflammation associated with asthma.

Several studies have evaluated the effect of adding a long-acting β_2 adrenergic agonist to inhaled glucocorticoid treatment in patients with persistent asthma (Jackson and Lipworth, 2004). Combinations examined include salmeterol–fluticasone and formoterol–budesonide. The data suggest that adding a long-acting β_2 adrenergic agonist to the inhaled steroid regimen is more effective than doubling the steroid dose. Thus, current management guidelines for asthma recommend that long-acting β_2 adrenergic agonists be added if symptoms persist in patients on low or medium doses of inhaled steroids. Because chronic treatment with long-lasting inhaled β_2 adrenergic agonists does not decrease airway inflammation significantly, most experts do not use them as sole agents for asthma treatment. A convenient fixed-dosage combination of salmeterol and fluticasone (ADVAIR) is marketed in the United States, and a fixed dosage combination of formoterol and budesonide is available in other countries.

Toxicity. Owing to their β_2 -receptor selectivity and topical delivery, inhaled β adrenergic receptor agonists at recommended doses have relatively few side effects. A portion of inhaled drug is inevitably absorbed into the systemic circulation. At higher doses, therefore, these drugs may lead to increased heart rate, cardiac arrhythmias, and central nervous system (CNS) effects associated with β adrenergic receptor activation, as described in Chapter 10. This is of particular concern in patients with poorly controlled asthma, in whom there may be excessive and inappropriate reliance on symptomatic treatment with short-acting β receptor agonists.

Oral Therapy with β Adrenergic Receptor Agonists.

The use of orally administered β adrenergic agonists for bronchodilation has not gained wide acceptance largely because of the greater risk of side effects, especially tremulousness, muscle cramps, cardiac tachyarrhythmias, and metabolic disturbances (see Chapter 10). There are two primary situations in which oral β adrenergic agonists are used. First, brief courses of oral therapy (albuterol or metaproterenol syrups) are well tolerated and effective in young children (<5 years old) who cannot manipulate metered-dose inhalers yet have occasional wheezing with viral upper respiratory infections. Second, in some patients with severe asthma exacerbations, any aerosol, whether delivered *via* a metered-dose inhaler or a nebulizer, can worsen cough and bronchospasm owing to local irritation. In this setting, oral therapy with β_2 adrenergic agonists (e.g., albuterol, metaproterenol, or terbutaline tablets) can be effective. However, the frequency of adverse systemic side effects with orally administered agents is higher in adults than in children.

Even though stimulation of β adrenergic receptors inhibits the release of inflammatory mediators from mast cells, long-term administration of β_2 -agonists, either orally or by inhalation, does not reduce bronchial hyperresponsiveness. Thus, other approaches are preferred for the treatment of chronic symptoms. As discussed below under “Pharmacogenetics,” polymorphisms of the β_2 adrenergic receptor may correlate with response to therapy and adverse effects with β -agonists.

Glucocorticoids

The history, chemistry, pharmacological properties, and mechanisms of action of glucocorticoids are discussed in Chapter 59. The discussion here is restricted to their uses in asthma, as reviewed by Barnes and Pedersen (1993).

Systemic glucocorticoids long have been used to treat severe chronic asthma or severe acute exacerbations of asthma (McFadden, 1993; Greenberger, 1992). The development of aerosol formulations significantly improved the safety of glucocorticoid treatment, allowing it to be used for moderate asthma (Busse, 1993). Asthmatic subjects who require inhaled β_2 adrenergic agonists four or more times weekly are viewed as candidates for inhaled glucocorticoids (Anonymous, 1991; Israel and Drazen, 1994; Barnes, 1995).

Mechanism of Glucocorticoid Action in Asthma. Asthma is associated with airway inflammation, airway hyperreactivity, and acute bronchoconstriction. Glucocorticoids do not directly relax airway smooth muscle and thus have little effect on acute bronchoconstriction. By contrast, these agents are singularly effective in inhibiting airway inflammation. Very few mechanisms of inflammation escape the inhibitory effects of these drugs (see Chapter 59; Schleimer, 1998). The antiinflammatory effects of glucocorticoids in asthma include modulation of cytokine and chemokine production; inhibition of eicosanoid synthesis; marked inhibition of accumulation of basophils, eosinophils, and other leukocytes in lung tissue; and decreased vascular permeability (Schleimer, 1998). The profound and generalized antiinflammatory action of this class of drugs explains why they are currently the most effective drugs used in the treatment of asthma.

Inhaled Glucocorticoids. Although glucocorticoids are very effective in controlling asthma, treatment with systemic glucocorticoids comes at the cost of considerable adverse effects (see Chapter 59). A major advance in asthma therapy was the development of inhaled glucocorticoids that targeted the drug directly to the relevant site of inflammation. These formulations greatly enhance the therapeutic index of the drugs, substantially diminishing the number and degree of side effects without sacrificing clinical utility. There are currently five glucocorticoids available in the United States for inhalation therapy: *beclomethasone dipropionate* (BECLOVENT, VANCERIL), *triamcinolone acetonide* (AZMACORT), *flunisolide* (AERO-BID), *budesonide* (PULMICORT), and *fluticasone propionate* (FLOVENT). While they differ markedly in their affinities for the glucocorticoid receptor, with fluticasone and budesonide having much higher affinities than beclomethasone, they are all effective in controlling asthma at the appropriate doses. Few studies have directly assessed the relative therapeutic index of the various formulations of inhaled steroids in the treatment of asthma, but available data indicate that none has a clearly superior therapeutic index (O’Byrne and Pedersen, 1998).

Inhaled glucocorticoids are used prophylactically to control asthma rather than acutely to reverse asthma symptoms. As with all prophylactic therapies, compliance is a significant concern. Issues relating to drug compliance, therefore, become relevant when choosing among the various steroid formulations. The newer, highly potent drugs (*e.g.*, fluticasone, flunisolide, and budesonide) can be effective with as little as one or two puffs administered twice or even once daily. This more convenient dosage regimen may be preferred by patients, providing improved compliance and better asthma control. The appropriate dose of steroid must be determined empirically. Important variables that influence the effective dose include the severity of disease, the particular steroid used, and the device used for drug delivery, which determines the actual quantity of drug delivered to the lungs (Smaldone, 1997). When determining the optimal dose, keep in mind that maximal improvement in lung function may not occur until after several weeks of treatment.

Asthmatic patients maintained on inhaled glucocorticoids show improvement in symptoms and lowered requirements for “rescue” with β_2 adrenergic agonists (Laitinen *et al.*, 1992; Haahtela *et al.*, 1994). Beneficial effects may be seen within 1 week; however, improvement, in terms of reduced bronchial hyperreactivity, may continue for several months (Juniper *et al.*, 1990). Inhaled glucocorticoids are superior to inhaled β_2 -agonists for symptom control. In one study, improved bronchial hyperreactivity persisted throughout 2 years of treatment with inhaled budesonide (600 μg twice daily), and most patients were able to reduce their dose to 200 μg twice daily thereafter without worsened symptoms (Haahtela *et al.*, 1994). Complete discontinuation of budesonide generally was associated with increased bronchial hyperreactivity and worsened symptoms, although symptoms did not worsen in a third of patients. Thus a trial discontinuation of inhaled glucocorticoids should be considered in patients who are extremely well controlled.

Systemic Glucocorticoids. Systemic glucocorticoids are used for acute asthma exacerbations and chronic severe asthma. Substantial doses of glucocorticoids (*e.g.*, 40 to 60 mg prednisone or equivalent daily for 5 days; 1 to 2 mg/kg per day for children) often are used to treat acute exacerbations of asthma (Weinberger, 1987). Although an additional week at somewhat reduced dosage may be required, the steroids can be withdrawn abruptly once control of the symptoms by other medications has been restored; any suppression of adrenal function dissipates within 1 to 2 weeks. More protracted bouts of severe asthma may require longer treatment and slower tapering of the dose to avoid exacerbating asthma symptoms and suppressing pituitary/adrenal function. Previously, alternate-day therapy with oral prednisone was employed commonly in persistent asthma. Now most patients with asthma are better treated with inhaled glucocorticoids.

Toxicity. Inhaled Glucocorticoids. While there is a great deal of enthusiasm for inhaled glucocorticoids in asthma, local and systemic adverse effects remain a concern (Table 27-1). Some portion of any inhaled drug is swallowed. Therefore, inhaled drugs can reach the circulation by direct absorption from the lung or by absorption from the gas-

trointestinal tract. The newer glucocorticoids have extremely low oral bioavailability owing to extensive first-pass metabolism by the liver and reach the circulation almost exclusively by absorption from the lung (Brattsand and Axelsson, 1997). In contrast to the beneficial effects on asthma, which plateau at about 1600 $\mu\text{g}/\text{day}$, the probability of adverse effects continues to increase at higher doses. Oropharyngeal candidiasis and, more frequently, dysphonia can be encountered. The incidence of candidiasis can be reduced substantially by rinsing the mouth and throat with water after each use and by employing spacer or reservoir devices attached to the dispenser to decrease drug deposition in the oral cavity (Johnson, 1987). Appreciable suppression of the hypothalamic-pituitary-adrenal axis is difficult to document at doses below 800 $\mu\text{g}/\text{day}$ and probably is rarely of physiologic importance even at doses up to 1600 $\mu\text{g}/\text{day}$. Modest but statistically significant decreases in bone mineral density do occur in female asthmatics receiving inhaled steroids, even when doses as low as 500 $\mu\text{g}/\text{day}$ are employed (Ip *et al.*, 1994). Others have shown increases in markers for bone mineral turnover (serum osteocalcin and urine hydroxyproline levels) during treatment with inhaled glucocorticoids (Pavord and Knox, 1993; Israel and Drazen, 1994). While the clinical relevance of these bone metabolism findings remains to be determined, it is argued that inhaled glucocorticoid treatment should be reserved for moderate or severe asthma because such treatment is likely to last for many years (Israel and Drazen, 1994). Nonetheless, it has been suggested that the small risk of adverse effects at high doses of inhaled glucocorticoids is outweighed by the risks of inadequately controlling severe asthma (Barnes, 1995).

Systemic Glucocorticoids. The adverse effects of systemic administration of glucocorticoids are well known (*see* Chapter 59), but treatment for brief periods (5 to 10 days) causes relatively little dose-related toxicity. The most common adverse effects during a brief course are mood disturbances, increased appetite, impaired glucose control in diabetics, and candidiasis.

Leukotriene-Receptor Antagonists and Leukotriene-Synthesis Inhibitors

Zafirlukast (ACCOLATE) and *montelukast* (SINGULAIR) are leukotriene-receptor antagonists. *Zileuton* (ZYFLO) is an inhibitor of 5-lipoxygenase, which catalyzes the formation of leukotrienes from arachidonic acid.

History. The history of leukotrienes can be traced back to the classical pharmacological studies in the late 1930s by Kellaway and Trethewie. On investigating antigen-induced responses in guinea pigs sensitized to egg albumin, they discovered a slow-reacting smooth muscle-stimulating substance. They named the active ingredient *slow-reacting substance* (SRS) based on its pharmacological activity and concluded that it was a unique substance found only in immunologically sensitized tissues subsequently challenged with antigen. Decades later, SRS was renamed *slow-reacting substance of anaphylaxis* (SRS-A).

Two pivotal discoveries were required before the importance of SRS-A in allergic responses was proven. First was the discovery in 1973 by scientists at Fisons Pharmaceutical Company of an SRS-A antagonist called FPL 55712 (Augstein *et al.*, 1973), and second was the elucidation by Samuelsson and colleagues of the structure of SRS-A as a 5-lipoxygenase product of arachidonic acid, which they termed *cysteinyl leukotriene* (Murphy *et al.*, 1979; *see* Chapter 25). Soon thereafter, an enormous effort was undertaken by the pharmaceutical industry to discover novel inhibitors of leukotrienes as potential therapeutic

Table 27-1
Potential Adverse Effects Associated with Inhaled Glucocorticoids

ADVERSE EFFECT	RISK
Hypothalamic–pituitary–adrenal axis suppression	No significant risk until dosages of budesonide or beclomethasone increased to >1500 $\mu\text{g}/\text{day}$ in adults or >400 $\mu\text{g}/\text{day}$ in children
Bone resorption	Modest but significant effects at doses possibly as low as 500 $\mu\text{g}/\text{day}$
Carbohydrate and lipid metabolism	Minor, clinically insignificant changes occur with dosages of beclomethasone >1000 $\mu\text{g}/\text{day}$
Cataracts	Anecdotal reports, risk unproven
Skin thinning	Dosage-related effect with beclomethasone dipropionate over a range of 400 to 2000 $\mu\text{g}/\text{day}$
Purpura	Dosage-related increase in occurrence with beclomethasone over a range of 400 to 2000 $\mu\text{g}/\text{day}$
Dysphonia	Usually of little consequence
Candidiasis	Incidence <5%, reduced by use of spacer device
Growth retardation	Difficult to separate effect of disease from effect of treatment, but no discernible effects on growth when all studies are considered

SOURCE: Modified from Pavord and Knox (1993) and Barnes (1995).

agents for asthma. The strategies taken were either to reduce the synthesis of leukotrienes by inhibiting the 5-lipoxygenase enzyme or to antagonize the effects of leukotrienes at their receptors. These efforts bore fruit in the 1990s with the release of three new drugs for the treatment of asthma in the United States: the leukotriene-receptor antagonists zafirlukast (Krell *et al.*, 1990) and montelukast (Jones *et al.*, 1995) and the leukotriene-synthesis inhibitor zileuton (Carter *et al.*, 1991).

Chemistry. The chemical structures of zafirlukast, montelukast, and zileuton are shown below.

Pharmacokinetics and Metabolism. The leukotriene-modifying drugs are administered orally. Zafirlukast is absorbed rapidly, with greater than 90% bioavailability. At therapeutic plasma concentrations, it is over 99% protein-bound. Zafirlukast is metabolized extensively by hepatic CYP2C9. The parent drug is responsible for its therapeutic activity, with metabolites being less than 10% as effective. The half-life of zafirlukast is approximately 10 hours.

Montelukast is absorbed rapidly, with about 60% to 70% bioavailability. At therapeutic concentrations, it is highly protein-bound (99%). It is metabolized extensively by CYP3A4 and CYP2C9. The half-life of montelukast is between 3 and 6 hours.

Zileuton is absorbed rapidly on oral administration and is metabolized extensively by CYPs and by UDP-glucuronosyltransferases. The parent molecule is responsible for its therapeutic action. Zileuton is a short-acting drug with a half-life of approximately 2.5 hours and also is highly protein-bound (93%).

Mechanism of Action in Asthma. Leukotriene-modifying drugs act either as competitive antagonists of leukotriene receptors or by inhibiting the synthesis of leukotrienes. The pharmacological properties of leukotrienes are discussed in detail in Chapter 25.

Leukotriene-Receptor Antagonists. Cysteinyl leukotrienes (cys-LTs) include leukotriene C₄ (LTC₄), leukotriene D₄ (LTD₄), and leukotriene E₄ (LTE₄). All the cys-LTs are potent constrictors of bronchial smooth muscle. On a molar basis, LTD₄ is approximately 1000 times more potent than is histamine as a bronchoconstrictor (Dahlen *et al.*, 1980). The receptor responsible for the bronchoconstrictor effect of leukotrienes is the cys-LT₁ receptor (Buckner *et al.*, 1986; Lynch *et al.*, 1999). Although each

of the cys-LTs is an agonist at the cys-LT₁ receptor, LTE₄ is less potent than either LTC₄ or LTD₄. Zafirlukast and montelukast are selective high-affinity competitive antagonists for the cys-LT₁ receptor (Krell *et al.*, 1990, Jones *et al.*, 1995). *Pranlukast* is another cys-LT₁-receptor antagonist used in some countries in the treatment of asthma, but it is not approved for use in the United States. Inhibition of cys-LT-induced bronchial smooth muscle contraction likely is involved in the therapeutic effects of these agents to relieve the symptoms of asthma.

The effects of cys-LTs that are potentially relevant to bronchial asthma are not limited to bronchial smooth muscle contraction. Cys-LTs can increase microvascular leakage, increase mucous production, and enhance eosinophil and basophil influx into the airways (Hay *et al.*, 1995). The extent to which inhibiting these non-smooth muscle effects of leukotrienes contributes to the therapeutic effects of the drugs is not known. It may be noteworthy, however, that zafirlukast significantly inhibits the influx of basophils and lymphocytes entering the airways following experimental allergen challenge in asthmatic subjects (Calhoun *et al.*, 1998).

Leukotriene-Synthesis Inhibitors. The formation of leukotrienes depends on lipoxygenase of arachidonic acid by 5-lipoxygenase. Zileuton is a potent and selective inhibitor of 5-lipoxygenase activity and thus inhibits the formation of all 5-lipoxygenase products. Thus, in addition to inhibiting the formation of the cys-LTs, zileuton also inhibits the formation of leukotriene B₄ (LTB₄), a potent chemotactic autacoid, and other eicosanoids that depend on leukotriene A₄ (LTA₄) synthesis. In theory, the therapeutic effects of a 5-lipoxygenase inhibitor would include all those observed with the cys-LT₁-receptor antagonists, as well as other effects that may result from inhibiting the formation of LTB₄ and other 5-lipoxygenase products.

The pharmacological actions of cys-LTs are not fully accounted for by activation of the cys-LT₁ receptor. For example, cys-LT-induced contraction of vascular smooth muscle (Gorenne *et al.*, 1995) and stimulation of expression of P-selectin by endothelial cells occur *via* cys-LT₂ receptors (Pedersen *et al.*, 1997). This provides another theoretical advantage of zileuton over zafirlukast and montelukast because 5-lipoxygenase inhibitors would inhibit cys-LT effects regardless of the receptor subtypes involved. These theoretical advantages notwithstanding, studies to date do not prove that zileuton is significantly more efficacious than the cys-LT₁-receptor antagonists in the treatment of asthma.

Toxicity. There are few adverse effects directly associated with inhibition of leukotriene synthesis or function. This likely is due to the fact that leukotriene production is limited predominantly to sites of inflammation.

Zafirlukast and Montelukast. In large clinical studies the adverse-effect profiles of these drugs were similar to that observed with placebo treatment. Very rarely, patients taking these drugs develop system-

ic eosinophilia and a vasculitis with features similar to Churg-Strauss syndrome. This problem, often associated with a reduction in glucocorticoid therapy, may represent the unmasking of a preexisting disease. Zafirlukast, but not montelukast, may interact with warfarin and increase prothrombin times, which should be monitored in patients subject to this interaction.

Zileuton. The adverse-effect profile in patients taking zileuton is similar to that in patients taking placebo. In about 4% to 5% of patients taking zileuton, however, there is an elevation in liver enzymes, generally within the first 2 months of therapy. Zileuton decreases the steady-state clearance of theophylline, substantially increasing its plasma concentrations. Zileuton also decreases warfarin clearance. Because of a variety of pharmacokinetic and safety issues, the drug is no longer used in the United States.

Use in Asthma. Although leukotriene inhibitors are effective prophylactic treatment for mild asthma, their role in asthma therapy is not clearly defined. Most clinical trials with these drugs have studied patients with mild asthma who were not taking glucocorticoids. In general, the studies show a modest but significant improvement in pulmonary function and a decrease in symptoms and asthma exacerbations. In a meta-analysis of clinical trials with zafirlukast, all studies showed some decrease in the rate of asthma exacerbations, with an average reduction of 50% (Barnes and Miller, 2000). When zafirlukast (Laitinen *et al.*, 1997) and montelukast (Malmstrom *et al.*, 1999) were compared with low-dose inhaled glucocorticoid therapy, the improvement in lung function and decreased dependence on short-acting β_2 adrenergic receptor agonist therapy was found to be greater in the glucocorticoid-treated subjects. There was little difference, however, between the steroid- and montelukast-treated subjects in the reduction in rate of asthma exacerbations. Clinical trials with antileukotriene drugs have revealed considerable heterogeneity in response to therapy, with patients falling into “responder” and “nonresponder” groups. For those who respond to antileukotriene therapy, the National Heart, Lung, and Blood Institute recognizes these drugs as alternatives to low-dose inhaled steroids for control of mild chronic asthma.

More studies are required to define the role of these drugs in moderate and severe asthma. Some clinical trials have demonstrated an ability of leukotriene antagonists to allow a reduction in the dose of inhaled steroid needed to control asthma exacerbations (Lofdahl *et al.*, 1999; Jarvis and Markham, 2000). If this is the case, it may be particularly relevant in children with more severe asthma. This class of drugs is not indicated for rapid bronchodilator therapy; thus patients are instructed to have short-acting β adrenergic receptor agonists available as rescue medication. Montelukast and zafirlukast are effective with once- or twice-daily treatment, respectively. In contrast, zileu-

ton is taken four times a day. Liver enzymes should be monitored in patients beginning zileuton therapy to guard against the potential of liver toxicity.

Anti-IgE Therapy

Omalizumab (XOLAIR) is the first “biological drug” approved for the treatment of asthma. Omalizumab is a recombinant humanized monoclonal antibody targeted against IgE. IgE bound to omalizumab cannot bind to IgE receptors on mast cells and basophils, thereby preventing the allergic reaction at a very early step in the process (Figure 27–3).

History. In 1921, Prausnitz and Kustner provided conclusive evidence that a serum factor that they termed *reagin* was able to passively transfer allergic reactions from an allergic individual to non-allergic subjects. It was some 45 years before the Ishizakas proved that reagin was a novel immunoglobulin termed E (IgE). IgE was found to bind with high affinity to receptors on mast cells and basophils, and the subsequent binding of antigen (allergen) to the bound IgE molecules resulted in cell activation and the release of various mediators of allergic inflammation (Tomioka and Ishizaka, 1971). It was recognized at once that a chemical that would prevent IgE from

Figure 27–3. *Omalizumab is a monospecific anti-IgE antibody.* Specific B-lymphocytes produce IgE antibodies. The Fc region of IgE heavy chains binds with high affinity to receptors (FcεRI) in the plasma membranes of mast cells and basophils (and other cells). Allergen interacts with the antigen-binding site of cell-bound IgE, causing FcεRI cross-linking and cell activation. Omalizumab neutralizes the free IgE in the serum by binding to the Fc regions of the heavy chains to form high-affinity IgE–anti-IgE complexes. This prevents the IgE from binding to FcεRI, thereby blocking allergen-induced cell activation.

binding to its receptor on mast cells and basophils would be a novel and powerful anti-allergy drug. Various anti-IgE strategies met with little success until the discovery and development of “humanized” monoclonal antibodies. The rational idea of developing a monoclonal antibody targeted specifically against the receptor-binding site of IgE ultimately led to the discovery of omalizumab.

Chemistry. Omalizumab is a DNA-derived humanized monoclonal antibody of the IgG1κ subclass. It has a molecular weight of approximately 149,000. The antibody is produced in Chinese hamster ovary cells in cell culture. It is sold as a preservative-free powder. A vial of XOLAIR contains 202 mg omalizumab, as well as sucrose, L-histidine, and polysorbate 20.

Pharmacokinetics and Metabolism. Omalizumab is delivered as a single subcutaneous injection every 2 to 4 weeks. It has a bioavailability of about 60%, reaching peak serum levels after 7 to 8 days. The serum elimination half-life is 26 days, with a clearance rate of about 2.5 ml/kg per day. The elimination of omalizumab–IgE complexes occurs in the liver reticuloendothelial system at a rate somewhat faster than that of free IgG. Some intact omalizumab is also excreted in the bile. There is little evidence of specific uptake of omalizumab by any tissue.

Mechanism of Action. The Fc region of IgE binds with high affinity to the Fc epsilon receptor I (FcεRI). FcεRI is expressed on the surfaces of mast cells and basophils, as well as several other cell types. When an allergen interacts with the antigen-binding domains of IgE bound to FcεRI on mast cells and basophils, it cross-links the receptors and activates the cell. This, in turn, triggers the release of pre-formed granule-associated mediators such as histamine and tryptase. In addition, it results in the immediate production of eicosanoids, most notably LTC₄ and prostaglandin D₂ (PGD₂) and, on a time scale of hours instead of minutes, the synthesis of various cytokines (Schroeder *et al.*, 2001; Krishnaswamy *et al.*, 2001). Omalizumab is an IgG antibody for which the antigen is the Fc region of the IgE antibody; thus it is an “anti-antibody antibody.” Omalizumab binds tightly to free IgE in the circulation to form omalizumab–IgE complexes that have no affinity for FcεRI (Figure 27-3). At the recommended doses, omalizumab reduces free IgE by more than 95%, thereby limiting the amount of IgE bound to FcεRI-bearing cells. Omalizumab treatment also decreases the amount of FcεRI expressed on basophils and mast cells (MacGlashan *et al.*, 1997). For example, after treatment with omalizumab, the number of FcεRIs expressed on the surfaces of basophils decreased by more than 95% from a starting value of about 200,000 receptors per cell. This decrease in surface FcεRIs results from increased turnover of unbound receptors rather than decreased FcεRI synthesis (MacGlashan *et al.*, 2001; Borkowski *et al.*, 2001). Thus the effectiveness of omalizumab in reducing the amount of allergen-specific IgE bound to mast cells and basophils depends on the reduction of both free IgE and available FcεRIs on cell surfaces. Normally, IgE-mediated basophil activation is extremely efficacious, requiring antigen to interact with only a small fraction of the bound IgE to evoke a half-maximal response (MacGlashan, 1993). This predicts that drugs such as omalizumab will have little clinical effect until doses are given that reduce free IgE by greater than 90%.

Besides mast cells and basophils, monocytes, lymphocytes, certain antigen-presenting cells, and eosinophils express FcεRI. The effects of omalizumab on decreasing IgE binding and FcεRI expression on these cells also may contribute to the therapeutic effect of omalizumab (Prussin *et al.*, 2003).

Toxicity. The safety of omalizumab so far has been evaluated in only three large, randomized, placebo-controlled multicenter studies. Omalizumab generally was well tolerated in several large, placebo-controlled trials. The most frequent adverse effect was injection-site reactions (*e.g.*, redness, stinging, bruising, and induration), but these reactions also were seen at comparable frequencies with placebo. Low titers of antibodies against omalizumab developed in 1 of 1723 treated patients, whereas anaphylaxis was seen in 0.1% of treated patients. Malignancies of various types were observed in 20 of 4127 patients taking omalizumab, a higher frequency than the 5 malignancies in 2236 patients taking other asthma and allergy drugs. Additional studies are needed to determine if omalizumab does indeed cause cancers.

Use in Asthma. Omalizumab is indicated for adults and adolescents older than 12 years of age with allergies and moderate-to-severe persistent asthma. In this population, omalizumab has proven to be effective in reducing the dependency on inhaled and oral corticosteroids and in decreasing the frequency of asthma exacerbations (Soler *et al.*, 2001; Busse *et al.*, 2001). Omalizumab is not an acute bronchodilator and should not be used as a rescue medication or as a treatment of status asthmaticus.

Based on its mechanism of action, omalizumab has been used in the treatment of other allergic disorders, such as nasal allergy (Lin *et al.*, 2004) and food allergy (Leung *et al.*, 2003), but large-scale clinical trials are limited to asthma.

Cromolyn Sodium and Nedocromil Sodium

History and Chemistry. *Cromolyn* was synthesized in 1965 in an attempt to improve on the bronchodilator activity of khellin. This chromone, derived from the plant *Ammi visnaga*, had been used by the ancient Egyptians for its spasmolytic properties. Although devoid of the bronchodilating effect of the parent compound, cromolyn was found to inhibit antigen-induced bronchospasm as well as the release of histamine and other autacoids from sensitized rat mast cells. Cromolyn has been used in the United States for the treatment of asthma since 1973. The initial clinical results were disappointing, in retrospect largely owing to a misplaced hope that cromolyn would reduce or eliminate the need for systemic glucocorticoids in the treatment of patients with relatively severe asthma. However, its therapeutic role has been reevaluated in recent years, and cromolyn has emerged as one of the first-line agents in the treatment of mild to moderate asthma. *Nedocromil*, a compound with similar chemical and biological properties, became available in 1992 (Wasserman, 1993; Brogden and Sorkin, 1993). Cromolyn sodium (disodium cromoglycate) and nedocromil sodium have the following structures:

CROMOLYN SODIUM

NEDOCROMIL SODIUM

Mechanism of Action. Cromolyn and nedocromil have a variety of activities that may relate to their therapeutic efficacy in asthma. These include inhibiting mediator release from bronchial mast cells (Pearce *et al.*, 1989); reversing increased functional activation in leukocytes obtained from the blood of asthmatic patients (Murphy and Kelly, 1987); suppressing the activating effects of chemotactic peptides on human neutrophils, eosinophils, and monocytes (Kay *et al.*, 1987; Moqbel *et al.*, 1988); inhibiting parasympathetic and cough reflexes (Hargreaves and Benson, 1995; Fuller *et al.*, 1987); and inhibiting leukocyte trafficking in asthmatic airways (Hoshino and Nakamura, 1997). Suffice it to say that the mechanism of action of cromolyn and nedocromil in asthma is not known.

Pharmacokinetics. For asthma, cromolyn is given by inhalation using either solutions (delivered by aerosol spray or nebulizer) or, in some countries but not in the United States, powdered drug (mixed with lactose and delivered by a special turboinhaler). The pharmacological effects result from the topical deposition of the drug in the lung, since only about 1% of an oral dose of cromolyn is absorbed. Once absorbed, the drug is excreted unchanged in the urine and bile in about equal proportions. Peak concentrations in plasma occur within 15 minutes of inhalation, and excretion begins after some delay such that the biological half-life ranges from 45 to 100 minutes. The terminal half-time of elimination following intravenous administration is about 20 minutes. The pharmacokinetic properties of cromolyn have been reviewed (Murphy and Kelly, 1987).

Toxicity. Cromolyn and nedocromil generally are well tolerated by patients. Adverse reactions are infrequent and minor and include bronchospasm, cough or wheezing, laryngeal edema, joint swelling and pain, angioedema, headache, rash, and nausea. Such reactions have been reported at a frequency of less than 1 in 10,000 patients (*see* Murphy and Kelly, 1987). Very rare instances of anaphylaxis also have been documented. Nedocromil and cromolyn can cause a bad taste.

Use in Asthma. The main use of cromolyn (INTAL) and nedocromil (TILADE) is to prevent asthmatic attacks in indi-

viduals with mild to moderate bronchial asthma. These agents are ineffective in treating ongoing bronchoconstriction. When inhaled several times daily, cromolyn inhibits both the immediate and the late asthmatic responses to antigenic challenge or to exercise. With regular use for more than 2 to 3 months, bronchial hyperreactivity is reduced, as measured by response to challenge with histamine or methacholine (see Murphy and Kelly, 1987; Hoag and McFadden, 1991). Nedocromil generally is more effective than cromolyn in animal models and human beings (Brogden and Sorkin, 1993). Nedocromil is approved for use in asthmatic patients 12 years of age and older; cromolyn is approved for all ages.

Cromolyn and nedocromil generally are less effective than inhaled glucocorticoids in controlling asthma. Cromolyn (2 mg inhaled four times daily) was less effective than 200 μg twice daily of beclomethasone (Svendsen *et al.*, 1987) or 4 mg four times daily of nedocromil (Brogden and Sorkin, 1993). Although nedocromil was roughly comparable with 200 μg beclomethasone inhaled twice daily, nedocromil was not as effective in controlling symptoms, reducing bronchodilator use, or improving bronchial hyperreactivity (Svendsen *et al.*, 1989). In a second study, 4 mg nedocromil four times daily was as effective as 100 μg beclomethasone four times daily (Bel *et al.*, 1990). In a thorough review, Brogden and Sorkin (1993) concluded that nedocromil is useful in patients with mild to moderate asthma as added therapy, as an alternative to regularly administered oral and inhaled β adrenergic agonists and oral methylxanthines, and possibly as an alternative to low-dose inhaled glucocorticoids.

The addition of cromolyn to inhaled glucocorticoid therapy yields no additional benefit in moderately severe asthma (Toogood *et al.*, 1981). Nedocromil may allow a reduction of steroids in patients receiving high doses of inhaled steroids (Brogden and Sorkin, 1993). These studies were short term; whether or not long-term reduction in steroid dose is possible remains to be determined. In one study, the addition of nedocromil 4 mg four times daily for 8 weeks to high-dose inhaled glucocorticoid treatment resulted in modest improvements in patients with moderately severe asthma (Svendsen and Jorgensen, 1991). Because of its limited efficacy, the use of cromolyn for the treatment of asthma in the United States is decreasing.

In patients with systemic mastocytosis who have gastrointestinal symptoms owing to an excessive number of mast cells in the gastrointestinal mucosa, an oral preparation of cromolyn (GASTRO-CROM) is effective in reducing symptoms (Horan *et al.*, 1990). The benefits reflect local action rather than systemic absorption; cromolyn is poorly absorbed, and only the gastrointestinal symptoms are improved in the treated patients.

Theophylline

Theophylline, a methylxanthine, is among the least expensive drugs used to treat asthma, and consequently, it remains a commonly used drug for this indication in many countries. In industrialized countries, the advent of inhaled glucocorticoids, β adrenergic receptor agonists,

and leukotriene-modifying drugs has diminished theophylline use significantly, and it has been relegated to a third- or fourth-line treatment in patients whose asthma is otherwise difficult to control.

Source and History. Theophylline, caffeine, and theobromine are three closely related plant alkaloids that are imbibed widely. At least half the population of the world consumes tea (containing caffeine and small amounts of theophylline and theobromine) prepared from the leaves of *Thea sinensis*, a bush native to southern China and now cultivated extensively in other countries. Cocoa and chocolate, from the seeds of *Theobroma cacao*, contain theobromine and some caffeine. Coffee, the most popular source of caffeine in the American diet, is extracted from the fruit of *Coffea arabica* and related species. Cola-flavored drinks usually contain considerable amounts of caffeine in part because of their content of extracts of the nuts of *Cola acuminata* and in part because caffeine is added during their production (see Graham, 1978).

The basis for the popularity of all caffeine-containing beverages is the ancient belief that they have stimulant and antisoporific actions that elevate mood, decrease fatigue, and increase capacity for work. Classical pharmacological studies principally of caffeine confirmed this belief and revealed that methylxanthines also possess other important pharmacological properties. These properties were exploited in a variety of therapeutic applications, in many of which caffeine now has been replaced by more effective agents. However, in recent years, there has been a resurgence of interest in the natural methylxanthines and their synthetic derivatives principally as a result of increased knowledge of their cellular basis of action.

Chemistry. Theophylline, caffeine, and theobromine are methylated xanthines. Caffeine is 1,3,7-trimethylxanthine; theophylline, 1,3-dimethylxanthine; and theobromine, 3,7-dimethylxanthine. The structural formulas of xanthine and the three naturally occurring xanthine derivatives are as follows:

The solubility of the methylxanthines is low and is much enhanced by the formation of complexes (usually 1:1) with a wide variety of compounds. The most notable of these complexes is that between theophylline and ethylenediamine (to form *aminophylline*). The formation of complex double salts (e.g., caffeine and sodium benzoate) or true salts [e.g., *choline theophyllinate* (*oxtriphylline*)] also enhances aqueous solubility. These salts or complexes dissoci-

ate in aqueous solution to yield the parent methylxanthines and should not be confused with covalently modified derivatives such as *diphylline* [1,3-dimethyl-7-(2, 3-dihydroxypropyl)xanthine].

A large number of derivatives of the methylxanthines have been prepared and examined for their ability to inhibit cyclic nucleotide phosphodiesterases (PDEs) (Beavo and Reifsnnyder, 1990) and to antagonize receptor-mediated actions of adenosine (Daly, 1982; Linden, 1991), the two best characterized cellular actions of the methylxanthines. Although certain modifications dissociate these two activities to some degree, these compounds are not used therapeutically.

Mechanism of Action. Theophylline inhibits cyclic nucleotide PDEs, thereby preventing breakdown of cyclic AMP and cyclic GMP to 5'-AMP and 5'-GMP, respectively. Inhibition of PDEs will lead to an accumulation of cyclic AMP and cyclic GMP, thereby increasing signal transduction through these pathways. The cyclic nucleotide PDEs are members of a superfamily of genetically distinct enzymes (Soderling and Beavo, 2000). Theophylline and related methylxanthines are relatively nonselective in the PDE subtypes they inhibit.

Cyclic nucleotide production is regulated by endogenous receptor–ligand interactions leading to activation of adenylyl cyclase and guanylyl cyclase. Inhibitors of PDEs therefore can be thought of as drugs that enhance the activity of endogenous autacoids, hormones, and neurotransmitters that signal *via* cyclic nucleotide messengers. This may explain why the *in vivo* potency often exceeds that observed *in vitro*.

Theophylline is a competitive antagonist at adenosine receptors (Fredholm and Persson, 1982). Adenosine can act as an autacoid and transmitter with myriad biological actions. Of particular relevance to asthma are the observations that adenosine can cause bronchoconstriction in asthmatics and potentiate immunologically induced mediator release from human lung mast cells (Cushley *et al.*, 1984; Peachell *et al.*, 1988). Inhibition of the actions of adenosine therefore also must be considered when attempting to explain the mechanism of action of theophylline (Feoktistov *et al.*, 1998).

Theophylline also may owe part of its antiinflammatory action to its ability to activate histone deacetylases in the nucleus (Ito *et al.*, 2002). In theory, the deacetylation of histones could decrease the transcription of several proinflammatory genes and potentiate the effect of corticosteroids.

Pulmonary System. Theophylline effectively relaxes airway smooth muscle; this bronchodilation likely contributes to its acute therapeutic efficacy in asthma. Both adenosine receptor antagonism and PDE inhibition are likely involved in the bronchodilating effect of theophylline. Adenosine does not contract isolated human bronchial smooth muscle directly, but when it is inhaled, it acts as a potent bronchoconstrictor in asthmatic subjects (Cushley *et al.*,

1984). Therefore, inhibition of this function of adenosine may contribute to theophylline-induced bronchodilation in some asthmatic subjects. Inhibition of PDE4 and PDE5 effectively relaxes human isolated bronchial smooth muscle (Torphy *et al.*, 1993). It thus seems likely that inhibition of PDEs also contributes to the bronchodilating effect of theophylline. Studies with the related methylxanthine enprofylline (3-propylxanthine), which has been investigated extensively for treatment of asthma in Europe, also support a mechanistic role for PDE inhibition in the bronchodilator actions of theophylline. Enprofylline is more potent than theophylline as a bronchodilator but is much less potent in inhibiting most types of adenosine receptors (Pauwels *et al.*, 1985). The latter point, however, must be interpreted cautiously. Activation of the A_{2B} subtype of adenosine receptor causes several proinflammatory effects, and both theophylline and enprofylline are potent competitive antagonists of A_{2B} adenosine receptors (Feoktistov *et al.*, 1998).

Theophylline also inhibits synthesis and secretion of inflammatory mediators from numerous cell types, including mast cells and basophils (Page, 1999). This effect of theophylline likely is due to PDE inhibition and can be mimicked in large part with drugs that selectively inhibit PDE4 isozyme (Torphy and Udem, 1991). At therapeutic concentrations, the antiinflammatory effect of theophylline may be more relevant to the drug's therapeutic actions than direct bronchodilation, but this remains unproven (Page, 1999).

Consistent with an important role of PDE4 in obstructive lung disease, selective PDE4 inhibitors have been evaluated in clinical trials for the treatment of asthma and chronic obstructive pulmonary disease (COPD). In one study, cilomilast (ARIFLO; 15 mg twice daily for 10 weeks) decreased inflammatory cell infiltration significantly in bronchial biopsies of patients with COPD. Further studies are needed to define the role of PDE4 inhibitors in asthma and COPD, but these drugs are promising candidates for new approaches to asthma therapy.

Absorption, Fate, and Excretion. The methylxanthines are absorbed readily after oral or parenteral administration. Absorption from rectal suppositories is slow and unreliable. Theophylline administered in liquids or uncoated tablets is absorbed rapidly and completely. Absorption also is complete from some, but not all, sustained-release formulations (*see* Hendeles and Weinberger, 1982). In the absence of food, solutions or uncoated tablets of theophylline produce maximal concentrations in plasma within 2 hours; caffeine is absorbed more rapidly, and maximal plasma concentrations are achieved within 1 hour. Numerous sustained-release preparations of theophylline are available, designed for dosing intervals of 8, 12, or 24 hours. There is marked interpatient variability with regard to the rate and extent of absorption and especially the effect of food and time of administration on these parameters (*see* Symposium, 1986a). Thus it is necessary to calibrate a given preparation in a given patient and to avoid substituting one apparently similar product for another.

Food ordinarily slows the rate of absorption of theophylline but does not limit its extent. With sustained-release preparations, food may decrease the bioavailability of theophylline with some products but may increase it with others. Recumbency or sleep also may reduce the rate or extent of absorption to an important degree. These factors make it difficult to maintain relatively constant concentrations of theophylline in plasma throughout the day. Concentrations required to alleviate asthmatic symptoms do not remain constant, and the emphasis has shifted toward designing dosing regimens that ensure peak concentrations in the early morning hours, when symptoms frequently worsen (*see* Symposium, 1988a).

Methylxanthines are distributed into all body compartments; they cross the placenta and pass into breast milk. The apparent volumes of distribution for caffeine and theophylline are between 0.4 and 0.6 L/kg. These values are considerably higher in premature infants. Theophylline is bound to plasma proteins to a greater extent than is caffeine, and the fraction bound declines as the concentration of methylxanthine increases. At therapeutic concentrations, the protein binding of theophylline averages about 60%, but it is decreased to about 40% in newborn infants and in adults with hepatic cirrhosis.

Methylxanthines are eliminated primarily by metabolism in the liver. Less than 15% and 5% of administered theophylline and caffeine, respectively, is recovered in the urine unchanged. Caffeine has a half-life in plasma of 3 to 7 hours; this increases by about twofold in women during the later stages of pregnancy or with long-term use of oral contraceptives. In premature infants, the rate of elimination of both methylxanthines is quite slow; the average half-life for caffeine is more than 50 hours, whereas the mean values for theophylline obtained in various studies range between 20 and 36 hours. However, the latter values include the extensive conversion of theophylline to caffeine in these infants (*see* Symposium, 1981; Roberts, 1984).

There is marked individual variation in the rate of elimination of theophylline owing to both genetic and environmental factors; fourfold differences are not uncommon (*see* Lesko, in Symposium, 1986a). The half-life averages about 3.5 hours in young children, whereas values of 8 or 9 hours are more typical in adults. In most patients the drug obeys first-order elimination kinetics within the therapeutic range. At higher concentrations, zero-order kinetics become evident because of saturation of metabolic enzymes, prolonging the decline of theophylline concentrations to nontoxic levels.

Methylxanthine metabolism also is influenced by other diseases or drugs (Symposium, 1996a). Hepatic cirrhosis, congestive heart failure, and acute pulmonary edema all increase the half-life, as does concurrent therapy with cimetidine or erythromycin. In contrast, clearance is increased twofold by phenytoin or barbiturates, whereas cigarette smoking, rifampin, and oral contraceptives induce smaller changes.

Although scarcely detectable in adults, the conversion of theophylline to caffeine is significant in preterm infants (*see* Symposium, 1981; Roberts, 1984). In this setting, caffeine accumulates in plasma to a concentration approximately 25% that of theophylline. About 50% of the theophylline administered to such infants appears in the urine unchanged; the excretion of 1,3-dimethyluric acid, 1-methyluric acid, and caffeine derived from theophylline accounts for nearly all the remainder.

Toxicology. Fatal intoxications with theophylline have been much more frequent than with caffeine. Rapid intravenous administration of therapeutic doses of *aminophylline* (500 mg) sometimes results in sudden death that is probably due to cardiac arrhythmias, and the drug should be injected slowly over 20 to 40 minutes to avoid severe toxic symptoms. These include headache, palpitation, dizziness, nausea, hypotension, and precordial pain. Additional symptoms of toxicity include tachycardia, severe restlessness, agitation, and emesis; these effects are associated with plasma concentrations of more than 20 $\mu\text{g/ml}$. Focal and generalized seizures also can occur, sometimes without prior signs of toxicity.

Most toxicity results from repeated administration of theophylline by either oral or parenteral routes. Although convulsions and death have occurred at plasma concentrations as low as 25 $\mu\text{g/ml}$, seizures are relatively rare at concentrations below 40 $\mu\text{g/ml}$ (*see* Goldberg *et al.*, in Symposium, 1986a). Patients with long-term theophylline intoxication appear to be much more prone to seizures than those who experience short-term overdoses. Such a dependence on the history of exposure to theophylline may contribute to the difficulty in establishing a relationship between the severity of toxic symptoms and the concentration of the drug in plasma (Aitken and Martin, 1987; Bertino and Walker, 1987), and greater caution is advised in treating intoxicated patients who have been ingesting theophylline regularly (*see* Paloucek and Rodvold, 1988). Treatment may include prophylactic administration of diazepam, perhaps in combination with phenytoin or phenobarbital; phenytoin also may be a useful alternative to lidocaine in the treatment of serious ventricular arrhythmias. Once seizures appear, they may be refractory to anticonvulsant therapy, sometimes necessitating general anesthesia or other measures used to treat status epilepticus (*see* Goldberg *et al.*, in Symposium, 1986a).

The widespread use of sustained-release preparations of theophylline has renewed emphasis on measures to prevent continued absorption, particularly the use of oral activated charcoal and sorbitol as a cathartic (Goldberg *et al.*, 1987). However, when plasma concentrations exceed 100 $\mu\text{g/ml}$, invasive measures usually are required, especially hemoperfusion through charcoal cartridges (*see* Paloucek and Rodvold, 1988).

Behavioral Toxicity. Moderate doses of caffeine can provoke intense feelings of anxiety, fear, or panic in some individuals. Even subjects with a history of light to moderate use of caffeine experience tension, anxiety, and dysphoria after ingesting 400 mg or more of the drug (*see* Griffiths and Woodson, in Symposium, 1988b). In infants who have received treatment for apnea of prematurity (*see* below), theophylline may produce persistent changes in sleep-wake patterns (Thoman *et al.*, 1985), but long-term effects on behavior or cognitive development have yet to be identified (*see* Aranda *et al.*, in Symposium, 1986a). There has been mounting concern that the treatment of asthmatic children with theophylline may produce depression, hyperactivity, or other behavioral toxicity. However, a study of academic performance of children treated or not with theophylline showed equal academic performance in asthmatic and nonasthmatic subjects (Lindgren *et al.*, 1992). Even though it is difficult to factor out specific effects of theophylline from those caused by the illness or by other features of the treatment regimen, many investigators believe that most children will benefit from the use of alternative means of controlling their symptoms.

Use in Asthma. Theophylline has proven efficacy as a bronchodilator in asthma and formerly was considered first-line therapy. It now is relegated to a far less prominent role primarily because of the modest benefits it affords, its narrow therapeutic window, and the required monitoring of drug levels (Stoloff, 1994; Nasser and Rees, 1993). Nocturnal asthma can be improved with slow-release theophylline preparations (Self *et al.*, 1992), but other interventions such as inhaled glucocorticoids or salmeterol probably are more effective (Meltzer *et al.*, 1992).

Therapy usually is initiated by the administration of 12 to 16 mg/kg per day of theophylline (calculated as the free

base) up to a maximum of 400 mg/day for at least 3 days (Weinberger, 1987). Children younger than 1 year of age require considerably less; the dose in milligrams per kilogram per day may be calculated as $0.2 \times (\text{age in weeks}) + 5$. Starting with these low doses minimizes the early side effects of nausea, vomiting, nervousness, and insomnia that often subside with continued therapy and virtually eliminates the possibility of exceeding plasma concentrations of 20 $\mu\text{g}/\text{ml}$ in patients older than age 1 year who do not have compromised hepatic or cardiac function. Thereafter, the dosage is increased in two successive stages to between 16 and 20 and, subsequently, 18 and 22 mg/kg per day (up to a maximum of 800 mg/day) depending on the age and clinical response of the patient and allowing at least 3 days between adjustments. The plasma concentration of theophylline is determined before a further adjustment in dosage is made. Although extended-release preparations of theophylline usually allow twice-daily dosing, variations in the rate and extent of absorption of such preparations require individualized calibration of dosing regimens for each patient and preparation.

Apnea of Preterm Infants. In premature infants, episodes of prolonged apnea lasting more than 15 seconds and accompanied by bradycardia pose the threat of recurrent hypoxemia and neurologic damage. Although they often are associated with serious systemic illness, in many instances no specific cause is found. Beginning with the work of Kuzemko and Paala (1973), methylxanthines have undergone numerous clinical trials for the treatment of apnea of undetermined origin. The oral or intravenous administration of methylxanthines can eliminate episodes of apnea that last more than 20 seconds and markedly reduces the number of episodes of shorter duration (*see* Symposium, 1981; Roberts, 1984; Aranda *et al.*, in Symposium, 1986a). Satisfactory responses may occur with plasma concentrations of theophylline of 4 to 8 $\mu\text{g}/\text{ml}$, but concentrations of nearly 13 $\mu\text{g}/\text{ml}$ are required more frequently (Muttitt *et al.*, 1988). Still higher concentrations may produce a more regular pattern of respiration without further reduction in the frequency of episodes of apnea and bradycardia, and these usually are associated with a definite tachycardia. Therapeutic concentrations are achieved with loading doses of about 5 mg/kg of theophylline (calculated as the free base) and can be maintained with 2 mg/kg given every 12 or 24 hours (*see* Roberts, 1984). Although caffeine was used less frequently than theophylline initially, some physicians now prefer it because the dosing regimens are simpler and more predictable.

Anticholinergic Agents

There is a long history of the use of anticholinergic agents in the treatment of asthma. These agents are discussed in detail in Chapter 7. With the advent of inhaled β adrenergic agonists, use of anticholinergic agents declined. Renewed interest in anticholinergic agents paralleled the realization that parasympathetic pathways are important in bronchospasm in some asthmatics and the

availability of *ipratropium bromide* (ATROVENT), a quaternary muscarinic receptor antagonist that has better pharmacological properties than prior drugs. A particularly good response to ipratropium may be seen in the subgroup of asthmatic patients who experience psychogenic exacerbations (Neild and Cameron, 1985).

The cholinergic receptor subtype responsible for bronchial smooth muscle contraction is the muscarinic M_3 receptor. Although iprotropium and related compounds block all five muscarinic receptor subtypes with similar affinity, it is likely that M_3 -receptor antagonism alone accounts for the bronchodilating effect. The bronchodilation produced by ipratropium in asthmatic subjects develops more slowly and usually is less intense than that produced by adrenergic agonists. Some asthmatic patients may experience a useful response lasting up to 6 hours. The variability in the response of asthmatic subjects to ipratropium presumably reflects differences in the strength of parasympathetic tone and in the degree to which reflex activation of cholinergic pathways participates in generating symptoms in individual patients. Hence the utility of ipratropium must be assessed on an individual basis by a therapeutic trial. The pharmacological properties and therapeutic uses of ipratropium have been reviewed (Gross, 1988; *see also* Symposium, 1986b).

Combined treatment with ipratropium and β_2 adrenergic agonists results in slightly greater and more prolonged bronchodilation than with either agent alone in baseline asthma (Bryant and Rogers, 1992). In acute bronchoconstriction, the combination of a β_2 adrenergic agonist and ipratropium is more effective than either agent alone and more effective than simply giving more β_2 adrenergic agonist (Bryant, 1985; Bryant and Rogers, 1992). A large multicenter study showed that the asthmatic subjects with the worst initial lung function benefited most from combination therapy (Rebuck *et al.*, 1987). Thus the combination of a selective β_2 adrenergic agonist and ipratropium should be considered in acute treatment of severe asthma exacerbations. Ipratropium is available in metered-dose inhalers and as a nebulizer solution. A metered-dose inhaler containing a mixture of ipratropium and albuterol (COMBIVENT) also is available in the United States. In Europe, metered-dose inhalers containing a mixture of ipratropium and fenoterol are available (DUOVENT, BERODUAL).

Recently, tiotropium (SPIRIVA), a structural analogue of ipratropium, has been approved for the treatment of COPD and emphysema. Like ipratropium, tiotropium has high affinity for all muscarinic receptor subtypes, but it dissociates from the receptors much more slowly than ipratropium (Barnes, 2000). In particular, binding and func-

tional studies indicate that tiotropium dissociates from muscarinic M_3 receptors more slowly than from muscarinic M_2 receptors. The high affinity of tiotropium for muscarinic receptors, combined with its very slow dissociation rate, permits once-daily dosing. The slow dissociation rate also provides a theoretical advantage in that it limits the capacity of large concentrations of the endogenous agonist acetylcholine to surmount the receptor blockade. Tiotropium is provided as a capsule containing a dry-powder formulation that is intended only for oral inhalation using the HandiHaler inhalation device.

Pharmacogenetics and Variability of Response to Asthma Medications. There is a wide degree of interindividual variability in the response of asthmatic subjects to pharmacotherapy. For example, some individuals benefit dramatically from treatment with leukotriene modifiers, whereas many others are essentially resistant to these treatments. Although more rare, the “steroid resistant” asthmatic receives relatively little benefit from treatment with inhaled corticosteroids. At present, it is impossible to predict who will benefit the most from a given treatment. This unpredictability of response largely reflects our limited understanding of the underlying pathophysiology of asthma. In addition, some component of this variability likely is explained by specific pharmacogenetic factors (Dewar and Hall, 2003).

Three functionally relevant mutations have been found in the promotor region of the gene encoding 5-lipoxygenase (In *et al.*, 1997). These mutations lead to a small decrease in promotor activity and leukotriene synthesis. About 35% of the population has at least one of these mutations in at least one allele. In one placebo-controlled clinical trial it was noted that individuals with mutations at both alleles responded less well to treatment with a 5-lipoxygenase inhibitor than did those with two wild-type alleles (Drazen *et al.*, 1999).

A variant of the β_2 adrenergic receptor in which glycine replaces arginine at position 16 (Gly 16) shows an increased rate of down-regulation in response to agonist exposure. This polymorphism occurs with equal frequency in asthmatic and nonasthmatic populations. There is some evidence that asthmatics who are homozygous for Gly 16 receptors are less responsive to β -agonist therapy than wild-type controls (Martinez *et al.*, 1997; Tan *et al.*, 1997). However, this was not noted in all studies (Hancox *et al.*, 1998).

There are several relatively rare genetic variants in the gene encoding the glucocorticoid receptor. Some of these variants produce receptors with a diminished affinity for glucocorticoid agonists. There is no evidence,

however, that any glucocorticoid-receptor polymorphism is strongly associated with clinically relevant steroid resistance (Koper *et al.*, 1997). Consequently, attention is shifting away from polymorphisms in the receptor *per se* toward the numerous other candidate genes in the functional pathway of glucocorticoids as potential explanations for the unresponsiveness of some individuals to steroid therapy.

Use of Asthma Drugs in Rhinitis

Seasonal allergic rhinitis (hay fever) is caused by deposition of allergens on the nasal mucosa, resulting in an immediate hypersensitivity reaction. This reaction usually is not accompanied by asthma because the allergenic particles are too large to be inhaled into the lower airways (*e.g.*, pollens). Treatment for allergic rhinitis is similar to that for asthma. Topical glucocorticoids, including *beclomethasone* (BECONASE), *mometasone* (NASONEX), *budesonide* (RHINOCORT), *flunisolide* (NASAREL), *fluticasone* (FLONASE), and *triamcinolone* (NASACORT), can be highly effective with minimal side effects, particularly if treatment is instituted immediately prior to the allergy season. Topical glucocorticoids can be administered twice daily (beclomethasone and flunisolide) or even once daily (budesonide, mometasone, fluticasone, and triamcinolone). Cromolyn usually requires dosing three to six times daily for full effects. Rare instances of local candidiasis have been reported with glucocorticoids and probably can be avoided by rinsing the mouth after use. Unlike in asthma, antihistamines (*see* Chapter 24) afford considerable, though incomplete, symptom relief in allergic rhinitis. Nasal decongestants rely on β adrenergic agonists (*e.g.*, pseudoephedrine and phenylephrine) as vasoconstrictors and are discussed in Chapter 10. Anticholinergic agents such as ipratropium bromide (ATROVENT) are effective in inhibiting parasympathetic reflex-evoked secretions from serous glands lining the nasal mucosa.

Use of Asthma Drugs in COPD

Emphysema can be prevented or its progression slowed if the patient stops smoking (Ferguson and Cherniack, 1993). Pharmacological interventions can help patients to stop smoking. *Nicotine gum* (NICORETTE), *nicotine transdermal patches* (NICODERM), and the antidepressant agent *bupropion* (ZYBAN) are moderately useful when combined with other interventions such as support groups and physician encouragement. Clonidine may be helpful in reducing the craving for cigarettes. Treatment of nicotine addiction is discussed in Chapter 23.

The pharmacological treatment of established emphysema resembles that of asthma largely because the inflammatory/bronchospastic component of a patient's disease is the aspect amenable to therapy (Ferguson and Cherniack, 1993). For patients with emphysema who have a significant degree of active inflammation with bronchospasm and excessive mucus production, symptomatic use of inhaled ipratropium or a β_2 adrenergic agonist may be helpful. Ipratropium or tiotropium usually produces about the same modest degree of bronchodilation in patients with COPD as do maximal doses of β_2 adrenergic agonists. As in asthmatic patients, continuous use of bronchodilators is controversial, with some studies suggesting that it is associated with an unfavorable course of COPD (van Schayck *et al.*, 1991). A subgroup of patients may respond favorably to short courses of oral glucocorticoids. Without a treatment trial, it is not possible to predict whether a particular patient will respond to glucocorticoids. Response to oral glucocorticoids may predict those patients who will respond to inhaled glucocorticoids. However, except for the treatment of acute bronchospastic episodes, glucocorticoids have given mixed results in the treatment of COPD (American Thoracic Society, 1987; Dompeling *et al.*, 1993). In some patients, theophylline may be effective (Murciano *et al.*, 1989); in others who have a profound response to β_2 adrenergic agonists, theophylline fails to produce additional bronchodilation beyond that achieved by maximal doses of the inhaled β adrenergic agonist.

In a minority of patients, emphysema results from a genetic deficiency of the plasma proteinase inhibitor α_1 -antiproteinase (also called α_1 -antitrypsin) (Crystal, 1990). Lung tissue destruction is caused by the unopposed action of neutrophil elastase and other proteinases. Purified α_1 -antiproteinase (PROLASTIN) from human plasma is available for intravenous replacement.

CLINICAL SUMMARY

The principles underlying the therapy of asthma have remained unchanged over the past several decades. Bronchodilating drugs, exemplified by the *short-acting* β_2 adrenergic receptor agonists, are used acutely to reverse the bronchospasm of an asthma attack. Antiinflammatory drugs such as inhaled *glucocorticoids* are used to quell bronchial inflammation in an effort to reduce the severity and frequency of asthma attacks. In hospitalized patients, a short course of systemic steroids often is given, followed by a rapid taper. In patients who remain sympto-

matic despite inhaled glucocorticoid therapy, *long-acting* β_2 adrenergic receptor agonists may be added to the steroid regimen with good success. Once used widely, the *methylxanthines* now are used much less frequently owing to modest efficacy and narrow therapeutic window. Selective *PDE4 inhibitors*, which may provide similar efficacy with fewer adverse effects, are under evaluation in clinical trials. Other newer agents are directed at specific mechanisms underlying the initiation or progression of asthma. These include the *leukotriene-receptor antagonists* and the anti-IgE therapy *omalizumab*. Finally, the anticholinergic agent *tiotropium* was approved recently for the treatment of COPD in the United States.

SECTION V

Drugs Affecting Renal and Cardiovascular Function

CHAPTER 28

DIURETICS

Edwin K. Jackson

Diuretics increase the rate of urine flow and sodium excretion and are used to adjust the volume and/or composition of body fluids in a variety of clinical situations, including hypertension, heart failure, renal failure, nephrotic syndrome, and cirrhosis. This chapter first describes renal anatomy and physiology; then introduces diuretics with regard to chemistry, mechanism of action, site of action, effects on urinary composition, and effects on renal hemodynamics; and finally, integrates diuretic pharmacology with a discussion of mechanisms of edema formation and the role of diuretics in clinical medicine. Therapeutic applications of diuretics are expanded on in Chapters 32 (hypertension) and 33 (heart failure).

RENAL ANATOMY AND PHYSIOLOGY

Renal Anatomy. The main renal artery branches near the renal hilum into segmental arteries, which, in turn, subdivide to form interlobar arteries that pierce the renal parenchyma. The interlobar arteries curve at the border of the renal medulla and cortex to form arched vessels known as *arcuate arteries*. Arcuate arteries give rise to perpendicular branches, called *interlobular arteries*, that enter the renal cortex and supply blood to the afferent arterioles. A single afferent arteriole penetrates the glomerulus of each nephron and branches extensively to form the glomerular capillary nexus. These branches coalesce to form the efferent arteriole. Efferent arterioles of superficial glomeruli ascend toward the kidney surface before splitting into peritubular capillaries that service the tubular elements of the renal cortex. Efferent arterioles of juxtamedullary glomeruli descend into the medulla and divide to form the descending vasa recta, which supply blood to the

capillaries of the medulla. Blood returning from the medulla *via* the ascending vasa recta drains directly into the arcuate veins, and blood from the peritubular capillaries of the cortex enters the interlobular veins, which, in turn, connect with the arcuate veins. Arcuate veins drain into interlobar veins, which drain into segmental veins; blood leaves the kidney *via* the main renal vein.

The basic urine-forming unit of the kidney is the nephron, which consists of a filtering apparatus, the glomerulus, connected to a long tubular portion that reabsorbs and conditions the glomerular ultrafiltrate. Each human kidney is composed of approximately one million nephrons. The nomenclature for segments of the tubular portion of the nephron has become increasingly complex as renal physiologists have subdivided the nephron into shorter and shorter named segments. These subdivisions were based initially on the axial location of the segments but increasingly have been based on the morphology of the epithelial cells lining the various nephron segments. Figure 28-1 illustrates subdivisions of the nephron.

Glomerular Filtration. In the glomerular capillaries, a portion of the plasma water is forced through a filter that has three basic components: the fenestrated capillary endothelial cells, a basement membrane lying just beneath the endothelial cells, and the filtration slit diaphragms formed by the epithelial cells that cover the basement membrane on its urinary space side. Solutes of small size flow with filtered water (solvent drag) into the urinary (Bowman's) space, whereas formed elements and macromolecules are retained by the filtration barrier. For each nephron unit, the rate of filtration [single-nephron glomerular filtration rate (SNGFR)] is a function of the hydrostatic pressure in the glomerular capillaries (P_{GC}), the hydrostatic pressure in Bowman's space (which can be equated with pressure in the proximal tubule, P_T), the mean colloid osmotic pressure in the glomerular capillaries (Π_{GC}), the colloid osmotic pressure in the proximal tubule (Π_T), and the ultrafiltration coefficient (K_f), according to the equation

$$\text{SNGFR} = K_f[(P_{GC} - P_T) - (\Pi_{GC} - \Pi_T)] \quad (28-1)$$

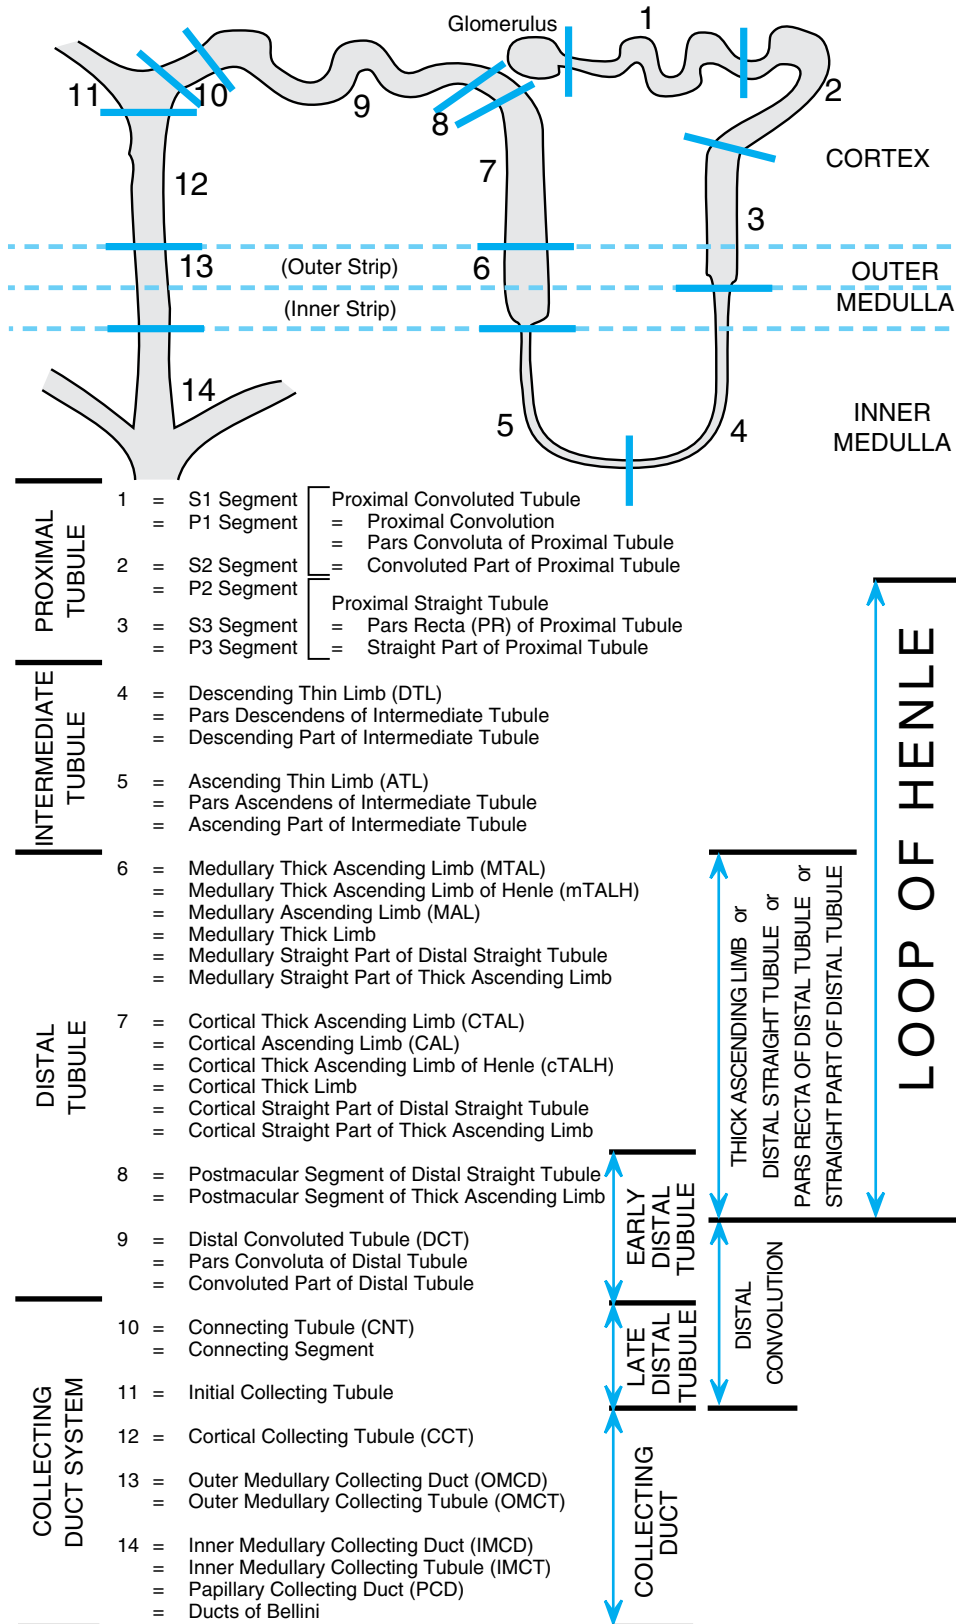

Figure 28–1. Anatomy and nomenclature of the nephron.

If $P_{GC} - P_T$ is defined as the transcapillary hydraulic pressure difference (ΔP), and if Π_T is negligible (as it usually is because little protein is filtered), then

$$\text{SNGFR} = K_f(\Delta P - \Pi_{GC}) \quad (28-2)$$

This latter equation succinctly expresses the three major determinants of SNGFR. However, each of these three determinants can be influenced by a number of other variables. K_f is determined by the physicochemical properties of the filtering membrane and by the surface area available for filtration. ΔP is determined primarily by the arterial blood pressure and by the proportion of the arterial pressure that is transmitted to the glomerular capillaries. This is governed by the relative resistances of preglomerular and postglomerular vessels. Π_{GC} is determined by two variables, *i.e.*, the concentration of protein in the arterial blood entering the glomerulus and the single-nephron blood flow (Q_A). Q_A influences Π_{GC} because as blood transverses the glomerular capillary bed, filtration concentrates proteins in the capillaries, causing Π_{GC} to rise with distance along the glomerular bed. When Q_A is high, this effect is reduced; however, when Q_A is low, Π_{GC} may increase to the point that $\Pi_{GC} = \Delta P$, and filtration ceases (a condition known as *filtration equilibrium*).

Overview of Nephron Function. The kidney is designed to filter large quantities of plasma, reabsorb substances that the body must conserve, and leave behind and/or secrete substances that must be eliminated. The two kidneys in humans produce together approximately 120 ml of ultrafiltrate, yet only 1 ml/min of urine is produced. Therefore, greater than 99% of the glomerular ultrafiltrate is reabsorbed at a staggering energy cost. The kidneys consume 7% of total-body oxygen intake despite the fact that the kidneys make up only 0.5% of body weight.

The proximal tubule is contiguous with Bowman's capsule and takes a tortuous path until finally forming a straight portion that dives into the renal medulla. Based on the morphology of the epithelial cells lining the tubule, the proximal tubule has been subdivided into S1, S2, and S3 segments. Normally, approximately 65% of filtered Na^+ is reabsorbed in the proximal tubule, and since this part of the tubule is highly permeable to water, reabsorption is essentially isotonic.

Between the outer and inner strips of the outer medulla, the tubule abruptly changes morphology to become the descending thin limb (DTL), which penetrates the inner medulla, makes a hairpin turn, and then forms the ascending thin limb (ATL). At the juncture between the inner and outer medulla, the tubule once again changes morphology and becomes the thick ascending limb, which is made up of three segments: a medullary portion (MTAL), a cortical portion (CTAL), and a postmacular segment. Together the proximal straight tubule, DTL, ATL, MTAL, CTAL, and postmacular segment are known as the *loop of Henle*. The DTL is highly permeable to water, yet its permeability to NaCl and urea is low. In contrast, the ATL is permeable to NaCl and urea but is impermeable to water. The thick ascending limb actively reabsorbs NaCl but is impermeable to water and urea. Approximately 25% of filtered Na^+ is reabsorbed in the loop of Henle, mostly in the thick ascending limb, which has a large reabsorptive capacity.

The thick ascending limb passes between the afferent and efferent arterioles and makes contact with the afferent arteriole *via* a cluster of specialized columnar epithelial cells known as the *macula densa*. The macula densa is strategically located to sense concentrations of NaCl leaving the loop of Henle. If the concentration of NaCl is too high, the macula densa sends a chemical signal (perhaps adenosine or ATP) to the afferent arteriole of the same nephron, causing it to constrict. This, in turn, causes a reduction in P_{GC} and

Q_A and decreases SNGFR. This homeostatic mechanism, known as *tubuloglomerular feedback* (TGF), serves to protect the organism from salt and volume wasting. Besides mediating the TGF response, the macula densa also regulates renin release from the adjacent juxtaglomerular cells in the wall of the afferent arteriole.

Approximately 0.2 mm past the macula densa, the tubule changes morphology once again to become the distal convoluted tubule (DCT). The postmacular segment of the thick ascending limb and the distal convoluted tubule often are referred to as the *early distal tubule*. Like the thick ascending limb, the DCT actively transports NaCl and is impermeable to water. Since these characteristics impart the ability to produce a dilute urine, the thick ascending limb and the DCT are collectively called the *diluting segment of the nephron*, and the tubular fluid in the DCT is hypotonic regardless of hydration status. However, unlike the thick ascending limb, the DCT does not contribute to the countercurrent-induced hypertonicity of the medullary interstitium (*see below*).

The collecting duct system (connecting tubule + initial collecting tubule + cortical collecting duct + outer and inner medullary collecting ducts, *e.g.*, segments 10 to 14 in Figure 28–1) is an area of fine control of ultrafiltrate composition and volume. It is here that final adjustments in electrolyte composition are made, a process modulated by the adrenal steroid aldosterone. In addition, antidiuretic hormone (ADH; *see* Chapter 29) modulates permeability of this part of the nephron to water.

The more distal portions of the collecting duct pass through the renal medulla, where the interstitial fluid is markedly hypertonic. In the absence of ADH, the collecting duct system is impermeable to water, and a dilute urine is excreted. In the presence of ADH, the collecting duct system is permeable to water, so water is reabsorbed. The movement of water out of the tubule is driven by the steep concentration gradient that exists between the tubular fluid and the medullary interstitium.

The hypertonicity of the medullary interstitium plays a vital role in the ability of mammals and birds to concentrate urine and therefore is a key adaptation necessary for living in a terrestrial environment. This is accomplished *via* a combination of the unique topography of the loop of Henle and the specialized permeability features of the loop's subsegments. Although the precise mechanisms giving rise to the medullary hypertonicity have remained elusive, the "passive countercurrent multiplier hypothesis" is an intuitively attractive model that is qualitatively accurate (*see* Sands and Kokko, 1996). According to this hypothesis, the process begins with active transport in the thick ascending limb, which concentrates NaCl in the interstitium of the outer medulla. Since this segment of the nephron is impermeable to water, active transport in the ascending limb dilutes the tubular fluid. As the dilute fluid passes into the collecting-duct system, water is extracted if, and only if, ADH is present. Since the cortical and outer medullary collecting ducts have a low permeability to urea, urea is concentrated in the tubular fluid. The inner medullary collecting duct, however, is permeable to urea, so urea diffuses into the inner medulla, where it is trapped by countercurrent exchange in the vasa recta. Since the DTL is impermeable to salt and urea, the high urea concentration in the inner medulla extracts water from the DTL and concentrates NaCl in the tubular fluid of the DTL. As the tubular fluid enters the ATL, NaCl diffuses out of the salt-permeable ATL, thus contributing to the hypertonicity of the medullary interstitium.

General Mechanism of Renal Epithelial Transport. Figure 28–2 illustrates seven mechanisms by which solutes may cross renal epithelial cell membranes. If bulk water flow occurs across a membrane, solute molecules will be transferred by convection across the membrane, a process known as *solvent drag*. Solute with sufficient lipid solubility

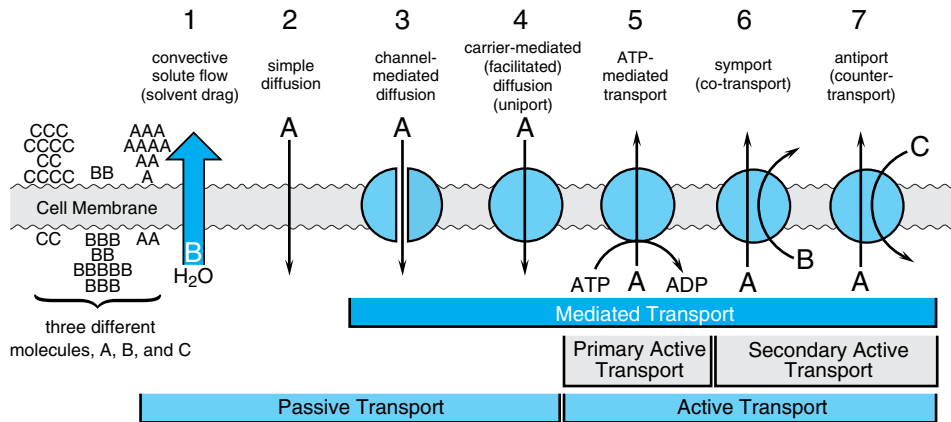

Figure 28–2. Seven basic mechanisms for transmembrane transport of solutes. 1, convective flow in which dissolved solutes are "dragged" by bulk water flow; 2, simple diffusion of lipophilic solute across membrane; 3, diffusion of solute through a pore; 4, transport of solute by carrier protein down electrochemical gradient; 5, transport of solute by carrier protein against electrochemical gradient with ATP hydrolysis providing driving force; 6 and 7, cotransport and countertransport, respectively, of solutes, with one solute traveling uphill against an electrochemical gradient and the other solute traveling down an electrochemical gradient.

also may dissolve in the membrane and diffuse across the membrane down their electrochemical gradients (simple diffusion). Many solutes, however, have limited lipid solubility, and transport must rely on integral proteins embedded in the cell membrane. In some cases the integral protein merely provides a conductive pathway (pore) through which the solute may diffuse passively (*channel-mediated diffusion*). In other cases the solute may bind to the integral protein and, owing to a conformational change in the protein, be transferred across the cell membrane down an electrochemical gradient (*carrier-mediated* or *facilitated diffusion*, also called *uniport*). However, this process will not result in net movement of solute against an electrochemical gradient. If solute must be moved "uphill" against an electrochemical gradient, then either primary active transport or secondary active transport is required. With primary active transport, ATP hydrolysis is coupled directly to conformational changes in the integral protein, thus providing the necessary free energy (*ATP-mediated transport*). Often, ATP-mediated transport is used to create an electrochemical gradient for a given solute, and the free energy of that solute gradient is then released to drive the "uphill" transport of other solutes. This process requires *symport* (cotransport of solute species in the same direction) or *antiport* (countertransport of solute species in opposite directions) and is known as *secondary active transport*.

The kinds of transport achieved in a particular nephron segment depend mainly on which transporters are present and whether they are embedded in the luminal or basolateral membrane. A general model of renal tubular transport is shown in Figure 28–3 and can be summarized as follows:

1. Na^+, K^+ -ATPase (sodium pump) in the basolateral membrane hydrolyzes ATP, which results in the transport of Na^+ into the intercellular and interstitial spaces, the movement of K^+ into the cell, and the establishment and maintenance of an electrochemical gradient for Na^+ across the cell membrane directed inward. Although other ATPases exist in selected renal epithelial cells and participate in the transport of specific solutes (e.g., Ca^{2+} -ATPase and H^+ -ATPase), the bulk of all transport in the kidney is due to the abundant supply of Na^+, K^+ -ATPase in the basolateral membranes of the renal epithelial cells and the separation of Na^+ and K^+ across the cell membrane.

2. Na^+ may diffuse across the luminal membrane *via* Na^+ channels into the epithelial cell down the electrochemical gradient for Na^+ that is established by the basolateral Na^+, K^+ -ATPases. In addition, the free energy available in the electrochemical gradient for Na^+ is tapped by integral proteins in the luminal membrane, resulting in cotransport of various solutes against their electrochemical gradients by symporters (e.g., Na^+ -glucose, Na^+ - H_2PO_4^- , and Na^+ -amino acid). This process results in movement of Na^+ and cotransported solutes out of the tubular lumen into the cell. Also, antiporters (e.g., Na^+ - H^+) move Na^+ out of and some solutes into the tubular lumen.
3. Na^+ exits the basolateral membrane into the intercellular and interstitial spaces *via* the Na^+ pump or *via* symporters or antiporters in the basolateral membrane.
4. The action of Na^+ -linked symporters in the luminal membrane causes the concentration of substrates for these symporters to rise in the epithelial cell. These electrochemical gradients then permit simple diffusion or mediated transport (e.g., symporters, antiporters, uniporters, and channels) of solutes into the intercellular and interstitial spaces.
5. Accumulation of Na^+ and other solutes in the intercellular space creates a small osmotic pressure differential across the epithelial cell. In water-permeable epithelium, water moves into the intercellular spaces driven by the osmotic pressure differential. Water moves through aqueous pores in both the luminal and the basolateral cell membranes, as well as through the tight junctions (paracellular pathway). Bulk water flow carries some solutes into the intercellular space by solvent drag.
6. Movement of water into the intercellular space concentrates other solutes in the tubular fluid, resulting in an electrochemical gradient for these substances across the epithelium. Membrane-permeable solutes then move down their electrochemical gradients into the intercellular space *via* both the transcellular (e.g., simple diffusion, symporters, antiporters, uniporters, and channels) and paracellular pathways. Membrane-impermeable solutes remain in the tubular lumen and are excreted in the urine with an obligatory amount of water.
7. As water and solutes accumulate in the intercellular space, the hydrostatic pressure increases, thus providing a driving force for bulk water flow. Bulk water flow carries solute (solute convection)

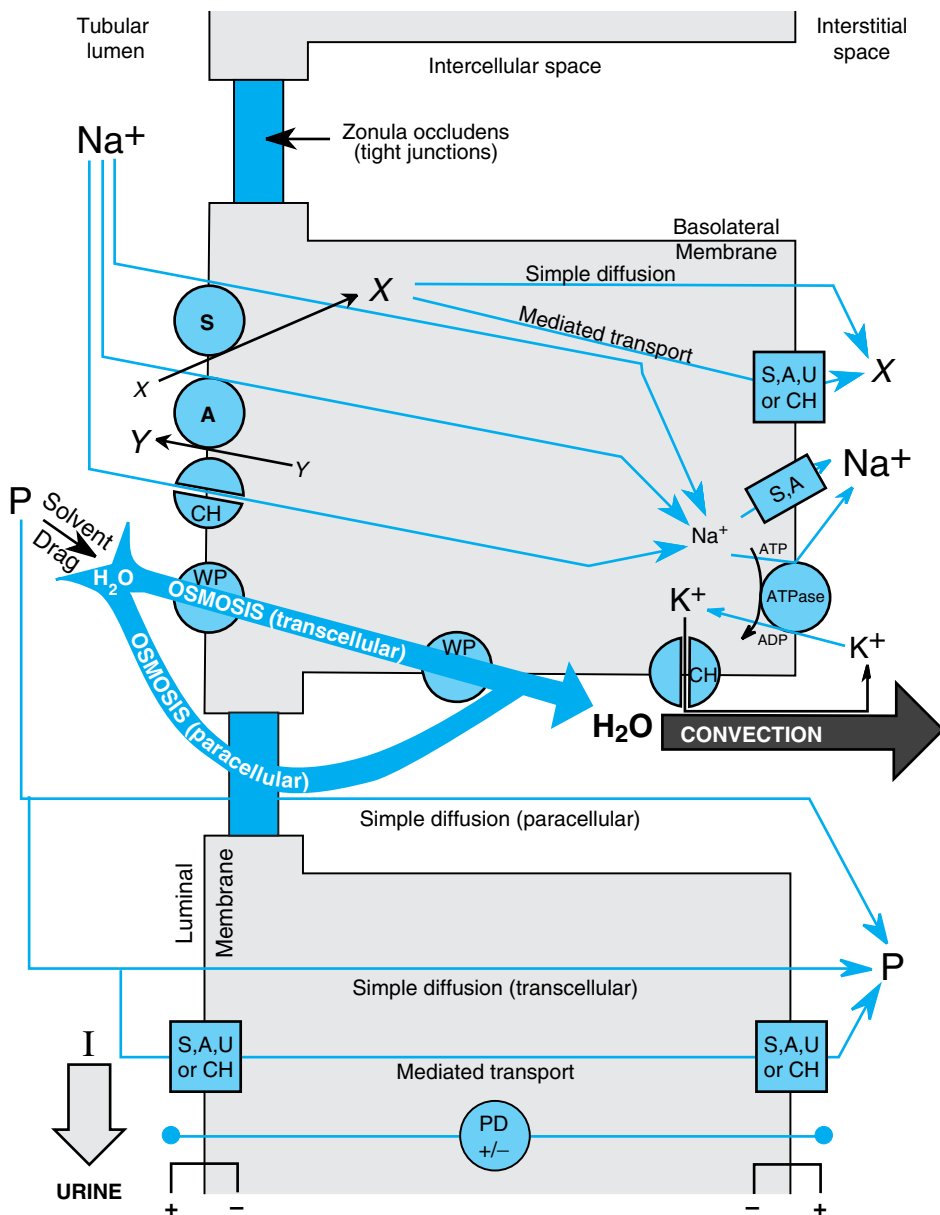

Figure 28–3. Generic mechanism of renal epithelial cell transport (see text for details). S, symporter; A, antiporter; CH, ion channel; WP, water pore; U, uniporter; ATPase, Na^+, K^+ -ATPase (sodium pump); X and Y, transported solutes; P, membrane-permeable (reabsorbable) solutes; I, membrane-impermeable (nonreabsorbable) solutes; PD, potential difference across indicated membrane or cell.

out of the intercellular space into the interstitial space and, finally, into the peritubular capillaries. The movement of fluid into the peritubular capillaries is governed by the same Starling forces that determine transcapillary fluid movement for any capillary bed.

Mechanism of Organic Acid and Organic Base Secretion. The kidney is a major organ involved in the elimination of organic chemicals from the body. Organic molecules may enter the renal tubules by glomerular filtration of molecules not bound to plasma proteins or may be actively secreted directly into the tubules. The proximal tubule has

a highly efficient transport system for organic acids and an equally efficient but separate transport system for organic bases. Current models for these secretory systems are illustrated in Figure 28–4. Both systems are powered by the sodium pump in the basolateral membrane, involve secondary and tertiary active transport, and use a facilitated-diffusion step. There are at least nine different organic acid and five different organic base transporters; the precise roles that these transporters play in organic acid and base transport remain ill-defined (Dresser *et al.*, 2001). A family of organic anion transporters (OATs) countertransport organic anions with dicarboxylates (Figure

Figure 28–4. Mechanisms of organic acid (A) and organic base (B) secretion in the proximal tubule. The numbers 1, 2, and 3 refer to primary, secondary, and tertiary active transport. A⁻, organic acid (anion); C⁺, organic base (cation); αKG^{2-} , α -ketoglutarate but also other dicarboxylates. BL and LM indicate basolateral and luminal membranes, respectively.

28–4A). OATs most likely exist as α -helical dodecaspanns connected by short segments of approximately 10 or fewer amino acids, except for large interconnecting stretches of amino acids between helices 1 and 2 and helices 6 and 7 (Eraly *et al.*, 2004).

Renal Handling of Specific Anions and Cations. Reabsorption of Cl⁻ generally follows reabsorption of Na⁺. In segments of the tubule with low-resistance tight junctions (*i.e.*, “leaky” epithelium), such as the proximal tubule and thick ascending limb, Cl⁻ movement can

occur paracellularly. With regard to transcellular Cl⁻ flux, Cl⁻ crosses the luminal membrane *via* antiport with formate and oxalate (proximal tubule), symport with Na⁺/K⁺ (thick ascending limb), symport with Na⁺ (DCT), and antiport with HCO₃⁻ (collecting-duct system). Cl⁻ crosses the basolateral membrane *via* symport with K⁺ (proximal tubule and thick ascending limb), antiport with Na⁺/HCO₃⁻ (proximal tubule), and Cl⁻ channels (thick ascending limb, DCT, collecting-duct system).

Eighty to ninety percent of filtered K⁺ is reabsorbed in the proximal tubule (diffusion and solvent drag) and thick ascending limb (diffusion) largely *via* the paracellular pathway. In contrast, the DCT and collecting-duct system secrete variable amounts of K⁺ *via* a conductive (channel-mediated) pathway. Modulation of the rate of K⁺ secretion in the collecting-duct system, particularly by aldosterone, allows urinary excretion of K⁺ to be matched with dietary intake. The transepithelial potential difference (V_T), lumen-positive in the thick ascending limb and lumen-negative in the collecting-duct system, provides an important driving force for K⁺ reabsorption and secretion, respectively.

Most of the filtered Ca²⁺ (approximately 70%) is reabsorbed by the proximal tubule by passive diffusion *via* a paracellular route. Another 25% of filtered Ca²⁺ is reabsorbed by the thick ascending limb in part *via* a paracellular route driven by the lumen-positive V_T and in part by active transcellular Ca²⁺ reabsorption modulated by parathyroid hormone (PTH; *see* Chapter 61). Most of the remaining Ca²⁺ is reabsorbed in the DCT *via* a transcellular pathway. The transcellular pathway in the thick ascending limb and DCT involves passive influx of Ca²⁺ across the luminal membrane *via* Ca²⁺ channels, followed by extrusion of Ca²⁺ across the basolateral membrane by a Ca²⁺-ATPase. Also, in the DCT, Ca²⁺ crosses the basolateral membrane *via* Na⁺-Ca²⁺ antiport.

Inorganic phosphate (P_i) is largely reabsorbed (80% of filtered load) by the proximal tubule. An Na⁺-P_i symporter uses the free energy of the Na⁺ electrochemical gradient to transport P_i into the cell. The Na⁺-P_i symporter is inhibited by PTH. P_i exits the basolateral membrane down its electrochemical gradient by a poorly understood transport system.

Only 20% to 25% of Mg²⁺ is reabsorbed in the proximal tubule, and only 5% is reabsorbed by the DCT and collecting-duct system. The bulk of Mg²⁺ is reabsorbed in the thick ascending limb *via* a paracellular pathway driven by the lumen-positive V_T . However, transcellular movement of Mg²⁺ also may occur with basolateral exit *via* Na⁺-Mg²⁺ antiport or *via* a Mg²⁺-ATPase.

The renal tubules play an extremely important role in the reabsorption of HCO₃⁻ and secretion of protons (tubular acidification) and thus participate critically in the maintenance of acid–base balance. These processes are described in the section on carbonic anhydrase inhibitors.

PRINCIPLES OF DIURETIC ACTION

By definition, diuretics are drugs that increase the rate of urine flow; however, clinically useful diuretics also increase the rate of excretion of Na⁺ (natriuresis) and of an accompanying anion, usually Cl⁻. NaCl in the body is the major determinant of extracellular fluid volume, and most clinical applications of diuretics are directed toward reduc-

ing extracellular fluid volume by decreasing total-body NaCl content. A sustained imbalance between dietary Na⁺ intake and Na⁺ loss is incompatible with life. A sustained positive Na⁺ balance would result in volume overload with pulmonary edema, and a sustained negative Na⁺ balance would result in volume depletion and cardiovascular collapse. Although continued administration of a diuretic causes a sustained net deficit in total-body Na⁺, the time course of natriuresis is finite because renal compensatory mechanisms bring Na⁺ excretion in line with Na⁺ intake, a phenomenon known as *diuretic braking*. These compensatory, or braking, mechanisms include activation of the sympathetic nervous system, activation of the renin–angiotensin–aldosterone axis, decreased arterial blood pressure (which reduces pressure natriuresis), hypertrophy of renal epithelial cells, increased expression of renal epithelial transporters, and perhaps alterations in natriuretic hormones such as atrial natriuretic peptide (Ellison, 1999).

Historically, the classification of diuretics was based on a mosaic of ideas such as site of action (loop diuretics), efficacy (high-ceiling diuretics), chemical structure (thiazide diuretics), similarity of action with other diuretics (thiazidelike diuretics), effects on potassium excretion (potassium-sparing diuretics), etc. However, since the mechanism of action of each of the major classes of diuretics is now well understood, a classification scheme based on mechanism of action is used in this chapter.

Diuretics not only alter the excretion of Na⁺ but also may modify renal handling of other cations (*e.g.*, K⁺, H⁺, Ca²⁺, and Mg²⁺), anions (*e.g.*, Cl⁻, HCO₃⁻, and H₂PO₄⁻), and uric acid. In addition, diuretics may alter renal hemodynamics indirectly. Table 28–1 gives a comparison of the general effects of the major classes of diuretics.

INHIBITORS OF CARBONIC ANHYDRASE

Acetazolamide (DIAMOX) is the prototype of a class of agents that have limited usefulness as diuretics but have played a major role in the development of fundamental concepts of renal physiology and pharmacology.

Chemistry. When sulfanilamide was introduced as a chemotherapeutic agent, metabolic acidosis was recognized as a side effect. This observation led to the demonstration that sulfanilamide is an inhibitor of carbonic anhydrase. Subsequently, an enormous number of sulfonamides were synthesized and tested for the ability to inhibit carbonic anhydrase; of these compounds, acetazolamide has been studied most extensively. Table 28–2 lists the chemical structures of the three carbonic anhydrase inhibitors currently available in the United States—acetazolamide, *dichlorophenamide* (DARANIDE), and

methazolamide (GLAUC TABS). The common molecular motif of available carbonic anhydrase inhibitors is an unsubstituted sulfonamide moiety.

Mechanism and Site of Action. Proximal tubular epithelial cells are richly endowed with the zinc metalloenzyme carbonic anhydrase, which is found in the luminal and basolateral membranes (type IV carbonic anhydrase, an enzyme tethered to the membrane by a glycosylphosphatidylinositol linkage), as well as in the cytoplasm (type II carbonic anhydrase). Carbonic anhydrase plays a key role in NaHCO₃ reabsorption and acid secretion.

In the proximal tubule, the free energy in the Na⁺ gradient established by the basolateral Na⁺ pump is used by a Na⁺–H⁺ antiporter [also referred to as a Na⁺–H⁺ exchanger (NHE)] in the luminal membrane to transport H⁺ into the tubular lumen in exchange for Na⁺ (Figure 28–5). In the lumen, H⁺ reacts with filtered HCO₃⁻ to form H₂CO₃, which decomposes rapidly to CO₂ and water in the presence of carbonic anhydrase in the brush border. Normally, the reaction between CO₂ and water occurs slowly, but carbonic anhydrase reversibly accelerates this reaction several thousand times. CO₂ is lipophilic and rapidly diffuses across the luminal membrane into the epithelial cell, where it reacts with water to form H₂CO₃, a reaction catalyzed by cytoplasmic carbonic anhydrase. (The actual reaction catalyzed by carbonic anhydrase is OH⁻ + CO₂ → HCO₃⁻; however, H₂O → OH⁻ + H⁺ and HCO₃⁻ + H⁺ → H₂CO₃, so the net reaction is H₂O + CO₂ → H₂CO₃.) Continued operation of the Na⁺–H⁺ antiporter maintains a low proton concentration in the cell, so H₂CO₃⁻ ionizes spontaneously to form H⁺ and HCO₃⁻, creating an electrochemical gradient for HCO₃⁻ across the basolateral membrane. The electrochemical gradient for HCO₃⁻ is used by a Na⁺–HCO₃⁻ symporter [also referred to as the Na⁺–HCO₃⁻ cotransporter (NBC)] in the basolateral membrane to transport NaHCO₃ into the interstitial space. The net effect of this process is transport of NaHCO₃ from the tubular lumen to the interstitial space, followed by movement of water (isotonic reabsorption). Removal of water concentrates Cl⁻ in the tubular lumen, and consequently, Cl⁻ diffuses down its concentration gradient into the interstitium *via* the paracellular pathway.

Carbonic anhydrase inhibitors potently inhibit (IC₅₀ for acetazolamide is 10 nM) both the membrane-bound and cytoplasmic forms of carbonic anhydrase, resulting in nearly complete abolition of NaHCO₃ reabsorption in the proximal tubule. Studies with a high-molecular-weight carbonic anhydrase inhibitor that inhibits only luminal enzyme because of limited cellular permeability indicate that inhibition of both the membrane-bound and cytoplasmic pools of carbonic anhydrase contributes to the diuret-

Table 28-1

*Excretory and Renal Hemodynamic Effects of Diuretics**

	CATIONS					ANIONS			URIC ACID		RENAL HEMODYNAMICS			
	Na ⁺	K ⁺	H ⁺ †	Ca ²⁺	Mg ²⁺	Cl ⁻	HCO ₃ ⁻	H ₂ PO ₄ ⁻	Acute	Chronic	RBF	GFR	FF	TGF
Inhibitors of carbonic anhydrase (primary site of action is proximal tubule)	+	++	-	NC	V	(+)	++	++	I	-	-	-	NC	+

ic activity of carbonic anhydrase inhibitors. Because of the large excess of carbonic anhydrase in proximal tubules, a high percentage of enzyme activity must be inhibited before an effect on electrolyte excretion is observed. Although the proximal tubule is the major site of action of carbonic anhydrase inhibitors, carbonic anhydrase also is involved in secretion of titratable acid in the collecting duct system (a process that involves a proton pump); therefore, the collecting duct system is a secondary site of action for this class of drugs.

Effects on Urinary Excretion. Inhibition of carbonic anhydrase is associated with a rapid rise in urinary HCO_3^- excretion to approximately 35% of filtered load. This, along with inhibition of titratable acid and NH_4^+ secretion in the collecting-duct system, results in an increase in urinary pH to approximately 8 and development of a metabolic acidosis. However, even with a high degree of inhibition of carbonic anhydrase, 65% of HCO_3^- is rescued from excretion by poorly understood mechanisms that may involve carbonic anhydrase-independent HCO_3^- reabsorption at downstream sites. Inhibition of the transport mechanism described in the preceding section results in increased delivery of Na^+ and Cl^- to the loop of Henle, which has a large reabsorptive capacity and captures most of the Cl^- and a portion of the Na^+ . Thus only a small increase in Cl^-

Figure 28–5. NaHCO_3 reabsorption in proximal tubule and mechanism of diuretic action of carbonic anhydrase inhibitors. A, antiporter; S, symporter; CH, ion channel. (The actual reaction catalyzed by carbonic anhydrase is $\text{OH}^- + \text{CO}_2 \rightarrow \text{HCO}_3^-$; however, $\text{H}_2\text{O} \rightarrow \text{OH}^- + \text{H}^+$, and $\text{HCO}_3^- + \text{H}^+ \rightarrow \text{H}_2\text{CO}_3$, so the net reaction is $\text{H}_2\text{O} + \text{CO}_2 \rightarrow \text{H}_2\text{CO}_3$.) Numbers in parentheses indicate stoichiometry. BL and LM indicate basolateral and luminal membranes, respectively.

excretion occurs, HCO_3^- being the major anion excreted along with the cations Na^+ and K^+ . The fractional excretion of Na^+ may be as much as 5%, and the fractional excretion of K^+ can be as much as 70%. The increased excretion of K^+ is in part secondary to increased delivery of Na^+ to the distal nephron. The mechanism by which increased distal delivery of Na^+ enhances K^+ excretion is described in the section on inhibitors of sodium channels. Other mechanisms contributing to enhanced K^+ excretion include flow-dependent enhancement of K^+ secretion by the collecting duct, nonosmotic vasopressin release, and activation of the renin–angiotensin–aldosterone axis (Wilcox, 1999). Carbonic anhydrase inhibitors increase phosphate excretion (mechanism unknown) but have little or no effect on the excretion of Ca^{2+} or Mg^{2+} . The effects of carbonic anhydrase inhibitors on renal excretion are self-limiting probably because the resulting metabolic acidosis decreases the filtered load of HCO_3^- to the point that the uncatalyzed reaction between CO_2 and water is sufficient to achieve HCO_3^- reabsorption.

Effects on Renal Hemodynamics. By inhibiting proximal reabsorption, carbonic anhydrase inhibitors increase delivery of solutes to the macula densa. This triggers TGF, which increases afferent arteriolar resistance and reduces renal blood flow (RBF) and glomerular filtration rate (GFR).

Other Actions. Carbonic anhydrase is present in a number of extrarenal tissues, including the eye, gastric mucosa, pancreas, central nervous system (CNS), and erythrocytes. Carbonic anhydrase in the ciliary processes of the eye mediates the formation of large amounts of HCO_3^- in aqueous humor. Inhibition of carbonic anhydrase decreases the rate of formation of aqueous humor and consequently reduces intraocular pressure (IOP). Acetazolamide frequently causes paresthesias and somnolence, suggesting an action of carbonic anhydrase inhibitors in the CNS. The efficacy of acetazolamide in epilepsy is due in part to the production of metabolic acidosis; however, direct actions of acetazolamide in the CNS also contribute to its anticonvulsant action. Owing to interference with carbonic anhydrase activity in erythrocytes, carbonic anhydrase inhibitors increase CO_2 levels in peripheral tissues and decrease CO_2 levels in expired gas. Large doses of carbonic anhydrase inhibitors reduce gastric acid secretion, but this has no therapeutic applications. Acetazolamide causes vasodilation in human beings by opening vascular Ca^{2+} -activated K^+ channels (Pickkers *et al.*, 2001); however, the clinical significance of this effect is unclear.

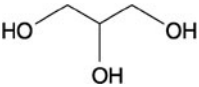

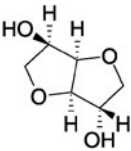

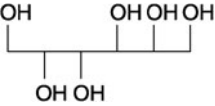

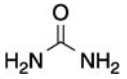

Absorption and Elimination. The oral bioavailability, plasma half-life, and route of elimination of the three currently available carbonic anhydrase inhibitors are listed in Table 28–2. Carbonic anhydrase inhibitors are avidly bound by carbonic anhydrase, and accordingly, tissues rich in this enzyme will have higher concentrations of carbonic anhydrase inhibitors following systemic administration.

Toxicity, Adverse Effects, Contraindications, Drug Interactions. Serious toxic reactions to carbonic anhydrase inhibitors are infrequent; however, these drugs are sulfonamide derivatives and, like other sulfonamides, may cause bone marrow depression, skin toxicity, sulfonamidelike renal lesions, and allergic reactions in patients hypersensitive to sulfonamides (*see* Chapter 43). With large doses, many patients exhibit drowsiness and paresthesias. Most adverse effects, contraindications, and drug interactions are secondary to urinary alkalization or metabolic acidosis, including (1) diversion of ammonia of renal origin from urine into the systemic circulation, a process that may induce or worsen hepatic encephalopathy (the drugs are contraindicated in patients with hepatic cirrhosis); (2) calculus formation and ureteral colic owing to precipitation of calcium phosphate salts in an alkaline urine; (3) worsening of metabolic or respiratory acidosis (the drugs are contraindicated in patients with hyperchloremic acidosis or severe chronic obstructive pulmonary disease); and (4) reduction of the urinary excretion rate of weak organic bases.

Therapeutic Uses. Although *acetazolamide* is used for treatment of edema, the efficacy of carbonic anhydrase inhibitors as single agents is low, and carbonic anhydrase inhibitors are not employed widely in this regard. However, studies by Knauf and Mutschler (1997) indicate that the combination of acetazolamide with diuretics that block Na^+ reabsorption at more distal sites in the nephron causes a marked natriuretic response in patients with low basal fractional excretion of Na^+ (<0.2%) who are resistant to diuretic monotherapy. Even so, the long-term usefulness of carbonic anhydrase inhibitors often is compromised by the development of metabolic acidosis.

The major indication for carbonic anhydrase inhibitors is open-angle glaucoma. Carbonic anhydrase inhibitors also may be employed for secondary glaucoma and preoperatively in acute angle-closure glaucoma to lower IOP before surgery (*see* Chapter 63). Acetazolamide also is used for the treatment of epilepsy (*see* Chapter 19). The rapid development of tolerance, however, may limit the usefulness of carbonic anhydrase inhibitors for epilepsy. Acetazolamide may provide symptomatic relief

Table 28–3
Osmotic Diuretics

DRUG	STRUCTURE	ORAL AVAILABILITY	$T_{1/2}$ (HOURS)	ROUTE OF ELIMINATION
Glycerin (OSMOGLYN)		Orally active	0.5–0.75	~80% M ~20% U
Isosorbide (ISMOTIC)		Orally active	5–9.5	R
Mannitol (OSMITROL)		Negligible	0.25–1.7*	~80% R ~20% M + B
Urea (UREAPHIL)		Negligible	ID	R

*In renal failure, 6–36. Abbreviations: R, renal excretion of intact drug; M, metabolism; B, excretion of intact drug into bile; U, unknown pathway of elimination; ID, insufficient data.

in patients with altitude sickness; however, it is more appropriate to give acetazolamide as a prophylactic measure (Coote, 1991). Acetazolamide also is useful in patients with familial periodic paralysis (Links *et al.*, 1988). The mechanism for the beneficial effects of acetazolamide in altitude sickness and familial periodic paralysis is not clear, but it may be related to the induction of a metabolic acidosis. Finally, carbonic anhydrase inhibitors can be useful for correcting a metabolic alkalosis, especially an alkalosis caused by diuretic-induced increases in H^+ excretion.

OSMOTIC DIURETICS

Osmotic diuretics are agents that are freely filtered at the glomerulus, undergo limited reabsorption by the renal tubule, and are relatively inert pharmacologically. Osmotic diuretics are administered in large enough doses to increase significantly the osmolality of plasma and tubular fluid. Table 28–3 gives the molecular structures of the four currently available osmotic diuretics—*glycerin* (OSMOGLYN), *isosorbide* (ISMOTIC), *mannitol* (OSMITROL), and *urea* (UREAPHIL).

Mechanism and Site of Action. For many years it was thought that osmotic diuretics act primarily in the proximal tubule. By acting as nonreabsorbable solutes, it was reasoned that osmotic diuretics limit the osmosis of water into the interstitial space and thereby reduce luminal Na^+ concentration to the point that net Na^+ reabsorption ceases. Although early micropuncture studies supported this concept, subsequent studies suggested that this mechanism, while operative, may be of only secondary importance and that the major site of action of osmotic diuretics is the loop of Henle.

By extracting water from intracellular compartments, osmotic diuretics expand the extracellular fluid volume, decrease blood viscosity, and inhibit renin release. These effects increase RBF, and the increase in renal medullary blood flow removes $NaCl$ and urea from the renal medulla, thus reducing medullary tonicity. Under some circumstances, prostaglandins may contribute to the renal vasodilation and medullary washout induced by osmotic diuretics. A reduction in medullary tonicity causes a decrease in the extraction of water from the DTL, which, in turn, limits the concentration of $NaCl$ in the tubular fluid entering the ATL. This latter effect diminishes the passive reabsorption of $NaCl$ in the ATL. In addition, the marked ability of osmotic diuretics to inhibit reabsorption

of Mg^{2+} , a cation that is reabsorbed mainly in the thick ascending limb, suggests that osmotic diuretics also interfere with transport processes in the thick ascending limb. The mechanism of this effect is unknown.

In summary, osmotic diuretics act both in the proximal tubule and the loop of Henle, with the latter being the primary site of action. Also, osmotic diuretics probably act by an osmotic effect in the tubules and by reducing medullary tonicity.

Effects on Urinary Excretion. Osmotic diuretics increase the urinary excretion of nearly all electrolytes, including Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , HCO_3^- , and phosphate.

Effects on Renal Hemodynamics. Osmotic diuretics increase RBF by a variety of mechanisms. Osmotic diuretics dilate the afferent arteriole, which increases P_{GC} , and dilute the plasma, which decreases Π_{GC} . These effects would increase GFR were it not for the fact that osmotic diuretics also increase P_T . In general, superficial SNGFR is increased, but total GFR is little changed.

Absorption and Elimination. The oral bioavailability, plasma half-life, and route of elimination of the four currently available osmotic diuretics are listed in Table 28–3. Glycerin and isosorbide can be given orally, whereas mannitol and urea must be administered intravenously.

Toxicity, Adverse Effects, Contraindications, Drug Interactions. Osmotic diuretics are distributed in the extracellular fluid and contribute to the extracellular osmolality. Thus water is extracted from intracellular compartments, and the extracellular fluid volume becomes expanded. In patients with heart failure or pulmonary congestion, this may cause frank pulmonary edema. Extraction of water also causes hyponatremia, which may explain the common adverse effects, including headache, nausea, and vomiting. On the other hand, loss of water in excess of electrolytes can cause hypernatremia and dehydration. In general, osmotic diuretics are contraindicated in patients who are anuric owing to severe renal disease or who are unresponsive to test doses of the drugs. Urea may cause thrombosis or pain if extravasation occurs, and it should not be administered to patients with impaired liver function because of the risk of elevation of blood ammonia levels. Both mannitol and urea are contraindicated in patients with active cranial bleeding. Glycerin is metabolized and can cause hyperglycemia.

Therapeutic Uses. A rapid decrease in GFR, *i.e.*, acute renal failure (ARF), is a serious medical condition that

occurs in 5% of hospitalized patients and is associated with a significant mortality rate. ARF can be caused by diverse conditions both extrinsic (prerenal and postrenal failure) and intrinsic to the kidney. Acute tubular necrosis (ATN), *i.e.*, damage to tubular epithelial cells, accounts for most cases of intrinsic ARF. In animal models, mannitol is effective in attenuating the reduction in GFR associated with ATN when administered before the ischemic insult or offending nephrotoxin. The renal protection afforded by mannitol may be due to removal of obstructing tubular casts, dilution of nephrotoxic substances in the tubular fluid, and/or reduction of swelling of tubular elements *via* osmotic extraction of water. Although prophylactic mannitol is effective in animal models of ATN, the clinical efficacy of mannitol is less well established. Most published clinical studies have been uncontrolled, and controlled studies have not shown a benefit over hydration *per se* (*see* Kellum, 1998). In patients with mild to moderate renal insufficiency, hydration with 0.45% sodium chloride is as good as or better than either mannitol or furosemide in protection against decreases in GFR induced by radiocontrast agents (Soloman *et al.*, 1994). Studies of prophylactic mannitol indicate effectiveness in jaundiced patients undergoing surgery. However, in vascular and open-heart surgery, prophylactic mannitol maintains urine flow but not GFR. In established ATN, mannitol will increase urine volume in some patients, and patients converted from oliguric to nonoliguric ATN appear to recover more rapidly and require less dialysis compared with patients who do not respond to mannitol (Levinsky and Bernard, 1988). It is not clear whether these benefits are due to the diuretic or whether “responders” have lesser degrees of renal damage from the outset compared with “nonresponders.” Repeated administration of mannitol to nonresponders is not recommended, and nowadays, loop diuretics are used more frequently to convert oliguric to nonoliguric ATN.

Another use for mannitol and urea is in the treatment of dialysis disequilibrium syndrome. Too rapid a removal of solutes from the extracellular fluid by hemodialysis or peritoneal dialysis results in a reduction in the osmolality of the extracellular fluid. Consequently, water moves from the extracellular compartment into the intracellular compartment, causing hypotension and CNS symptoms (*i.e.*, headache, nausea, muscle cramps, restlessness, CNS depression, and convulsions). Osmotic diuretics increase the osmolality of the extracellular fluid compartment and thereby shift water back into the extracellular compartment.

By increasing the osmotic pressure of the plasma, osmotic diuretics extract water from the eye and brain. All four osmotic diuretics are used to control IOP during

acute attacks of glaucoma and for short-term reductions in IOP both preoperatively and postoperatively in patients who require ocular surgery. Also, mannitol and urea are used to reduce cerebral edema and brain mass before and after neurosurgery.

INHIBITORS OF $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ SYMPORT (LOOP DIURETICS, HIGH-CEILING DIURETICS)

Drugs in this group of diuretics inhibit the activity of the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporter in the thick ascending limb of the loop of Henle; hence these diuretics also are referred to as *loop diuretics*. Although the proximal tubule reabsorbs approximately 65% of the filtered Na^+ , diuretics acting only in the proximal tubule have limited efficacy because the thick ascending limb has a great reabsorptive capacity and reabsorbs most of the reabsorbate from the proximal tubule. Diuretics acting predominantly at sites past the thick ascending limb also have limited efficacy because only a small percentage of the filtered Na^+ load reaches these more distal sites. In contrast, inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport in the thick ascending limb are highly efficacious, and for this reason, they sometimes are called *high-ceiling diuretics*. The efficacy of inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport in the thick ascending limb of the loop of Henle is due to a combination of two factors: (1) Approximately 25% of the filtered Na^+ load normally is reabsorbed by the thick ascending limb, and (2) nephron segments past the thick ascending limb do not possess the reabsorptive capacity to rescue the flood of reabsorbate exiting the thick ascending limb.

Chemistry. Inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport are a chemically diverse group (Table 28-4). Only *furosemide* (LASIX), *bumetanide* (BUMEX), *ethacrynic acid* (EDECRIN), and *torseamide* (DEMADEX) are available currently in the United States. Furosemide and bumetanide contain a sulfonamide moiety. Ethacrynic acid is a phenoxyacetic acid derivative and torseamide is a sulfonylurea.

Mechanism and Site of Action. Inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport act primarily in the thick ascending limb. Micropuncture of the DCT demonstrates that loop diuretics increase the delivery of solutes out of the loop of Henle. Also, *in situ* microperfusion of the loop of Henle and *in vitro* microperfusion of the CTAL indicate inhibition of transport by low concentrations of furosemide in the perfusate. Some inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport may have additional effects in the proximal tubule; however, the significance of these effects is unclear.

It was thought initially that Cl^- was transported by a primary active electrogenic transporter in the luminal membrane independent of Na^+ . Discovery of furosemide-sensitive $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport in other tissues prompted a more careful investigation of the Na^+ dependence of Cl^- transport in the isolated perfused rabbit CTAL. Scrupulous removal of Na^+ from the luminal perfusate demonstrated the dependence of Cl^- transport on Na^+ .

It is now well accepted that flux of Na^+ , K^+ , and Cl^- from the lumen into the epithelial cells in the thick ascending limb is mediated by a $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporter (Hebert, 1999) (Figure 28-6). This symporter captures the free energy in the Na^+ electrochemical gradient established by the basolateral Na^+ pump and provides for “uphill” transport of K^+ and Cl^- into the cell. K^+ channels in the luminal membrane (called *ROMK*) provide a conductive pathway for the apical recycling of this cation, and basolateral Cl^- channels (called *CLC-Kb*) provide a basolateral exit mechanism for Cl^- . The luminal membranes of epithelial cells in the thick ascending limb have a large conductive pathway (channels) for K^+ ; therefore, the apical membrane voltage is determined by the equilibrium potential for K^+ (E_K) and is hyperpolarized. In contrast, the basolateral membrane has a large conductive pathway (channels) for Cl^- , so the basolateral membrane voltage is less negative than E_K ; *i.e.*, conductance for Cl^- depolarizes the basolateral membrane. Hyperpolarization of the luminal membrane and depolarization of the basolateral membrane result in a transepithelial potential difference of approximately 10 mV, with the lumen positive with respect to the interstitial space. This lumen-positive potential difference repels cations (Na^+ , Ca^{2+} , and Mg^{2+}) and thereby provides an important driving force for the paracellular flux of these cations into the interstitial space.

As the name implies, inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport bind to the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporter in the thick ascending limb and block its function, bringing salt transport in this segment of the nephron to a virtual standstill. The molecular mechanism by which this class of drugs blocks the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporter is unknown, but evidence suggests that these drugs attach to the Cl^- -binding site (Hannafin *et al.*, 1983) located in the symporter’s transmembrane domain (Isenring and Forbush, 1997). Inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport also inhibit Ca^{2+} and Mg^{2+} reabsorption in the thick ascending limb by abolishing the transepithelial potential difference that is the dominant driving force for reabsorption of these cations.

$\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporters are an important family of transport molecules found in many secretory and absorbing epithelia. The rectal gland of the dogfish shark is a particularly rich source of the protein,

Table 28-4*Inhibitors of Na⁺-K⁺-2Cl⁻ Symport (Loop Diuretics, High-Ceiling Diuretics)*

DRUG	STRUCTURE	RELATIVE POTENCY	ORAL AVAILABILITY	T _{1/2} (HOURS)	ROUTE OF ELIMINATION
Furosemide (LASIX)		1	~60%	~1.5	~65% R, ~35% M [‡]

Figure 28–6. *NaCl reabsorption in thick ascending limb and mechanism of diuretic action of $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symport inhibitors.* S, symporter; CH, ion channel. Numbers in parentheses indicate stoichiometry. Designated voltages are the potential differences across the indicated membrane or cell. The mechanisms illustrated here apply to the medullary, cortical, and postmacular segments of the thick ascending limb. BL and LM indicate basolateral and luminal membranes, respectively.

and a cDNA encoding a $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symporter was isolated from a cDNA library obtained from the dogfish shark rectal gland by screening with antibodies to the shark symporter (Xu *et al.*, 1994). Molecular cloning revealed a deduced amino acid sequence of 1191 residues containing 12 putative membrane-spanning domains flanked by long N and C termini in the cytoplasm. Expression of this protein resulted in $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symport that was sensitive to bumetanide. The shark rectal gland $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symporter cDNA was used subsequently to screen a human colonic cDNA library, and this provided $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symporter cDNA probes from this tissue. These latter probes were used to screen rabbit renal cortical and renal medullary libraries, which allowed cloning of the rabbit renal $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symporter (Payne and Forbush, 1994). This symporter is 1099 amino acids in length, is 61% identical to the dogfish shark secretory $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symporter, has 12 predicted transmembrane helices, and contains large N- and C-terminal cytoplasmic regions. Subsequent studies demonstrated that $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symporters are of two varieties (*see* Kaplan *et al.*, 1996). The “absorptive” symporter (called *ENCC2*, *NKCC2*, or *BSC1*) is expressed only in the kidney, is localized to the apical membrane and subapical intracellular vesicles of the thick ascending limb, and is regulated by cyclic AMP/protein kinase A (Obermüller *et al.*, 1996; Kaplan *et al.*, 1996; Nielsen *et al.*, 1998; Plata *et al.*, 1999). At least six different isoforms of the absorptives symporter are generated by alternative mRNA splicing (Mount *et al.*, 1999), and alternative splicing of the absorptive symporter determines the dependency of transport on K^+ (Plata *et al.*, 2001). The “secretory” symporter (called *ENCC3*, *NKCC1*, or *BSC2*) is a “housekeeping” protein that is expressed wide-

ly and, in epithelial cells, is localized to the basolateral membrane. The affinity of loop diuretics for the secretory symporter is somewhat less than for the absorptive symporter (*e.g.*, fourfold difference for bumetanide). A model of $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symport has been proposed based on ordered binding of ions to the symporter (Lytle *et al.*, 1998). Mutations in the genes coding for the absorptive $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symporter, the apical K^+ channel, or the basolateral Cl^- channel are one cause of Bartter’s syndrome (inherited hypokalemic alkalosis with salt wasting and hypotension) (*see* Simon and Lifton, 1998).

Effects on Urinary Excretion. Owing to blockade of the $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symporter, loop diuretics increase in the urinary excretion of Na^+ and Cl^- profoundly (*i.e.*, up to 25% of the filtered load of Na^+). Abolition of the transepithelial potential difference also results in marked increases in the excretion of Ca^{2+} and Mg^{2+} . Some (*e.g.*, furosemide) but not all (*e.g.*, bumetanide) sulfonamide-based loop diuretics have weak carbonic anhydrase-inhibiting activity. Drugs with carbonic anhydrase-inhibiting activity increase the urinary excretion of HCO_3^- and phosphate. The mechanism by which inhibition of carbonic anhydrase increases phosphate excretion is not known. All inhibitors of $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symport increase the urinary excretion of K^+ and titratable acid. This effect is due in part to increased delivery of Na^+ to the distal tubule. The mechanism by which increased distal delivery of Na^+ enhances excretion of K^+ and H^+ is discussed in the section on inhibitors of Na^+ channels. Other mechanisms contributing to enhanced K^+ and H^+ excretion include flow-dependent enhancement of ion secretion by the collecting duct, nonosmotic vasopressin release, and activation of the renin–angiotensin–aldosterone axis (Wilcox, 1999). Acutely, loop diuretics increase the excretion of uric acid, whereas chronic administration of these drugs results in reduced excretion of uric acid. The chronic effects of loop diuretics on uric acid excretion may be due to enhanced transport in the proximal tubule secondary to volume depletion, leading to increased uric acid reabsorption, or to competition between the diuretic and uric acid for the organic acid secretory mechanism in the proximal tubule, leading to reduced uric acid secretion.

By blocking active NaCl reabsorption in the thick ascending limb, inhibitors of $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symport interfere with a critical step in the mechanism that produces a hypertonic medullary interstitium. Therefore, loop diuretics block the kidney’s ability to concentrate urine during hydropenia. Also, since the thick ascending limb is part of the diluting segment, inhibitors of $\text{Na}^+\text{--K}^+\text{--}2\text{Cl}^-$ symport markedly impair the kidney’s ability to excrete a dilute urine during water diuresis.

Effects on Renal Hemodynamics. If volume depletion is prevented by replacing fluid losses, inhibitors of $\text{Na}^+\text{--}$

K^+-2Cl^- symport generally increase total RBF and redistribute RBF to the midcortex. However, the effects on RBF are variable. The mechanism of the increase in RBF is not known but may involve prostaglandins. Nonsteroidal antiinflammatory drugs (NSAIDs) attenuate the diuretic response to loop diuretics in part by preventing prostaglandin-mediated increases in RBF. Loop diuretics block TGF by inhibiting salt transport into the macula densa so that the macula densa no longer can detect NaCl concentrations in the tubular fluid. Therefore, unlike carbonic anhydrase inhibitors, loop diuretics do not decrease GFR by activating TGF. Loop diuretics are powerful stimulators of renin release. This effect is due to interference with NaCl transport by the macula densa and, if volume depletion occurs, to reflex activation of the sympathetic nervous system and to stimulation of the intrarenal baroreceptor mechanism. Prostaglandins, particularly prostacyclin, may play an important role in mediating the renin-release response to loop diuretics.

Other Actions. Loop diuretics may cause direct vascular effects (Dormans *et al.*, 1996). Loop diuretics, particularly furosemide, acutely increase systemic venous capacitance and thereby decrease left ventricular filling pressure. This effect, which may be mediated by prostaglandins and requires intact kidneys, benefits patients with pulmonary edema even before diuresis ensues. Furosemide and ethacrynic acid can inhibit $Na^+,K^+-ATPase$, glycolysis, mitochondrial respiration, the microsomal Ca^{2+} pump, adenylyl cyclase, phosphodiesterase, and prostaglandin dehydrogenase; however, these effects do not have therapeutic implications. *In vitro*, high doses of inhibitors of $Na^+-K^+-2Cl^-$ symport can inhibit electrolyte transport in many tissues. Only in the inner ear, where alterations in the electrolyte composition of endolymph may contribute to drug-induced ototoxicity, is this effect important clinically.

Absorption and Elimination. The oral bioavailabilities, plasma half-lives, and routes of elimination of inhibitors of $Na^+-K^+-2Cl^-$ symport are listed in Table 28–4. Because furosemide, bumetanide, ethacrynic acid, and torsemide are bound extensively to plasma proteins, delivery of these drugs to the tubules by filtration is limited. However, they are secreted efficiently by the organic acid transport system in the proximal tubule and thereby gain access to their binding sites on the $Na^+-K^+-2Cl^-$ symport in the luminal membrane of the thick ascending limb. Probenecid shifts the plasma concentration–response curve to furosemide to the right by competitively inhibiting furosemide secretion by the organic acid transport system (Brater, 1983).

Approximately 65% of furosemide is excreted unchanged in the urine, and the remainder is conjugated to glucuronic acid in the kidney. Accordingly, in patients with renal, but not liver, disease, the elimination half-life of furosemide is prolonged. In contrast, bumetanide and torsemide have significant hepatic metabolism, so the elimination half-lives of these loop diuretics are prolonged by liver, but not renal, disease (Shankar and Brater, 2003).

Although the average oral availability of furosemide is approximately 60%, oral availability of furosemide varies from 10% to 100%. In contrast, oral availabilities of bumetanide and torsemide are reliably high. Heart failure patients have fewer hospitalizations and better quality of life with torsemide than with furosemide perhaps because of the more reliable absorption of torsemide (Shankar and Brater, 2003).

As a class, loop diuretics have short elimination half-lives, and prolonged-release preparations are not available. Consequently, often the dosing interval is too short to maintain adequate levels of loop diuretics in the tubular lumen. Note that torsemide has a longer $t_{1/2}$ than other agents available in the United States (Table 28–4). As the concentration of loop diuretic in the tubular lumen declines, nephrons begin to avidly reabsorb Na^+ , which often nullifies the overall effect of the loop diuretic on total-body Na^+ . This phenomenon of “postdiuretic Na^+ retention” can be overcome by restricting dietary Na^+ intake or by more frequent administration of the loop diuretic (Ellison, 1999).

Toxicity, Adverse Effects, Contraindications, Drug Interactions. Adverse effects unrelated to the diuretic efficacy are rare, and most adverse effects are due to abnormalities of fluid and electrolyte balance. Overzealous use of loop diuretics can cause serious depletion of total-body Na^+ . This may be manifest as hyponatremia and/or extracellular fluid volume depletion associated with hypotension, reduced GFR, circulatory collapse, thromboembolic episodes, and in patients with liver disease, hepatic encephalopathy. Increased delivery of Na^+ to the distal tubule, particularly when combined with activation of the renin–angiotensin system, leads to increased urinary excretion of K^+ and H^+ , causing a hypochloremic alkalosis. If dietary K^+ intake is not sufficient, hypokalemia may develop, and this may induce cardiac arrhythmias, particularly in patients taking cardiac glycosides. Increased Mg^{2+} and Ca^{2+} excretion may result in hypomagnesemia (a risk factor for cardiac arrhythmias) and hypocalcemia (rarely leading to tetany). Recent evidence suggests that loop diuretics should be avoided in postmenopausal osteopenic women, in whom

increased Ca^{2+} excretion may have deleterious effects on bone metabolism (Rejnmark *et al.*, 2003).

Loop diuretics can cause ototoxicity that manifests as tinnitus, hearing impairment, deafness, vertigo, and a sense of fullness in the ears. Hearing impairment and deafness are usually, but not always, reversible. Ototoxicity occurs most frequently with rapid intravenous administration and least frequently with oral administration. Ethacrynic acid appears to induce ototoxicity more often than do other loop diuretics and should be used only in patients who cannot tolerate the other loop diuretics. Loop diuretics also can cause hyperuricemia (occasionally leading to gout) and hyperglycemia (infrequently precipitating diabetes mellitus) and can increase plasma levels of low-density lipoprotein (LDL) cholesterol and triglycerides while decreasing plasma levels of high-density lipoprotein (HDL) cholesterol. Other adverse effects include skin rashes, photosensitivity, paresthesias, bone marrow depression, and gastrointestinal disturbances.

Contraindications to the use of loop diuretics include severe Na^+ and volume depletion, hypersensitivity to sulfonamides (for sulfonamide-based loop diuretics), and anuria unresponsive to a trial dose of loop diuretic.

Drug interactions may occur when loop diuretics are coadministered with (1) aminoglycosides (synergism of ototoxicity caused by both drugs), (2) anticoagulants (increased anticoagulant activity), (3) digitalis glycosides (increased digitalis-induced arrhythmias), (4) lithium (increased plasma levels of lithium), (5) propranolol (increased plasma levels of propranolol), (6) sulfonyleureas (hyperglycemia), (7) cisplatin (increased risk of diuretic-induced ototoxicity), (8) NSAIDs (blunted diuretic response and salicylate toxicity when given with high doses of salicylates), (9) probenecid (blunted diuretic response), (10) thiazide diuretics (synergism of diuretic activity of both drugs leading to profound diuresis), and (11) amphotericin B (increased potential for nephrotoxicity and toxicity and intensification of electrolyte imbalance).

Therapeutic Uses. A major use of loop diuretics is in the treatment of acute pulmonary edema. A rapid increase in venous capacitance in conjunction with a brisk natriuresis reduces left ventricular filling pressures and thereby rapidly relieves pulmonary edema. Loop diuretics also are used widely for the treatment of chronic congestive heart failure when diminution of extracellular fluid volume is desirable to minimize venous and pulmonary congestion (*see* Chapter 33). In this regard, a meta-analysis of randomized clinical trials demonstrates that diuretics cause a significant reduction in mortality and the risk of worsening heart failure, as well as an improvement in exercise capacity (Faris *et al.*, 2002).

Diuretics are used widely for the treatment of hypertension (*see* Chapter 32), and controlled clinical trials demonstrating reduced morbidity and mortality have been conducted with $\text{Na}^+\text{-Cl}^-$ symport (thiazides and thiazidelike diuretics) but not $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport inhibitors. Nonetheless, $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport inhibitors appear to lower blood pressure as effectively as $\text{Na}^+\text{-Cl}^-$ symport inhibitors while causing smaller perturbations in the lipid profile (van der Heijden *et al.*, 1998). However, the short elimination half-lives of loop diuretics render them less useful for hypertension than thiazide-type diuretics. The edema of nephrotic syndrome often is refractory to other classes of diuretics, and loop diuretics often are the only drugs capable of reducing the massive edema associated with this renal disease. Loop diuretics also are employed in the treatment of edema and ascites of liver cirrhosis; however, care must be taken not to induce encephalopathy or hepatorenal syndrome. In patients with a drug overdose, loop diuretics can be used to induce a forced diuresis to facilitate more rapid renal elimination of the offending drug. Loop diuretics, combined with isotonic saline administration to prevent volume depletion, are used to treat hypercalcemia. Loop diuretics interfere with the kidney's capacity to produce a concentrated urine. Consequently, loop diuretics combined with hypertonic saline are useful for the treatment of life-threatening hyponatremia. Loop diuretics also are used to treat edema associated with chronic renal insufficiency. However, animal studies have demonstrated that loop diuretics increase P_{GC} by activating the renin-angiotensin system, an effect that could accelerate renal injury (Lane *et al.*, 1998). Most patients with ARF receive a trial dose of a loop diuretic in an attempt to convert oliguric ARF to nonoliguric ARF. However, there is no evidence that loop diuretics prevent ATN or improve outcome in patients with ARF (Kellum, 1998).

INHIBITORS OF $\text{Na}^+\text{-Cl}^-$ SYMPORT (THIAZIDE AND THIAZIDELIKE DIURETICS)

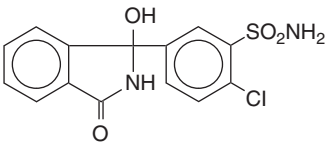

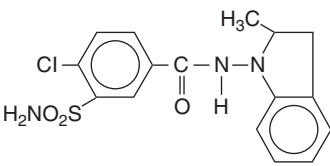

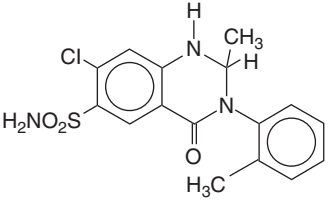

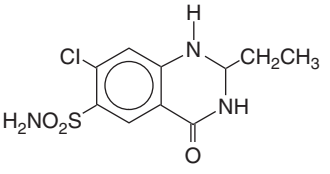

The benzothiadiazides were synthesized in an effort to enhance the potency of inhibitors of carbonic anhydrase. However, unlike carbonic anhydrase inhibitors, which primarily increase NaHCO_3 excretion, benzothiadiazides were found predominantly to increase NaCl excretion, an effect shown to be independent of carbonic anhydrase inhibition.

Chemistry. Inhibitors of $\text{Na}^+\text{-Cl}^-$ symport are sulfonamides (Table 28-5), and many are analogues of 1,2,4-benzothiadiazine-1,1-dioxide. Because the original inhibitors of $\text{Na}^+\text{-Cl}^-$ symport were benzothiadiazides,

azine derivatives, this class of diuretics became known as *thiazide diuretics*. Subsequently, drugs that are pharmacologically similar to thiazide diuretics but are not thiazides were developed and are called *thiazidelike diuretics*. The term *thiazide diuretics* is used here to refer to all members of the class of inhibitors of $\text{Na}^+\text{-Cl}^-$ symport.

Mechanism and Site of Action. Some studies using split-droplet and stationary-microperfusion techniques have described reductions in proximal tubule reabsorption by thiazide diuretics; however, free-flow micropuncture studies have not consistently demonstrated increased solute delivery out of the proximal tubule following administration of thiazides. In contrast, micropuncture and *in situ* microperfusion studies clearly indicate that thiazide diuretics inhibit NaCl transport in the DCT. The DCT expresses thiazide binding sites and is accepted as the primary site of action of thiazide diuretics; the proximal tubule may represent a secondary site of action.

Figure 28–7 illustrates the current model of electrolyte transport in the DCT. As with other nephron segments, transport is powered by an Na^+ pump in the basolateral membrane. The free energy in the electrochemical gradient for Na^+ is harnessed by a $\text{Na}^+\text{-Cl}^-$ symporter in the luminal membrane that moves Cl^- into the epithelial cell against its electrochemical gradient. Cl^- then exits the basolateral membrane passively *via* a Cl^- channel. Thiazide diuretics inhibit the $\text{Na}^+\text{-Cl}^-$ symporter. In this regard, Na^+ or Cl^- binding to the $\text{Na}^+\text{-Cl}^-$ symporter modifies thiazide-induced inhibition of the symporter, suggesting that the thiazide-binding site is shared or altered by both Na^+ and Cl^- (Monroy, *et al.*, 2000).

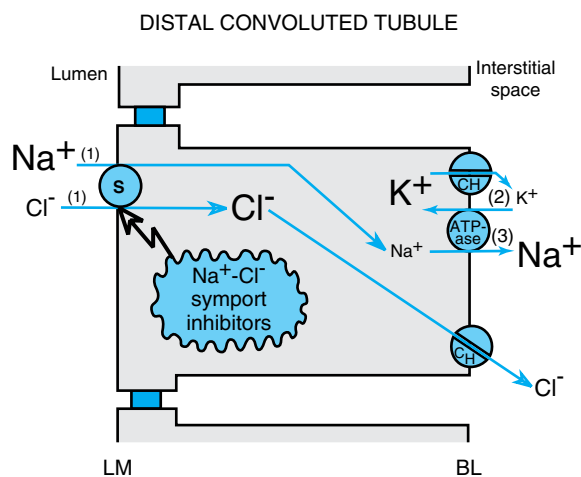

Figure 28–7. NaCl reabsorption in distal convoluted tubule and mechanism of diuretic action of $\text{Na}^+\text{-Cl}^-$ symport inhibitors. S, symporter; CH, ion channel. Numbers in parentheses indicate stoichiometry. BL and LM indicate basolateral and luminal membranes, respectively.

Using a functional expression strategy (Cl^- -dependent Na^+ uptake in *Xenopus* oocytes), Gamba *et al.* (1993) isolated a cDNA clone from the urinary bladder of the winter flounder that codes for a $\text{Na}^+\text{-Cl}^-$ symporter. This $\text{Na}^+\text{-Cl}^-$ symporter is inhibited by a number of thiazide diuretics (but not by furosemide, acetazolamide, or an amiloride derivative) and has 12 putative membrane-spanning domains, and its sequence is 47% identical to the cloned dogfish shark rectal gland $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporter. Subsequently, Gamba *et al.* (1994) cloned the rat and Mastroianni *et al.* (1996) cloned the human $\text{Na}^+\text{-Cl}^-$ symporter. The human $\text{Na}^+\text{-Cl}^-$ symporter has a predicted sequence of 1021 amino acids, 12 transmembrane domains, and 2 intracellular hydrophilic amino and carboxyl termini and maps to chromosome 16q13. The $\text{Na}^+\text{-Cl}^-$ symporter (called *ENCC1* or *TSC*) is expressed predominantly in the kidney (Chang *et al.*, 1996) and is localized to the apical membrane of DCT epithelial cells (Bachmann *et al.*, 1995; Obermüller *et al.*, 1995; Plotkin *et al.*, 1996). Expression of the $\text{Na}^+\text{-Cl}^-$ symporter is regulated by aldosterone (Velázquez *et al.*, 1996; Kim *et al.*, 1998; Bostonjoglo *et al.*, 1998). Mutations in the $\text{Na}^+\text{-Cl}^-$ symporter cause a form of inherited hypokalemic alkalosis called *Gitelman's syndrome* (Simon and Lifton, 1998).

Effects on Urinary Excretion. As would be expected from their mechanism of action, inhibitors of $\text{Na}^+\text{-Cl}^-$ symport increase Na^+ and Cl^- excretion. However, thiazides are only moderately efficacious (*i.e.*, maximum excretion of filtered load of Na^+ is only 5%) because approximately 90% of the filtered Na^+ load is reabsorbed before reaching the DCT. Some thiazide diuretics also are weak inhibitors of carbonic anhydrase, an effect that increases HCO_3^- and phosphate excretion and probably accounts for their weak proximal tubular effects. Like inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport, inhibitors of $\text{Na}^+\text{-Cl}^-$ symport increase the excretion of K^+ and titratable acid by the same mechanisms discussed for loop diuresis. Acute administration of thiazides increases the excretion of uric acid. However, uric acid excretion is reduced following chronic administration by the same mechanisms discussed for loop diuretics. The acute effects of inhibitors of $\text{Na}^+\text{-Cl}^-$ symport on Ca^{2+} excretion are variable; when administered chronically, thiazide diuretics decrease Ca^{2+} excretion (*see* Chapter 61). The mechanism involves increased proximal reabsorption owing to volume depletion, as well as direct effects of thiazides to increase Ca^{2+} reabsorption in the DCT. In this regard, inhibition of the $\text{Na}^+\text{-Cl}^-$ symporter in the luminal membrane decreases intracellular Na^+ levels, thereby increasing the basolateral exit of Ca^{2+} *via* enhanced $\text{Na}^+\text{-Ca}^{2+}$ exchange (Friedman and Bushinsky, 1999). Thiazide diuretics may cause a mild magnesuria by a poorly understood mechanism, and there is increasing awareness that long-term use of thiazide diuretics may cause magnesium deficiency, particularly in the elderly (Wilcox, 1999). Since inhibitors of $\text{Na}^+\text{-Cl}^-$ symport inhibit transport in the cortical diluting segment, thiazide diuretics attenuate the ability of the kidney to

excrete a dilute urine during water diuresis. However, since the DCT is not involved in the mechanism that generates a hypertonic medullary interstitium, thiazide diuretics do not alter the kidney's ability to concentrate urine during hydropenia.

Effects on Renal Hemodynamics. In general, inhibitors of $\text{Na}^+\text{-Cl}^-$ symport do not affect RBF and only variably reduce GFR owing to increases in intratubular pressure. Since thiazides act at a point past the macula densa, they have little or no influence on TGF.

Other Actions. Thiazide diuretics may inhibit cyclic nucleotide phosphodiesterases, mitochondrial oxygen consumption, and renal uptake of fatty acids; however, these effects are not of clinical significance.

Absorption and Elimination. The relative potency, oral bioavailability, plasma half-life, and route of elimination of inhibitors of $\text{Na}^+\text{-Cl}^-$ symport are listed in Table 28–5. Of special note is the wide range of half-lives for this class of drugs. Sulfonamides are organic acids and therefore are secreted into the proximal tubule by the organic acid secretory pathway. Since thiazides must gain access to the tubular lumen to inhibit the $\text{Na}^+\text{-Cl}^-$ symporter, drugs such as probenecid can attenuate the diuretic response to thiazides by competing for transport into the proximal tubule. However, plasma protein binding varies considerably among thiazide diuretics, and this parameter determines the contribution that filtration makes to tubular delivery of a specific thiazide.

Toxicity, Adverse Effects, Contraindications, Drug Interactions. Thiazide diuretics rarely cause CNS (*e.g.*, vertigo, headache, paresthesias, xanthopsia, and weakness), gastrointestinal (*e.g.*, anorexia, nausea, vomiting, cramping, diarrhea, constipation, cholecystitis, and pancreatitis), hematological (*e.g.*, blood dyscrasias), and dermatological (*e.g.*, photosensitivity and skin rashes) disorders. The incidence of erectile dysfunction is greater with $\text{Na}^+\text{-Cl}^-$ symport inhibitors than with several other antihypertensive agents (*e.g.*, β adrenergic receptor antagonists, Ca^{2+} channel blockers, angiotensin converting enzyme inhibitors, and α_1 -receptor antagonists) (Grimm *et al.*, 1997) but usually is tolerable. As with loop diuretics, most serious adverse effects of thiazides are related to abnormalities of fluid and electrolyte balance. These adverse effects include extracellular volume depletion, hypotension, hypokalemia, hyponatremia, hypochloremia, metabolic alkalosis, hypomagnesemia, hypercalcemia, and hyperuricemia. Thiazide diuretics have caused

fatal or near-fatal hyponatremia, and some patients are at recurrent risk of hyponatremia when rechallenged with thiazides.

Thiazide diuretics also decrease glucose tolerance, and latent diabetes mellitus may be unmasked during therapy. The mechanism of the impaired glucose tolerance is not completely understood but appears to involve reduced insulin secretion and alterations in glucose metabolism. Hyperglycemia may be related in some way to K^+ depletion, in that hyperglycemia is reduced when K^+ is given along with the diuretic (Wilcox, 1999). In addition to contributing to hyperglycemia, thiazide-induced hypokalemia compromises the antihypertensive effect (Wilcox, 1999) and cardiovascular protection (Franse *et al.*, 2000) afforded by thiazides in patients with hypertension.

Thiazide diuretics also may increase plasma levels of LDL cholesterol, total cholesterol, and total triglycerides. Thiazide diuretics are contraindicated in individuals who are hypersensitive to sulfonamides.

With regard to drug interactions, thiazide diuretics may diminish the effects of anticoagulants, uricosuric agents used to treat gout, sulfonyleureas, and insulin and may increase the effects of anesthetics, diazoxide, digitalis glycosides, lithium, loop diuretics, and vitamin D. The effectiveness of thiazide diuretics may be reduced by NSAIDs, whether nonselective or selective COX-2 inhibitors, and bile acid sequestrants (reduced absorption of thiazides). Amphotericin B and corticosteroids increase the risk of hypokalemia induced by thiazide diuretics.

A potentially lethal drug interaction warranting special emphasis is that involving thiazide diuretics and quinidine (Roden, 1993). Prolongation of the QT interval by quinidine can lead to the development of polymorphic ventricular tachycardia (*torsades de pointes*) owing to triggered activity originating from early after-depolarizations (*see* Chapter 34). Although usually self-limiting, *torsades de pointes* may deteriorate into fatal ventricular fibrillation. Hypokalemia increases the risk of quinidine-induced *torsades de pointes*, and thiazide diuretics cause hypokalemia. Thiazide diuretic-induced K^+ depletion may account for many cases of quinidine-induced *torsades de pointes*.

Therapeutic Uses. Thiazide diuretics are used for the treatment of the edema associated with heart (congestive heart failure), liver (hepatic cirrhosis), and renal (nephrotic syndrome, chronic renal failure, and acute glomerulonephritis) disease. With the possible exceptions of metolazone and indapamide, most thiazide diuretics are ineffective when the GFR is less than 30 to 40 ml/min.

Thiazide diuretics decrease blood pressure in hypertensive patients by increasing the slope of the renal

pressure–natriuresis relationship (Saito and Kimura, 1996), and thiazide diuretics are used widely for the treatment of hypertension either alone or in combination with other antihypertensive drugs (*see* Chapter 32). In this regard, thiazide diuretics are inexpensive, as efficacious as other classes of antihypertensive agents, and well tolerated. Thiazides can be administered once daily, do not require dose titration, and have few contraindications. Moreover, thiazides have additive or synergistic effects when combined with other classes of antihypertensive agents. Although thiazides may increase the risk of sudden death (Hoes and Grobbee, 1996) and renal cell carcinoma marginally (Grossman *et al.*, 1999), in general, these agents are safe and reduce cardiovascular morbidity and mortality in hypertensive patients. Because the adverse effects of thiazides increase progressively in severity at doses higher than maximally effective antihypertensive doses, only low doses should be prescribed for hypertension (Kaplan, 1999). A common dose for hypertension is 25 mg/day of hydrochlorothiazide or the dose equivalent of another thiazide. The ALLHAT study (ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group, 2002) provides strong evidence that thiazide diuretics are the best initial therapy for uncomplicated hypertension, a conclusion endorsed by the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (Chobanian *et al.*, 2003). Concern regarding the risk of diabetes should not cause physicians to avoid thiazides in nondiabetic hypertensives (Gress *et al.*, 2000). Recent studies suggest that

the antihypertensive response to thiazides is influenced by polymorphisms in the angiotensin-converting enzyme and α -adducin genes (Sciarrone *et al.*, 2003).

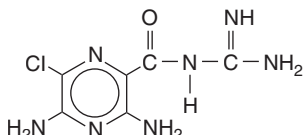

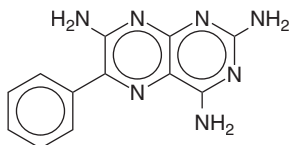

Thiazide diuretics, which reduce urinary excretion of Ca^{2+} , sometimes are employed to treat calcium nephrolithiasis and may be useful for the treatment of osteoporosis (*see* Chapter 61). Thiazide diuretics also are the mainstay for treatment of nephrogenic diabetes insipidus, reducing urine volume by up to 50%. The mechanism of this paradoxical effect remains unknown (Grønbeck *et al.*, 1998). Since other halides are excreted by renal processes similar to those for Cl^- , thiazide diuretics may be useful for the management of Br^- intoxication.

INHIBITORS OF RENAL EPITHELIAL Na^+ CHANNELS (K^+ -SPARING DIURETICS)

Triamterene (DYRENIUM, MAXZIDE) and *amiloride* (MIDAMOR) are the only two drugs of this class in clinical use. Both drugs cause small increases in NaCl excretion and usually are employed for their antikaliuretic actions to offset the effects of other diuretics that increase K^+ excretion. Consequently, triamterene and amiloride, along with spironolactone (*see* next section), often are classified as *potassium (K^+)-sparing diuretics*.

Chemistry. Amiloride is a pyrazinoylguanidine derivative, and triamterene is a pteridine (Table 28–6). Both drugs are organic bases and are transported by the organic base secretory mechanism in the proximal tubule.

Table 28–6
Inhibitors of Renal Epithelial Na^+ Channels (K^+ -Sparing Diuretics)

DRUG	STRUCTURE	RELATIVE POTENCY	ORAL AVAILABILITY	$T_{1/2}$ (HOURS)	ROUTE OF ELIMINATION
Amiloride (DYRENIUM)		1	15–25%	~21	R
Triamterene (MIDAMOR)		0.1	~50%	~4.2	M

Abbreviations: R, renal excretion of intact drug; M, metabolism; however, triamterene is transformed into an active metabolite that is excreted in the urine.

Mechanism and Site of Action. Available data suggest that triamterene and amiloride have similar mechanisms of action. Of the two, amiloride has been studied much more extensively, so its mechanism of action is known with a higher degree of certainty. As illustrated in Figure 28–8, principal cells in the late distal tubule and collecting duct have, in their luminal membranes, epithelial Na^+ channels that provide a conductive pathway for the entry of Na^+ into the cell down the electrochemical gradient created by the basolateral Na^+ pump. The higher permeability of the luminal membrane for Na^+ depolarizes the luminal membrane but not the basolateral membrane, creating a lumen-negative transepithelial potential difference. This transepithelial voltage provides an important driving force for the secretion of K^+ into the lumen *via* K^+ channels (ROMK) in the luminal membrane. Carbonic anhydrase inhibitors, loop diuretics, and thiazide diuretics increase the delivery of Na^+ to the late distal tubule and collecting duct, a situation that often is associated with increased K^+ and H^+ excretion. It is likely that the elevation in luminal Na^+ concentration in the distal nephron induced by such diuretics augments depolarization of the luminal membrane and thereby enhances the lumen-negative V_T , which facilitates K^+ excretion. In addition to principal cells, the collecting duct also contains type A intercalated cells that mediate the secretion of H^+ into the tubular lumen. Tubular acidification is driven by a luminal H^+ -ATPase (proton pump), and this pump is aided by the partial depolarization of the luminal membrane. The luminal H^+ -ATPase is of the vacuolar-type and is distinct from the gastric H^+ - K^+ -ATPase that is inhibited by drugs such as omeprazole. However, increased distal delivery of Na^+ is not the only mechanism by which diuretics increase K^+ and H^+ excretion. Activation of the renin-angiotensin-aldosterone axis by diuretics also contributes to diuretic-induced K^+ and H^+ excretion, as discussed in the section on mineralocorticoid antagonists.

Considerable evidence indicates that amiloride blocks epithelial Na^+ channels in the luminal membrane of principal cells in the late distal tubule and collecting duct perhaps by competing with Na^+ for negatively charged areas within the pore of the Na^+ channel. This evidence includes data from epithelia of nonrenal origin (amphibian skin and toad bladder), electrophysiological studies in isolated mammalian collecting ducts, and molecular studies that reconstitute channel subunits in lipid bilayers or express channel subunits in *Xenopus* oocytes. The renal epithelial Na^+ channels inhibited by this class of diuretics are not the same as voltage-gated Na^+ channels found in many electrically active cell types (*e.g.*, neurons and myocytes).

Figure 28–8. Na^+ reabsorption in late distal tubule and collecting duct and mechanism of diuretic action of epithelial Na^+ -channel inhibitors. Cl^- reabsorption (not shown) occurs both paracellularly and transcellularly, and the precise mechanism of Cl^- transport appears to be species-specific. A, antiporter; CH, ion channel; CA, carbonic anhydrase. Numbers in parentheses indicate stoichiometry. Designated voltages are the potential differences across the indicated membrane or cell. BL and LM indicate basolateral and luminal membranes, respectively.

The amiloride-sensitive Na^+ channel (called *ENaC*) consists of three subunits (α , β , and γ) (Kleyman *et al.*, 1999). Although the α subunit is sufficient for channel activity, maximal Na^+ permeability is induced when all three subunits are coexpressed in the same cell, probably forming a tetrameric structure consisting of two α subunits, one β subunit, and one γ subunit. Studies in *Xenopus* oocytes expressing *ENaC* suggest that triamterene and amiloride bind to *ENaC* by similar mechanisms (Busch *et al.*, 1996). The K_i of amiloride for *ENaC* is submicromolar, and molecular studies have identified critical domains in *ENaC* that participate in amiloride binding (Kleyman *et al.*, 1999). Liddle's syndrome (pseudohyperaldosteronism) is an autosomal dominant form of low-renin, volume-expanded hypertension that is due to mutations in the β or γ subunits, leading to increased basal activity of *ENaC* (Ismailov *et al.*, 1999).

Effects on Urinary Excretion. Since the late distal tubule and collecting duct have a limited capacity to reab-

sorb solutes, blockade of Na^+ channels in this part of the nephron only mildly increases the excretion rates of Na^+ and Cl^- (approximately 2% of filtered load). Blockade of Na^+ channels hyperpolarizes the luminal membrane, reducing the lumen-negative transepithelial voltage. Since the lumen-negative potential difference normally opposes cation reabsorption and facilitates cation secretion, attenuation of the lumen-negative voltage decreases the excretion rates of K^+ , H^+ , Ca^{2+} , and Mg^{2+} . Volume contraction may increase reabsorption of uric acid in the proximal tubule; hence chronic administration of amiloride and triamterene may decrease uric acid excretion.

Effects on Renal Hemodynamics. Amiloride and triamterene have little or no effect on renal hemodynamics and do not alter TGF.

Other Actions. Amiloride, at concentrations higher than needed to elicit therapeutic effects, also blocks the Na^+-H^+ and $\text{Na}^+-\text{Ca}^{2+}$ antiporters and inhibits $\text{Na}^+, \text{K}^+-\text{ATPase}$.

Absorption and Elimination. The relative potency, oral bioavailability, plasma half-life, and route of elimination for amiloride and triamterene are listed in Table 28–6. Amiloride is eliminated predominantly by urinary excretion of intact drug. Triamterene is metabolized extensively to an active metabolite, 4-hydroxytriamterene sulfate, and this metabolite is excreted in the urine. The pharmacological activity of 4-hydroxytriamterene sulfate is comparable with that of the parent drug. Therefore, the toxicity of triamterene may be enhanced in both hepatic disease (decreased metabolism of triamterene) and renal failure (decreased urinary excretion of active metabolite).

Toxicity, Adverse Effects, Contraindications, Drug Interactions. The most dangerous adverse effect of Na^+ -channel inhibitors is hyperkalemia, which can be life-threatening. Consequently, amiloride and triamterene are contraindicated in patients with hyperkalemia, as well as in patients at increased risk of developing hyperkalemia (e.g., patients with renal failure, patients receiving other K^+ -sparing diuretics, patients taking angiotensin-converting enzyme inhibitors, or patients taking K^+ supplements). Even NSAIDs can increase the likelihood of hyperkalemia in patients receiving Na^+ -channel inhibitors. Pentamidine and high-dose trimethoprim are used often to treat *Pneumocystis carinii* pneumonia in patients with acquired immune deficiency syndrome (AIDS). Because these compounds are weak inhibitors of ENaC, they too may cause hyperkalemia, and this may explain the frequent

occurrence of hyperkalemia in AIDS patients (Kleyman *et al.*, 1999). Cirrhotic patients are prone to megaloblastosis because of folic acid deficiency, and triamterene, a weak folic acid antagonist, may increase the likelihood of this adverse event. Triamterene also can reduce glucose tolerance and induce photosensitization and has been associated with interstitial nephritis and renal stones. Both drugs can cause CNS, gastrointestinal, musculoskeletal, dermatological, and hematological adverse effects. The most common adverse effects of amiloride are nausea, vomiting, diarrhea, and headache; those of triamterene are nausea, vomiting, leg cramps, and dizziness.

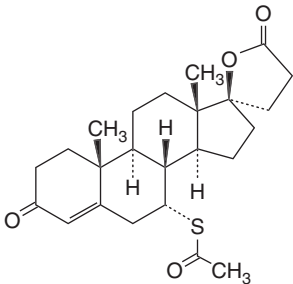

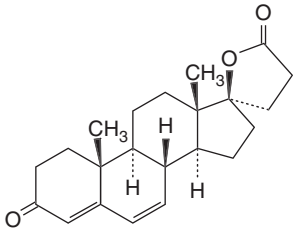

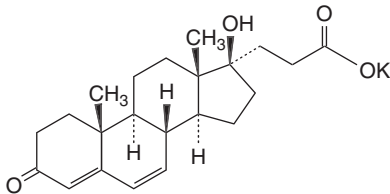

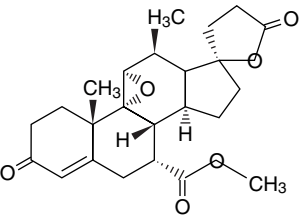

Therapeutic Uses. Because of the mild natriuresis induced by Na^+ -channel inhibitors, these drugs seldom are used as sole agents in the treatment of edema or hypertension. Rather, their major utility is in combination with other diuretics. Coadministration of a Na^+ -channel inhibitor augments the diuretic and antihypertensive response to thiazide and loop diuretics. More important, the ability of Na^+ -channel inhibitors to reduce K^+ excretion tends to offset the kaliuretic effects of thiazide and loop diuretics; consequently, the combination of a Na^+ -channel inhibitor with a thiazide or loop diuretic tends to result in normal values of plasma K^+ (Hollenberg and Mickiewicz, 1989). Liddle's syndrome can be treated effectively with Na^+ -channel inhibitors. Approximately 5% of people of African origin carry a *T594M* polymorphism in the β subunit of ENaC, and amiloride is particularly effective in lowering blood pressure in patients with hypertension who carry this polymorphism (Baker *et al.*, 2002). Aerosolized amiloride has been shown to improve mucociliary clearance in patients with cystic fibrosis. By inhibiting Na^+ absorption from the surfaces of airway epithelial cells, amiloride augments hydration of respiratory secretions and thereby improves mucociliary clearance. Amiloride also is useful for lithium-induced nephrogenic diabetes insipidus because it blocks Li^+ transport into the cells of the collecting tubules.

ANTAGONISTS OF MINERALOCORTICOID RECEPTORS (ALDOSTERONE ANTAGONISTS, K^+ -SPARING DIURETICS)

Mineralocorticoids cause retention of salt and water and increase the excretion of K^+ and H^+ by binding to specific mineralocorticoid receptors. Early studies indicated that some spiro lactones block the effects of mineralocorti-

Table 28–7

Mineralocorticoid Receptor Antagonists (Aldosterone Antagonists, Potassium-Sparing Diuretics)

Eplerenone (INSPIRA)		ID	~5	M

*Not available in United States. Abbreviations: M, metabolism; ID, insufficient data.

coids; this finding led to the synthesis of specific antagonists for the mineralocorticoid receptor (MR). Currently, two MR antagonists are available in the United States, *spironolactone* (a 17-spirolactone) and *eplerenone*; two others are available elsewhere (Table 28–7).

Mechanism and Site of Action. Epithelial cells in the late distal tubule and collecting duct contain cytosolic MRs that have a high affinity for aldosterone. This receptor is a member of the superfamily of receptors for steroid

hormones, thyroid hormones, vitamin D, and retinoids (see Chapter 1). Aldosterone enters the epithelial cell from the basolateral membrane and binds to MRs; the MR–aldosterone complex translocates to the nucleus, where it binds to specific sequences of DNA (hormone-responsive elements) and thereby regulates the expression of multiple gene products called *aldosterone-induced proteins* (AIPs). Figure 28–9 illustrates some of the proposed effects of AIPs, including activation of “silent” Na^+ channels and “silent” Na^+ pumps that pre-exist in the cell

Figure 28–9. Effects of aldosterone on late distal tubule and collecting duct and diuretic mechanism of aldosterone antagonists. AIP, aldosterone-induced proteins; ALDO, aldosterone; MR, mineralocorticoid receptor; CH, ion channel; 1, activation of membrane-bound Na^+ channels; 2, redistribution of Na^+ channels from cytosol to membrane; 3, *de novo* synthesis of Na^+ channels; 4, activation of membrane-bound Na^+, K^+ -ATPase; 5, redistribution of Na^+, K^+ -ATPase from cytosol to membrane; 6, *de novo* synthesis of Na^+, K^+ -ATPase; 7, changes in permeability of tight junctions; 8, increased mitochondrial production of ATP. BL and LM indicate basolateral and luminal membranes, respectively.

membrane, alterations in the cycling of Na^+ channels and Na^+ pumps between the cytosol and cell membrane such that more channels and pumps are located in the membrane, increased expression of Na^+ channels and Na^+ pumps, changes in permeability of the tight junctions, and increased activity of enzymes in the mitochondria that are involved in ATP production. The precise mechanisms by which AIPs alter transport are incompletely understood. However, the net effect of AIPs is to increase Na^+ conductance of the luminal membrane and sodium pump activity of the basolateral membrane. Consequently, transepithelial NaCl transport is enhanced, and the lumen-negative transepithelial voltage is increased. The latter effect increases the driving force for secretion of K^+ and H^+ into the tubular lumen.

Drugs such as spironolactone and eplerenone competitively inhibit the binding of aldosterone to the MR. Unlike the MR–aldosterone complex, the MR–spironolactone complex is not able to induce the synthesis of AIPs. Since spironolactone and eplerenone block the biological effects of aldosterone, these agents also are referred to as *aldosterone antagonists*. MR antagonists are the only diuretics that do not require access to the tubular lumen to induce diuresis.

Effects on Urinary Excretion. The effects of MR antagonists on urinary excretion are very similar to those induced by renal epithelial Na^+ -channel inhibitors. However, unlike that of the Na^+ -channel inhibitors, the clinical efficacy of MR antagonists is a function of endogenous levels of aldosterone. The higher the levels of endogenous aldosterone, the greater are the effects of MR antagonists on urinary excretion.

Effects on Renal Hemodynamics. MR antagonists have little or no effect on renal hemodynamics and do not alter TGF.

Other Actions. Spironolactone has some affinity toward progesterone and androgen receptors and thereby induces side effects such as gynecomastia, impotence, and menstrual irregularities. Owing to the 9,11-epoxide group, eplerenone has very low affinity for progesterone and androgen receptors (<1% and <0.1%, respectively) compared with spironolactone. Therapeutic concentrations of spironolactone block *ether-a-go-go*-related gene channels, and this may account for the antiarrhythmic effects of spironolactone in heart failure (Caballero *et al.*, 2003). High concentrations of spironolactone have been reported to interfere with steroid biosynthesis by inhibiting cytochrome P450 steroid hydroxylases (*e.g.*, CYP11A1, CYP11B1, CYP11B2, CYP17, and CYP21). These effects have limited clinical relevance (*see* Chapter 59).

Absorption and Elimination. Spironolactone is absorbed partially (approximately 65%), is metabolized extensively (even during its first passage through the liver), undergoes enterohepatic recirculation, is highly protein-bound, and has a short half-life (approximately 1.6 hours). However, an active metabolite of spironolactone, canrenone, has a half-life of approximately 16.5 hours, which prolongs the biological effects of spironolactone. Although not available in the United States, canrenone and the K^+ salt of canrenoate also are in clinical use. Canrenoate is not active *per se* but is converted to canrenone in the body. Eplerenone has good oral availability and is eliminated primarily by metabolism (mediated by the hepatic cyto-

chrome P450 isozyme CYP3A4) to inactive metabolites, with a $t_{1/2}$ of approximately 5 hours.

Toxicity, Adverse Effects, Contraindications, Drug Interactions. As with other K^+ -sparing diuretics, MR antagonists may cause life-threatening hyperkalemia. Indeed, hyperkalemia is the principal risk of MR antagonists. Therefore, these drugs are contraindicated in patients with hyperkalemia and in those at increased risk of developing hyperkalemia either because of disease or because of administration of other medications. MR antagonists also can induce metabolic acidosis in cirrhotic patients.

Salicylates may reduce the tubular secretion of canrenone and decrease the diuretic efficacy of spironolactone, and spironolactone may alter the clearance of digitalis glycosides. Owing to its affinity for other steroid receptors, spironolactone may cause gynecomastia, impotence, decreased libido, hirsutism, deepening of the voice, and menstrual irregularities. Spironolactone also may induce diarrhea, gastritis, gastric bleeding, and peptic ulcers (the drug is contraindicated in patients with peptic ulcers). CNS adverse effects include drowsiness, lethargy, ataxia, confusion, and headache. Spironolactone may cause skin rashes and, rarely, blood dyscrasias. Breast cancer has occurred in patients taking spironolactone chronically (cause and effect not established), and high doses of spironolactone have been associated with malignant tumors in rats. Whether or not therapeutic doses of spironolactone can induce malignancies remains an open question. Strong inhibitors of CYP3A4 (*see* Chapter 3) may increase plasma levels of eplerenone, and such drugs should not be administered to patients taking eplerenone, and vice versa. Other than hyperkalemia and gastrointestinal disorders, the rate of adverse events for eplerenone is similar to that of placebo (Pitt *et al.*, 2003).

Therapeutic Uses. As with other K^+ -sparing diuretics, spironolactone often is coadministered with thiazide or loop diuretics in the treatment of edema and hypertension. Such combinations result in increased mobilization of edema fluid while causing lesser perturbations of K^+ homeostasis. Spironolactone is particularly useful in the treatment of primary hyperaldosteronism (adrenal adenomas or bilateral adrenal hyperplasia) and of refractory edema associated with secondary aldosteronism (cardiac failure, hepatic cirrhosis, nephrotic syndrome, and severe ascites). Spironolactone is considered the diuretic of choice in patients with hepatic cirrhosis. Spironolactone, added to standard therapy, substantially reduces morbidity and mortality (Pitt *et al.*, 1999) and ventricular arrhyth-

mias (Ramires *et al.*, 2000) in patients with heart failure (*see* Chapter 34).

Clinical experience with eplerenone is limited. Nonetheless, eplerenone appears to be a safe and effective antihypertensive drug (Ouzan *et al.*, 2002; Krum *et al.*, 2002; White *et al.*, 2003; Weinberger *et al.*, 2002). In patients with acute myocardial infarction complicated by left ventricular systolic dysfunction, addition of eplerenone to optimal medical therapy significantly reduces morbidity and mortality (Pitt *et al.*, 2003).

CLINICAL SUMMARY

Site and Mechanism of Action of Diuretics. An understanding of the site and mechanism of action of diuretics enhances comprehension of the clinically salient aspects of diuretic pharmacology. Figure 28–10 provides an overview of the many sites and mechanisms of actions of diuretics. Much of the pharmacology of diuretics can be deduced from this figure.

Mechanism of Edema Formation. A complex set of interrelationships (Figure 28–11) exists among the cardiovascular system, the kidneys, the CNS (Na^+ appetite, thirst regulation), and the tissue capillary beds [distribution of extracellular fluid volume (ECFV)], so perturbations at one of these sites can affect all the remaining sites. A primary law of the kidney is that Na^+ excretion is a steep function of mean arterial blood pressure (MABP) such that small increases in MABP cause marked increases in Na^+ excretion (Guyton, 1991). Over any given time interval, the net change in total-body Na^+ (either positive or negative) is simply the dietary Na^+ intake minus the urinary excretion rate minus other losses (*e.g.*, sweating, fecal losses, and vomiting). When a net positive Na^+ balance occurs, the concentration of Na^+ in the extracellular fluid (ECF) will increase, stimulating water intake (thirst) and reducing urinary water output (*via* ADH release). Opposite changes occur during a net negative Na^+ balance. Changes in water intake and output adjust ECFV concentration toward normal, thereby expanding or contracting total ECFV. Total ECFV is distributed among many body compartments; however, since the volume of ECF on the arterial side of the circulation pressurizes the arterial tree, it is this fraction of ECFV that determines MABP, and it is this fraction of ECFV that is “sensed” by the cardiovascular system and kidneys. Since MABP is a major determinant of Na^+ output, a closed loop is established (Figure 28–11). This loop cycles until net Na^+

Figure 28–10. Summary of the site and mechanism of action of diuretics. Three important features of this summary figure are worth special note: (1) Transport of solute across epithelial cells in all nephron segments involves highly specialized proteins, which, for the most part, are apical and basolateral membrane integral proteins, (2) diuretics target and block the action of epithelial proteins involved in solute transport, and (3) the site and mechanism of action of a given class of diuretics are determined by the specific protein inhibited by the diuretic. CA, carbonic anhydrase; MR, mineralocorticoid receptor; MRA, mineralocorticoid receptor antagonist; Aldo, aldosterone.

accumulation is zero; *i.e.*, in the long run, Na^+ intake must equal Na^+ loss.

The preceding discussion implies that three fundamental types of perturbations contribute to venous congestion and/or edema formation:

1. A shift to the right in the renal pressure–natriuresis relationship (*e.g.*, chronic renal failure) causes reduced Na^+ excretion for any level of MABP. If all other factors remain constant, this would increase total-body Na^+ , ECFV, and MABP. The additional ECFV would be distributed throughout various body compartments according to the state of cardiac function and prevailing Starling forces and would predispose toward venous congestion and/or edema. Even so, in the absence of any other predisposing factors for venous congestion and/or edema, a rightward shift in the renal pressure–natriuresis curve generally causes hypertension with only a slight (usually immeasurable) increase

in ECFV. As elucidated by Guyton and coworkers (Guyton, 1991), ECFV expansion triggers the following series of events: expanded ECFV \rightarrow augmented cardiac output \rightarrow enhanced vascular tone (*i.e.*, total-body autoregulation) \rightarrow increased total peripheral resistance \rightarrow elevated MABP \rightarrow pressure natriuresis \rightarrow reduction of ECFV and cardiac output toward normal. Most likely, a sustained rightward shift in the renal pressure–natriuresis curve is a necessary and sufficient condition for long-term hypertension but is only a predisposing factor for venous congestion and/or edema.

2. An increase in dietary Na^+ intake would have the same effects as a rightward shift in the renal pressure–natriuresis relationship (*i.e.*, increased MABP and predisposition to venous congestion/edema). However, changes in salt intake may have minimal or large effects depending on the shape of the patient’s renal pressure–natriuresis curve.

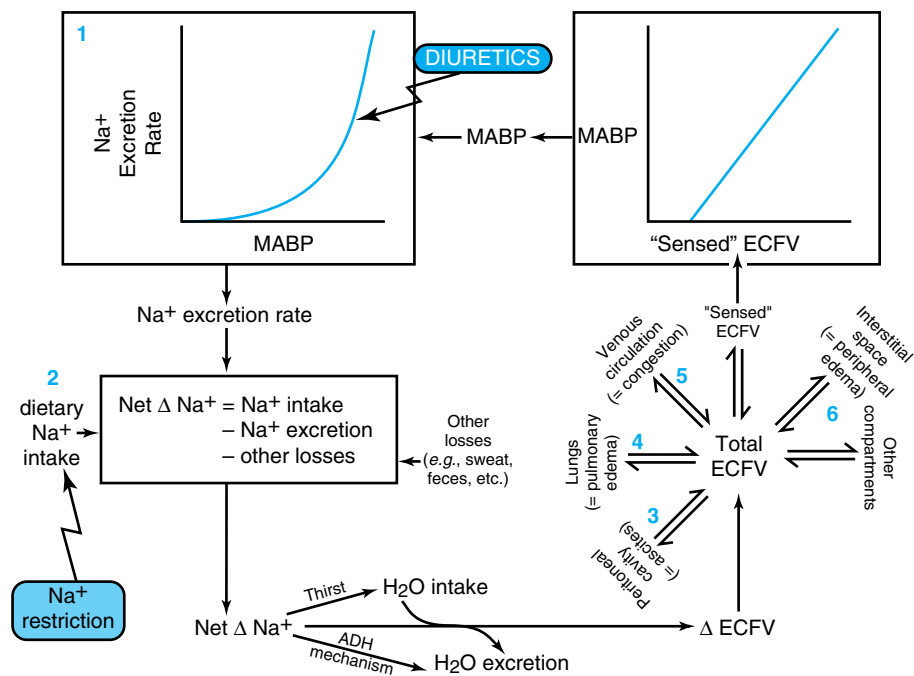

Figure 28–11. Interrelationships among renal function, Na^+ intake, water homeostasis, distribution of extracellular fluid volume, and mean arterial blood pressure. Pathophysiological mechanisms of edema formation: 1, rightward shift of renal pressure natriuresis curve; 2, excessive dietary Na^+ intake; 3, increased distribution of extracellular fluid volume (ECFV) to peritoneal cavity (e.g., liver cirrhosis with increased hepatic sinusoidal hydrostatic pressure) leading to ascites formation; 4, increased distribution of ECFV to lungs (e.g., left-sided heart failure with increased pulmonary capillary hydrostatic pressure) leading to pulmonary edema; 5, increased distribution of ECFV to venous circulation (e.g., right-sided heart failure) leading to venous congestion; 6, peripheral edema caused by altered Starling forces causing increased distribution of ECFV to interstitial space (e.g., diminished plasma proteins in nephrotic syndrome, severe burns, and liver disease).

3. Any pathophysiological alterations in the forces that govern the distribution of ECFV among the various body compartments would cause abnormal amounts of ECFV to be trapped at the site of altered forces. This would deplete the “sensed” ECFV, which would be restored back to normal by the mechanisms described earlier. ECFV may be trapped at several sites by different mechanisms. For instance, cirrhosis of the liver increases lymph in the space of Disse, leading to spill-over *via* the glissonian wall into the peritoneal cavity (ascites). Left-sided heart failure, both acute and chronic, increases hydrostatic pressure in the lung capillaries, leading to pulmonary edema. Chronic right-sided heart failure redistributes ECFV from the arterial to the venous circulation, resulting in venous, hepatic, and splenic congestion and peripheral tissue edema. Decreased levels of plasma protein, particularly albumin (e.g., in nephrotic syndrome, severe burns, and hepatic disease), increase the distribution of ECFV into the interstitial spaces, causing generalized peripheral edema. Peripheral edema also may be “idiopathic”

owing to unknown alterations in the Starling forces at the capillary bed.

The Role of Diuretics in Clinical Medicine. Another implication of the mechanisms illustrated in Figure 28–11 is that three fundamental strategies exist for mobilizing edema fluid: Correct the underlying disease, restrict Na^+ intake, or administer diuretics. The most desirable course of action would be to correct the primary disease; however, this often is impossible. For instance, the increased hepatic sinusoidal pressure in cirrhosis of the liver and the urinary loss of protein in nephrotic syndrome are due to structural alterations in the portal circulation and glomeruli, respectively, that may not be remediable. Restriction of Na^+ intake is the favored nonpharmacologic approach to the treatment of edema and hypertension and should be attempted; however, compliance is a major obstacle. Diuretics, therefore, remain the cornerstone for the treatment of edema or volume overload, particularly that owing to congestive heart failure, ascites, chronic renal failure, and nephrotic syndrome.

Whether a patient should receive diuretics and, if so, what therapeutic regimen should be used (*i.e.*, type of diuretic, dose, route of administration, and speed of mobilization of edema fluid) depend on the clinical situation. Massive pulmonary edema in patients with acute left-sided heart failure is a medical emergency requiring rapid, aggressive therapy including intravenous administration of a loop diuretic. In this setting, use of oral diuretics or diuretics with lesser efficacy is inappropriate. On the other hand, mild pulmonary and venous congestion associated with chronic heart failure is best treated with an oral loop or thiazide diuretic, the dosage of which should be titrated carefully to maximize the benefit-to-risk ratio. As mentioned previously, meta-analysis indicates that loop and thiazide diuretics decrease morbidity and mortality in heart failure patients (Faris *et al.*, 2002), and two randomized clinical trials with MR antagonists also demonstrate reduced morbidity and mortality in heart failure patients receiving optimal therapy with other drugs (Pitt *et al.*, 1999, 2003). Periodic administration of diuretics to cirrhotic patients with ascites may eliminate the necessity for or reduce the interval between paracenteses, adding to patient comfort and sparing protein reserves that are lost during the paracenteses. Although diuretics can reduce edema associated with chronic renal failure, increased doses of the more powerful loop diuretics usually are required. In the nephrotic syndrome, the response to diuretics often is disappointing. In chronic renal failure and cirrhosis, edema will not pose an immediate health risk. Even so, uncomfortable, oppressive, and/or disfiguring edema can greatly reduce quality of life, and the decision to treat will be based in part on quality-of-life issues. In such cases, only partial removal of edema fluid should be attempted, and the fluid should be mobilized slowly using a diuretic regimen that accomplishes the task with minimal perturbation of normal physiology. Brater (1998) provides a logically compelling algorithm for diuretic therapy (specific recommendations for drug, dose, route, and drug combinations) in patients with edema caused by renal, hepatic, or cardiac disorders. The basic features of “Brater’s algorithm” are summarized in Figure 28-12.

In many clinical situations, edema is not caused by an abnormal intake of Na^+ or by an altered renal handling of Na^+ . Rather, edema is the result of altered Starling forces at the capillary beds, *i.e.*, a “Starling trap.” Use of diuretics in these clinical settings represents a judicious compromise between the edematous state and the hypovolumic state. In such conditions, reducing total ECFV with diuretics will decrease edema but also will cause depletion of “sensed” ECFV, possibly leading to hypotension, malaise, and asthenia.

Diuretic resistance refers to edema that is or has become refractory to a given diuretic. If diuretic resistance develops against a less efficacious diuretic, a more efficacious diuretic should be substituted, *e.g.*, a loop diuretic for a thiazide. However, resistance to loop diuretics is not uncommon and can be due to several causes. NSAIDs block prostaglandin-mediated increases in RBF and increase the expression of the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter in the thick ascending limb (Fernández-Llama *et al.*, 1999), resulting in resistance to loop diuretics. Diuretic resistance induced by NSAIDs also occurs with selective COX-2 inhibitors (Kammerl *et al.*, 2001). In chronic renal failure, a reduction in RBF decreases the delivery of diuretics to the kidney, and accumulation of endogenous organic acids competes with loop diuretics for transport at the proximal tubule. Consequently, the concentration of diuretic at the active site in the tubular lumen is diminished. In nephrotic syndrome, the binding of diuretics has been postulated to limit response to the drugs; however, a recent study challenges the validity of this concept (Agarwal *et al.*, 2000). In hepatic cirrhosis, nephrotic syndrome, or heart failure, nephrons may have a diminished responsiveness to diuretics because of increased proximal tubular Na^+ reabsorption, leading to diminished delivery of Na^+ to the distal nephron segments (Knauf and Mutschler, 1997).

Faced with resistance to loop diuretics, the clinician has several options:

1. Bed rest may restore drug responsiveness by improving the renal circulation.
2. An increase in the dose of loop diuretic may restore responsiveness; however, nothing is gained by increasing the dose above that which causes a near-maximal effect (*i.e.*, the ceiling dose) of the diuretic.
3. Administration of smaller doses more frequently or a continuous intravenous infusion of a loop diuretic (Rudy *et al.*, 1991; Dormans *et al.*, 1996; Ferguson *et al.*, 1997) will increase the length of time that an effective concentration of the diuretic is at the active site.
4. Use of combination therapy to sequentially block more than one site in the nephron may result in a synergistic interaction between two diuretics. For instance, a combination of a loop diuretic with a K^+ -sparing or a thiazide diuretic may improve therapeutic response; however, nothing is gained by the administration of two drugs of the same type. Thiazide diuretics with significant proximal tubular effects, *e.g.*, metolazone, are particularly well suited for sequential blockade when coadministered with a loop diuretic.
5. Reducing salt intake will diminish postdiuretic Na^+ retention that can nullify previous increases in Na^+ excretion.

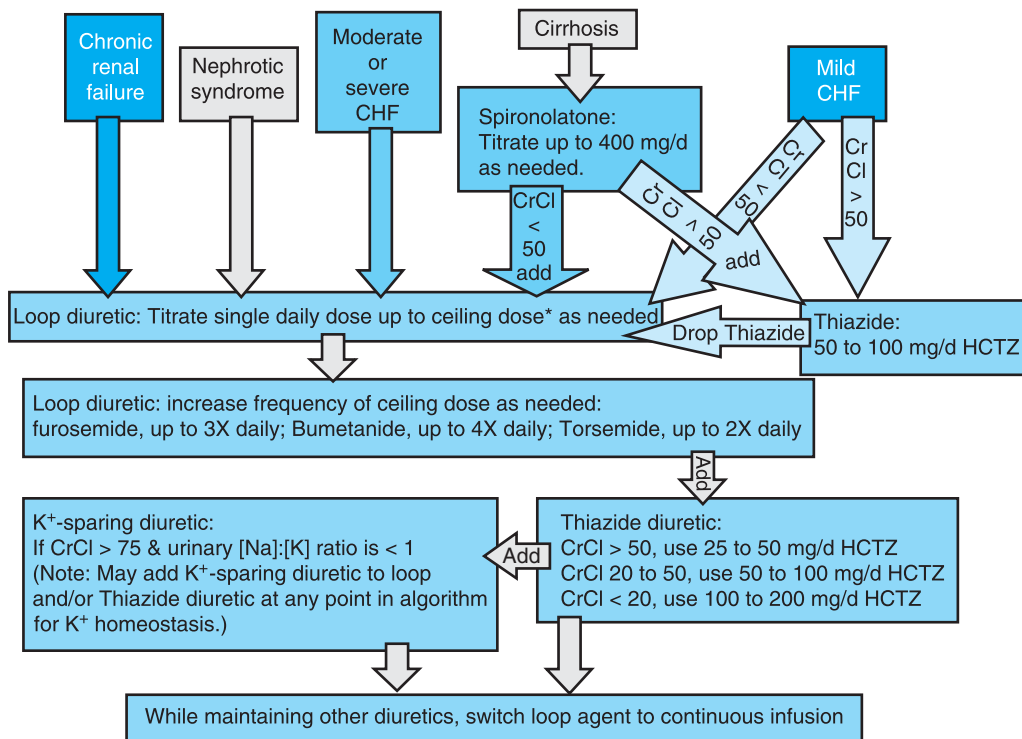

Figure 28–12. “Brater’s algorithm” for diuretic therapy of chronic renal failure, nephrotic syndrome, congestive heart failure, and cirrhosis. Follow algorithm until adequate response is achieved. If adequate response is not obtained, advance to the next step. For illustrative purposes, the thiazide diuretic used in Brater’s algorithm is hydrochlorothiazide (HCTZ). An alternative thiazide-type diuretic may be substituted with appropriate dosage adjustment so as to be pharmacologically equivalent to the recommended dose of HCTZ. Do not combine two K^+ -sparing diuretics because of the risk of hyperkalemia. CrCl indicates creatinine clearance in milliliters per minute, and ceiling dose refers to the smallest dose of diuretic that produces a near-maximal effect. Ceiling doses of loop diuretics and dosing regimens for continuous intravenous infusions of loop diuretics are disease-state-specific. In this regard, see Brater (1998) for recommended dosages. Doses are for adults only.

6. Scheduling of diuretic administration shortly before food intake will provide effective concentrations of diuretic in the tubular lumen when the salt load is highest.

All currently available diuretics perturb K^+ homeostasis. However, studies in animals have established that blockade of adenosine A_1 receptors induces a brisk natriuresis without significantly increasing urinary K^+ excretion (Kuan *et al.*, 1993). Two clinical studies with FK453, a highly selective A_1 -receptor antagonist, confirm that blockade of A_1 receptors induces natriuresis in human beings with minimal effects on K^+ excretion (Balakrishnan *et al.*, 1993; van Buren *et al.*, 1993). The natriuretic mechanism of this novel class of diuretics has been partially elucidated (Takeda *et al.*, 1993). Elevated intracellular cyclic AMP reduces basolateral $Na^+-HCO_3^-$ symport in proximal tubular cells. Endogenous adenosine normally acts on A_1 receptors in these cells to

inhibit adenylyl cyclase and reduce cyclic AMP accumulation. Blockade of A_1 receptors removes this inhibition, permits cellular cyclic AMP to rise, and results in reduced activity of the $Na^+-HCO_3^-$ symporter. Because A_1 receptors are involved in TGF, A_1 -receptor antagonists uncouple increased distal delivery of Na^+ from activation of TGF (Wilcox, 1999). Other mechanisms, including an effect in the collecting tubules, contribute to the natriuretic response to A_1 -receptor antagonists; however, it is not known why this class of diuretics has little effect on K^+ excretion. In some patients, loop diuretics may compromise renal hemodynamics and actually reduce GFR, a phenomenon known as *diuretic intolerance*. Importantly, A_1 -receptor antagonists tend to improve GFR in the setting of diuretic intolerance. A_1 -receptor antagonists are in clinical trials as “renal friendly” diuretics for the treatment of edema owing to heart failure (Gottlieb *et al.*, 2002; Jackson, 2002).

VASOPRESSIN AND OTHER AGENTS AFFECTING THE RENAL CONSERVATION OF WATER

Edwin K. Jackson

Precise regulation of body fluid osmolality is essential. It is controlled by a finely tuned, intricate homeostatic mechanism that operates by adjusting both the rate of water intake and the rate of solute-free water excretion by the kidneys—*i.e.*, water balance. Abnormalities in this homeostatic system can result from genetic diseases, acquired diseases, or drugs and may cause serious and potentially life-threatening deviations in plasma osmolality. This chapter describes the physiological mechanisms that regulate plasma osmolality, discusses the diseases that perturb those mechanisms, and examines pharmacological approaches for treating disorders of water balance.

Arginine vasopressin (the antidiuretic hormone in human beings) is the main hormone that regulates body fluid osmolality. Many diseases of water homeostasis and many pharmacological strategies for correcting such disorders pertain to vasopressin. Accordingly, this chapter focuses on vasopressin, including (1) chemistry (including the chemistry of vasopressin agonists and antagonists), (2) physiology (including anatomical considerations; the synthesis, transport, and storage of vasopressin; and the regulation of vasopressin secretion), (3) basic pharmacology (including vasopressin receptors and their signal-transduction pathways, renal actions of vasopressin, pharmacological modification of the antidiuretic response to vasopressin, and nonrenal actions of vasopressin), (4) diseases affecting the vasopressin system (diabetes insipidus, syndrome of inappropriate secretion of antidiuretic hormone, and other water-retaining states), and (5) clinical pharmacology of vasopressin peptides (therapeutic uses, pharmacokinetics, toxicities, adverse effects, contraindications, and drug interactions). A small number of other drugs can be used to treat abnormalities of water balance; a discussion of these

agents is integrated into the section on diseases affecting the vasopressin system.

INTRODUCTION TO VASOPRESSIN

Immunoreactive vasopressin occurs in neurons from organisms belonging to the first animal phylum with a nervous system (*e.g.*, *Hydra attenuata*), and vasopressinlike peptides have been isolated and characterized from both mammalian and nonmammalian vertebrates, as well as from invertebrates (Table 29–1). Genes encoding vasopressinlike peptides probably evolved more than 700 million years ago.

With the emergence of life on land, vasopressin became the mediator of a remarkable regulatory system for the conservation of water. The hormone is released by the posterior pituitary whenever water deprivation causes an increased plasma osmolality or whenever the cardiovascular system is challenged by hypovolemia and/or hypotension. In amphibians, the target organs for vasopressin are skin and the urinary bladder, whereas in other vertebrates, including humans, vasopressin acts primarily in the renal collecting duct. In each of these target tissues, vasopressin increases the permeability of the cell membrane to water, thus permitting water to move passively down an osmotic gradient across skin, bladder, or collecting duct into the extracellular compartment.

In view of the long evolutionary history of vasopressin, it is not surprising that vasopressin acts at sites in the nephron other than the collecting duct and on tissues other than the kidney. Vasopressin is a potent vasopressor; indeed, its name was chosen originally in recognition of this vasoconstrictor action. Vasopressin is a neurotransmitter; among its

actions in the central nervous system (CNS) are apparent roles in the secretion of adrenocorticotrophic hormone (ACTH) and in the regulation of the cardiovascular system, temperature, and other visceral functions. Vasopressin also promotes the release of coagulation factors by the vascular endothelium and increases platelet aggregability; therefore, it may play a role in hemostasis.

PHYSIOLOGY OF VASOPRESSIN

Anatomy. The antidiuretic mechanism in mammals involves two anatomical components: a CNS component for the synthesis, transport, storage, and release of vasopressin and a renal collecting-duct system composed of epithelial cells that respond to vasopressin by increasing their permeability to water. The CNS component of the

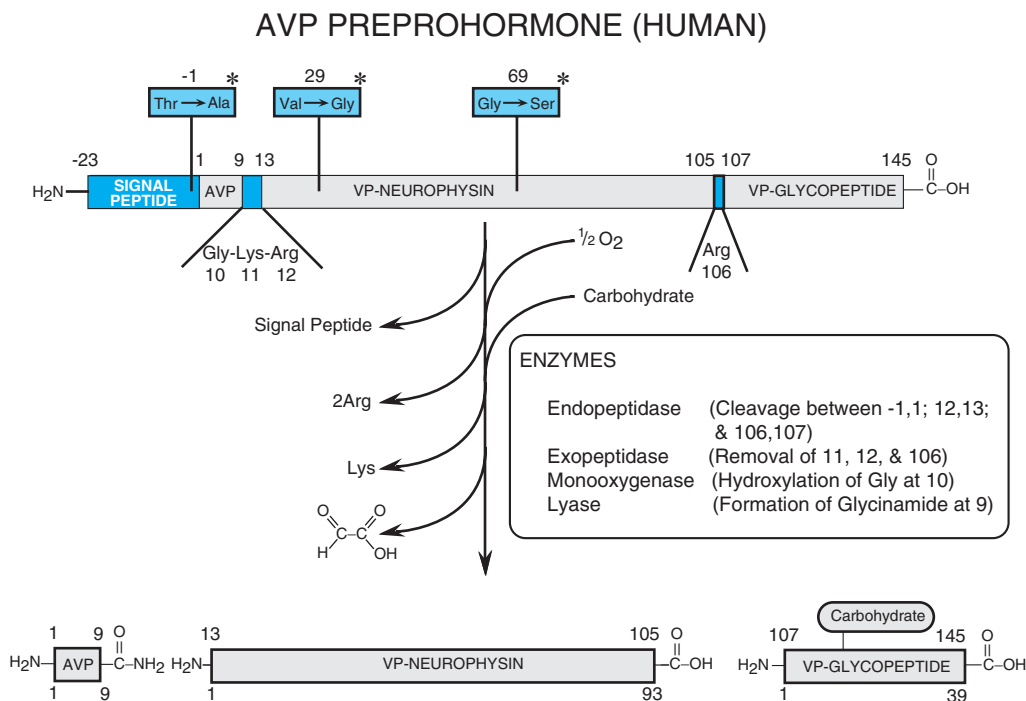

Figure 29–1. Processing of the 168–amino acid human 8–arginine vasopressin (AVP) preprohormone to AVP, vasopressin (VP)–neurophysin, and VP–glycopeptide. At least 40 mutations in the single gene on chromosome 20 that encodes AVP preprohormone give rise to central diabetes insipidus. *Boxes indicate mutations leading to central diabetes insipidus.

antidiuretic mechanism is called the *hypothalamoneurohypophyseal system* and consists of neurosecretory neurons with perikarya located predominantly in two specific hypothalamic nuclei, the supraoptic nucleus (SON) and the paraventricular nucleus (PVN). The long axons of magnocellular neurons in the SON and PVN transverse the external zone of the median eminence to terminate in the neural lobe of the posterior pituitary (neurohypophysis), where they release vasopressin and oxytocin. In addition, axons of parvicellular neurons project to the external zone of the median eminence and release vasopressin directly into the pituitary portal circulation. The relevant anatomy of the renal collecting-duct system is described in Chapter 28.

Synthesis. Vasopressin and oxytocin are synthesized mainly in the perikarya of magnocellular neurons in the SON and PVN; the two hormones are synthesized predominantly in separate neurons. Parvicellular neurons in the PVN also synthesize vasopressin. Vasopressin synthesis appears to be regulated solely at the transcriptional level. In human beings, a 168–amino acid preprohormone (Figure 29–1) is synthesized, and a signal peptide (residues –23 to –1) ensures incorporation of the nascent polypeptide into ribosomes. During synthesis, the signal peptide is removed to form the vasopressin prohormone, which then is processed and incorporated into the Golgi compartment and then into membrane-associated granules. The prohormone contains three domains: vasopressin (residues 1 to 9), vasopressin (VP)–neurophysin (residues 13 to 105), and VP–glycopeptide (residues 107 to 145). The vasopressin domain is linked to the VP–neurophysin domain through a glycine–lysine–arginine–processing signal, and the VP–neurophysin is linked to the VP–glycopeptide domain by an arginine–processing signal. In the secretory granules, an endopeptidase, exopeptidase, monooxygenase,

and lyase act sequentially on the prohormone to produce vasopressin, VP–neurophysin (sometimes referred to as *neurophysin II* or *MSEL–neurophysin*), and VP–glycopeptide (sometimes called *copeptin*). The synthesis and transport of vasopressin depend on the conformation of the preprohormone. In particular, VP–neurophysin binds vasopressin and is critical to the correct processing, transport, and storage of vasopressin. Genetic mutations in either the signal peptide or VP–neurophysin give rise to central diabetes insipidus.

Transport and Storage. The process of axonal transport of vasopressin- and oxytocin-containing granules is rapid, and these hormone-laden granules arrive at their destinations within 30 minutes, ready for release by exocytosis when the magnocellular or parvicellular neurons are stimulated appropriately.

Maximal release of vasopressin occurs when impulse frequency is approximately 12 spikes per second for 20 seconds. Higher frequencies or longer periods of stimulation lead to diminished hormone release (fatigue). Appropriately, vasopressin-releasing cells demonstrate an atypical pattern of spike activity characterized by rapid phasic bursts (5 to 12 spikes per second for 15 to 60 seconds) separated by quiescent periods (15 to 60 seconds in duration). This pattern is orchestrated by activation and inactivation of ion channels in the magnocellular neurons and provides for optimal release of vasopressin.

Vasopressin Synthesis Outside the CNS. Vasopressin also is synthesized by the heart (Hupf *et al.*, 1999) and adrenal gland (Guillon *et al.*, 1998). In the heart, elevated wall stress increases vasopressin synthesis severalfold. Cardiac synthesis of vasopressin is predominantly vascular and perivascular and may contribute to impaired ventricular relaxation and coronary vasoconstriction. Vasopressin

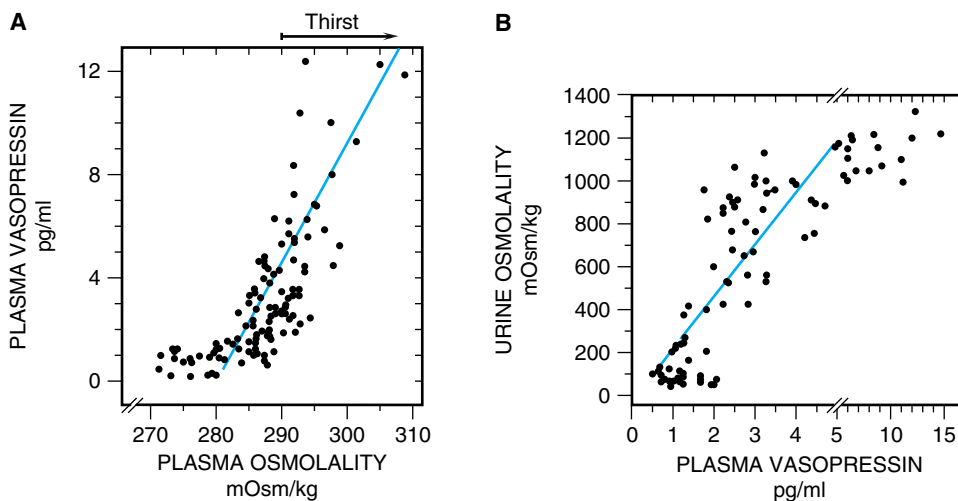

Figure 29-2. A. The relationship between plasma osmolality and plasma vasopressin levels. Plasma osmolality associated with thirst is indicated by arrow. B. The relationship between plasma vasopressin levels and urine osmolality. (From Robertson *et al.*, 1977, and Kovacs and Robertson, 1992, with permission.)

synthesis in the adrenal medulla stimulates catecholamine secretion from chromaffin cells and may promote adrenal cortical growth and stimulate aldosterone synthesis.

Regulation of Vasopressin Secretion. An increase in plasma osmolality is the principal physiological stimulus for vasopressin secretion by the posterior pituitary (Bankir, 2001). Severe hypovolemia/hypotension also is a powerful stimulus for vasopressin release. In addition, pain, nausea, and hypoxia can stimulate vasopressin secretion, and several endogenous hormones and pharmacological agents can modify vasopressin release.

Hyperosmolality. The relationship between plasma osmolality and plasma vasopressin concentration is shown in Figure 29-2A, and the relationship between plasma vasopressin levels and urine osmolality is illustrated in Figure 29-2B. The osmolality threshold for secretion is approximately 280 mOsm/kg. Below the threshold, vasopressin is barely detectable in plasma, and above the threshold, vasopressin levels are a steep and relatively linear function of plasma osmolality. A small increase in plasma osmolality leads to enhanced vasopressin secretion. Indeed, a 2% elevation in plasma osmolality causes a two- to three-fold increase in plasma vasopressin levels, which, in turn, causes increased solute-free water reabsorption, with an increase in urine osmolality. Increases in plasma osmolality above 290 mOsm/kg lead to an intense desire for water (thirst). Thus the vasopressin system affords the organism longer thirst-free periods and, in the event that water is unavailable, allows the organism to survive longer periods of water deprivation. It is important to point out, however,

that above a plasma osmolality of approximately 290 mOsm/kg, plasma levels of vasopressin exceed 5 pM. Since urinary concentration is maximal (about 1200 mOsm/kg) when vasopressin levels exceed 5 pM, further defense against hypertonicity depends entirely on water intake rather than on decreases in water loss.

Several CNS structures are involved in osmotic stimulation of vasopressin release by the posterior pituitary; these structures are collectively referred to as the *osmoreceptive complex*. Although magnocellular neurons in the SON and PVN are osmosensitive, afferent inputs from other components of the osmoreceptive complex are required for a normal vasopressin response. The SON and PVN receive projections from the subfornical organ (SFO) and the organum vasculosum of the lamina terminalis (OVLT) either directly or indirectly *via* the median preoptic nucleus (MnPO). Subgroups of neurons in the SFO, OVLT, and MnPO are either osmoreceptors or osmosponders (*i.e.*, are stimulated by osmoreceptive neurons located at other sites). Thus a web of interconnecting neurons contributes to osmotically induced vasopressin secretion.

Aquaporin 4, a water-selective channel, is associated with CNS structures involved in osmoregulation and may confer osmosensitivity. In the CNS, aquaporin 4 resides on glial and ependymal cells rather than on neurons, suggesting that osmotic status may be communicated to the neuronal cell by a glial-neuron interaction (Wells, 1998).

Hepatic Portal Osmoreceptors. An oral salt load activates hepatic portal osmoreceptors leading to increased vasopressin release. This mechanism augments plasma

vasopressin levels even before the oral salt load increases plasma osmolality (Stricker *et al.*, 2002).

Hypovolemia and Hypotension. Vasopressin secretion also is regulated hemodynamically by changes in effective blood volume and/or arterial blood pressure (Robertson, 1992). Regardless of the cause (*e.g.*, hemorrhage, sodium depletion, diuretics, heart failure, hepatic cirrhosis with ascites, adrenal insufficiency, or hypotensive drugs), reductions in effective blood volume and/or arterial blood pressure may be associated with high circulating concentrations of vasopressin. However, unlike osmoregulation, hemodynamic regulation of vasopressin secretion is exponential; *i.e.*, small decreases (5% to 10%) in blood volume and/or pressure have little effect on vasopressin secretion, whereas larger decreases (20% to 30%) can increase vasopressin levels to 20 to 30 times normal levels (exceeding the concentration of vasopressin required to induce maximal antidiuresis). Vasopressin is one of the most potent vasoconstrictors known, and the vasopressin response to hypovolemia or hypotension serves as a mechanism to stave off cardiovascular collapse during periods of severe blood loss and/or hypotension. Hemodynamic regulation of vasopressin secretion does not disrupt osmotic regulation; rather, hypovolemia/hypotension alters the set point and slope of the plasma osmolality–plasma vasopressin relationship (Figure 29–3).

The neuronal pathways that mediate hemodynamic regulation of vasopressin release are different from those involved in osmoregulation. Baroreceptors in the left atrium, left ventricle, and pulmonary veins sense blood volume (filling pressures), and baroreceptors in the carotid sinus and aorta monitor arterial blood pressure. Nerve impulses reach brainstem nuclei predominantly through the vagal trunk and glossopharyngeal nerve; these signals are relayed to the solitary tract nucleus, then to the A_1 -noradrenergic cell group in the caudal ventrolateral medulla, and finally to the SON and PVN.

Hormones and Neurotransmitters. Vasopressin-synthesizing magnocellular neurons have a large array of receptors on both perikarya and nerve terminals; therefore, vasopressin release can be accentuated or attenuated by chemical agents acting at both ends of the magnocellular neuron. Also, hormones and neurotransmitters can modulate vasopressin secretion by stimulating or inhibiting neurons in nuclei

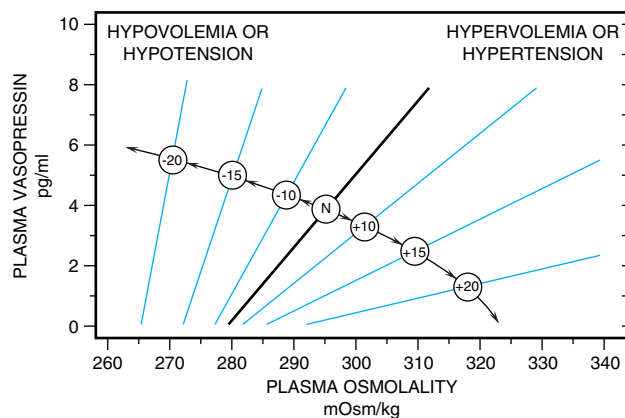

Figure 29–3. Interactions between osmolality and hypovolemia/hypotension. Numbers in circles refer to percentage increase (+) or decrease (–) in blood volume or arterial blood pressure. N indicates normal blood volume/blood pressure. (From Robertson, 1992, with permission.)

that project, either directly or indirectly, to the SON and PVN. Because of these complexities, the results of any given investigation may depend critically on the route of administration of the agent and on the experimental paradigm. In many cases, the precise mechanism by which a given agent modulates vasopressin secretion is either unknown or controversial, and the physiological relevance of modulation of vasopressin secretion by most hormones and neurotransmitters is unclear.

Nonetheless, several agents are known to stimulate vasopressin secretion, including acetylcholine (*via* nicotinic receptors), histamine (*via* H_1 receptors), dopamine (*via* both D_1 and D_2 receptors), glutamine, aspartate, cholecystokinin, neuropeptide Y, substance P, vasoactive intestinal polypeptide, prostaglandins, and angiotensin II. Inhibitors of vasopressin secretion include atrial natriuretic peptide, γ -aminobutyric acid, and opioids (particularly dynorphin *via* κ receptors). The effects of angiotensin II have received the most attention. Angiotensin II, applied directly to magnocellular neurons in the SON and PVN, increases neuronal excitability; when applied to the MnPO, angiotensin II indirectly stimulates magnocellular neurons in the SON and PVN. In addition, angiotensin II stimulates angiotensin-sensitive neurons in the OVLT and SFO (circumventricular nuclei lacking a blood–brain barrier) that project to the SON/PVN. Thus angiotensin II synthesized in the brain and circulating angiotensin may stimulate vasopressin release. Inhibition of the conversion of angiotensin II to angiotensin III blocks angiotensin II–induced vasopressin release, suggesting that angiotensin III is the main effector peptide of the brain renin–angiotensin system controlling vasopressin release (Reaux *et al.*, 2001).

Pharmacological Agents. A number of drugs alter urine osmolality by stimulating or inhibiting the secretion of vasopressin. In some cases the mechanism by which a drug alters vasopressin secretion involves direct effects on one or more CNS structures that regulate vasopressin secretion. In other cases vasopressin secretion is altered indirectly by the effects of a drug on blood volume, arterial blood pressure, pain, or nausea. In most cases the mechanism is not known. Stimulators of vasopressin secretion include vincristine, cyclophosphamide, tricyclic antidepressants, nicotine, epinephrine, and high doses of morphine. Lithium, which inhibits the renal effects of vasopressin, also enhances vasopressin secretion. Inhibitors of vasopressin secretion include ethanol, phenytoin, low doses of morphine, glucocorticoids, fluphenazine, haloperidol, promethazine, oxilofphan, and butorphanol. Carbamazepine has a renal action to produce antidiuresis in patients with central diabetes insipidus but actually inhibits vasopressin secretion *via* a central action.

BASIC PHARMACOLOGY OF VASOPRESSIN

Vasopressin Receptors. The cellular effects of vasopressin are mediated mainly by interactions of the hormone with the three types of receptors, V_{1a} , V_{1b} , and V_2 . The V_{1a} receptor is the most widespread subtype of vasopressin receptor; it is found in vascular smooth muscle, the adrenal gland, myometrium, the bladder, adipocytes, hepatocytes, platelets, renal medullary interstitial cells, vasa recta in the renal microcirculation, epithelial cells in the

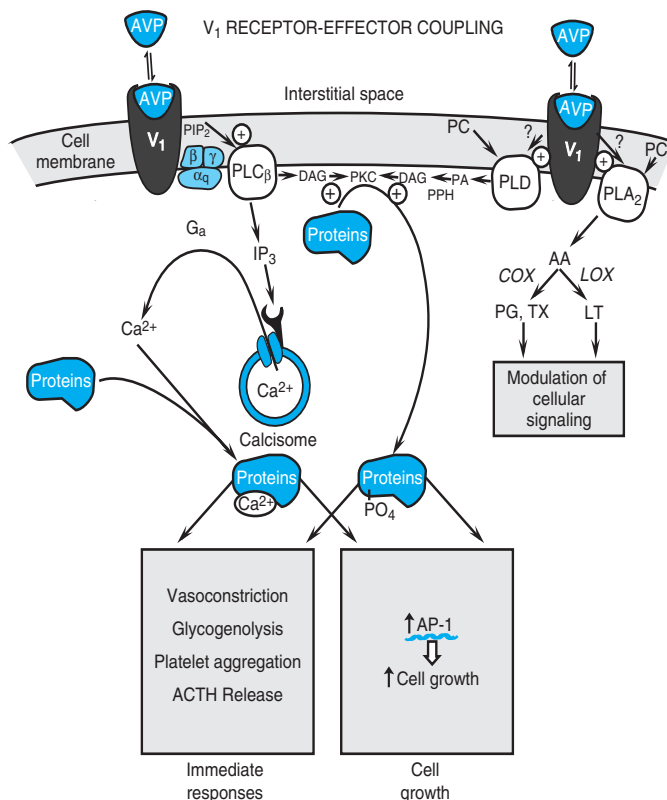

Figure 29–4. Mechanism of V₁ receptor–effector coupling. Binding of 8-arginine vasopressin (AVP) to V₁ vasopressin receptors (V₁) stimulates several membrane-bound phospholipases. Stimulation of the G_q–PLC–β pathway results in IP₃ formation, mobilization of intracellular Ca²⁺, and activation of PKC. Activation of V₁ receptors also causes influx of extracellular Ca²⁺ by an unknown (?) mechanism. PKC and Ca²⁺/calmodulin–activated protein kinases phosphorylate cell-type-specific proteins leading to cellular responses. A further component of the AVP response derives from the production of eicosanoids secondary to the activation of PLA₂; the resulting mobilization of arachidonic acid (AA) provides substrate for eicosanoid synthesis via the cyclooxygenase (COX) and lipoxygenase (LOX) pathways, leading to local production of prostaglandins (PG), thromboxanes (TX), and leukotrienes (LT), which may activate a variety of signaling pathways, including those linked to G_s and G_q. Biological effects mediated by the V₁ receptor include vasoconstriction, glycogenolysis, platelet aggregation, ACTH release, and growth of vascular smooth muscle cells. The effects of vasopressin on cell growth involve transcriptional regulation via the FOS/JUN AP-1 transcription complex.

renal cortical collecting-duct, spleen, testis, and many CNS structures. V_{1b} receptors have a more limited distribution and are found in the anterior pituitary, several brain regions, the pancreas, and the adrenal medulla. V₂ receptors are located predominantly in principal cells of the renal collecting-duct system but also are present on epithelial cells in the thick ascending limb and on vascular endothelial cells. Although originally defined by pharmacological criteria, vasopressin receptors now are defined by their primary amino acid sequences. The cloned vasopressin receptors are typical heptahelical G protein–coupled receptors. Manning and coworkers (1999) have synthesized novel hypotensive vasopressin peptide agonists that do not interact with V_{1a}, V_{1b}, or V₂ receptors and may stimulate a putative vasopressin vasodilatory receptor.

Finally, two additional putative receptors for vasopressin have been cloned. A vasopressin-activated Ca²⁺-mobilizing receptor with one transmembrane domain binds vasopressin and increases intracellular Ca²⁺ (Serradeil-Le Gal *et al.*, 2002b). A dual angiotensin II–vasopressin heptahelical receptor activates adenylyl cyclase in response to both angiotensin II and vasopressin (Serradeil-Le Gal *et al.*, 2002b). The physiological roles of these putative vasopressin receptors are unclear.

V₁ Receptor–Effector Coupling. Figure 29–4 summarizes the current model of V₁ receptor–effector coupling. Vasopressin binding to V₁ receptors activates the G_q–PLC pathway, thereby increasing the generation of IP₃ and diacylglycerol (*see* Chapter 1 for further discussion of these signal-transduction pathways). These mediators, in turn, increase the intracellular Ca²⁺ concentration and activate pro-

tein kinase C, ultimately causing biological effects that include immediate responses (*e.g.*, vasoconstriction, glycogenolysis, platelet aggregation, and ACTH release) and growth of smooth muscle cells. This mitogenic effect involves activation of the AP-1 transcription factor and its *c-fos* and *c-jun* subunits. Other effects of V_1 -receptor activation may be mediated by stimulation of small G proteins, activation of PLD and PLA_2 , and activation of V_1 -sensitive Ca^{2+} influx. Some effects of V_1 -receptor activation are secondary to synthesis of prostaglandins and epoxyeicosatrienoic acids, which act through the eicosanoid receptors (*see* Chapter 25).

V_2 Receptor–Effector Coupling. Principal cells in the renal collecting duct have V_2 receptors on their basolateral membranes that couple to G_s to stimulate adenylyl cyclase activity (Figure 29–5) when vasopressin binds to V_2 receptors. The resulting increase in cellular cyclic AMP content and protein kinase A (PKA) activity triggers an increased rate of insertion of water channel–containing vesicles (WCVs) into the apical membrane and a decreased rate of endocytosis of WCVs from the apical membrane (Snyder *et al.*, 1992). The distribution of WCVs between the cytosolic compartment and the apical membrane compartment is thus shifted in favor of the apical membrane compartment (Nielsen *et al.*, 1999). Because WCVs contain preformed functional water channels (aquaporin 2), their net shift into apical membranes in response to V_2 -receptor stimulation greatly increases the water permeability of the apical membrane.

Aquaporins are a family of water channel proteins that allow water molecules to cross biological membranes (Marple *et al.*, 1999; Nielsen *et al.*, 2001; Agre and Konzo, 2003). Aquaporins have six membrane domains connected by five loops (A to E; Figure 29–6). Loops B and E dip into the cell membrane, and the asparagine–proline–alanine sequences in each B and E loop interact to form a water pore. Aquaporins generally form tetramers in cell membranes. Of the 10 cloned mammalian aquaporins, at least 7 are found in the kidney. Aquaporin 1 is present in the apical and basolateral membrane of the proximal tubule and in the thin descending limb. Aquaporin 2 resides in the apical membrane and WCVs of the collecting-duct principal cells, whereas aquaporins 3 and 4 are present in the basolateral membrane of principal cells. Aquaporin 7 is in the apical brush border of the straight proximal tubule. Aquaporins 6 and 8 are located intracellularly in the collecting-duct principal cells. Aquaporin 2, the water channel in WCVs, is phosphorylated on serine 256 by PKA, ultimately leading to vasopressin-induced insertion of WCVs into apical membranes (Nishimoto *et al.*, 1999). PKA is targeted to WCVs by specific anchoring proteins (Klusmann and Rosenthal, 2001). In addition to increasing the insertion of aquaporin 2 into apical membranes in collecting-duct principal cells, vasopressin also increases the expression of aquaporin 2 mRNA and protein (Marple *et al.*, 1999), largely mediated by increased phosphorylation of the cyclic AMP–response element–binding protein (CREB) and increased transcription of the gene encoding aquaporin 2. Thus chronic dehydration leads to long-term up-regulation of aquaporin 2 and water transport in the collecting duct.

For maximum concentration of urine, large amounts of urea must be deposited in the interstitium of the inner medullary collecting duct. It is not surprising, therefore, that V_2 -receptor activation also increases urea permeability by 400% in the terminal portions of the inner medullary collecting duct. The V_2 receptors increase urea permeability by activating a vasopressin-regulated urea transporter (termed *VRUT*, *UT1*, or *UT-A1*), most likely by PKA-induced phosphorylation (Sands, 2003). The kinetics of vasopressin-induced water and urea permeability differ, and vasopressin-induced regula-

V_2 RECEPTOR-EFFECTOR COUPLING

Figure 29–5. Mechanism of V_2 receptor–effector coupling. Binding of vasopressin (AVP) to the V_2 receptor activates the G_s –adenylyl cyclase–cAMP–PKA pathway and shifts the balance of aquaporin 2 trafficking toward the apical membrane of the principal cell of the collecting duct, thus enhancing water permeability. Although phosphorylation of serine 256 of aquaporin 2 is involved in V_2 receptor signaling, other proteins located both in the water channel–containing vesicles and the apical membrane of the cytoplasm also may be involved.

tion of VRUT does not entail vesicular trafficking to the plasma membrane (Inoue *et al.*, 1999).

In addition to increasing the water permeability of the collecting duct and the urea permeability of the inner medullary collecting duct, V_2 -receptor activation also increases Na^+ transport in the thick ascending limb and collecting duct. Increased Na^+ transport in the thick ascending limb is mediated by three mechanisms that affect the Na^+ – K^+ – $2Cl^-$ symporter, *i.e.*, rapid phosphorylation of the sym-

Figure 29-6. Structure of aquaporins. Aquaporins have six transmembrane domains, and the NH_2 and COOH termini are intracellular. Loops B and E each contain an asparagine–proline–alanine (NPA) sequence. Aquaporins fold with transmembrane domains 1, 2, and 6 in close proximity and transmembrane domains 3, 4 and 5 in juxtaposition. The long B and E loops dip into the membrane, and the NPA sequences align to create a pore through which water can diffuse. Most likely aquaporins form a tetrameric oligomer. At least seven aquaporins are expressed at distinct sites in the kidney. Aquaporin 1, abundant in the proximal tubule and descending thin limb, is essential for concentration of urine. Aquaporin 2, exclusively expressed in the principal cells of the connecting tubule and collecting duct, is the major vasopressin-regulated water channel. Aquaporin 3 and aquaporin 4 are expressed in the basolateral membranes of collecting-duct principal cells and provide exit pathways for water reabsorbed apically *via* aquaporin 2. Aquaporins 6 to 8 are also expressed in kidney; their functions remain to be clarified. Vasopressin regulates water permeability of the collecting duct by influencing the trafficking of aquaporin 2 from intracellular vesicles to the apical plasma membrane. Binding of AVP to V_2 receptors activates the G_s –adenylyl cyclase–cAMP–PKA pathway, leading to phosphorylation of ser256 on aquaporin 2. Phosphorylation (of three of the four monomers) promotes insertion of the tetramers into the apical membrane, increasing permeability to water. PKA also mediates longer-term regulation by enhancing transcription of the aquaporin 2 gene, thereby promoting aquaporin 2 synthesis. For details, *see* text and Nielsen *et al.*, 2001.

porter, translocation of the symporter into the luminal membrane, and increased expression of symporter protein (Ecelbarger *et al.*, 2001; Giménez and Forbush, 2003). Enhanced Na^+ transport in the collecting duct is mediated by increased expression of subunits of the epithelial sodium channel (Ecelbarger *et al.*, 2001). The multiple

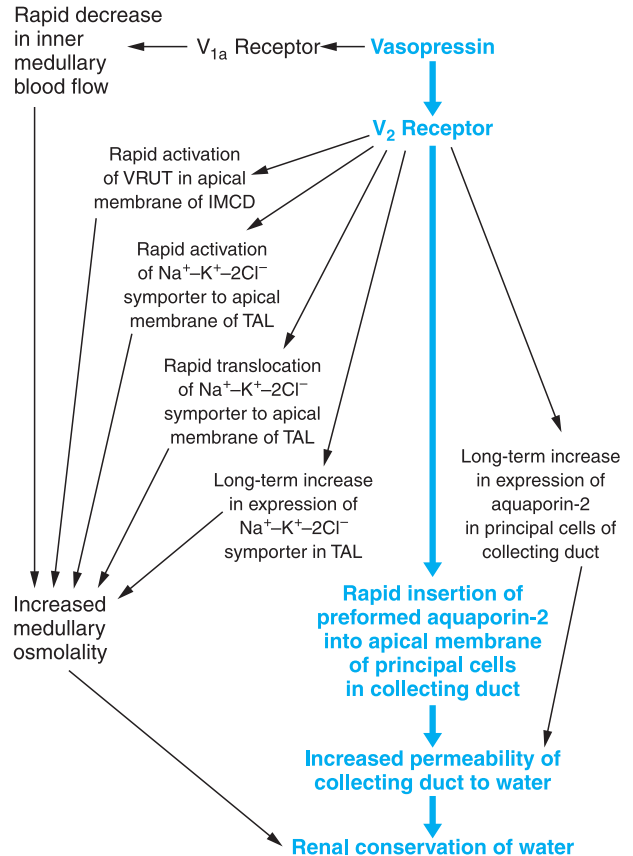

Figure 29-7. Mechanisms by which vasopressin increases the renal conservation of water. IMCD, inner medullary collecting duct; TAL, thick ascending limb; VRUT, vasopressin-regulated urea transporter. Thick and thin arrows denote major and minor pathways, respectively.

mechanisms by which vasopressin increases water reabsorption are summarized in Figure 29-7.

Renal Actions of Vasopressin. Several sites of vasopressin action in the kidney involve both V_1 and V_2 receptors (Bankir, 2001). V_1 receptors mediate contraction of mesangial cells in the glomerulus and contraction of vascular smooth muscle cells in the vasa recta and efferent arteriole. Indeed, V_1 -receptor-mediated reduction of inner medullary blood flow contributes to the maximum concentrating capacity of the kidney (Franchini and Cowley, 1996) (Figure 29-7). V_1 receptors also stimulate prostaglandin synthesis by medullary interstitial cells. Since prostaglandin E_2 inhibits adenylyl cyclase in the collecting duct, stimulation of prostaglandin synthesis by V_1 receptors may counterbalance V_2 -receptor-mediated antidiuresis. V_1 receptors on principal cells in the cortical collecting duct may inhibit V_2 -receptor-mediated water flux *via* activation of protein

kinase C (PKC). V_2 receptors mediate the most prominent response to vasopressin, *i.e.*, increased water permeability of the collecting duct. Indeed, vasopressin can increase water permeability in the collecting duct at concentrations as low as 50 fM. Thus V_2 -receptor-mediated effects of vasopressin occur at concentrations far lower than are required to engage V_1 -receptor-mediated actions. This differential sensitivity may not be due to differences in receptor affinities because cloned rat V_{1a} and V_2 receptors have similar affinities for vasopressin ($K_d = 0.7$ and 0.4 nM, respectively) but rather may be due to differential amplification of their signal-transduction pathways.

The collecting-duct system is critical for water conservation. By the time tubular fluid arrives at the cortical collecting duct, it has been rendered hypotonic by the upstream diluting segments of the nephron that reabsorb NaCl without reabsorbing water. In the well-hydrated subject, plasma osmolality is in the normal range, concentrations of vasopressin are low, the entire collecting duct is relatively impermeable to water, and the urine is dilute. Under conditions of dehydration, plasma osmolality is increased, concentrations of vasopressin are elevated, and the collecting duct becomes permeable to water. The osmotic gradient between the dilute tubular urine and the hypertonic renal interstitial fluid (which becomes progressively more hypertonic in deeper regions of the renal medulla) provides for the osmotic flux of water out of the collecting duct. The final osmolality of urine may be as high as 1200 mOsm/kg in human beings, and a significant saving of solute-free water thus is possible.

Other renal actions mediated by V_2 receptors include increased urea transport in the inner medullary collecting duct and increased Na^+ transport in the thick ascending limb; both effects contribute to the urine-concentrating ability of the kidney (Figure 29–7). V_2 receptors also increase Na^+ transport in the cortical collecting duct (Ecelbarger *et al.*, 2001), and this may synergize with aldosterone to enhance Na^+ reabsorption during hypovolemia.

Pharmacological Modification of the Antidiuretic Response to Vasopressin. Nonsteroidal antiinflammatory drugs (NSAIDs) (see Chapter 26), particularly *indomethacin*, enhance the antidiuretic response to vasopressin. Since prostaglandins attenuate antidiuretic responses to vasopressin and NSAIDs inhibit prostaglandin synthesis, reduced prostaglandin production probably accounts for the potentiation of vasopressin's antidiuretic response. *Carbamazepine* and *chlorpropamide* also enhance the antidiuretic effects of vasopressin by unknown mechanisms. In rare instances, chlorpropamide can induce water intoxication.

A number of drugs inhibit the antidiuretic actions of vasopressin. *Lithium* is of particular importance because of its use in the treatment of manic–depressive disorders. Lithium-induced polyuria is usually, but not always, reversible. Acutely, lithium appears to reduce V_2 -receptor-mediated stimulation of adenylyl cyclase. Also, lithium increases plasma levels of parathyroid hormone, a partial antagonist to vasopressin. In most patients, the antibiotic *demeclocycline* attenuates the antidiuretic effects of vasopressin, probably owing to decreased accumulation and action of cyclic AMP.

Nonrenal Actions of Vasopressin. Vasopressin and related peptides are ancient hormones in evolutionary terms, and they are found in species that do not concentrate urine. Thus it is not surprising that vasopressin has nonrenal actions in mammals.

Cardiovascular System. The cardiovascular effects of vasopressin are complex, and vasopressin's role in physiological situations is ill-defined. Vasopressin is a potent vasoconstrictor (V_1 -receptor-mediated), and resistance vessels throughout the circulation may be affected. Vascular smooth muscle in the skin, skeletal muscle, fat, pancreas, and thyroid gland appear most sensitive, with significant vasoconstriction also occurring in the gastrointestinal tract, coronary vessels, and brain. Despite the potency of vasopressin as a direct vasoconstrictor, vasopressin-induced pressor responses *in vivo* are minimal and occur only with vasopressin concentrations significantly higher than those required for maximal antidiuresis. To a large extent, this is due to circulating vasopressin actions on V_1 receptors to inhibit sympathetic efferents and potentiate baroreflexes. In addition, V_2 receptors cause vasodilation in some blood vessels.

A large body of data supports the conclusion that vasopressin helps to maintain arterial blood pressure during episodes of severe hypovolemia/hypotension. At present, there is no convincing evidence for a role of vasopressin in essential hypertension in human beings (Kawano *et al.*, 1997).

The effects of vasopressin on the heart (reduced cardiac output and heart rate) are largely indirect and result from coronary vasoconstriction, decreased coronary blood flow, and alterations in vagal and sympathetic tone. In humans, the effects of vasopressin on coronary blood flow can be demonstrated easily, especially if large doses are employed. The cardiac actions of the hormone are of more than academic interest. Some patients with coronary insufficiency experience angina even in response to the relatively small amounts of vasopressin required to control diabetes insipidus, and vasopressin-induced myocardial ischemia has led to severe reactions and even death.

Central Nervous System (CNS). It is likely that vasopressin plays a role as a neurotransmitter and/or neuromodulator. Vasopressin may participate in the acquisition of certain learned behaviors (Dantzer and Bluthé, 1993), in the development of some complex social processes (Young *et al.*, 1998), and in the pathogenesis of specific psychiatric diseases such as depression (Scott and Dinan, 2002). However, the physiological/pathophysiological relevance of these findings is controversial, and some of the actions of vasopressin on memory and learned behavior may be due to visceral autonomic effects. Many studies support a physiological role for vasopressin as a naturally occurring antipyretic factor (Cridland and Kasting, 1992). Although vasopressin can modulate CNS autonomic systems controlling heart rate, arterial blood pressure, respiration rate, and sleep patterns, the

physiological significance of these actions is unclear. Finally, secretion of ACTH is enhanced by vasopressin released from parvocellular neurons in the PVN and secreted into the pituitary portal capillaries from axon terminals in the median eminence. Although vasopressin is not the principal corticotropin-releasing factor, vasopressin may provide for sustained activation of the hypothalamic–pituitary–adrenal axis during chronic stress (Aguilera and Rabadan-Diehl, 2000) (see Chapter 59). The CNS effects of vasopressin appear to be mediated predominantly by V_1 receptors.

Blood Coagulation. Activation of V_2 receptors by desmopressin or vasopressin increases circulating levels of procoagulant factor VIII and of von Willebrand factor. These effects are mediated by extrarenal V_2 receptors (Bernat *et al.*, 1997). Presumably, vasopressin stimulates the secretion of von Willebrand factor and of factor VIII from storage sites in vascular endothelium. However, since release of von Willebrand factor does not occur when desmopressin is applied directly to cultured endothelial cells or to isolated blood vessels, intermediate factors are likely to be involved.

Other Nonrenal Effects of Vasopressin. At high concentrations, vasopressin stimulates contraction of smooth muscle in the uterus (*via* oxytocin receptors) and gastrointestinal tract (*via* V_1 receptors). Vasopressin is stored in platelets, and activation of V_1 receptors stimulates platelet aggregation. Also, activation of V_1 receptors on hepatocytes stimulates glycogenolysis. The physiological significance of these effects of vasopressin is not known.

VASOPRESSIN RECEPTOR AGONISTS AND ANTAGONISTS

A number of vasopressinlike peptides occur naturally (Table 29–1). All are nonapeptides, contain cysteine residues in positions 1 and 6, have an intramolecular disulfide bridge between the two cysteine residues (essential for agonist activity), have additional conserved amino acids in positions 5, 7, and 9 (asparagine, proline, and glycine, respectively), contain a basic amino acid in position 8, and are amidated on the carboxyl terminus. In all mammals except swine, the neurohypophyseal peptide is 8-arginine vasopressin, and the terms *vasopressin*, *arginine vasopressin* (AVP), and *antidiuretic hormone* (ADH) are used interchangeably. The chemical structure of *oxytocin* is closely related to that of vasopressin: Oxytocin is [Ile³, Leu⁸]AVP. As discussed further in Chapter 55, oxytocin binds to specific oxytocin receptors on myoepithelial cells in the mammary gland and on smooth muscle cells in the uterus, causing milk ejection and uterine contraction, respectively. Inasmuch as vasopressin and oxytocin are structurally similar, it is not surprising that vasopressin and oxytocin agonists and antagonists can bind to each other's receptors. Therefore, most of the available peptide vasopressin agonists and antagonists have some affinity for oxytocin receptors; at high doses, they may block or mimic the effects of oxytocin.

Many vasopressin analogues were synthesized with the goal of increasing duration of action and selectivity for vasopressin receptor subtypes (V_1 versus V_2 vasopressin receptors, which mediate pressor responses and antidiuretic responses, respectively). Deamination at position 1 increases duration of action and increases antidiuretic activity without increasing vasopressor activity. Substitution of D-arginine for L-arginine greatly reduces vasopressor activity without reducing antidiuretic activity. Thus the antidiuretic-to-vasopressor ratio for 1-deamino-8-D-arginine vasopressin (Table 29–1), also called *desmopressin* (DDAVP), is approximately 3000 times greater than that for vasopressin, and desmopressin now is the preferred drug for the treatment of central diabetes insipidus. Substitution of valine for glutamine in position 4 further increases the antidiuretic selectivity, and the antidiuretic-to-vasopressor ratio for deamino[Val⁴, D-Arg⁸]AVP (Table 29–1) is approximately 11,000 times greater than that for vasopressin. Recently, Nakamura and colleagues (2000) synthesized a nonpeptide V_2 -receptor agonist (Table 29–1).

Increasing V_1 selectivity has proved more difficult than increasing V_2 selectivity, but a limited number of agonists with modest selectivity for V_1 receptors have been developed (Table 29–1). Vasopressin receptors in the adenohypophysis that mediate vasopressin-induced ACTH release are neither classical V_1 nor V_2 receptors. Since the vasopressin receptors in the adenohypophysis appear to share a common signal-transduction mechanism with classical V_1 receptors, and since many vasopressin analogues with vasoconstrictor activity release ACTH, V_1 receptors have been subclassified into V_{1a} (vascular/hepatic) and V_{1b} (pituitary) receptors. V_{1b} receptors also are called *V_3 receptors*. Vasopressin analogues that are agonists selective for V_{1a} or V_{1b} receptors have been described (Table 29–1).

Chemistry of Vasopressin Receptor Antagonists. The impetus for the development of specific vasopressin receptor antagonists is the belief that such drugs may be useful in a number of clinical settings. Based on receptor physiology, selective V_{1a} antagonists may be beneficial when total peripheral resistance is increased (*e.g.*, congestive heart failure and hypertension), whereas selective V_2 antagonists could be useful whenever reabsorption of solute-free water is excessive (*e.g.*, the syndrome of inappropriate secretion of antidiuretic hormone and hyponatremia associated with a reduced effective blood volume). Combined V_{1a}/V_2 receptor antagonists might be beneficial in diseases associated with a combination of increased peripheral resistance and dilutional hyponatremia (*e.g.*, congestive heart failure).

Highly selective V_1 and V_2 peptide antagonists that are structural analogues of vasopressin have been synthesized (*see* Table 29–2 for examples), including both cyclic and

linear peptides. [1-(β -Mercapto- β , β -cyclopentamethylene-propionic acid),2-*O*-methyltyrosine]arginine vasopressin, also known as d(CH₂)₅[Tyr(Me)²]AVP, has a greater affinity for V_{1a} receptors than for either V_{1b} or V_2 receptors; this antagonist has been employed widely in physiological and pharmacological studies. Although [1-deaminopenicil-

lamine, 2-*O*-methyltyrosine]arginine vasopressin, also called dP[Tyr(Me)²]AVP, is a potent V_{1b} receptor antagonist with little affinity for the V_2 receptor, it also blocks V_{1a} receptors. No truly selective peptide V_{1b} -receptor antagonist is available. Peptide antagonists have limited oral activity, and the potency of peptide V_2 antagonists is species-

dependent. Also, with prolonged infusion, peptide V_2 antagonists have significant agonist activity.

DISEASES AFFECTING THE VASOPRESSIN SYSTEM

Diabetes Insipidus (DI). DI is a disease of impaired renal conservation of water owing either to an inadequate secretion of vasopressin from the neurohypophysis (central DI) or to an insufficient renal response to vasopressin (nephrogenic DI). Very rarely, DI can be caused by an abnormally high rate of degradation of vasopressin by circulating vasopressinases. Pregnancy may accentuate or reveal central and/or nephrogenic DI by increasing plasma levels of vasopressinase and by reducing the renal sensitivity to vasopressin. Patients with DI excrete large volumes (more than 30 ml/kg per day) of dilute (less than 200 mOsm/kg) urine and, if their thirst mechanism is functioning normally, are polydipsic. In contrast to the sweet urine excreted by patients with diabetes mellitus, urine from patients with DI is tasteless, hence the name *insipidus*. The urinary taste test for DI has been supplanted by the approach of observing whether the patient is able to reduce urine volume and increase urine osmolality after a period of carefully observed fluid deprivation. Central DI can be distinguished from nephrogenic DI by administration of desmopressin, which will increase urine osmolality in patients with central DI but have little or no effect in patients with nephrogenic DI. DI can be differentiated from primary polydipsia by measuring plasma osmolality, which will be low to low-normal in patients with primary polydipsia and high to high-normal in patients with DI. For a more complete discussion of diagnostic procedures, see Robertson (2001).

Central DI. Head injury, either surgical or traumatic, in the region of the pituitary and/or hypothalamus may cause central DI. Postoperative central DI may be transient, permanent, or triphasic (recovery followed by permanent relapse). Other causes include hypothalamic or pituitary tumors, cerebral aneurysms, CNS ischemia, and brain infiltrations and infections (Robertson, 2001). Finally, central DI may be idiopathic or familial. Familial central DI usually is autosomal dominant (chromosome 20), and vasopressin deficiency occurs several months or years after birth and worsens gradually. Autosomal dominant central DI is linked to mutations in the vasopressin prohormone gene that cause the prohormone to misfold and oligomerize improperly. The long-term result is accumulation of the mutant vasopressin precursor in the

affected neuron because the precursor cannot move from the endoplasmic reticulum into the secretory pathway. Accumulation of mutant vasopressin precursor causes neuronal death, hence the dominant mode of inheritance (Robertson, 2001). Rarely, familial central DI is autosomal recessive owing to a mutation in the vasopressin peptide itself that gives rise to an inactive vasopressin mutant.

Antidiuretic peptides are the primary treatment for central DI, with desmopressin being the peptide of choice. For patients with central DI who cannot tolerate antidiuretic peptides because of side effects or allergic reactions, other treatment options are available. *Chlorpropamide*, an oral sulfonamide, potentiates the action of small or residual amounts of circulating vasopressin and will reduce urine volume in more than half of all patients with central DI. A dose of 125 to 500 mg daily is particularly effective in patients with partial central DI. If polyuria is not controlled satisfactorily with chlorpropamide alone, addition of a thiazide diuretic (see Chapter 28) to the regimen usually results in an adequate reduction in the volume of urine. *Carbamazepine* (800 to 1000 mg daily in divided doses) and *clofibrate* (1 to 2 g daily in divided doses) also reduce urine volume in patients with central DI. Long-term use of these agents may induce serious adverse effects; therefore, carbamazepine and clofibrate are used rarely to treat central DI. The antidiuretic mechanisms of chlorpropamide, carbamazepine, and clofibrate are not clear. These agents are not effective in nephrogenic DI, which indicates that functional V_2 receptors are required for the antidiuretic effect. Since carbamazepine inhibits and chlorpropamide has little effect on vasopressin secretion, it is likely that carbamazepine and chlorpropamide act directly on the kidney to enhance V_2 -receptor-mediated antidiuresis.

Nephrogenic DI. Nephrogenic DI may be congenital or acquired. Hypercalcemia, hypokalemia, postobstructive renal failure, lithium, foscarnet, clozapine, demeclocycline, and other drugs can induce nephrogenic DI. As many as one in three patients treated with lithium may develop nephrogenic DI. X-linked nephrogenic DI is caused by mutations in the gene encoding the V_2 receptor, which maps to Xq28. A number of missense, nonsense, and frame-shift mutations in the gene encoding the V_2 receptor have been identified in patients with this disorder (Knoers and Deen, 2001). Mutations in the V_2 -receptor gene may cause impaired routing of the V_2 receptor to the cell surface, defective coupling of the receptor to G proteins, or decreased affinity of the receptor for vasopressin. The effects of these mutations range from a complete loss of responsiveness to vasopressin to a shift to the left of the concentration–response curve. Autosomal recessive and dominant nephrogenic DI result from inactivating

mutations in aquaporin 2. These findings indicate that aquaporin 2 is essential for the antidiuretic effect of vasopressin in human beings.

Although the mainstay of treatment of nephrogenic DI is assurance of an adequate intake of water, drugs also can be used to reduce polyuria. *Amiloride* (see Chapter 28) blocks the uptake of lithium by the sodium channel in the collecting-duct system and is considered the drug of choice for lithium-induced nephrogenic DI despite the absence of Food and Drug Administration (FDA) approval. Paradoxically, *thiazide diuretics* reduce the polyuria of patients with DI and often are used to treat non-lithium-induced nephrogenic DI. The use of thiazide diuretics in infants with nephrogenic DI may be crucially important because uncontrolled polyuria may exceed the child's capacity to imbibe and absorb fluids. The antidiuretic mechanism of thiazides in DI is incompletely understood. It is possible that the natriuretic action of thiazides and resulting depletion of extracellular fluid volume play an important role in the thiazide-induced antidiuresis. In this regard, whenever extracellular fluid volume is reduced, compensatory mechanisms increase reabsorption of NaCl in the proximal tubule, reducing the volume delivered to the distal tubule. Consequently, less free water can be formed, which should diminish polyuria. However, studies in rats with vasopressin-deficient DI challenge this hypothesis (Grønbeck *et al.*, 1998). Nonetheless, the antidiuretic effects appear to parallel the ability of thiazides to cause natriuresis, and the drugs are given in doses similar to those used to mobilize edema fluid. In patients with DI, a 50% reduction of urine volume is a good response to thiazides. Moderate restriction of sodium intake can enhance the antidiuretic effectiveness of thiazides.

A number of case reports describe the effectiveness of indomethacin in the treatment of nephrogenic DI; however, other prostaglandin synthase inhibitors (*e.g.*, *ibuprofen*) appear to be less effective. The mechanism of the effect may involve a decrease in glomerular filtration rate, an increase in medullary solute concentration, and/or enhanced proximal reabsorption of fluid. Also, since prostaglandins attenuate vasopressin-induced antidiuresis in patients with at least a partially intact V_2 -receptor system, some of the antidiuretic response to indomethacin may be due to diminution of the prostaglandin effect and enhancement of the effects of vasopressin on the principal cells of the collecting duct.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone (SIADH). SIADH is a disease of impaired water excretion with accompanying hyponatremia and hypo-osmolality caused by the *inappropriate* secretion of
